It is important to distinguish the demands made by Kerberos as a technology and the demands made by Kerberos as a security system. Kerberos technology makes modest demands on the environment, and satisfying those demands should be well within the means of most organizations. Kerberos as a security system can make very insignificant or very oppressive demands on the environment, depending on the level of security an organization needs or chooses to enforce. We use the term “appropriate” to describe that level of security and to qualify those elements that are outside the scope of Kerberos—or any security technology. If an organization decides that “appropriate security” means “very high security,” then demands, assumptions, cost, and effort will all increase.

93.10.1 Users

One of the first concerns usually raised by network and system administrators is “What is this going to do to my users?” That is a justifiable concern, because any change that is visible to users will tend to produce a heavy influx of support calls. Kerberos can be virtually invisible and undemanding of users, or extremely visible and oppressive in its demands. That choice is a function of the level of security the site chooses to enforce using Kerberos. For the security needs of the vast majority of sites, Kerberos need not be visible to the user community.

Users are generally unaware of Kerberos, except during the initial authentication process (i.e., sign-on), when they must provide their Kerberos principal identifier and a password, or some other proof of identity. If the Kerberos sign-on is integrated into the host sign-on, Kerberos can be made invisible to the user. If the Kerberos sign-on is not integrated into the host sign-on, or the host has no concept of a sign-on, a separate Kerberos utility to allow the user to sign on and complete the initial authentication process is required.

The result of the Kerberos initial authentication is a ticket-granting ticket (TGT), which is placed into a credentials cache, and which applications may subsequently use for obtaining service tickets in order to authenticate to services. The process of obtaining service tickets using the TGT, and the subsequent authentication exchange between the client and the service, is invisible to the user. Kerberos utilities are typically provided to view the tickets contained in the credentials cache. However, with the exception of diagnostics and troubleshooting, those utilities are typically not used and are unnecessary.

One of the few times a user might encounter different behavior due to Kerberos is if their TGT expires. All tickets, including the TGT, have a lifetime. Applications will automatically request a new ticket if the old one has expired. However, an application cannot request a new TGT without user involvement. That is, the user must go through the initial authentication process to obtain a TGT. Whether the user community ever encounters that behavior will depend on the lifetime chosen for TGTs. If that lifetime is longer than the average workday, most users will never see this behavior.

93.10.2 Assumptions

Kerberos makes certain assumptions about the environment and the security of the various systems and individuals that make up the Kerberos environment. When discussing these assumptions it is important to distinguish what is required for any distributed or network environment, what is required for any distributed security system, what requirements are specific to Kerberos, and what requirements are specific to a Kerberos implementation.

Minimal assumptions and requirements necessary for any distributed environment include:

- A functional network for clients and services to interact.
- A functional network directory service for clients and services to locate each other.
- A functional software distribution system to distribute software to computer systems that host clients and services.

Assumptions and requirements that are common to virtually all distributed security systems are negotiable and depend on acceptable cost and risk. These include:

- Appropriately secure systems for hosting clients and services
- Appropriately secure software distribution service
- Appropriate protection of identity information by individuals (passwords, smart cards, tokens, etc.)

Assumptions and requirements that are Kerberos-specific are negotiable and depend on acceptable cost and risk. These include:

- Appropriately secure systems for hosting KDCs
- Appropriately secure time service, with loosely synchronized clocks on all systems on which Kerberos operates

The following discussion provides security recommendations for the assumptions and requirements enumerated above. These recommendations are common to virtually all implementations. However, they do not account for budget or other organizational constraints, and actual requirements will depend on cost-risk tradeoffs, which will be different for each deployment.

93.10.2.1 Directory Service

Kerberos typically requires the Internet domain name service (DNS) to construct the names of service-based principals and locate those principals on the network. An ineffective DNS or an inconsistent naming structure can make this job more cumbersome. Although many network services depend on a network naming system to function, a compromised name service does not present a security threat to Kerberos, other than possibly a denial-of-service attack. Note that such a denial-of-service attack would likely affect many network services, and not just Kerberos.

93.10.2.2 Software Distribution Service

Any large distributed environment requires a software distribution service for cost-effectively distributing and installing software on physically remote systems. That distribution system should be secure to ensure that the integrity of the security software itself is not compromised.

93.10.2.3 Secure Time Service

Loosely synchronized clocks are typically required between the KDCs, and between KDCs and application servers (e.g., within five minutes). Implementations vary in their requirements for clock synchronization. Unsynchronized clocks primarily represent a security threat due to replay attacks. Depending on the Kerberos implementation and the protocols used, clock synchronization may or may not be required. However, synchronized clocks are generally desirable in any large network, especially for auditing and network and system management to correlate activities and events across the network. If timestamps are used as the basis for replay protection, the time service used to synchronize clocks should be secure.

93.10.2.4 KDCs

Because the KDC is the trusted third party for all principals in the realms it serves, the KDC should be both logically and physically secure. Failure to secure the KDC can result in the compromise of an entire realm. The KDC should support no applications, users, or protocols other than Kerberos. (That is, everything except Kerberos has been removed from the machine.) Ideally, the system will not support remote network access except by means of the Kerberos services it offers. Remote administration of KDCs and principals is a fact of life in today's environment. Most modern Kerberos implementations provide a secure remote administration facility.

93.10.2.5 Services

Systems that host services, or "application servers," should be secured to the level required by the most sensitive application or data on that server. Failure to adequately secure the application servers may result in the compromise of services that operate on that application server, and their data. Note that a compromise of an application server compromises only those applications on the server and does not compromise any other principals.

93.10.2.6 Clients

Client systems should be secured to the level required by the most sensitive user of the client or the most sensitive application that is accessed from that client. Failure to adequately secure client systems may result in the compromise of any users of the client system or compromise of data accessed from the system. A compromised client puts all users of the client at risk. For example, a password grabber on a client compromises anyone who uses the client; a virus potentially compromises the data of any application accessed from that client. A compromised client does not compromise principals that do not use that client. However a client compromise could spread if one of the users of that client has elevated privileges, e.g., a Kerberos administrator. Kerberos administrators (or anyone with elevated privileges) should not use a client system unless they have an appropriate level of trust in that system.

93.10.2.7 Identity Information

Identity information, no matter what the form, requires appropriate protection of that information by individuals. If passwords are used, those passwords should be sufficiently strong. Most modern Kerberos implementations provide password policy enforcement to minimize the use of weak passwords. If public key credentials are used, protection of those credentials is as important as password protection. If additional security is required, technologies that provide two-factor authentication, such as token cards or smart cards, may be used; appropriate care in protecting those devices must still be exercised by the individual. Note that a compromise of an individual does not implicitly compromise any other Kerberos component or principal. However, as with any system, administrative personnel who have elevated privileges should be of special concern. For those individuals, two-factor authentication may be appropriate.

93.10.3 Operation

In terms of operational management, clients are by far the most important, with services a distant second, followed by KDCs. Implicit in that ranking are the associated infrastructure elements that are required for each Kerberos component to perform its function. That ranking obtains from the relative numbers of the components. Clients are typically the most numerous by orders of magnitude, and their sheer numbers magnify even the smallest manageability problem. That is not to say that management of KDCs is unimportant, but if given the choice between a few skilled people trained and dedicated to managing a few KDCs vs. 100,000 users and clients, the choice should be obvious.

93.10.3.1 Clients

Other than installation, the primary manageability concern with clients is locating KDCs and services (discussed later in this chapter).

93.10.3.2 Servers

The primary management overhead associated with service principals is the maintenance of the key table. As previously discussed, the key table holds a service principal's key. Communication of the key should be done securely, which means either manually communicating the key out-of-band or pulling the key from the KDC using a key management utility on the system on which the service operates. The latter method of pulling the key from the KDC is preferable.

For example, once Kerberos client software is installed on the application server, a key management utility can be used by an administrator to access the KDC, establish a secure session, generate the service key, and place the service key into the service's key table. The administrator effectively provides the secure channel for securely communicating the initial service key. Once the initial keys are established, secure key update, or "key rollover," can be automated. That key rollover can be initiated on the server to pull a new key from the KDC to the server, or a KDC can push a new key to the server. Implementations vary in the sophistication of the key management utilities available and the facilities for automating the key rollover process.

93.10.3.3 KDCs

A fully equipped KDC generally includes a variety of services for administration and management, database propagation, password change, etc. Some of those services can be quite complex. However, the main services provided by a KDC are for authentication and are quite simple. Those services do not, as a rule, maintain state or require write-access to the principal database.

Most implementations differentiate between "primary" and "secondary" (or "master" and "slave") KDCs depending on the services they provide. A primary KDC typically provides a reference copy of the principal database, as well as hosting services that require write-access to the database. Secondary KDCs typically maintain read-only copies of the database. Implementations vary tremendously in the mechanisms used to propagate information from primary to secondary KDCs. In the most primitive mechanisms, a bulk propagation of the entire database is performed at fixed intervals. More sophisticated mechanisms incrementally propagate only those database records that change in real time. The issues associated with periodic bulk propagation are numerous and significant. Incremental propagation is a prerequisite for any large-scale production implementation.

Services that require write access to the principal database include those required for day-to-day administration of the principal database, such as adding, deleting, and changing principals. Administrative functions are generally performed using a special administrative tool, either locally on the KDC, or remotely. Password-change operations also require write access to the principal database. Password-change is typically the only operation in which the general client population requires access to a service on the primary KDC—that is, a service that has write-access to the principal database. Although implementations vary, the inability of clients to access the primary KDC will typically preclude password-change operations. That argues for a primary KDC configuration that provides system and network redundancy and automatic failover. Beyond the administrative functions associated with principals, there is little additional work involved in managing a KDC.

The primary services used by clients—the authentication service (AS) and ticket-granting service (TGS)—do not generally require write-access to the database. Thus, secondary KDCs should, as a rule, be the client's first selection when locating a KDC to provide those services. It is not unusual for all AS and TGS requests to be serviced by secondary KDCs, and to dedicate the primary KDC to administrative services. This allows the resources of the primary KDC to be dedicated to services that only the primary KDC can provide, which allows it to serve a much larger client community.

Each entry in the principal database is typically encrypted in a "master key" that is defined when the database is created. That master key prevents compromise of the realm should a backup of the principal database be inadvertently released, for example. However, for unattended restart of the KDC and unattended operation of services that must manipulate the database, the master key must be kept in persistent storage. If unattended KDC restart is not required, the master key can be typed in on the console when the KDC starts. However, that typically does not make the master key available to other services that may require access to the database, such as administrative services. Because of those issues, virtually all implementations use a master key that is kept in persistent storage, such as a disk file. Obviously, keeping the master key secure is of paramount importance, and any backups should exclude storage containing a copy of the master key.

93.10.3.4 Realms

Most of the issues involved in the use of multiple realms revolve around the client's ability to locate KDCs and services in a realm. The ease or difficulty with which clients can perform those functions, and the associated management overhead, are usually the determining factors in whether or not an organization uses multiple realms.

If multiple realms are used, cross-realm keys must be established between realms, and appropriate entries placed into the principal database. Key generation and creation of the principal database entries require very little effort. However, those cross-realm keys must be communicated between realms in a secure fashion. Unless a secure channel already exists between realms, those keys should be communicated using a secure, out-of-band mechanism, such as physical mail. Once those initial keys are established, a secure channel can be formed to change the keys periodically.

Note that a user can have identities in multiple realms. For example, the same physical individual may have a principal identity in multiple realms. Although those two identities may represent the same individual, Kerberos does not make that association. By the same token, there is nothing that prevents a client computer system from being used for authenticating an individual to any realm or accessing a service in any realm. That situation would not be unusual in an environment with multiple realms and a roving user community. Although it is typical for client systems to define a default realm as a convenience for users, that default realm is only a convenience and, unless otherwise constrained, does not limit the use of the client by individuals in a single realm.

A service, or more precisely, the instantiation of an application on a host computer system, may also operate in multiple realms. While it is unusual, and there are security implications that must be considered, there is nothing that prevents one system from hosting applications that have identities in multiple realms. Nor is there anything that prevents the same application on the same system from having an identity in multiple realms. Having a common system or application that has an identity in multiple realms may be an alternative to cross-realm authentication. For example, consider a database that is shared between two groups in different realms. The database service can be placed into one realm, with the other group using cross-realm authentication to access it. Alternatively, the database can have an identity in both realms, with each group accessing the database as a service in their own realm, thus eliminating the need for cross-realm authentication. Again, there are security implications in such an approach that must be taken into account. Specifically, management of the service keys must be carefully considered.

93.10.3.5 Principals

Management of principals is similar to that of any system that maintains identity information. Principals must be added, removed, and modified. A principal identifier should not be reused until all services that may have local copies of the principal identifier have been notified. For example, if a service uses a principal identifier in a local access control list (ACL), the ACL must be updated before the principal identifier is reused to ensure that the new entity does not have unwarranted access to that service.

All implementations provide tools to perform administrative functions. For large-scale deployments, it may also be desirable to couple Kerberos administration to an enterprise administrative system. As with any system that uses passwords, resetting passwords is probably the most common administrative function performed in Kerberos. Some implementations allow administrative functions to be tightly constrained (for example, limiting help desk personnel to performing password resets and not allowing them to perform other administrative functions, such as adding, removing, or otherwise examining or modifying principal entries).

93.10.3.6 Key Strength and Rollover

As mentioned above, there are a number of keys that should be rolled over periodically. Those keys are generally randomly generated bit strings and are very resistant to any attack short of an exhaustive key search. Thus, the strength of the keys and the required rollover frequency depend almost entirely on the key length used. This suggests that the strongest possible key strength, such as triple-DES, should be used for critical keys. An exhaustive search of the triple-DES key space is well beyond the means of any organization today or for the foreseeable future, with the possible exception of a few government intelligence agencies.

As for all services, the key strength and rollover frequency for a service should be appropriate for the sensitivity of the service. One service stands out as demanding the highest possible level of protection: the ticket-granting service (TGS). All ticket-granting tickets (TGTs) received by clients are sealed in the key of the TGS, and all authentication with services is ultimately rooted in that TGT. If the TGS' key is compromised, the TGS can be impersonated, and with it the entire realm. Obviously, protecting the TGS's key is of paramount importance. Close behind the TGS in importance are the keys used for administrative services and cross-realm authentication.

Automation of the key-rollover process should eliminate virtually all management overhead associated with key rollover. For remote systems, rollover can be initiated from the KDC and pushed to the service, or it may be initiated by the service and pulled from the KDC. However it is done, automation of the rollover process for services on remote systems implies that an existing key is used to establish the secure channel for key rollover. If shared secrets and symmetric key cryptography are used as the basis for establishing that secure channel, the rollover process should strive to camouflage the key rollover sequence. That minimizes the probability of an attacker recording the sequence containing the new key and the subsequent compromise of the new key based on an old key.

93.10.4 Names and Locations

The majority of the management and operational issues with Kerberos revolve around names, the association of those names with physical or logical entities, and the location of those entities in the network. The naming and location issues faced by Kerberos are not unique to Kerberos and are faced by virtually all distributed environments.

Historically, services have been tied to machines, and those machines have a name that people know and understand, and the network software can be used to connect a client to that machine and implicitly to a service. In many environments, a single system or service might be known by many names, and as long as the client is able to connect to the service, no one much cares. When a system such as Kerberos is introduced that relies on names to identify and authenticate unique entities, names start to matter much more. All of a sudden, the name may be used not only for location, but authentication, and the client, the service, and Kerberos must all agree on what those names are attached to, and the network naming or directory service must also agree with where they are located.

Name services such as DNS provide solutions to the simple client–server connection problem. However, as the coupling between physical systems and services becomes more tenuous, we are left with the problem of finding an instance of the service (i.e., a system on which the service is operating) somewhere in the network. That service name may or may not have any relationship to a computer system's network name. Although there are many solutions to this problem, as of this writing there are no solutions that an implementation can rely on in most environments.

93.10.4.1 Name Spaces

Kerberos defines a name space consisting of realms and principals. Other than their own principal name, most users will have little or no knowledge of other Kerberos principal names, especially those associated with services. Thus it is left up to the Kerberos software and the environment to somehow map the names that people are familiar with to the corresponding Kerberos principal identities and locate those entities in the network. If Kerberos names are associated with an existing name space, such as DNS, and a name in one name space can be mapped trivially to another, most of the issues become relatively innocuous. If the names in the Kerberos name space are not associated with an existing name space, management effort and the probability of errors goes up significantly, as should be obvious from the discussion below.

93.10.4.2 Services

Services typically use an “instance” in the principal name to help distinguish different instances of the same service, e.g., name/instance@REALM. For example, the instance may distinguish the same service operating on different computer systems. Although it is generally the case that the same principal name would imply similar functions across different instances, that is by convention only. Different principal identifiers—the concatenation of the name, instance, and realm—are treated as completely different entities by Kerberos.

The instance is used by virtually all Kerberos implementations to locate the service on the network. For service principals, Kerberos clients by convention use the fully qualified DNS domain name of the host computer system on which a service operates as the instance. For example, wadmin/www.z.com@Z.COM might be a Web administrative service application on the system www.z.com. Other services may also be present on the same system, and each of those services could have its own name with the same instance. For example, ccare/www.z.com@Z.COM might be a customer care service application running on the same system.

By convention, there is a generic host principal used for authentication to generic host services, such as telnet. By convention, those generic services share the principal name “host.” For example, telnet clients would use the service principal name host/y.z.com@Z.COM to access to a telnet server running on system y.z.com. The principal identifier host/x.z.com@Z.COM represents the same principal name (host) with a different instance (x.z.com). Although host/y.z.com@Z.COM and host/x.z.com@Z.COM may imply a common service (i.e., a common function) on different systems, Kerberos makes no such implication. From the perspective of Kerberos, those principal identifiers are different, and therefore represent different entities; any implied similarity is by convention only.

Note that there is an implied relationship between the instance and the location of the service, and a client must know both in order to use a service. To establish a connection with the service (regardless of whether Kerberos is used), the location must be known, and the principal name must be known for the client to form the correct service name for that service and obtain the correct service ticket. This implied relationship can be either a great convenience or a great pain, depending on whether the relationship holds true.

Within a single realm, the principal names used for services and the manner in which a client forms the identifier of a service principal have a significant effect on the usability of the implementation. Services that use the common and generic “host” principal name are well defined and not a problem. For other services, those services’ principal identifiers must be defined and known to the client. The instance name used for service principals can also present a problem for the client. Although the Kerberos convention is to use the fully qualified DNS domain name, or “long form,” for the instance in the principal identifier, some DNS implementations return the “short form.” This can present problems if one system uses the short form and another system uses the long form. From the perspective of Kerberos, those two identifiers are different, and hence different principals. Both of those identifiers must have a principal entry and an entry in the key table for the service—which increases management overhead—or an error will result when a client uses the wrong principal identifier to attempt to access the service.

93.10.4.3 KDCs

Before a client can do anything with Kerberos, it must locate a KDC in order to authenticate and obtain tickets for the individual using the client. Note that unlike service principals, which generally use the instance portion of the principal name to also locate the machine on which the service is operating, there is no implied KDC location based in the realm name. The only inference one can make from a realm name is that a KDC is operating on a system somewhere in the corresponding domain. For example, we can infer that a KDC for the realm Z.COM is probably located on a system somewhere in domain z.com.

If multiple KDCs are used for availability or performance, there must also be some means of directing the client to the appropriate KDC, or for the client to automatically locate a KDC should the first choices be unavailable. For systems that use primary and secondary KDCs, the client will also need to know how to locate the primary KDC for a realm for password-change operations.

Different individuals in different realms may use the same client. It is unrealistic to expect those individuals to know the names or addresses of KDCs in their realm, and therefore the job of locating a KDC falls to the Kerberos client software. Applications on the client may also access different services in different realms. As with individual principals, it is unrealistic for those applications to have embedded within them knowledge as to the location of KDCs in different realms, and again that job falls to the Kerberos client software.

Traversing multiple realms can also present problems for the client. Kerberos defines a standard mechanism for traversing realms that are arranged in a hierarchy. For other realm structures, there is no defined mechanism. Moreover, the client must know the realm in which a service resides. If a service is in a different realm, the client must perform cross-realm authentication to get to that service. In order to perform that cross-realm authentication, the client again must locate a KDC in each of the realms it must traverse.

The basic KDC-realm location problem has a variety of solutions, and implementations vary in how they solve the problem. The simplest and most primitive solution is to use a configuration file on the client. Typically, that configuration file defines a default realm and KDC, which the client uses unless told otherwise. That solution is sufficient for basic implementations. That configuration file may also enumerate a list of alternate KDCs and realms, and the primary KDC for each realm. Thus, changes to the environment may require that configuration file to be updated on many clients. For a relatively static environment, that may be acceptable. For even a moderately dynamic environment, that is unacceptable.

To solve the KDC realm location problem in an effective manner, as much static configuration information as possible must be removed from the client. Solutions that address the problem may make use of naming conventions for KDCs and may include the use of DNS aliases, rotaries, and informational records. Other solutions may use “referrals” or “redirection” to direct the client to the appropriate source. This solution requires only that the client be able to contact at least one KDC; that KDC is assumed to have the knowledge of how to get to other KDCs and realms, and can refer or redirect the client as needed.

93.10.5 Interoperability

The Kerberos 5 protocol defines what is necessary for implementations to be “wire-level” interoperable, and different implementations tend to be quite good about wire-level interoperability. However, the Kerberos standard does not address many of the host-specific or environmental issues that every functional Kerberos implementation must deal with, and there is no guarantee that two implementations will deal with the same issue the same way. De facto standards have typically developed on different platforms to address these issues. If a platform vendor provides a Kerberos implementation, that vendor will generally set the standard on their platform. Thus, while these issues are generally not significant, they are worth noting.

- Locating a KDC within a realm may be done in different ways. This can result in duplicate management effort in order to maintain consistency between two different representations of that information.
- Credentials cache locations and formats may vary. The primary concern is the ability for applications to access the TGT for obtaining service tickets. Unless applications use a common credentials cache to hold the TGT, the user may be forced to go through an additional sign-on.

The most significant interoperability issues between KDCs and clients are not a function of the Kerberos protocol, but specific features that KDCs or clients may require or support. This usually manifests itself in the types of preauthentication mechanisms supported, such as token cards, public key X.509 certificates, etc.

Although the standard defines client–KDC interactions, no standards, neither formal nor *de facto*, define KDC propagation mechanisms and administrative interfaces. Thus, those propagation mechanisms and administrative interfaces tend to be vendor-specific. The result is that, although it is quite feasible to use a mixture of clients and KDCs from different vendors, all KDCs within a realm must typically come from the same vendor. Between realms, cross-realm authentication couples the KDCs in those realms (not database propagation). Because cross-realm authentication is defined by the Kerberos standard, KDCs from different vendors in different realms should have no trouble interoperating.

93.10.6 Performance

Performance is the degree to which Kerberos can perform its intended function with a given level of resources. Kerberos will consume some resources, and the efficiency of Kerberos can be gauged by how effectively it uses those resources. Resources take the form of network bandwidth, and disk and CPU on clients, servers, KDCs, and personnel.

For performance, the KDC is typically the most important component, with services a distant second and clients third. That order obtains from the relative concentration of work performed by each of those components and the effects of inefficiencies or failure on other components. An inefficient KDC can affect a large number of clients and services, whereas an inefficient client generally affects only that client. Implicit in that ranking are the infrastructure elements needed to support each component. The efficiency of a KDC, by any measure, makes little difference if the network or directory service needed for clients to communicate with the KDC is inefficient or inoperable.

93.10.6.1 Encryption

One of the first concerns that usually comes to mind with any security system that uses encryption is the additional CPU and network overhead. In Kerberos, the use of encryption for authentication in the authentication service (AS), ticket-granting service (TGS), and application (AP) messages is intentionally limited, and the resulting cryptographic overhead is minor.

For applications that encrypt and decrypt data, the overhead may be very noticeable (whether or not those applications use Kerberos). That overhead depends on the amount of data that is encrypted, the encryption algorithms used, the efficiency of the implementation's algorithms, and the availability and use of hardware cryptographic acceleration by the implementation. Data encryption and decryption overhead is generally not an issue on clients, as even moderately efficient software cryptographic implementations on today's client platforms are normally faster than the network. However, for servers the situation may be reversed, as those servers are typically the focal points for many clients. That is, the cost of encryption and decryption is spread over many clients, and a much smaller number of servers. Those servers may justify the investment in hardware cryptographic accelerators if performance is an issue.

Encryption of application data adds no measurable overhead to the network. The sole exception to this are protocols that exchange a very small amount of information in each message and that use a block cipher such as DES. This causes messages that are shorter than the block size of the cipher to be padded out to the block size of the cipher. For example, DES is a block cipher with a block size of eight bytes; encrypting a single byte results in an output that is eight bytes. However, the additional overhead added by Kerberos in this case will likely be unnoticeable, as it will be dwarfed by the overhead of the message envelope. Simply put, any protocol that transmits a few bytes of data in each message is, by definition, horribly inefficient at moving data—encrypted or not—and encryption will cause a very minor increase in that inefficiency.

93.10.6.2 Network

The demands Kerberos places on a network are modest and rarely an issue. Network demands will depend on several factors, including the behavioral pattern of clients, network topology, and the location of KDCs within the network. The KDC can communicate with clients using either UDP or TCP. Because of its greater efficiency, UDP is the preferred method. However, if firewalls are placed between clients and KDCs, UDP may not be feasible; for those clients, TCP may be used.

The additional network traffic produced by the Kerberos authentication process is simple to determine:

- *Initial authentication.* A single exchange between the client and a KDC at the beginning of the workday (AS–REQ and AS–REP). This exchange may involve more than one message in each direction, depending on the technology used for initial authentication. For example, a challenge-response token card typically requires an additional exchange between the client and a KDC.
- *Obtaining a service ticket.* A single exchange between the client and a KDC the first time an application service is accessed during the workday (TGS–REQ and TGS–REP). Different services require different service tickets, and thus each time a service is accessed the first time during the workday, this exchange will occur.
- *Client-to-service authentication.* A single message from the client to the service (AP–REQ). If the client requests mutual authentication, there is one additional message from the service to the client (AP–REP). The Kerberos authentication exchange between the client and service may be embedded in the application's session establishment messages and will not show up as an additional message, but rather as a nominal increase in size of the standard session establishment messages.

The size of the messages varies depending on various options and the amount of authorization information embedded in tickets. Assuming no authorization information, message sizes range from approximately 100 to 500 bytes.

93.10.6.3 KDCs

KDC performance is rarely an issue. The primary services provided by a KDC—those that are most used and have the greatest effect on performance—are the authentication service (AS) and ticket-granting service (TGS). The AS and TGS typically do not require local state, and typically require only read-access to the principal database. This allows liberal placement of KDCs within the network and eliminates the need to bind clients to specific KDCs. Moreover, because of the very simple and symmetric message exchanges and the reuse of common syntax and semantics in the protocol, KDC implementations tend to be quite compact and very efficient in their use of memory and CPU. Rates in excess of 20 AS and TGS exchanges per second for a KDC on a small system are not unusual.

The limiting factor on KDC performance is usually the I/O associated with the principal database. CPU overhead for encryption and decryption is usually a distant second (assuming that symmetric-key cryptography is being used), owing to the relatively small size of the messages processed by the KDC and the limited use of encryption for those messages. Disk resource requirements depend on the database used and the number of principals in the database; although requirements vary, a rule of thumb is 1 Kb of disk for each principal in the database.

93.10.6.4 Clients and Services

Implementations vary in what they require of systems that host clients and services. Generally, the additional overhead imposed on clients, services, and the additional network overhead for an application is unobtrusive. Disk and memory usage on those systems is typically quite small; the primary variation and resource consumption is typically not in the implementation of the Kerberos protocol, but in ancillary facilities such as graphical user interfaces. Again, although the basic Kerberos authentication process is typically unobtrusive, applications that encrypt large amounts of data may see very visible effects on performance.

93.10.7 Provisioning

As discussed previously, the inherent demands Kerberos places on the network are quite modest. Most modern networks should have little or no trouble with the additional network traffic. However, the network topology, KDC placement, and the location of clients and servers relative to each other and KDCs can have either an insignificant or a very significant effect on the network. Most network operations groups have the knowledge and experience to properly provision and locate KDCs in the network, and those groups should be consulted when determining provisioning requirements.

93.10.7.1 Key Services

Many modern networks have the concept of "key services," which are required for the proper functioning of a modern enterprise network. Key services typically include naming services, such as DNS, and may include time services, such as NTP. The systems that host those services are typically located in facilities at key points in the network, and those facilities are intended to ensure the availability of key services to all users in the face of network outages and other failures.

Those key service facilities will typically have a higher level of physical security than many other facilities. Key services facilities will usually define the location of KDCs in the network, as well as secure time services, if used. Those key service facilities also provide a baseline for the physical security of the KDCs. That security may or may not be sufficient.

93.10.7.2 Primary KDC

The primary KDC should be dedicated to administrative functions and data distribution. The primary KDC should use a high-availability platform with no single point of failure. The number of secondary KDCs and their propagation requirements obviously contributes to sizing of the primary KDC. The most significant effect on sizing the primary KDC is client password-change frequency. For example, for a user population of 100,000, with a password expiration of three months (approximately 60 working days), the system will be required to handle an average of approximately 1700 password-change operations per day. Virtually all of those password changes will occur at sign-on (when the expiration is detected and the user is forced to change his password), and most will center on a narrow band at 8 AM in any time zone. That can present a potentially significant load on the primary KDC. Network connectivity should be appropriate for that load. This also points out the need to distribute password expiration as evenly as possible when loading the principal database.

93.10.7.3 Secondary KDCs

Secondary KDCs should perform the vast majority of the day-to-day work: providing the authentication and ticket-granting services most used by clients. There is a great deal of freedom in the sizing and location of secondary KDCs. User communities of 5,000 to 20,000 are within the performance range of a small to moderate-sized secondary KDC. Availability, not performance requirements, will be the major factor in determining secondary KDC provisioning. Clients should, as a rule, always be directed to a nearby secondary KDC as their first choice. This argues for a greater number of smaller secondary KDCs placed closer to clients.

If availability is a concern, large subnets, campuses, or other major user communities that may be separated by a network failure should have two secondary KDCs, in order to eliminate a single point of failure. Exact physical placement of that secondary pair will be determined by network topology. For example, the pair may be physically distant from each other and still provide a high level of redundancy and availability, depending on the network topology. On the other hand, placing both secondary KDCs on a single network segment that may fail increases cost and does little for redundancy.

If Kerberos is used for local work station access control, availability to the client is critical. If clients and application servers are separated, and if access to those application servers is the predominant factor, then secondary KDCs should be close to the application servers, and not to the clients. Simply put, if the network between the client and the application server is inoperable, a secondary KDC local to the client will not do much good if the objective is to allow the client to securely communicate with the application server.

93.10.7.4 Clients and Servers

Client and server platforms will not, as a rule, require any additional resources for Kerberos. However, if large amounts of application data are encrypted, servers may require additional CPU capability or hardware cryptographic accelerators. Encryption of application data does not add any measurable overhead to the network. Additional CPU requirements should scale linearly with the amount of data and will depend on the strength of the cryptographic algorithm, and the key size used. Thus, the additional CPU required to meet the demands of the application can be determined with simple timing tests. If hardware cryptographic accelerators are used, scheduling overhead and key setup time for the accelerator may put an upper bound on performance for small messages. Simple metrics such as the number of bytes per second that can be encrypted or decrypted are not sufficient to determine the real-world performance of hardware accelerators.

93.10.8 Deployment

The appropriate deployment strategy for Kerberos depends both on the intended application and the infrastructure that is in place. Typically, the application will define what demands are placed on Kerberos, and that will, in turn, define the demands on the organization and infrastructure. Other than client software distribution and configuration, those organizational and infrastructure demands are typically the gating factor in any Kerberos deployment. For narrowly focused applications, deployment is generally not an issue and is driven exclusively by the application requirements, with Kerberos simply a component embedded in, and deployed with, that application. For broad-based applications, such as secure single sign-on or enterprise access control, the deployment strategy is typically much more complex. That complexity arises not so much from the technology, but from the more complex and varied organizational and environmental requirements of those deployments.

Deployment stakeholders typically include the user community, security groups, network operations groups, and user administration groups, among others. All will be affected by any large-scale deployment, and all will have a say, directly or indirectly, in a deployment. The introduction of a broad-based security system will, by definition, cross organizational and functional boundaries, and friction is usually the result. If pushed too far and too fast, that deployment friction can generate heat sufficient to incinerate even a well-oiled machine. Unless the organization has a demonstrated need and desire to take big steps, small steps should be the rule. That applies to all security systems.

Successful large-scale deployments tend to be done in two phases: partial infrastructure deployment, followed by incremental client deployment, along with any incremental requirements in the supporting infrastructure. Supporting infrastructure, including any KDCs required for availability and performance, can occur in tandem with deployment of pockets of clients. Alternatively, a KDC “backbone” can be deployed prior to any client deployments.

93.10.8.1 DNS

The identifier space for DNS should be a concern. Although rationalizing the DNS structure for many organizations was an issue five years ago, it tends to be a much smaller issue now. Because of the growth in TCP/IP and intranets, most organizations have already been forced to deal with that issue over the past years. That said, if the DNS machine name space is chaotic, the DNS structure should be rationalized.

The DNS subdomains that are rationalized must consider the relative locations of clients and services and their interaction. Putting Kerberos into two different subdomains—where clients and servers cross between those subdomains—without first rationalizing the name space in both domains will usually result in problems. Again, this is usually best done incrementally, one subdomain at a time, with rationalization preceding deployment within a subdomain. However, it is not unusual to find that rationalizing one subdomain causes unexpected problems elsewhere. It would be wise to let those perturbations settle before embarking on a Kerberos deployment.

93.10.8.2 Identities

Typically, the most significant problem encountered in large-scale deployments is rationalizing the identifier spaces for people. Everyone in most organizations has at least one, and typically many more than one, ID. Rationalizing those spaces in the form of secure single sign-on can itself be the justification for a Kerberos deployment. However, no technology provides a solution to the fundamental problem: people are known by different identities within different and discrete name spaces within the enterprise, and the binding of those multiple identities to a specific individual cannot be known. That problem is the result of years of evolution. Binding of multiple identities to a specific individual can be inferred in some cases. The cost and effort of solving this problem, and level of trust in the resulting environment, depend on the level of assurance provided by that inference.

If there is at least one identifier that is relatively universal, and that identity can be trusted, or there are discrete sets of identifiers with little or no overlap, then the job is much easier. If, on the other hand, the identifier space is chaotic, then more time and energy will be required to rationalize IDs. That time and energy can be due to several factors, including the need to change some names; the need to gain user acceptance when names are changed; and the need to rectify any problems caused by name changes (e.g., systems or applications that are hard-wired with specific names or groups). The actual implementation of the solution is best performed incrementally. This implies an extended deployment, or at least an extended period over which the system is enabled and visible to users. While possible, changing even a relatively small fraction of 100,000 user or system identifiers all at once will likely result in chaos and mass hysteria.

The problem is not eliminated if identity mapping is used to map local identifiers (e.g., a local host or application user ID) to a more uniform identifier, such as a Kerberos principal identifier. Identity mapping may obscure or hide that uniform identifier from users, and thus obviate at least some of the issues with changing identifiers. However, although this approach has an intuitive appeal, it does not eliminate the need for someone or something to go through and map identifiers between different name spaces (the uniform name space being one of those). Building such an “identity map” can be a labor-intensive, time-consuming, and error-prone process. The cost and effort of such a solution should be weighed against the cost and effort in promoting a visible uniform identifier before an approach is selected. Note that Kerberos does not provide implicit capabilities for identifier mapping. Using multiple realms may help but can bring additional issues. Also note that when mapping identities, more-trusted identities should always be used to derive less-trusted identities; less-trusted identities should never be used to derive more-trusted identities.

93.10.8.3 Enrollment

Even with a rational identifier space, users must still be enrolled in the Kerberos database. That is, the principal database must be populated with the names and the passwords of users. There are several ways of populating the principal database depending on what information is available from existing sources, such as legacy user databases, and the form of that information. Depending on what is available, initially populating the principal database can be either a very trivial or a very significant effort.

If a legacy database exists with IDs and passwords, that legacy database can be used to bulk-load the principal database. That database must have clear-text passwords, or keys that are based on an algorithm that is compatible with Kerberos. If clear-text passwords exist in the legacy database, bulk loading is a simple and straightforward process. If the password algorithm used for the legacy database is incompatible with Kerberos, the keys must be transformed to an algorithm that is acceptable to Kerberos, which can be difficult or impossible, depending on the legacy algorithm used.

If keys that use a standard Kerberos algorithm are unavailable, an alternative is to add support for the legacy algorithms to Kerberos, specifically for the purpose of deployment or initially loading the principal database. This requires creating local-use encryption types within the Kerberos implementation (which the protocol allows for). The Kerberos principal database is then loaded with the existing password values from the legacy databases. Those principal entries would also be flagged to require a change-password operation the first time the user logs in. As part of that change-password operation, the new password would be used to update the principal database entry using a standard Kerberos algorithm. After all users have been registered in this manner, support for the legacy algorithm should be removed.

The use of a legacy algorithm as the basis for initial authentication can reduce the security of the system, and thus its use should be limited to enrollment or deployment. Although this approach may expose a weak derivation of the password on the network, that exposure is limited. Moreover, if clear-text passwords or a weak derivation is currently being used and transmitted across the network, this approach does not make the situation any worse and allows us to rapidly improve the situation. If no legacy databases exist, an existing interface (e.g., the existing login process) can be modified to capture and use passwords to enroll those users and populate the principal database with their passwords. As a last resort, new passwords/keys can be issued to users.

93.10.8.4 Realm Design

Other than environmental factors and provisioning requirements discussed previously, the greatest effect on the operation and deployment of a Kerberos implementation will depend on realm design. As always, the rule should be to keep it simple. Unless there is a reason for multiple realms, a single realm should be used. The reasons for using multiple realms might include separation of duties or trust between realms, or the need to distribute the number of primary KDCs (one per realm) for availability of administrative services.

The ability of clients to automatically determine the realm of a service, locate a KDC within a realm, and traverse realms will determine the additional management overhead of a multiple-realm design. If services are available to automate those client needs, multiple realms will not add measurable management overhead. Performance issues due to additional cross-realm authentication operations may also affect the design, but that is usually a distant second behind management overhead. DNS informational records and redirection and referral capability by KDCs can be used to significantly reduce the management overhead of multiple realms. The following discussion assumes that those facilities are unavailable to, or unused by, the Kerberos implementation.

If automated services are not available to mitigate client realm issues, multiple realms should be arranged in a hierarchy, or tree, and that tree should follow the organization’s existing DNS domain structure in order to simplify the association of a service name with, or locating a KDC within, a realm. This argues for realms that map directly to each and every subdomain that provides services that clients in other domains (and hence realms) access. This also implies that when a new subdomain is created, a new realm is created as well. This typically implies a large number of realms, which may not be feasible due to the number of KDCs required. An implementation that allows multiple realms to be serviced by a single KDC can mitigate KDC provisioning issues but does not address separation of security or trust, or the availability of a primary KDC.

The key to the success of this strategy is maintaining congruency between realms and DNS domains to whatever depth of the DNS hierarchy is appropriate. This is required in order to minimize the amount of information required by clients and to maximize the amount of information that can be inferred by clients. For example, if congruency to first-level subdomains is appropriate, then each and every first-level subdomain must have a realm; if congruency to second-level subdomains is appropriate, then each and every second-level subdomain must also have a realm. This also implies that creation or removal of a subdomain implies creation or removal of the corresponding realm.

Maintaining realm-domain congruency allows clients to infer a realm implicitly given a DNS name; the client would have to be explicitly told to what depth the realm-domain structure is congruent (e.g., first, second, etc., level of subdomains). Note that this does not provide any information as to the name of a KDC within a realm. KDC-location by clients can be handled using appropriate naming conventions. For example, using KDC's with names such as "kerberos.sub.domain" might be used to locate KDCs within "sub.domain," and implicitly "sub.realm." If secondary KDCs are used, a DNS rotary can be used, or additional conventions such as "kerberos*n*.sub.domain" (where *n* denotes secondary KDCs).

93.11 Ongoing Development

This section give\s a snapshot of ongoing development efforts surrounding Kerberos and related technologies. Given the rapid development of security technology today, this discussion can only be illustrative and is by no means complete or definitive.

93.11.1 Standards

This section provides an overview of standards efforts relating to Kerberos. Some of these efforts are ongoing and have not yet been approved by the IETF.

93.11.1.1 Authorization

Ongoing standards efforts are intended to define commonly used authorization data types for identifying the source of authorization information[15] (for example, to distinguish between client- and KDC-supplied authorization information). This effort is also aimed at standardizing the behavior of servers in the presence, or absence, of certain authorization information.

93.11.2 PKINIT

The Public Key Initial Authentication (PKINIT) effort is designed to standardize the use of Public Key credentials (certificates and key pairs) and asymmetric-key cryptography for authentication as part of the Kerberos initial authentication exchange.[16] Using PKINIT, users with Public Key credentials can gain access to Kerberos services within the enterprise. Simple public–private key pairs, without credentials (i.e., issued by a CA), may also be used. PKINIT uses the preauthentication facility of the initial authentication process to incorporate public key capabilities.

93.11.3 PKCROSS

The Public Key Cross-Realm (PKCROSS) effort is based on the PKINIT effort and is designed to standardize the use of Public Key credentials and asymmetric-key cryptography for cross-realm authentication.[17] PKCROSS allows *ad hoc* and direct trust relationships to be established between different realms, thus eliminating the key management required of current implementations, as well as

minimizing trust issues associated with transited realms for clients. This minimizes the need for clients or transited realms to have information about realm topology or relationships.

93.11.4 PKTAPP

Public Key Utilizing Tickets for Application Servers (PKTAPP) allows the use of the Kerberos ticketing mechanism without the requirement for a central KDC.[18] PKTAPP proposes a variation of the PKINIT mechanism for allowing application servers to issue tickets for themselves, instead of having the tickets issued by a KDC.

93.11.5 Related Technologies

These technologies are related to Kerberos or are commonly integrated with, or interact with, Kerberos implementations. As of this writing, all of these technologies have ongoing Kerberos-related development efforts associated with them, either within the standards community or by specific vendors.

93.11.5.1 Public Key

Public key may describe a system that uses certificates or the underlying public key (i.e., asymmetric-key) cryptography on which such a system is based, or both. A public key system implies asymmetric-key cryptography; asymmetric-key cryptography does not imply a public key system. (By the same token, Kerberos implies support for DES, whereas DES does not imply Kerberos.)

In the traditional public key (PK) model, clients are issued credentials, or “certificates,” by a “Certificate Authority” (CA). The CA is a trusted third party. PK certificates contain the user’s name, the expiration date of the certificate, etc. The most prevalent certificate format is X.509, which is an international standard. PK certificates typically have lifetimes measured in months or years. Because of the long-lived nature of PK certificates, certificate revocation is a key element in PK infrastructures (PKIs). The authentication process in PK authentication systems also provides the information necessary for a client and server to establish a session key for subsequent data encryption (that is, encryption of application data).

PK credentials, in the form of certificates and public–private key pairs, can provide a strong, distributed authentication system. The private key, which is the most important secret possessed by an individual, runs to hundreds or thousands of bits in length. Thus, a persistent storage system is required to hold the private key, and access to this storage must be protected using a more mundane and conventional mechanism, such as a password. Conventional PK systems still suffer from lack of tools and techniques for managing client credentials. Smart cards hold some promise for secure and mobile private key storage. However, that technology is still relatively new and expensive to deploy on any but a limited scale. Lower-cost solutions, which store the credentials on a local (e.g., work station) disk file, have mobility or security issues. Revocation of PK credentials is still a problem, and standard, scalable and efficient solutions have yet to be provided.

The Kerberos and PK trust models are very similar. A Kerberos ticket is analogous to a PK certificate. However, Kerberos tickets usually have lifetimes measured in hours or days, instead of months or years. Because of their relatively short lifetime, Kerberos tickets are typically allowed to expire instead of being explicitly revoked. The Kerberos session key is analogous to the private key associated with the public key contained in a PK certificate. Possession of the private key is required to prove the authenticity of the sender in a PK system. That is typically done by signing, or encrypting, information with the private key. That signed or encrypted information, along with the certificate, allows a receiver to verify the association between that information and the certificate. As with Kerberos, the trust the receiver places in the identity of the sender is a function of the trust the receiver places in the issuing authority. In the public key

[18] Neuman, C., Hur, M., Medvinsky, A., and Alexander Medvinsky. 1997. “Public Key Utilizing Tickets for Application Servers (PKTAPP),” Internet Draft, March 1998. See also: Sirbu, M. Chuang. J. “Distributed Authentication in Kerberos Using Public Key Cryptography,” Symposium On Network and Distributed System Security.

systems, that issuing authority is the certificate authority (CA); in Kerberos, that issuing authority is the KDC.

The use of authentication mechanisms such as public key has the potential for minimizing the need for a central online authentication service such as Kerberos. However, authentication is only one of the functions required of an enterprise security service, and the removal of authentication is unlikely to affect Kerberos' role in supporting access control, authorization, and delegation. Moreover, applications where the performance of asymmetric-key cryptography is unacceptable will still require the use of a system that can provide robust services based on symmetric-key cryptography. Advances in cryptography, such as optimizations of elliptic curve algorithms and hardware acceleration, promise improvements in the performance and cost-effectiveness of asymmetric-key cryptography. When the cost will reach a level that allows wide-scale adoption is unclear. In any case, Kerberos can incorporate that technology today for those who can afford it.

PK systems have been integrated into Kerberos using the preauthentication facility of the initial authentication exchange. For example, the client can provide a signed message, with or without an X.509 certificate, as a preauthentication element in the request to the Kerberos authentication service. The result of that exchange is a standard Kerberos 5 credential.

93.11.5.2 OSF DCE

The Open Software Foundation, Distributed Computing Environment (OSF DCE) uses Kerberos 5 as the underlying security mechanism.[19] DCE extends the basic Kerberos credential to include other information, such as authorization, and defines an authorization system that is separate but typically co-located with the authentication and ticket-granting services on the DCE security server. DCE clients also use RPC (Remote Procedure Call) as their basic communication mechanism, which requires that both client and server utilize the same secure RPC to be interoperable; the RPC is secured using Kerberos 5.

DCE applications are not interoperable with Kerberos 5 applications. However, many DCE implementations also provide support for standard Kerberos 5 clients. That is, the DCE security server may also provide a standard Kerberos 5 authentication service (AS) and ticket-granting service (TGS). That support for standard Kerberos 5 clients does not make DCE and Kerberos 5 applications interoperable; authorization and RPC transport are still barriers to interoperability between applications. As the term "computing environment" implies, DCE requires additional infrastructure components beyond the basic security service, such as a cell directory service, time service, etc.

93.11.5.3 Kerberos 4

Kerberos 4 is the predecessor of Kerberos 5. Kerberos 5 addresses many Kerberos 4 security issues, as well as other scalability and portability issues associated with Kerberos 4. Although conceptually similar, Kerberos 5 and Kerberos 4 are quite different. Kerberos 4 has seen fairly extensive use in educational and commercial environments, and in a few key applications. One of the most widely used applications is AFS (Andrew File System), which is a secure distributed file system (similar to the OSF DCE distributed file service, DFS).

Kerberos 5 and Kerberos 4 applications are not interoperable. Some Kerberos 5 implementations also include support for Kerberos 4 and provide facilities to improve interoperation between Kerberos 4 and Kerberos 5 environments. Interoperation may be achieved by direct support for Kerberos 4 authentication and ticket-granting services by the KDC, or by allowing a Kerberos 4 ticket to be used to obtain a Kerberos 5 ticket (or vice versa).

93.11.5.4 GSS-API

The Generic Security Service Applications Programming Interface (GSS-API) is a standard that provides applications with a standard API for using different security mechanisms. The objective of the GSS-API is

[19] Blakley, B. October 1995. "Security Requirements for DCE," Open Software Foundation Request for Comments 8.1.

to shield applications from variations in the underlying security mechanisms. In its simplest form, the GSS-API is a thin veneer that sits above an underlying mechanism; that mechanism, such as Kerberos 5, provides the actual security services. Although applications are shielded from the underlying mechanism, the infrastructure for each security mechanism is still required.

The original GSS-API specification is referred to as V1.[20] V1 of the GSS-API does not support mechanism negotiation. V2 of the GSS-API specification provides the ability for implementations to support multiple mechanisms.[21] As an API, the GSS-API must define specific language bindings, and there are separate standards for each language binding, such as Java.[22] As of this writing, only "C" language bindings are standardized.[23] GSS-API mechanism specifications may also encapsulate existing mechanisms, in which case a protocol, and not just an API, is defined as part of the GSS-API mechanism standard.

Kerberos 5 was one of the first mechanisms implemented under the GSS-API. Several other mechanisms have also been implemented, including SPKM[24] (Simple Public Key Mechanism) and IDUP[25] (Independent Data Unit Protocol). Two GSS-API applications are compatible only if the underlying GSS-API mechanisms are compatible. GSS-API applications using a Kerberos 5 mechanism and "native" Kerberos 5 applications are not interoperable, because the GSS-API defines not only an API, but a protocol as well.[26] Although the GSS-API Kerberos 5 mechanism uses messages that are the same as Kerberos 5, those messages are encapsulated in a protocol that is different from Kerberos 5.

93.11.5.5 Microsoft SSPI

The Microsoft Security Service Provider Interface (SSPI) is the Microsoft equivalent of the GSS-API.[27] A mechanism such as Kerberos 5 is a "security provider," and applications use security providers through the "provider interface" (the API). The SSPI Kerberos 5 mechanism is wire-level compatible with the GSS-API Kerberos 5 mechanism. The SSPI API is not compatible with the GSS-API. Thus, although the APIs differ, clients and servers written to use either SSPI or GSS-API can interoperate using a common Kerberos 5 mechanism.

93.11.5.6 SNEGO

The Simple and Protected GSS-API Negotiation Mechanism (SNEGO), is a special GSS-API mechanism that allows the secure negotiation of the mechanism to be used by two different GSS-API implementations.[28] In essence, SNEGO defines a universal but separate mechanism, solely for the purpose of negotiating the use of other security mechanisms. SNEGO itself does not define or provide authentication or data protection, although it can allow negotiators to determine if the negotiation has been subverted, once a mechanism is established. GSS-API implementations that do not support SNEGO cannot negotiate, and therefore the client and server must agree a priori what mechanism or mechanisms will be used.

93.11.5.7 SSL

Secure Sockets Layer (SSL), and the related Transport Layer Security (TLS), are secure point-to-point protocols that define both authentication and message confidentiality protection.[29] SSL uses public key authentication. Because SSL is point-to-point, it is suitable only as a low-level transport protocol. An SSL authentication exchange results in the establishment of a shared secret key on both the client and server. That key, and conventional symmetric-key cryptography, is used to provide message confidentiality protection.

SSL has also been used to provide an initial authentication exchange between a client and a Kerberos KDC. In essence, SSL is used to replace the standard Kerberos initial authentication exchange, and a special authentication service (AS) is used on the KDC. SSL authentication is used in place of the client's initial authentication request, which may or may not involve the use of a password by the client. SSL is then used to securely transport the TGT back to the client. SSL is presently one of the few protocols that do not have a standard way of integrating Kerberos authentication to provide message integrity and confidentiality, although such integration has been proposed.[30]

93.11.5.8 SASL

Simple Authentication and Security Layer (SASL) is a framework for negotiating a security mechanism for session-oriented protocols.[31] SASL specifies a naming convention for registered mechanisms, as well as profile information required for clients and servers to use a mechanism to protect a specific protocol. Registered SASL mechanisms include Kerberos 4 and GSS-API, among others.

93.11.5.9 IPSec

Internet Protocol Security (IPSec), provides integrity or confidentiality services at the network layer.[32] All data protection is performed using symmetric-key cryptography. Establishment of the session keys for data protection is also defined by IPSec, and may use both symmetric- and asymmetric-key cryptography.

Although IPSec provides data protection, it does not provide the key management infrastructure necessary for a large number of IPSec systems to authenticate and establish the session keys needed for data protection. As a network layer protection service, IPSec is targeted primarily at machine-to-machine security; authentication of individuals and applications is outside the scope of IPSec, and depends entirely on the key management infrastructure used, and the integration of that key management infrastructure with the IPSec implementation.

Kerberos can provide key management for IPSec implementations, and this has been proposed through the use of the GSS-API mechanism.[33] In essence, the Kerberos principals are simply machines, or more accurately, the service on each machine that provides IPSec network layer protection. Kerberos can also provide the key management for binding individuals and applications to IPSec implementations.

93.11.5.10 RADIUS

The Remote Authentication Dial-In User Service (RADIUS) allows a RADIUS client (typically a network access device, such as a terminal server), to authenticate a user on a remote computer and control that user's access to the network.[34] The RADIUS client uses the RADIUS protocol to talk to a RADIUS server

to authenticate the user. The RADIUS server may contain a simple database containing IDs and passwords, or may use another server to authenticate the client, such as a token card server, or a Kerberos KDC. RADIUS has gained significant acceptance among network and token card vendors.

RADIUS protects the communication between a RADIUS client (e.g., a terminal server), and a RADIUS server. RADIUS does not protect the communications between a remote client and a RADIUS client. Thus, information passed between the remote client (e.g., a laptop computer) and the RADIUS client is unprotected. RADIUS does not have the concept of a credential, and the result of authentication using RADIUS is a yes–no answer. Thus, RADIUS is primarily used as a simple access control mechanism. DIAMETER, part of the AAA (Authentication, Authorization, and Accounting) effort in the IETF, is working to address some of the limitations of RADIUS.[35]

RADIUS has been integrated with Kerberos by using the RADIUS server as a surrogate Kerberos client. That is, the RADIUS server acts as a client to verify an ID and password against a KDC; that ID and password come from the end user at the remote computer system. Although the RADIUS server obtains a Kerberos credential as the result of that authentication, there is no way to send that credential back to the end client through the RADIUS client. The benefit of using RADIUS in this manner is that a single authentication database can be used (the KDC's principal database), even though the result of authentication does not provide the client a credential. Note that RADIUS does not protect the user's password between the end client and the RADIUS, and the RADIUS client and server have access to the user's Kerberos ID and password. Thus, use of RADIUS as part of a Kerberos implementation should ensure that the resulting exposure is acceptable.

93.11.5.11 CDSA

Common Data Security Architecture (CDSA) provides a standard API for many security services, including encryption, authentication, and credential storage and management.[36] CDSA also defines standard methods for incorporating a variety of security service providers, both hardware and software, and a variety of mechanisms, including public key and biometrics. CDSA is similar to Microsoft's Cryptographic API (MS CAPI) in purpose. CDSA was originally developed by Intel and has now been adopted by the Open Group.[37]

93.11.5.12 Token Cards

Token cards are an example of a very simple trusted third party authentication system. A user, in possession of a token, keys in information from the token. That information is then sent to the application, which verifies the information with a token card server (the trusted third party) provided by the token card vendor. Typically, the value presented by the token is usable only once (to prevent replays) or has a very limited life, and is generated using a key contained within the token card (which is tamperproof) and a key known to the vendor's token card server.

Token cards secure only the authentication to the application and do not provide any security for the application's data. That is, no information in the authentication process is available for establishing a session key for subsequently encrypting application data. Moreover, token cards must be used for authentication to each application, just as a password is. While the user is not required to remember passwords—the token card in effect generates the passwords—the user must still key a "password" in for each application authentication.

There are three basic types of token cards: challenge-response, time synchronous, and event synchronous. Regardless of type, all have a common attribute: the card is (or should be) tamperproof, and the card contains a secret key shared between the card and the security server. Use of the card

[37] The Open Group, "New Security Standard from The Open Group Brings the Realization of High-Value E-Commerce for Everyone a Step Further" Press Release January 6, 1998.

typically requires both physical possession of the card (something you have) and a PIN (something you know). The requirement that those two factors be present for authentication to succeed is the basis for the term "two-factor authentication." Software may also be used to achieve the same effect as a hardware token card. Obviously a software "token card" does not provide the two factors provided by a hardware token.

A variety of token card systems have been integrated into Kerberos using the preauthentication facility of the initial authentication service. The KDC then contacts the token card server, instead of the client contacting the token card server. This allows a mix of token card technologies to be used. The result of the initial authentication exchange is a standard Kerberos 5 credential.

93.11.5.13 Smart Cards

Smart cards are so named because they have processing intelligence on a card that is the same form factor as a credit card. The processing power and memory capacity varies depending on the card. Smart cards have received prominent attention recently, primarily because of the promise they hold for addressing public key client credential management and security issues, by holding the user's private key in tamper-proof storage, and performing cryptographic operations on the card. Thus, the user's private key never leaves the card.

Smart card costs are dropping rapidly. However, a wide-scale smart card deployment requires not only cards, but also readers. As of this writing, cards with the necessary processing power and storage, and the associated readers, are still too expensive for wide-scale deployment. Although smart cards are most often associated with public key systems, smart cards are also used to provide symmetric-key cryptography. Symmetric-key smart cards may provide secure key storage and associated cryptographic functions for use as challenge-response devices, for example.

Public key smart cards have been integrated into Kerberos using the preauthentication mechanism. This allows users with smart cards to authenticate to the Kerberos authentication service using the public key credentials on a smart card.

93.11.5.14 Encryption Algorithms

The two broad classifications of cryptographic systems are symmetric-key and asymmetric-key. Both Kerberos and public key systems (as well as other authentication systems) may incorporate one or both cryptographic systems. Common symmetric-key systems include DES (Data Encryption Standard), and the triple-DES variant.[38] Common asymmetric-key systems include ECC[39] (elliptic curve) and RSA[40] (Rivest–Shamir–Adleman). The strength of these different systems is difficult to compare and is only one element that determines their application. For example, based on exhaustive key search, a triple-DES (112-bit) key is approximately equal to a 1792-bit RSA key (i.e., key modulus);[41] and a 1024-bit RSA key is approximately equal to a 160-bit ECC key.[42]

The distinguishing characteristic of these systems is the symmetry of the keys used for encryption and decryption. Symmetric-key systems use the same key for encryption and decryption. Thus, two parties must share the same key (presumably secret) in order to encrypt and decrypt information. Asymmetric-

[42] "Remarks on the Security of the Elliptic Curve Cryptosystem," Certicom Corporation ECC whitepaper (September 1997).

key systems use different, but related, keys for encryption and decryption: information encrypted with one key can only be decrypted with the other key. That key pair is typically referred to as a public–private key pair. One of the keys is public and known to many people; the other key is private (presumably secret) and known to only one person.

Another distinguishing characteristic of these systems is the CPU speed or hardware complexity for encryption and decryption operations. Symmetric-key systems tend to be quite fast. Asymmetric-key systems tend to be CPU intensive and are typically used only for encrypting small amounts of data—typically only that needed for authentication (as with digital signatures). Because of its speed advantages, symmetric key cryptography is still used by all security systems for encrypting application data. Symmetric- and asymmetric-key are often used together. For example, asymmetric-key is used to establish a session key for symmetric-key by encrypting a symmetric session key (that symmetric-key usually being a very a small amount of data). Higher-performance symmetric-key is then used to encrypt and decrypt the application data. The speed of cryptographic operations in symmetric-key systems is typically symmetric. That is, encrypt and decrypt speeds are generally the same (for the same implementation running on the same hardware). The speed of cryptographic operations in asymmetric-key systems is typically asymmetric, and depends on what function is being performed.

Cryptographic systems alone do not constitute a secure authentication system. Kerberos and public key are secure, distributed, authentication systems that use cryptographic systems, define the rules of how cryptography is used, and that define the syntax and semantics for various protocol messages and data formats. Although the rules and protocols for different authentication systems tend to be very different, the problems that must be solved to build a practical, secure, distributed, authentication system are largely invariant.

Kerberos defines the use of symmetric-key cryptography, including both DES and triple-DES, for both authentication and data encryption. Asymmetric-key cryptography has also been integrated into Kerberos using the preauthentication facility of the initial authentication service.

93.11.5.15 Secure Hash Algorithms

Secure distributed authentication systems require secure hash functions and not just encryption and decryption, although secure hash functions are often built using a cryptographic algorithm. A secure hash function takes a large amount of data and hashes it down to a small amount of data (e.g., 128 bits), or the "hash value." The attributes of a secure hash function are no two inputs should produce the same output ("collision proof"), and you cannot work backwards from the hash value to the input. Think of the secure hash value as a fingerprint: the hash value uniquely defines the input but does not tell you anything about the input. Note that a simple checksum, such as CRC32, is not a secure hash function—too many inputs produce the same output. A secure hash is sometimes referred to as a message digest or cryptographic checksum.

A secure hash is typically used to provide integrity protection and is also used in digital signature applications. The hash value of a document is generated, and that value is encrypted using an individual's key. Encrypting only the hash value, or signature, eliminates the need to encrypt the entire document for integrity protection. That encrypted value is also the digital signature of the individual applied to a document. Verifying the signature against the document simply regenerates the hash value of the document, decrypts the encrypted hash value, and compares the two. If someone changes either the signature or the document, the hash will change, and verification will fail. The most common hash functions are MD5[43] (Message Digest 5) and SHA-1[44] (Secure Hash Algorithm 1).

Kerberos defines the use of several secure hash functions, including DES and triple-DES message authentication code (MAC) hashing functions, as well as MD5 and SHA-1.

93.12 Lessons Learned

As discussed in previous sections, most of the technical issues surrounding the implementation and deployment of Kerberos are tractable, and when properly understood, those issues should not present serious problems. The significant technical issues that remain—such as fragmented or dysfunctional namespaces—and their solutions are dependent on the environment. Various methods can minimize those issues, but there is little that Kerberos, or any security system, can do to fix the underlying problems. And as with all security systems, the primary obstacles to success are not technical, but fundamental to the role of information security in today's business and organizational environments. Kerberos does what it can technically by providing a robust and cost-effective distributed security system. The rest is up to us.

93.12.1 Risk, Fear, and Value

Kerberos is fundamentally a strong distributed authentication system. It can be used for a single application within a single group or a set of applications that span an enterprise. Whatever the use, successful deployments usually address applications that can benefit from what Kerberos has to offer. That applies whether Kerberos is being used for a single application or to implement enterprise wide secure single sign-on. As obvious as it may seem, the security that Kerberos brings with it must be perceived to be of value to the organization. Although security practitioners may appreciate the intrinsic value of strong authentication, the broader community within most organizations generally does not perceive that value. Without perceived value, cost and effort will be viewed as wasted. To put it another way, without perceived value, any deployment problems will be magnified, and the probability of success will rapidly approach zero.

Applications that can benefit from a distributed security system such as Kerberos are growing more common than in the past. However, the fundamentals still hold true. As enterprises move to more distributed environments, services are often pushed out toward the consumer. For example, providing on-demand access to human resources data (typically some of the most sensitive information in an organization) by employees from individual desktops. Such "self-service" applications require a strong, distributed authentication system that can also provide data encryption, and provide those capabilities at reasonable cost. The cost of the security infrastructure can often be justified by the cost savings obtained by removing the "human firewall" of clerks that typically guard access to those applications' data.

Because the intrinsic value of a system such as Kerberos is not always appreciated, it is up to security practitioners to identify the applications that can benefit. That requires more than an understanding of security. It also requires understanding the application, and the business needs that surround the application. It requires knowledge sufficient to make the benefits of security intrinsically obvious to the application owners, or sufficient knowledge to quantify the risks and costs to the application owners. Risk and cost are a business decision. Making an informed decision requires understanding both. Risk is often difficult to quantify, and unquantified risk, in the form of fear, can sometimes be a great motivator. However, decisions based on fear are often subject to reversal and second-guessing, and are poor substitutes for informed decision making.

Security based on value and informed decisions will find a more accepting audience, and much easier deployment, than those based on fear.

93.12.2 Distributed Security

The rules that a security system enforces represent demands and assumptions made of the environment. If those rules are too onerous, the security implementation will fail as predictably, and for the same reasons, as any technology that makes unrealistic assumptions or resource demands on its environment. As a security *technology*, Kerberos provides very good performance and makes relatively modest demands and assumptions on its environment. As a security *system*, the demands and assumptions made by Kerberos are entirely dependent on an organization's definition of acceptable security.

The tradeoff between acceptable security and what is practical in an organization, is the first question that the security practitioner must answer. The answer to that question varies from organization to organization, and technology generally plays a minor role in the equation. Moreover, the organic nature of most distributed environments is not receptive to the introduction of a broad-based security system. Introduction of such a system into those environments—with implicitly greater uniformity and rigidity—will cause friction. If Kerberos is used to enforce draconian security measures in environments that have previously had very informal or isolated security practices, problems are very likely to occur. Technology cannot solve those problems.

The very nature of distributed environments increases diversity and indeterminacy. That introduces a greater degree of uncertainty into the security equation. That uncertainty is something the security community has historically been very uncomfortable with. Probabilistic models of security require quantification and analysis. Today, that quantification and analysis are extremely difficult at best, impossible at worst, and so rare as to be non-existent. Thus we are left to make a value judgment, and for most it is far easier to retreat into the absolutes of the past than to risk uncertainty. After all, risk reduction and aversion is what security is all about.

While the level of certainty that we are historically accustomed to is achievable in distributed environments, it is not achievable at a cost that any organization can afford. That is extremely unlikely to change. Diversity and indeterminacy are increasing with every passing day. Successful distributed security implementations recognize and embrace those changes, making incremental improvements as organizations and technology adapt and converge on an acceptable paradigm. Unsuccessful distributed security implementations shun those changes and attempt to impose unrealistic demands based on time-worn assumptions about what is feasible, necessary, or desirable.

The one lesson that stands out from years of Kerberos implementations is that uncertainty is a fact of life in distributed security. Learn to deal with it.

94

Methods of Attacking and Defending Cryptosystems

Joost Houwen

Encryption technologies have been used for thousands of years and, thus, being able read the secrets they are protecting has always been of great interest. As the value of our secrets have increased, so have the technological innovations used to protect them. One of the key goals of those who want to keep secrets is to keep ahead of techniques used by their attackers. For today's IT systems, there is increased interest in safeguarding company and personal information, and therefore the use of cryptography is growing. Many software vendors have responded to these demands and are providing encryption functions, software, and hardware. Unfortunately, many of these products may not be providing the protection that the vendors are claiming or customers are expecting. Also, as with most crypto usage throughout history, people tend to defeat much of the protection afforded by the technology through misuse or inappropriate use. Therefore, the use of cryptography must be appropriate to the required goals and this strategy must be constantly reassessed. To use cryptography correctly, the weaknesses of systems must be understood.

This chapter reviews various historical, theoretical, and modern methods of attacking cryptographic systems. Although some technical discussion is provided, this chapter is intended for a general information technology and security audience.

94.1 Cryptography Overview

A brief overview of definitions and basic concepts is in order at this point. Generally, *cryptography* refers to the study of the techniques and methods used to hide data, and *encryption* is the process of disguising a message so that its meaning is not obvious. Similarly, decryption is the reverse process of encryption. The original data is called *cleartext* or *plaintext*, and the encrypted data is called *ciphertext*. Sometimes, the words *encode/encipher* and *decode/decipher* are used in the place of *encrypt* and *decrypt*. A cryptographic algorithm is commonly called a *cipher*. *Cryptanalysis* is the science of breaking cryptography, thereby gaining knowledge about the plaintext. The amount of work required to break an encrypted message or mechanism is call the *work factor*. *Cryptology* refers to the combined disciplines of cryptography and cryptanalysis.

Cryptography is one of the tools used in information security to assist in ensuring the primary goals of confidentiality, integrity, authentication, and non-repudiation.

Some of the things a cryptanalyst needs to be successful are:

- Enough ciphertext
- Full or partial plaintext
- Known algorithm
- Strong mathematical background
- Creativity
- Time, time, and more time for analysis
- Large amounts of computing power

Motivations for a cryptanalyst to attack a cryptosystem include:

- Financial gain, including credit card and banking information
- Political or espionage
- Interception or modification of e-mail
- Covering up another attack
- Revenge
- Embarrassment of vendor (potentially to get them to fix problems)
- Peer or open-source review
- Fun/education (cryptographers learn from others' and their own mistakes)

It is important to review the basic types of commonly used ciphers and some historical examples of cryptosystems. The reader is strongly encouraged to review cryptography books, but especially Bruce Schneier's essential *Applied Cryptography*[1] and *Cryptography and Network Security*[2] by William Stallings.

94.2 Cipher Types

94.2.1 Substitution Ciphers

A simple yet highly effective technique for hiding text is the use of substitution cipher, where each character is switched with another. There are several of these types of ciphers with which the reader should be familiar.

94.2.1.1 Monoalphabetic Ciphers

One way to create a substitution cipher is to switch around the alphabet used in the plaintext message. This could involve shifting the alphabet used by a few positions or something more complex. Perhaps the most famous example of such a cipher is the Caesar cipher, used by Julius Caesar to send secret messages. This cipher involves shifting each letter in the alphabet by three positions, so that "A" becomes "D," and "B" is replaced by "E," etc. Although this may seems simple today, it is believed to have been very successful in ancient Rome. This is probably due, in large part, to the fact the even the ability to read was uncommon, and therefore writing was probably a code in itself.

A more modern example of the use of this type of cipher is the UNIX *crypt* utility, which uses the ROT13 algorithm. ROT13 shifts the alphabet 13 places, so that "A" is replaced by "N," "B" by "M," etc. Obviously, this cipher provides little protection and is mostly used for obscuration rather than encryption, although with a utility named *crypt*, some users may assume there is actually some real protection in place. Note that this utility should not be confused with the UNIX *crypt()* software routine that is used in the encryption of passwords in the password file. This routine uses the repeated application of the DES algorithm to make decrypting these passwords extremely difficult.[3]

94.2.1.2 Polyalphabetic Ciphers

By using more than one substitution cipher (alphabet), one can obtain improved protection from a frequency analysis attack. These types of ciphers were successfully used in the American Civil War[4] and have been used in commercial word-processing software. Another example of this type of cipher is the Vigenère cipher, which uses 26 Caesar ciphers that are shifted. This cipher is interesting as well because it uses a keyword to encode and decode the text.

94.2.2 One-Time Pad

In 1917, Joseph Mauborgne and Gilbert Vernam invented the unbreakable cipher called a one-time pad. The concept is quite effective, yet really simple. Using a random set of characters as long as the message, it is possible to generate ciphertext that is also random and therefore unbreakable even by brute-force attacks. In practice, having—and protecting—shared suitably random data is difficult to manage but this technique has been successfully used for a variety of applications. It should be understood by the reader that a true, and thus unbreakable, one-time pad encryption scheme is essentially a theoretical concept as it is dependent on true random data, which is very difficult to obtain.

[1] Schneier, Bruce. 1995. *Applied Cryptography*, p.19, John Wiley, New York.

[2] Stallings, William. 2002. *Cryptography and Network Security: Principles and Practice*, p. 19, Prentice-Hall, Englewood Cliffs.

[3] Spafford. 2003. *Practical UNIX and Internet Security*, p. 19, O'Reilly & Associates, Sebastapol, CA.

[4] Schneier, Bruce. 1995. *Applied Cryptography*, p. 11, John Wiley, New York.

94.2.3 Transposition Cipher

This technique generates ciphertext by performing some form of permutation on plaintext characters. One example of this technique is to arrange the plaintext into a matrix and perform permutations on the columns. The effectiveness of this technique is greatly enhanced by applying it multiple times.

94.2.4 Stream Cipher

When large amounts of data need to enciphered, a cipher must be used multiple times. To efficiently encode this data, a stream is required. A stream cipher uses a secret key and then accepts a stream of plaintext producing the required ciphertext.

94.2.4.1 Rotor Machines

Large numbers of computations using ciphers can be time-consuming and prone to errors. Therefore, in the 1920s, mechanical devices called rotors were developed. The rotors were mechanical wheels that performed the required substitutions automatically. One example of a rotor machine is the Enigma used by the Germans during World War II. The initial designs used three rotors and an operator plugboard. After the early models were broken by Polish cryptanalysts, the Germans improved the system only to have it broken by the British.

94.2.4.2 RC4

Another popular stream cipher is the Rivest Cipher #4 (RC4) developed by Ron Rivest for RSA.

94.2.5 Block Cipher

A block cipher takes a block of plaintext, a key, and produces a block of ciphertext. Current block ciphers produce ciphertext blocks that are the same size as the corresponding plaintext block.

94.2.5.1 DES

The Data Encryption Standard (DES) was developed by IBM for the National Institute of Standards and Technology (NIST) as Federal Information Processing Standard (FIPS) 46. Data is encrypted using a 56-bit key and 8 parity bits with 64-bit blocks.

94.2.5.2 3DES

To improve the strength of DES-encrypted data, the algorithm can be applied in the triple-DES form. In this algorithm, the DES algorithm is applied three times, either using two keys (112-bit) encrypt–decrypt–encrypt, or using three keys (168-bit) encrypt–encrypt–encrypt modes. Both forms of 3DES are considered much stronger than single DES. There have been no reports of breaking 3DES.

94.2.5.3 IDEA

The International Data Encryption Algorithm (IDEA) is another block cipher developed in Europe. This algorithm uses 128-bit keys to encrypt 64-bit data blocks. IDEA is used in Pretty Good Privacy (PGP) for data encryption.

94.3 Types of Keys

Most algorithms use some form of secret key to perform encryption functions. There are some differences in these keys that should be discussed.

1. *Private/Symmetric*. A private, or symmetric, key is a secret key that is shared between the sender and receiver of the messages. This key is usually the only key that can decipher the message.

2. *Public/Asymmetric*. A public, or asymmetric, key is one that is made publicly available and can be used to encrypt data that only the holder of the uniquely and mathematically related private key can decrypt.
3. *Data/Session*. A symmetric key, which may or may not be random or reused, is used for encrypting data. This key is often negotiated using standard protocols or sent in a protected manner using secret public or private keys.
4. *Key Encrypting*. Keys that are used to protect data encrypting keys. These keys are usually used only for key updates and not data encryption.
5. *Split Keys*. To protect against intentional or unintentional key disclosure, it is possible to create and distribute parts of larger keys which only together can be used for encryption or decryption.

94.4 Symmetric Key Cryptography

Symmetric key cryptography refers to the use of a shared secret key that is used to encrypt and decrypt the plaintext. Hence, this method is sometimes referred to as secret key cryptography. In practice, this method is obviously dependent on the "secret" remaining so. In most cases, there needs to be a way that new and updated secret keys can be transferred. Some examples of symmetric key cryptography include DES, IDEA, and RC4.

94.5 Asymmetric Key Cryptography

Asymmetric key cryptography refers to the use of public and private key pairs, and hence this method is commonly referred to as public key encryption. The public and private keys are mathematically related so that only the private key can be used to decrypt data encrypted with the public key. The public key can also be used to validate cryptographic signatures generated using the corresponding private key.

94.5.1 Examples of Public Key Cryptography

94.5.1.1 RSA

This algorithm was named after its inventors, Ron Rivest, Adi Shamir, and Leonard Adleman, and based on the difficulty in factoring large prime numbers. RSA is currently the most popular public key encryption algorithm and has been extensively cryptanalyzed. The algorithm can be used for both data encryption and digital signatures.

94.5.1.2 Elliptic Curve Cryptography (ECC)

ECC utilizes the unique mathematical properties of elliptic curves to generate a unique key pair. To break the ECC cryptography, one must attack the "elliptic curve discrete logarithm problem." Some of the potential benefits of ECC are that it uses significantly shorter key lengths and that is well-suited for low bandwidth/CPU systems.

94.6 Hash Algorithms

Hash or digest functions generate a fixed-length hash value from arbitrary-length data. This is usually a one-way process, so that it impossible to reconstruct the original data from the hash. More importantly, it is, in general, extremely difficult to obtain the same hash from two different data sources. Therefore, these types of functions are extremely useful for integrity checking and the creation of electronic signatures or fingerprints.

94.6.1 MD5

The Message Digest (MD) format is probably the most common hash function in use today. This function was developed by Ron Rivest at RSA, and is commonly used as a data integrity checking tool, such as in Tripwire and other products. MD5 generates a 128-bit hash.

94.6.2 SHA

The Secure Hash Algorithm (SHA) was developed by the NSA. The algorithm is used by PGP, and other products, to generate digital signatures. SHA produces a 160-bit hash.

94.7 Steganography

Steganography is the practice used to conceal the existence of messages. That is different from encryption, which seeks to make the messages unintelligible to others.[5]

A detailed discussion of this topic is outside the scope of this chapter, but the reader should be aware that there are many techniques and software packages available that can be used to hide information in a variety of digital data.

94.8 Key Distribution

One of the fundamental problems with encryption technology is the distribution of keys. In the case of symmetric cryptography, a shared secret key must be securely transmitted to users. Even in the case of public key cryptography, getting private keys to users and keeping public keys up-to-date and protected remain difficult problems. There are a variety of key distribution and exchange methods that can be used. These range from manual paper delivery to fully automated key exchanges. The reader is advised to consult the references for further information.

94.9 Key Management

Another important issue for information security professionals to consider is the need for proper key management. This is an area of cryptography that is often overlooked and there are many historical precedents in North America and other parts of the world. If an attacker can easily, or inexpensively, obtain cryptographic keys through people or unprotected systems, there is no need to break the cryptography the hard way.

94.10 Public versus Proprietary Algorithms and Systems

It is generally an accepted fact among cryptography experts that closed or proprietary cryptographic systems do not provide good security. The reason for this is that creating good cryptography is very difficult and even seasoned experts make mistakes. It is therefore believed that algorithms that have undergone intense public and expert scrutiny are far superior to proprietary ones.

94.11 Classic Attacks

Attacks on cryptographic systems can be classified under the following threats:

- Interception
- Modification

[5] Stallings, William. 2002. *Cryptography and Network Security: Principles and Practices*, p. 26, Prentice-Hall, Englewood Cliffs.

- Fabrication
- Interruption

Also, there are both passive and active attacks. Passive attacks involve the listening-in, eavesdropping, or monitoring of information, which may lead to interception of unintended information or traffic analysis where information is inferred. This type of attack is usually difficult if not impossible to detect. However, active attacks involve actual modification of the information flow. This may include:[6]

- Masquerade
- Replay
- Modification of messages
- Denial of service

There are many historical precedents of great value to any security professional considering the use of cryptography. The reader is strongly encouraged to consult many of the excellent books listed in the bibliography, but especially the classic, *The Codebreakers: The Story of Secret Writing*, by David Kahn.[7]

94.12 Standard Cryptanalysis

Cryptanalysis strives to break the encryption used to protect information, and to this end there are many techniques available to the modern cryptographer.

94.12.1 Reverse Engineering

Arguably, one of the simplest forms of attack on cryptographic systems is reverse engineering, whereby an encryption device (method, machine, or software) is obtained through other means and then deconstructed to learn how best to extract plaintext. In theory, if a well-designed crypto hardware system is obtained and even its algorithms are learned, it may still be impossible to obtain enough information to freely decrypt any other ciphertext.[8] During World War II, efforts to break the German Enigma encryption device were greatly aided when one of the units was obtained. Also, today when many software encryption packages that claim to be foolproof are analyzed by cryptographers and security professionals, they are frequently found to have serious bugs that undermine the system.

94.12.2 Guessing

Some encryption methods may be trivial for a trained cryptanalyst to decipher. Examples of this include simple substitutions or obfuscation techniques that are masquerading as encryption. A common example of this is the use of the logical XOR function, which when applied to some data will output seemingly random data, but in fact the plaintext is easily obtained. Another example of this is the Caesar cipher, where each letter of the alphabet is shifted by three places so that A becomes D, B becomes E, etc. These are types of cryptograms that commonly present in newspapers and puzzle books.

The *Principle of Easiest Work* states that one cannot expect the interceptor to choose the hard way to do something.[9]

[9] Pfleeger, E. Charles. 1996. *Security in Computing*, p. 19, Prentice-Hall, Englewood Cliffs.

94.12.3 Frequency Analysis

Many languages, especially English, contain words that repeatedly use the same patterns of letters. There have been numerous English letter frequency studies done that give an attacker a good starting point for attacking much ciphertext. For example, by knowing that the letters E, T, and R appear the most frequently in English text, an attacker can fairly quickly decrypt the ciphertext of most monoalphabetic and polyalphabetic substitution ciphers. Of course, critical to this type of attack is the ready supply of sufficient amounts of ciphertext from which to work. These types of frequency and patterns also appear in many other languages, but English appears particularly vulnerable. Monoalphabetic ciphers, such as the Caesar cipher, directly transpose the frequency distribution of the underlying message.

94.12.4 Brute Force

The process of repeatedly trying different keys to obtain the plaintext are referred to as brute-force techniques. Early ciphers were made stronger and stronger in order to prevent human “computers” from decoding secrets; but with the introduction of mechanical and electronic computing devices, many ciphers became no longer usable. Today, as computing power grows daily, it has become a race to improve the resistance, or work factor, to these types of attacks. This of course introduces a problem for applications that may need to protect data that may be of value for many years.

94.12.5 Ciphertext-Only Attack

The cryptanalyst is presented only with the unintelligible ciphertext, from which she tries to extract the plaintext. For example, by examining only the output of a simple substitution cipher, one is able to deduce patterns and ultimately the entire original plaintext message. This type of attack is aided when the attacker has multiple pieces of ciphertext generated from the same key.

94.12.6 Known Plaintext Attack

The cryptanalyst knows all or part of the contents of the ciphertext’s original plaintext. For example, the format of an electronic funds transfer might be known except for the amount and account numbers. Therefore, the work factor to extract the desired information from the ciphertext is significantly reduced.

94.12.7 Chosen Plaintext Attack

In this type of attack, the cryptanalyst can generate ciphertext from arbitrary plaintext. This scenario occurs if the encryption algorithm is known. A good cryptographic algorithm will be resistant even to this type of attack.

94.12.8 Birthday Attack

One-way hash functions are used to generate unique output, although it is possible that another message could generate an identical hash. This instance is called a collision. Therefore, an attacker can dramatically reduce the work factor to duplicate the hash by simply searching for these “birthday” pairs.

94.12.9 Factoring Attacks

One of the possible attacks against RSA cryptography is to attempt to use the public key and factor the private key. The security of RSA depends on this being a difficult problem, and therefore takes significant computation. Obviously, the greater the key length used, the more difficult the factoring becomes.

94.12.10 Replay Attack

An attacker may be able to intercept an encrypted "secret" message, such as a financial transaction, but may not be able to readily decrypt the message. If the systems are not providing adequate protection or validation, the attacker can now simply send the message again, and it will be processed again.

94.12.11 Man-in-the-Middle Attack

By interjecting oneself into the path of secure communications or key exchange, it possible to initiate a number of attacks. An example that is often given is the case of an online transaction. A customer connects to what is thought to be an online bookstore; but in fact, the attacker has hijacked the connection to monitor and interact with the data stream. The customer connects normally because the attacker simply forwards the data onto the bookstore, thereby intercepting all the desired data. Also, changes to the data stream can be made to suit the attacker's needs.

In the context of key exchange, this situation is potentially even more serious. If an attacker is able to intercept the key exchange, he may be able to use the key at will (if it is unprotected) or substitute his own key.

94.12.12 Dictionary Attacks

A special type of known-plaintext and brute-force attack can be used to guess the passwords on UNIX systems. UNIX systems generally use the *crypt()* function to generate theoretically irreversible encrypted password hashes. The problem is that some users choose weak passwords that are based on real words. It is possible to use dictionaries containing thousands of words and to use this well-known function until there is a match with the encoded password. This technique has proved immensely successful in attacking and compromising UNIX systems. Unfortunately, Windows NT systems are not immune from this type of attack. This is accomplished by obtaining a copy of the NT SAM file, which contains the encrypted passwords, and as in the case of UNIX, comparing combinations of dictionary words until a match is found. Again, this is a popular technique for attacking this kind of system.

94.12.13 Attacking Random Number Generators

Many encryption algorithms utilize random data to ensure that an attacker cannot easily recognize patterns to aid in cryptanalysis. Some examples of this include the generation of initialization vectors or SSL sessions. However, if these random number generators are not truly random, they are subject to attack. Furthermore, if the random number generation process or function is known, it may be possible to find weaknesses in its implementation. Many encryption implementations utilize pseudorandom number generators (PRNGs), which as the name the name suggests, attempt to generate numbers that are practically impossible to predict. The basis of these PRNGs is the initial random seed values, which obviously must be selected properly. In 1995, early versions of the Netscape Navigator software were found to have problems with the SSL communication security.[10] The graduate students who reverse engineered the browser software determined that there was a problem with the seeding process used by the random number generator. This problem was corrected in later versions of the browser.

94.12.14 Inference

A simple and potential low-tech attack on encrypted communication can be via simple inference. Although the data being sent back and forth is unreadable to the interceptor, it is possible that the mere

[10] Smith, Richard, E. 1997. *Internet Cryptography*, p. 91, Addison-Wesley, Reading, MA.

fact of this communication may mean there is some significant activity. A common example of this is the communication between military troops, where the sudden increase in traffic, although completely unreadable, may signal the start of an invasion or major campaign. Therefore, these types of communications are often padded so as not to show any increases or decreases in traffic. This example can easily be extended to the business world by considering a pending merger between two companies. The mere fact of increased traffic back and forth may signal the event to an attacker. Also, consider the case of encrypted electronic mail. Although the message data is well encrypted, the sender and recipient are usually plainly visible in the mail headers and message. In fact, the subject line of the message (e.g., “merger proposal”) may say it all.

94.13 Modern Attacks

Although classical attacks still apply and are highly effective against modern ciphers, there have been a number of recent cases of new and old cryptosystems failing.

94.13.1 Bypass

Perhaps one of the simplest attacks that has emerged, and arguably is not new, is to simply go around any crypto controls. This may be as simple as coercion of someone with access to the unencrypted data or by exploiting a flaw in the way the cipher is used. There are currently a number of PC encryption products on the market and the majority of these have been found to have bugs. The real difference in these products has been the ways in which the vendor has fixed the problem (or not). A number of these products have been found to improperly save passwords for convenience or have backdoor recovery mechanisms installed. These bugs were mostly exposed by curious users exploring how the programs work. Vendor responses have ranged from immediately issuing fixes to denying there is a problem.

Another common example is the case of a user who is using some type of encryption software that may be protecting valuable information or communication. An attacker could trick the user into running a Trojan horse program, which secretly installs a backdoor program, such as BackOrifice on PCs. On a UNIX system, this attack may occur via an altered installation script run by the administrator. The administrator can now capture any information used on this system, including the crypto keys and passphrases. There have been several demonstrations of these types of attacks where the target was home finance software or PGP keyrings. The author believes that this form of attack will greatly increase as many more users begin regularly using e-mail encryption and Internet banking.

94.13.2 Operating System Flaws

The operating system running the crypto function can itself be the cause of problems. Most operating systems use some form of virtual memory to improve performance. This “memory” is usually stored on the system’s hard disk in files that may be accessible. Encryption software may cache keys and plaintext while running, and this data may remain in the system’s virtual memory. An attacker could remotely or physically obtain access to these files and therefore may have access to crypto keys and possibly even plaintext.

94.13.3 Memory Residue

Even if the crypto functions are not cached in virtual memory or on disk, many products still keep sensitive keys in the system memory. An attacker may be able to dump the system memory or force the system to crash, leaving data from memory exposed. Hard disks and other media may also have residual data that may reside on the system long after use.

94.13.4 Temporary Files

Many encryption software packages generate temporary files during processing and may accidentally leave plaintext on the system. Also, application packages such as word processors leave many temporary files on the system, which may mean that even if the sensitive file is encrypted and there are no plaintext versions of the file, the application may have created plaintext temporary files. Even if temporary files have been removed, they usually can be easily recovered from the system disks.

94.13.5 Differential Power Analysis

In 1997, Anderson and Kuhn proposed inexpensive attacks against through which knowledgeable insiders and funded organizations could compromise the security of supposed tamper-resistant devices such as smart cards.[11] While technically not a crypto attack, these types of devices are routinely used to store and process cryptographic keys and provide other forms of assurance. Further work in this field has been done by Paul Kocher and Cryptographic Research, Inc. Basically, the problem is that statistical data may "leak" through the electrical activity of the device, which could compromise secret keys or PINs protected by it. The cost of mounting such an attack appears to be relatively low but it does require a high technical skill level. This excellent research teaches security professionals that new forms of high-security storage devices are highly effective but have to be used appropriately and that they do not provide *absolute* protection.

94.13.6 Parallel Computing

Modern personal computers, workstations, and servers are very powerful and are formidable cracking devices. For example, in *Internet Cryptography*,[12] Smith writes that a single workstation will break a 40-bit export crypto key, as those used by Web browsers, in about ten months. However, when 50 workstations are applied to this problem processing in parallel, the work factor is reduced to about six days. This type of attack was demonstrated in 1995 when students using a number of idle workstations managed to obtain the plaintext of an encrypted Web transaction.

Another example of this type of processing is *Crack* software, which can be used to brute-force guess UNIX passwords. The software can be enabled on multiple systems that will work cooperatively to guess the passwords.

Parallel computing has also become very popular in the scientific community due the fact that one can build a supercomputer using off-the-shelf hardware and software. For example, Sandia National Labs has constructed a massively parallel system called Cplant, which was ranked the 44th fastest among the world's 500 fastest supercomputers (http://www.wired.com/news/technology/0,1282,32706,00.html). Parallel computing techniques mean that even a moderately funded attacker, with sufficient time, can launch very effective and low-tech brute-force attacks against medium to high value ciphertext.

94.13.7 Distributed Computing

For a number of years, RSA Security has proposed a series of increasingly difficult computation problems. Most of the problems require the extraction of RSA encrypted messages and there is usually a small monetary award. Various developers of elliptic curve cryptography (ECC) have also organized such contests. The primary reason for holding these competitions is to test current minimum key lengths and obtain a sense of the "real-world" work factor.

Perhaps the most aggressive efforts have come from the Distributed.Net group, which has taken up many such challenges. The Distributed team consists of thousands of PCs, midrange, and high-end

[11] Anderson, Ross, Kuhn, and Markus. 1997. Low Cost Attacks on Tamper Resistant Devices, *Security Protocols, 5th Int. Workshop.*

[12] Smith, Richard, E. *Internet Cryptography*, p. 19.

systems that collaboratively work on these computation problems. Other Internet groups have also formed and have spawned distributed computing rivalries. These coordinated efforts show that even inexpensive computing equipment can be used in a distributed or collaborative manner to decipher ciphertext.

94.13.8 DES Cracker

In 1977, Whitfield Diffie and Martin Hellman proposed the construction of a DES-cracking machine that could crack 56-bit DES keys in 20 hours. Although the cost of such a device is high, it seemed well within the budgets of determined attackers. Then in 1994, Michael Weiner proposed a design for a device built from existing technology which could crack 56-bit DES keys in under four hours for a cost of $1 million. The cost of this theoretical device would of course be much less today if one considers the advances in the computer industry.

At the RSA Conferences held in 1997 and 1998, there were contests held to crack DES-encrypted messages. Both contests were won by distributed computing efforts. In 1998, the DES message was cracked in 39 days. Adding to these efforts was increased pressure from a variety of groups in the United States to lift restrictive crypto export regulations. The Electronic Freedom Foundation (EFF) sponsored a project to build a DES cracker. The intention of the project was to determine how cheap or how expensive it would be to build a DES cracker.

In the summer of 1998, the EFF DES cracker was completed, costing $210,000 and taking only 18 months to design, test, and build. The performance of the cracker was estimated at about five days per key. In July 1998, EFF announced to the world that it had easily won the RSA Security "DES Challenge II," taking less than three days to recover the secret message. In January 1999, EFF announced that in a collaboration with Distributed.Net, it had won the RSA Security "DES Challenge III," taking 22 hours to recover the plaintext. EFF announced that this "put the final nail into the Data Encryption Standard's coffin." EFF published detailed chip design, software, and implementation details and provided this information freely on the Internet.

94.13.9 RSA-155 (512-bit) Factorization

In August 1999, researchers completed the factorization of the 155-digit (512-bit) RSA Challenge Number. The total time taken to complete the solution was around five to seven months without dedicating hardware. By comparison, RSA-140 was solved in nine weeks. The implications of this achievement in relatively short time may put RSA keys at risk from a determined adversary. In general, it means that 768- or 1024-bit RSA keys should be used as a minimum.

94.13.10 TWINKLE RSA Cracker

In summer 1999, Adi Shamir, co-inventor of the RSA algorithm, presented a design for The Weizmann Institute Key Locating Engine (TWINKLE), which processes the "sieving" required for factoring large numbers. The device would cost about $5000 and provide processing equivalent to 100–1000 PCs. If built, this device could be used similarly to the EFF DES Cracker device. This device is targeted at 512-bit RSA keys, so it reinforces the benefits of using of 768- or 1024-bit, or greater keys.

94.13.11 Key Recovery and Escrow

Organizations implementing cryptographic systems usually require some way to recover data encrypted with keys that have been lost. A common example of this type of system is a public key infrastructure, where each private (and public) key is stored on the Certificate Authority, which is protected by a root key(s). Obviously, access to such a system has to be tightly controlled and monitored to prevent a compromise of all the organization's keys. Usually, only the private data encrypting, but not signing, keys are "escrowed."

In many nations, governments are concerned about the use of cryptography for illegal purposes. Traditional surveillance becomes difficult when the targets are using encryption to protect communications. To this end, some nations have attempted to pursue strict crypto regulation, including requirements for key escrow for law enforcement.

In general, key recovery and escrow implementations could cause problems because they are there to allow access to all encrypted data. Although a more thorough discussion of this topic is beyond the scope of this chapter, the reader is encouraged to consult the report entitled "The Risks of Key Recovery, Key Escrow, and Trusted Third Party Encryption," which was published in 1997 by an *ad hoc* group of cryptographers and computer scientists. Also, Whitfield Diffie and Susan Landau's *Privacy on the Line* is essential reading on the topic.

94.14 Protecting Cryptosystems

Creating effective cryptographic systems requires balancing business protection needs with technical constraints. It is critical that these technologies be included as part of an effective and holistic protection solution. It is not enough to simply implement encryption and assume all risks have been addressed. For example, just because an e-mail system is using message encryption, it does not necessarily mean that e-mail is secure, or even any better than plaintext. When considering a protection system, not only must one look at and test the underlying processes, but one must also look for ways around the solutions and address these risks appropriately. It is vital to understand that crypto solutions can be dangerous because they can easily lead to a false sense of information security.

94.14.1 Design, Analysis, and Testing

Fundamental to the successful implementation of a cryptosystem are thorough design, analysis, and testing methodologies. The implementation cryptography is probably one of the most difficult and most poorly understood IT fields. Information technology and security professionals must fully understand that cryptographic solutions that are simply dropped into place are doomed to failure.

It is generally recommended that proprietary cryptographic systems are problematic and usually end up being not quite what they appear to be. The best algorithms are those that have undergone rigorous public scrutiny by crypto experts. Just because a cryptographer cannot break his or her own algorithm, this does not mean that this is a safe algorithm. As Bruce Schneier points out in "Security Pitfalls in Cryptography," the output from a poor cryptographic system is very difficult to differentiate from a good one.

Smith[13] suggests that preferred crypto algorithms should have the following properties:

- No reliance on algorithm secrecy
- Explicitly designed for encryption
- Available for analysis
- Subject to analysis
- No practical weaknesses

When designing systems that use cryptography, it is also important to build in proper redundancies and compensating controls, because it is entirely possible that the algorithms or implementation may fail at some point in the future or at the hands of a determined attacker.

94.14.2 Selecting Appropriate Key Lengths

Although proper design, algorithm selection, and implementation are critical factors for a cryptosystem, the selection of key lengths is also very important. Security professionals and their IT peers often

[13] Smith, Richard, E. *Internet Cryptography*, p. 52.

associate the number of “bits” a product uses with the measure of its level of protection. As Bruce Schneier so precisely puts it in his paper “Security Pitfalls in Cryptography”: “…reality isn’t that simple. Longer keys don’t always mean more security.”[14] As stated earlier, the cryptographic functions are but part of the security strategy. Once all the components and vulnerabilities of a encryption strategy have been reviewed and addressed, one can start to consider key lengths.

In theory, the greater the key length, the more difficult the encryption is to break. However, in practice, there are performance and practical concerns that limit the key lengths to be used. In general, the following factors will determine what key sizes are used:

- Value of the asset it is protecting (compare to cost to break it)
- Length of time it needs protecting (minutes, hours, years, centuries)
- Determination of attacker (individual, corporate, government)
- Performance criteria (seconds versus minutes to encrypt/decrypt)

Therefore, high value data that needs to protected for a long time, such as trade secrets, requires long key lengths. Whereas, a stock transaction may only be of value for a few seconds, and therefore is well protected with shorter key lengths. Obviously, it is usually better to err toward longer key sizes than shorter. It is fairly common to see recommendations of symmetric key lengths, such as for 3DES or IDEA, of 112–128-bits, while 1024–2048-bit lengths are common for asymmetric keys, such as for RSA encryption.

94.14.3 Random Number Generators

As discussed earlier, random number generators are critical to effective cryptosystems. Hardware-based RNG are generally believed to be the best, but more costly form of implementation. These devices are generally based on random physical events, and therefore should generate data that is nearly impossible to predict.

Software RNGs obviously require additional operating system protection, but also protection from covert channel analysis. For example, systems that use system clocks may allow an attacker access to this information via other means, such as remote system statistics or network time protocols. Bruce Schneier has identified software random number generators as being a common vulnerability among crypto implementations [SOURCE], and to that end has made an excellent free PRNG available, with source code, to anyone. This PRNG has undergone rigorous independent review.

94.14.4 Source Code Review

Even if standard and publicly scrutinized algorithms and methods are used in an application, this does not guarantee that the application will work as expected. Even open-source algorithms are difficult to implement correctly because there are many nuances (e.g., cipher modes in DES and proper random number generation) that the programmer may not understand. Also, as discussed in previous sections, many commercial encryption packages have sloppy coding errors such as leaving plaintext temporary files unprotected. Cryptographic application source code should be independently reviewed to ensure that it actually does what is expected.

94.14.5 Vendor Assurances

Vendor assurances are easy to find. Many products claim that their data or communications are encrypted or are secure; however, unless they provide any specific details, it usually turns out that this protection is not really there or is really just “obfuscation” at work. There are some industry evaluations

[14] Schneier, Bruce. *Security Pitfalls in Cryptography*, http://www.counterpane.com/pitfalls.html.

and standards that may assist in selecting a product. Some examples are the Federal Information Processing Standards (FIPS), the Common Criteria evaluations, ICSA, and some information security publications.

94.14.6 New Algorithms

94.14.6.1 Advanced Encryption Algorithm (AES)

A new robust encryption algorithm was needed to replace the aging Data Encryption Standard (FIPS 46-3), which had been developed in the 1970s. In September 1997, NIST issued a Federal Register notice soliciting an unclassified, publicly disclosed encryption algorithm that would be available royalty-free, worldwide. Following the submission of 15 candidate algorithms and three publicly held conferences to discuss and analyze the candidates, the field was narrowed to five candidates:

- MARS (IBM)
- RC6TM (RSA Laboratories)
- RIJNDAEL (Joan Daemen, Vincent Rijmen)
- Serpent (Ross Anderson, Eli Biham, Lars Knudsen)
- Twofish (Bruce Schneier, John Kelsey, Doug Whiting, David Wagner, Chris Hall, Niels Ferguson).

NIST continued to study all available information and analyses about the candidate algorithms, and selected one of the algorithms, the Rijndael algorithm, to propose for the AES. The Secretary of Commerce approved FIPS 197, Advanced Encryption Standard (AES), which, effective May 26, 2002, makes it compulsory and binding on federal agencies for the protection of sensitive, unclassified information. The development and public review process has proven very interesting, showing the power of public review of cryptographic algorithms.

94.15 Conclusion

The appropriate use of cryptography is critical to modern information security, but it has been shown that even the best defenses can fail. It is critical to understand that cryptography, while providing excellent protection, can also lead to serious problems if the whole system is not considered. Ultimately, practitioners must understand not only the details of the crypto products they are using, but what they are in fact protecting, why these controls are necessary, and who they are protecting these assets against.

95

Perimeter Security

R. Scott McCoy

95.1 Introduction

When most information security practitioners hear the term *perimeter security*, they usually think of firewalls, intrusion detection, and intrusion prevention systems. In larger companies, the physical perimeter is the responsibility of either a physical security department or facilities. Medium- and small-sized companies may have someone such as a facilities manager who is responsible for physical security, but it is an additional duty and not a specialty. This should be a concern for all information security practitioners because physical security (or the lack of it) is one of the biggest gaps in most information security programs.

Strong passwords, two factor authentication, and strong firewall policies can all be circumvented if unauthorized personnel can get into a facility and onto an unlocked computer. Even access to an open port may be all someone needs to compromise a network. In smaller companies, a CISSP may be the only trained and experienced security professional in the company. Even if there are physical security professionals, they may not understand the vulnerabilities of the network or data centers or the consequences a compromised system.

This chapter will describe the many layers of a defense in depth model for a physical security perimeter. Because all sites have different requirements depending on their criticality and level of risk, not all of the methods of hardening a site discussed here may be necessary or even cost effective. Each security practitioner needs to select the appropriate techniques and equipment based on the results of a physical security risk assessment and associated countermeasure costs or benefit analysis.

95.2 Corporate Culture

All of the systems a company can put in place to protect the physical and electronic perimeters are useless unless workers follow good security practices. It is crucial that a security practitioner have a clear understanding of the company's culture. What is the current adherence to security policy, and how quickly after a new concept is introduced can it be made part of that culture? Wearing a security badge and locking the computer when it is not in use are all basics, but if they are not in place, there is a steep learning curve ahead. Executive support is critical to introduce or even maintain good security practices.

If there is a compliance gap with existing practices or, worse, a lack of documented practices, the first step is a corporate-level security policy. Most companies require corporate policies to be approved and signed by senior management, most often by the CEO. Document the basic practices of access control and protection of assets in policy form. Depending on the culture, this can be in one combined physical and electronic security policy or two separate policies.

Getting approval for these policies is the first step, but in order to change behavior at the worker level, there needs to be a comprehensive security awareness program. Online training is a good refresher, but in-person training with real life examples of why good security practices are important to the success of a company is crucial. A good ongoing security awareness program is a combination of electronic, print, and presentations to reinforce the key message while providing helpful and interesting information. The best place to do this is in new worker orientation. Security has a huge role to play in the on boarding of new workers, and it needs to be in front of new staff to deliver the key messages in order to change the corporate culture over time.

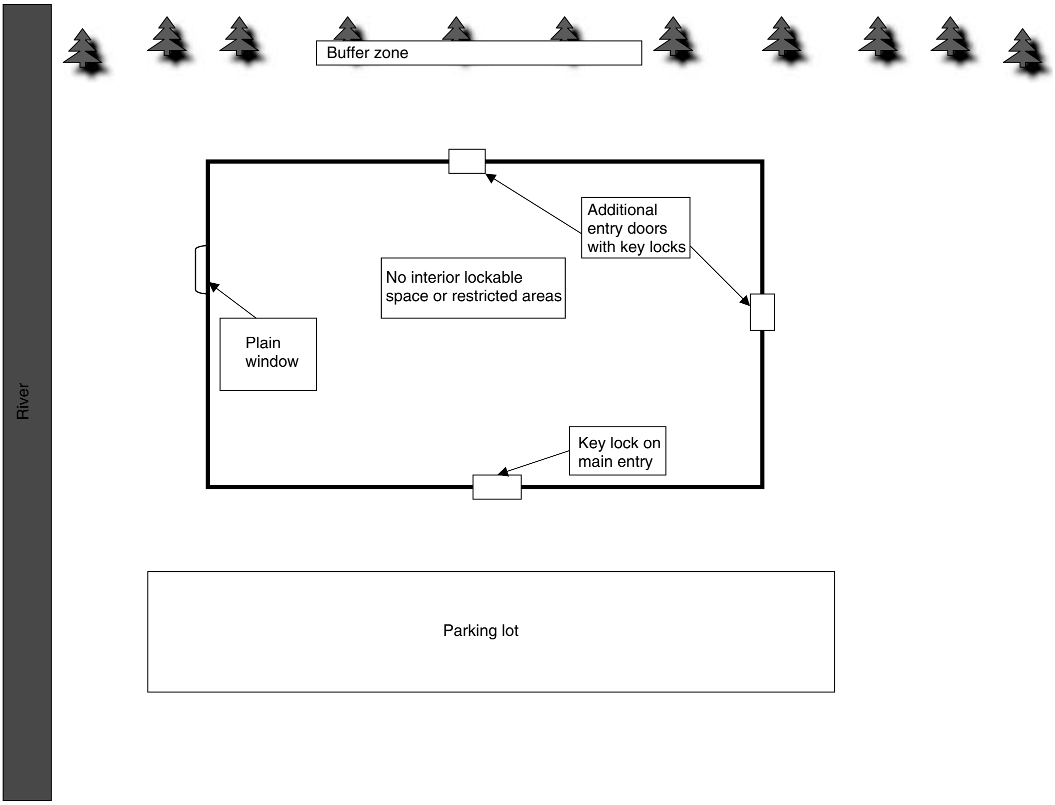
95.3 Risk Assessment Methodologies

There are several methodologies currently in use, and it seems new ones are coming along at an increasing rate. Selecting the right methodology can be daunting depending on the security practitioner's level of expertise. There are a few good books (a list is available online at www.asisonline.org/store/search.xml) on the subject and a white paper by the North American Electric Reliability Council's Critical Infrastructure Protection Committee. Although it is specific to the electric industry, most of it can be adapted for other sectors (www.esisac.com/publicdocs/assessment_methods/RiskAsmntWP_09sept2005.pdf).

Regardless what methodology is used, it is critical that the plan to secure the site stems from the recommendations of the risk assessment. A word caution about risk assessment software packages: a security practitioner needs to understand what assumptions have gone into the software. A value will be given as the end result after the practitioner is asked a number of questions, but without understanding and agreeing with all of the assumptions behind the formulas, the result may not be optimal. In a perfect world, the formulas that measure threats, risks, and mitigation strategies would be explained in detail, and the user would have the option to modify them based on the knowledge of the security professional; however, this is rarely the case.

95.4 Buffer Zone

As shown in Exhibit 95.1, a buffer zone is the outermost part of the perimeter. It may or may not be owned by the company. In a busy city, this may only include a sidewalk, but in rural areas, it could be 200



Buffer zone
River
Additional entry doors with key locks
No interior lockable space or restricted areas
Plain window
Key lock on main entry
Parking lot

EXHIBIT 95.1 A Buffer zone is the outermost part of the perimeter.

acres of state-owned land no more than 100 ft. from the back door. The makeup of this buffer zone and a company's ability to modify it will greatly affect the selection of devices to be installed at the outer barrier.

It is rare that a security professional is fortunate enough to be involved with the design and layout of a new site. This is a serious flaw because such involvement can reduce the amount of thefts and vandalisms the company may suffer both during construction and over time. Every company is different, and most large companies have several types of facilities. Depending on the function, a site may be either hidden from view or put on display. As with all other aspects of a perimeter, the risk assessments should be the guide. Does the site have shift workers or is it only a daytime use structure? Are there valuable assets stored inside? Is the company's data its most valuable assets? Asking these types of questions will allow the security professional to design a program that will best serve the company's needs. Designing a site from scratch to include the location of the site is the best choice, but most likely, it is an existing structure that needs to be assessed and improved upon.

95.4.1 Buffer Zone Program

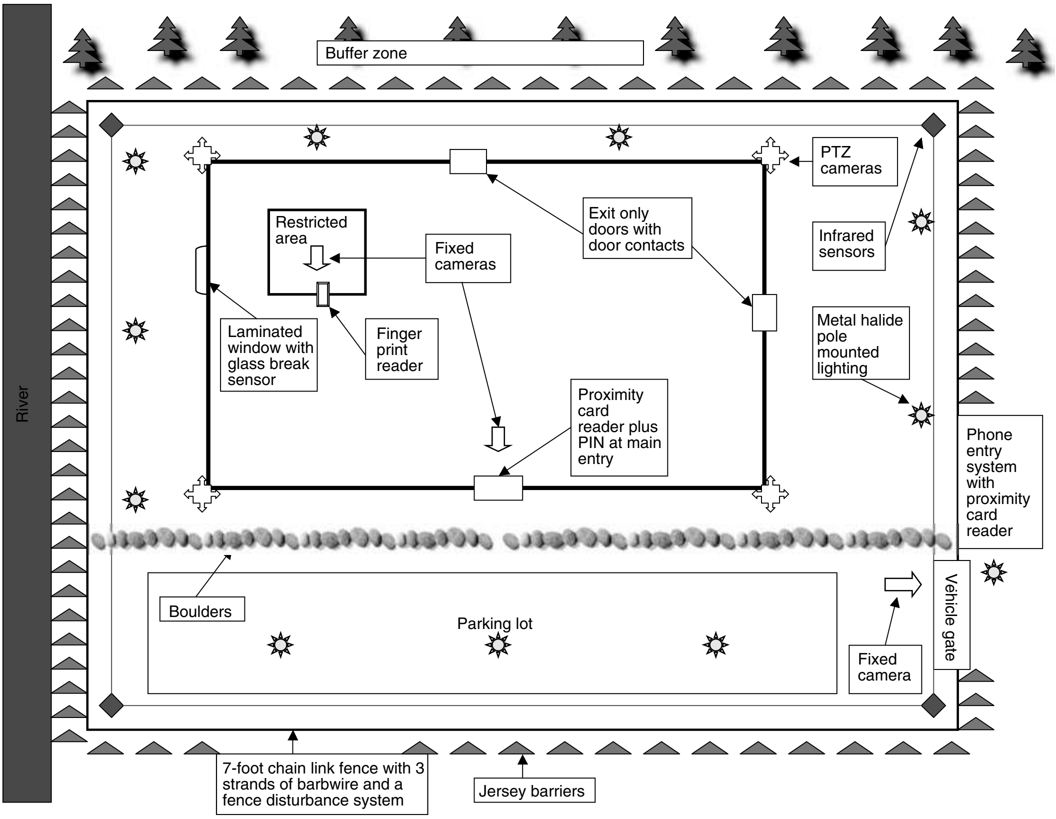
There is a program from the Department of Homeland Security called the Buffer Zone Project. The idea is that grant money will be used at critical infrastructure sites to create a buffer zone around the site. This is usually done by adding cameras, but it is also supposed to include local law enforcement patrols. The goal is to prevent a terrorist attack at a critical infrastructure site if possible and, if not, then to have a faster and better response because of plans that have been drilled by first responders in conjunction with company personnel.

95.5 Outer Barriers

Exhibit 95.2 is a diagram of outer perimeter barriers for a site. Exhibit 95.3 details the risk levels of various perimeter defenses.

95.5.1 Fences

If called for, the outermost barrier in the defense in depth model could be a fence. Again, depending on the risk, this could be for no other purpose than to keep individuals honest by stopping someone from easily approaching a storage yard or building. A fence is poor protection because most fences can be easily cut or climbed. If necessary, there are more expensive fence materials that will make both types of attempts more difficult and cause more of a delay that increases the likelihood of discovery. Alarms can also be added to the fence to give early warning. There is no set standard for fence height, but a fence shorter than 7 ft. is not advisable. On top of the fence, there should be three strands of wire angled away from the property at a 45-degree angle. This run of three strands of barbed wire should be approximately one foot in length. Because it is not straight up and down, it does not add a full foot to the fence height, but it does make it difficult to climb over the top. There should be a tension wire that runs the full length of the fence's bottom, making it difficult to lift up a section. Where break-ins are more likely, other reinforcements can be added to include cement around the perimeter to prevent erosion or digging under the fence or replacing the three strands of barbed wire on top with razor wire. The delay factor can be increased by adding a second fence 4–6 ft. inside the first fence and placing sensor equipment on or in between the fences. Finally, a type of solid wall construction can be used, preferably a minimum of 8 ft. in



Buffer zone
River
PTZ cameras
Exit only doors with door contacts
Restricted area
Fixed cameras
Infrared sensors
Metal halide pole mounted lighting
Laminated window with glass break sensor
Finger print reader
Proximity card reader plus PIN at main entry
Phone entry system with proximity card reader
Boulders
Parking lot
Vehicle gate
Fixed camera
7-foot chain link fence with 3 strands of barbwire and a fence disturbance system
Jersey barriers

EXHIBIT 95.2 Diagram of outer perimeter barriers for a site.

EXHIBIT 95.3 The Risk Levels of Various Perimeter Defenses.

Risk Level	Fences	Gates	Key System	Access Control
Low	No fence	No gate	5 Pin common issue	Key only
Low	A fence less than 7 ft.	A slide gate	6 Pin or higher common issue	Key only
Low	A fence at least 7 ft.	A slide gate	6 Pin or higher common issue	Manual key pad
Medium	A 7′ fence with a three strand top guard angled 45-degrees outward or razor wire	A slide gate with a security officer to monitor access	6 Pin or higher restricted	Picture ID or token
Medium	A 7′ fence topped with razor wire	A slide gate with a security officer or camera to remotely monitor access	6 Pin or higher restricted with separate key system on exterior	Token or randomized electronic keypad
Medium	A 7′ fence made of material other than chain link with a top guard of three strand barbed wire or razor wire	A slide gate with a security officer or camera to remotely monitor access	6 Pin or higher, system available only to specific company with separate key system on exterior	Token plus pin number
High	Two 7′ fences spaced about 6′ apart with top guards that have a fence disturbance system	A speed gate with a security officer to monitor access	6 Pin or higher, system available only to specific company and can only be ordered by signature card with separate key system on exterior	Token plus pin number or biometrics
High	Two 7′ fences spaced about 6′ apart with top guards that have a fence disturbance system and other sensors in between	Two gates set up as a vehicle trap with a security officer to monitor access	7 Pin or higher, tamper resistant locks, key system available only to specific company and can only be ordered by signature card with separate key system on exterior	Layers with combination of token, pin number and biometrics
High	A solid wall of 8′ or more in height	Two gates set up as a vehicle trap with a security officer to monitor access	7 Pin or higher, tamper resistant locks, key system available only to specific company and can only be ordered by signature card with separate key system on exterior	Layers with combination of token, pin number and biometrics

height. Regardless of what type or style of fence that is chosen, it should only be viewed as a tool to slow intruders and prevent casual trespass.

95.5.2 Gates

A vehicle gate is common in most fenced enclosures and is also the most common point of breach for a perimeter fence. There is no need to cut or climb a fence when the gate takes 30 s to close. Traditional slide gates serve a purpose, but without a security officer present to assist in controlling access, they are a liability. There are faster gates that tilt up or even swing open, but they cannot be effectively used in parts of the county that routinely have high winds. One solution for a secure gate entrance is a vehicle trap. The first gate opens, and the vehicle enters a fenced passage. The vehicle approaches a second gate but is not allowed entry until the previous gate closes behind it, making it impossible for a second vehicle to tailgate its way in. The levels of escalation for a gate, therefore, would be to have no gate; a traditional slide gate; a slide gate with a security officer to monitor access; a speed gate; a vehicle trap. Each of these gates could be augmented with other access control and monitoring devices that will be covered later in this chapter.

95.5.3 Barriers

When the risk associated with a vehicle-born improvised explosive device is deemed realistic, vehicle barriers can be used to prevent forced entry through a fence or gate or to enforce a standoff distance to a building. Gates are only to prevent people from sneaking in; if someone realty wants in and does not mind paint scratches then a gate will only slow that person down a bit. There are several kinds of vehicle barriers with different levels of protection based on estimated vehicle weight and speed. When this threat is deemed likely, additional barriers in the approach road and even redesigning the road to minimize approach speeds are advisable. Vehicle barriers can be used in conjunction with a gate or, depending on the model, can be used instead of a gate.

95.5.4 Jersey Barriers

Jersey barriers are usually made of reinforced concrete, but they also come in the plastic variety that can be filled with water or sand. They are usually cabled together to reinforce a fence perimeter in order to prevent vehicles from driving through. They are also often used around sensitive equipment like microwave towers, and they are used to ensure that no vehicles can get within so many feet from them or a building. In some states, because of concrete prices and the availability of natural materials, boulders may be a less expensive and more visually pleasing alternative. Make sure size, not just weight, is specified because the idea is to create an effective barrier.

95.5.5 Bollards

Bollard is a generic term for a form of barrier that is usually made from cement or steel. The standard model is a tube of approximately 6″ in diameter and securely anchored in the ground. Bollards are usually placed 3 ft. or higher above ground. They can look like anything, and when placed near nice office buildings, they are usually color matched and cosmetically pleasing. Their purpose is to prevent a vehicle from getting too close to something.

95.5.6 Lighting

Lighting serves multiple security purposes. It can be used as a deterrent for criminals who would be clearly exposed to nearby streets or other buildings if they tried to approach through a well-lit area. It is also used as prevention from personal attacks in parking lots and ramps. Sometimes lighting is only triggered by motion detection to alert someone to an unwanted presence and startle intruders. If the site is in the middle of nowhere and is not frequented by customers, too much lighting could actually attract criminals.

Lighting is also used in order to support security cameras. There are a lot of very good low-light cameras on the market that are able to view images with less than 0.01 lux. The problem is that when a day or night camera switches to low-light mode, the picture changes to black and white. At very low levels, it is possible to see someone moving, but it is not easy to get a detailed description of the individual. Having appropriate lighting in the area under camera surveillance is crucial to getting a usable picture. Where low light is preferred so as not to advertise the site's location, infrared illuminators can be used to assist the camera without drawing unwanted attention. Infrared illuminators will not allow the day or night camera to stay in day mode with full color, but it will give enough light to clearly identify who or what is within the camera's view.

95.5.7 Building Exterior

95.5.7.1 Doors

If the site is worth protecting, then exterior doors need to be more functional than attractive. Less glass and more steel are preferable. The hinges should be on the inside of the building, and there should to be a cover plate over the latch to prevent tampering and to make it harder to pry the door open. Limit the number of entrances, and make all of the exit only doors truly exit only by removing the exterior door hardware.

95.5.7.2 Walls

Most often, the walls are already there, and security is not called in to design a new site. The most obvious weak point in a wall are the windows, but depending on the make up of the wall and the location of the facility, there may be a need to strengthen the existing outer wall to resist penetration from bullets (an unexpected cause of server down time in some neighborhoods) or even a break-in if the perimeter wall is a shared wall of sheet rock in an office complex and not a stand alone building. As always, it depends on the risk to and the criticality of each site. Inner walls of a restricted access room should cover the entire distance from the floor deck to the ceiling deck. Because this can cause heating, ventilation, and air conditioning (HVAC) problems, strong steel mesh or grill work can be used to allow air to pass through, not people, above a false ceiling. Floor deck and ceiling deck walls are also effective in inhibiting the rapid spread of fire throughout a floor area.

95.5.7.3 Windows

Windows are made for breaking and entering. If possible, make them from a material that will resist this type of tampering. Depending on the neighborhood, it may be necessary to include bars over the windows at ground and even the second level. Laminate may also be called for to minimize the spread of broken glass in the event of a nearby explosion, and in extreme cases, bullet resistant glass may be needed.

95.5.7.4 Roof

Roofs are frequently overlooked, and hatches on roofs are an easy method of entry. Make sure all roof access is securely locked regardless of the building’s size. Adding an alarm contact to the roof latch is also a good idea.

95.5.7.5 Other Openings

Grates, grills, and air vents could be used to gain entry into a building. A lot of money should not be spent on securing all the obvious entry points only to miss one of these. Older structures are especially susceptible here, and the access points can usually be blocked off with metal grates that are welded or locked securely into place.

95.6 Access Control

95.6.1 Keys

There are many ways to handle a key system for a building. The first is to use the same keyway on all doors for a building, interior and exterior, and divide up the building into functional areas. A change key is an individual door key that works only on one specific door. All master keys open a specific series of change keys that fall under them. There are sub-masters, master grand masters, and great grand masters. A master key could be used to open all of the change keys on a specific floor, and a grand master could work on all of the keys in an entire building that has any number of individual master keys in it. Once the building is divided up, create a system of master keys, sub-masters, and individual change keys based on the size and complexity of operations. In any key system, a grand master exists, but it may not ever be issued or even cut. The more pins a lock core has that match the number of cuts in a key, the more mathematical options and expandability a key system has. Homes may have a common 5-pin system, but most businesses have at least a 6- or possibly 7-pin system. The more separation of functional areas, the more master keys will need to be in use and the more tempting it is to issue a grand master. The other option is to have large rings of change keys for cleaning and maintenance crews, and this is usually not well accepted and fails. It is often better to minimize the number of master keys and issue as many change keys as practical under a master for interior keys.

Limit the number of master keys issued, and keep track of them carefully. Even for companies that still have employees as cleaning staff, master keys should not be taken offsite. Have a system for storing and issuing and returning such keys sets each day.

Most likely, the key system has not been changed in a long time. Since it was created (assuming it was initially done well), many reorganizations and moves have occurred. Take the opportunity to evaluate the site while trying to minimize the number of doors that have key access. A keyway may have been added as a default during construction, but doors should not have keys if there is nothing inside that needs securing.

The next level of security is to have a different key system on the exterior of the building. This will minimize the likelihood of losing a key that would require the expense of rekeying the entire building because the loss of an interior change key is not as relevant as long as the outer perimeter of the building remains secure. Even the loss of an interior master key may not justify the expense of rekeying a site as long as the perimeter is not compromised.

It is very important to minimize the issuance of exterior door keys regardless of which system is in use because such keys can compromise the entire building and cause the additional expense of replacement when one is lost. To minimize the possibility of the aforementioned problems, if it is necessary to issue an exterior perimeter key, choose only one or two of the doors, key them alike, and issue those keys sparingly. It is also a good idea to have another set of cores and keys prepared in advance should integrity be lost for a quick change out. On the other exterior doors, either have no key access or use a separate change key that is not issued. For fire safety, it is better to have keyed doors and to have both perimeter keys in the fire department box (sometimes called a Knox box) on the outside of the building. To differentiate between the two keys, each key and its associated doors can be color-coded for easy identification by fire fighters.

Restricted key blanks are the best way to ensure that no one can copy a key issued to them. Assuming there is good key control in place and all keys are returned when workers leave the company, these workers may still have copies they had made at the local hardware store or locksmiths. Printing "Do Not Duplicate" on all key blanks is a good and necessary step, but it is not foolproof. Choosing a keyway that does not commercially exist and that is licensed only to a specific company gives a much higher level of control.

If electronic access control systems are in use on interior doors for restricted areas, it is also a good idea to not issue keys for those doors. Either by using the same key system as the rest of the interior doors and simply not issuing them or by going the additional step of using a restricted and separate key system, it is important not to have keys in circulation for doors with electronic access control systems on them.

Key control is critical for maintaining the integrity of the perimeter whether it is for the building perimeter or the perimeter of an interior restricted area. It is important to have a tracking system that can be queried when a worker leaves to ensure recovery of all keys.

95.6.2 Electronic Access Control

Electronic access control systems come in a variety of types from keypad to token-based to biometrics. Regardless of which token or method is used, there is always a database that is used to manage access. On the lower end, there are stand-alone electronic locks that are updated by some handheld device, whereas on the upper end, there are control panels that are assigned a static IP on a WAN and that is in constant contact with a centralized database. Because the access control system is the main protection against unwanted access, extra security should be built around it if the risk warrants it. Additional security could be to use encryption for communication between the server and the control panels or to have the application reside in its own domain or by placing it behind its own firewall. Whatever protection is given for other critical applications, because this system most likely protects the data center, it has as high of a priority as the most critical system it is used to protect, including recovery time for contingency planning.

It is a good idea to use different access methods at different security layers. A picture ID may work at the outermost perimeter with a security officer, but at the next level, a token could be used. At a more restricted level of the building, a token plus pin number could be required. At the most secure restricted area of the company, a biometric reader could perhaps be used. The security level escalation could be a picture ID, keypad access on a static keypad, keypad access where the numbers of the keypad are randomized each time, a token reader, a token reader plus pin number, a biometric reader, and finally, a biometric reader plus some sort of token or pin number.

95.7 Restricted Areas

There are a couple of ways to handle levels of access. The first is to make security categories, then put workers in their associated access groups. There may be several levels; however, for example purposes, low, medium, and high are used. The company in question would designate by job classification which employees would be allowed in each security level. The company could designate each access-controlled area as low, medium, and high. Therefore, someone with medium access could get into all low and medium restricted areas, and someone with high access could get into all areas. This may work well for smaller and even medium-sized companies with several levels.

Larger companies, especially those that are heavily regulated, may need to follow a restricted area owner model. This model requires that a primary owner and at least one backup decide who should have access to a specific restricted area. Any new access requests would need to be approved by the restricted area owner, and the owner should review the access list at least quarterly. This method is more administratively intensive, but it is more defendable to auditors and allows for tighter restrictions on access.

An additional layer of security for highly restricted areas is to have a video record at the access point. Areas such as data centers usually have a limited number of access points and a short list of authorized people with access. A camera showing the access point and storing the recorded image at least 30 days (90 days preferable) is suggested.

Other options for highly restricted areas include mantraps or revolving doors, but both of these options, although more secure than a single door, do not negate the need for a camera. A mantrap is configured with two doors linked by a short hallway. The outer door is released, allowing access to any number of persons, but the second door will not allow even authorized access unless the first outer door is shut. Conversely, if someone happens to be exiting the inner door while someone is attempting to access the other door, the outer door will not allow access. The main goal is to never allow both doors to be open at the same time. This is designed to minimize the chance that an unauthorized person could piggyback (follow along with someone who has access) into a restricted area, but this application of access control has the same failure point as a plain door because people could still piggyback unless all workers are trained to challenge individuals who are attempting to gain access. A revolving door is designed to only let one person into a restricted area at a time by revolving just far enough at each granted access to allow whomever is in the door partition only to gain access. Because a revolving door is not as confining a most turnstiles, it is still wise to have a camera to monitor access.

95.8 Intrusion Detection

95.8.1 Fence Disturbance Systems

A fence disturbance system is mounted to a fence, and it is supposed to detect disturbances on the fence. There are a couple of different types, and they have been out on the market for some time. Previously, they were prone to a lot of false alarms and were maintenance intensive. Newer technology has allowed for algorithms that can discern the difference between the wind and a person climbing or cutting.

The current systems also allow for more flexibility with zones, and it is easier to track where on the fence line the disturbance occurred.

95.8.2 Ground Sensors

These systems are able to detect small seismic disturbances caused by walking. If properly installed, these systems can work in a wide range of environments, including deep snow. They also have advanced algorithms to discern a person from an animal.

95.8.3 Infrared

These systems work by setting up two or more poles or towers with infrared beams going between them. Ranges vary by product, but the latest models can go up to 1,000 ft. yet are prone to more false alarms at this maximum distance. When something breaks one or more beams, an alarm is sent.

95.8.4 Microwave

The sensor puts out a harmless microwave field that can detect the addition of any new object within the perimeter. Most microwave sensors have a maximum range of about 100 ft.

95.8.5 Door Contacts

Although not as sophisticated as other technologies, door contacts are often overlooked or improperly installed. Every perimeter door needs to have contacts to indicate if the door is open or closed. These can be integrated into a standard burglar system or an electronic access system. When used in conjunction with access control, the software is programmed to ignore a break in the contact when access is granted. The access control software can be programmed to alarm when a door is forced (possibly caused by someone using a key instead of a token) and also when a door is held open too long.

95.8.6 Glass Breaks

These sensors can detect the ultrasonic frequency sound glass makes when it is broken.

95.8.7 Passive Infrared

Passive infrared motion detects the changes in the thermal energy patterns of moving intruders.

95.8.8 Pixel Analysis

Often called video motion, pixel analysis is actually what occurs in a frame-by-frame comparison of a video image that looks for changes in the pixels from one frame to the previous frame. Most systems have a range of sensitivity, and an image can be ignored or focused on once it is broken down into zones. By selecting only certain zones of an image and by adjusting the sensitivity to avoid false alarms because of shadows (or headlights at night), these systems can be quite effective.

95.8.9 Intelligent Video

Images from a camera are run through a complex algorithm that is programmed to detect what it is told is objectionable behavior. New and better version are frequently released, but there currently are systems that can track a person's movement, but not an alarm, unless the person moves vertically (indicating climbing a fence) or even if he or she moves an arm in a certain manner (such as to throw a punch). They can also be programmed to identify when an object is brought into the camera view and left.

95.9 Assessment

95.9.1 Cameras

Cameras are one of the first things that people think of when they think about security. It is a shame that they are often improperly installed. The type and placement of cameras need to be specifically based on the results of a risk assessment, not where they are easiest to install. The choice to use fixed or Pan, Tilt, Zoom (PTZ) cameras depends also on each situation. There are infinite possibilities and no absolutes, but here are a few suggestions. When trying to track access to a restricted area, place a fixed camera inside the area set back far enough and with the proper lens to capture a good image of everyone's faces coming in. When outside, if there are access points that need constant monitoring, stick with fixed cameras. If there is a person able to assess the cameras in real time, install as many PTZ cameras as necessary to assess the perimeter; however, do not rely on a PTZ to cover both a fixed critical point and provide perimeter assessment. It cannot cover both at the same time. All current PTZ cameras can be programmed with multiple presets and even go on a constant tour mode from view to view and change tours based on the time of day. This may appear to be a good option, but it will shorten the life of the camera's motor. If there is something critical that needs to be monitored, stick with fixed cameras that are also much cheaper. It is true that the labor required to install cameras can be offset with one installed PTZ, but most likely, the PTZ will not be facing where the company needs it. PTZs can be significant assets; however, they are usually only beneficial when there is a person at the site that has control of them and a security force that can respond. Regardless if there is an alarm system or access control system, the video needs to be integrated with it. Digital recorders can be set to record more frames per second and increase the resolution during alarm events, and PTZ cameras can be programmed to zoom to a the door that is in alarm. All systems built since 2000 have had this capability to some extent, yet few security professionals take advantage of these features.

95.9.2 Alarms

Alarms can be local or connected to a system as well as audible or silent. There are burglar panels whose main function is to report alarm conditions to a central station, and electronic access control systems also have alarm inputs. If staff is constantly propping open exterior doors or restricted area doors, a local audible alarm can be used. Most other alarms are silent at the source and send a signal back somewhere. It could be at an enunciator panel on a security officer station within the building as well as tied to another reporting system. Alarms are a critical component of an intrusion detection system and can be initiated from many different types of devices described earlier in this chapter. Sadly, alarms are not as effective as they should be due to false or nuisance alarm events. The term *false alarm* is often used to describe any alarm that was not triggered by an actual breach, but this is not accurate. An actual false alarm is caused by a mechanical or programming error. Examples would be an alarm that has a short in the wires or a door that moves when the wind blows. The door contacts or the door itself should be adjusted to not trigger under these circumstances. A nuisance alarm is one where the alarm functions as designed but goes off because someone did not following procedure. Leaving a door propped open or using a key on a door with access control will cause an alarm event to occur when no breach has occurred. The system cannot tell the difference between someone's using a key or a crowbar to open the door; it only knows what was programmed. It is almost impossible to eliminate all unwanted alarm events; however, careful planning during any new installation, proper maintenance, policy enforcement, and abundant communication to company workers will go a long way to improving the reliability of alarm systems.

95.9.3 Electronic Access History

Companies that have sites where workers come and go at all times can use access history combined with digital video retrieval to discern an actual breach from a worker's breach of policy. In a perfect scenario, a central station would have a camera covering every access point and the total site perimeter as well as every point of possible unauthorized access. Each alarm event could be quickly dismissed as a worker's misusing an entrance or confirmed as a breach. Most companies, however, are lucky to have a small camera system. Access history that shows a worker entering at 2:00 a.m. from the main lobby and confirmed by a fixed camera as being the worker could explain another interior door alarm minutes later and save the cost of alarm response.

95.10 Alarm Monitoring and Response

Alarms are worthless if no one know when they are tripped. There are sites that stand alone with 24-hours staffing that respond only to alarms at that specific site, but most alarms go somewhere else. It is not cost effective for most small and medium-sized companies to have a proprietary central station, so most are sent to a contracted alarm-monitoring company. Most of these companies require certain brands of alarm panel and usually require that they install them. These larger alarm-monitoring companies do not usually bring in video from sites where they monitor alarms; therefore, they base their alarm response only from the alarm condition and their written instructions. Companies that have proprietary systems with camera and electronic access control systems can reduce the cost of nuisance alarms by not sending a response if it can be validated that it is not needed.

Alarm response is costly no matter if it is a contracted security company or the police that respond. Most jurisdictions will either not respond without confirmation of a break in, or if they find it to be a false alarm or nuisance, they will fine the company. The fine is almost always more than a contract company charges, and after so many fines, a police department will refuse to respond. Because of these reasons, it is important to carefully design the system and monitor its installation to ensure it is installed per the specification. It is also important that the design and use of the system is communicated effectively and regularly to avoid misuse by workers.

95.11 Inspection and Maintenance

95.11.1 Preventative Maintenance

Preventative maintenance (PM) is the key to keeping systems functioning as designed. Wear and tear on all types of components can cause a failure at an inopportune time. Some companies incorporate security equipment with the rest of their site maintenance checklist. Most companies have this work contracted out, or they do not have a plan. Most installation vendors offer (and some demand that) a maintenance agreement is included for all installations. A maintenance agreement does not automatically include PM. Preventative maintenance, is a routine inspection for functionality and wear and tear on all parts of a system. Parts that meet certain wear criteria are replaced ahead of time in order to avoid a malfunction. Most systems have backup batteries and changing these on a scheduled basis is a common example of a PM. In order to reduce the cost of PMs, companies can request that their vendors wait to go to a site until there is another service or installation call during the year. If there is no call, then the company can request that this visit occur by the end of the year.

A maintenance agreement is a type of insurance policy based on a percentage of the value of equipment at a given site. It is usually set for a period of three to five years, depending on the life expectancy of the equipment. It is a non changing rate paid every year whether anything breaks or not, and it usually excludes natural damage such as lightning, flooding, or accidental damage such as a truck backing over a card reader. Despite the fact that a maintenance agreement's cost is usually significantly higher than the cost for normal equipment failure, a lot of people prefer it because there is no budget surprise if a couple of expensive pieces fail in a given month. Sadly, most companies expect managers to either accurately predict all equipment failures or spread the average assumed cost per year across twelve months. If no expense occurs for the first six months, this is seen as an under run and could be claimed as a savings and taken out of the annual budget. When the failure does occur, it is seen as a spike, and the manager is held accountable. This type of thinking is the reason so many people accept expensive maintenance contracts that end up costing their companies much more over the long term.

95.12 Conclusion

Regardless of the industry, facility type, or level of criticality, if there is network connectivity at a site, there needs to be appropriate perimeter security. There will most likely be many other factors not related to IT that go into deciding what level of protection is needed; however, too often when a company conducts a risk assessment to determine its mitigation strategy, the risk to the network is not included in the calculation. Small office buildings in rural areas with little crime usually do not warrant much in the way of physical security, but those network connections are usually behind the firewall and pose the same threat as connectivity in the corporate headquarters. A solid IT perimeter can be easily defeated with simple and unobserved access to such connections, and IT security professionals need to be included in determining what level of physical security protective measures are appropriate for every site in the company.

96

Melding Physical Security and Traditional Information Systems Security

Kevin Henry

The melding of physical security into the traditional information system's security area has added a new area of responsibility and required knowledge for information systems security professionals. This merging of these two formerly distinct disciplines has been necessitated by the rapid growth of enterprise-wide and global computing, the rollout of information systems across all areas of the enterprise, and the provisioning of access to networks and systems throughout all organizational facilities and buildings.

The first challenge faced by an organization that is merging these two groups is the organizational placement and structure of the new security group. Some organizations have chosen to keep the two areas separate both from an administrative and management perspective, yet even in those instances it is important that the two groups learn to support each other and communicate frequently. It may be difficult to determine who will lead a new merged organization and where in the corporate structure it should be placed. Ideally, the security department will report to a senior manager, perhaps a chief security officer (CSO) or chief risk officer (CRO). However, in many instances, the organization is not in a position, either through size or organizational structure, to create such a position. This recognition of the importance of information security and the delegation of a senior manager to oversee information security has become mandated in some countries through government regulation. Regardless, however, of the administrative placement and reporting structure of the security department, the security personnel must generate the credibility to gain influence in the boardroom and amidst the strategic planners for the organization. This is imperative because information security plays an increasingly important role in establishing the secure infrastructure for the business to continue to operate, and provides the platform for future growth, acceptance of new technologies, and automation of traditional business systems.

The head of the security department (whether a CSO or other title) must understand the delicate but essential balance between security concepts and supporting business operations. This person needs to understand what we are trying to protect—the critical assets of the organization, whether physical or information, or both.

These two cannot exist without each other. It is not possible to protect either facilities or information systems and information without understanding how information systems are reliant on many environmental controls and good physical protection. Similarly, almost all physical controls are also dependent on information systems for monitoring, alarm signal transmission, and analysis.

There is always a need for more training. Personnel that have been focused primarily on physical security need an appreciation for information systems and the correct manner of handling and using such systems. Information systems security personnel need to understand the importance of considering the physical and environmental security aspects of protecting their systems, including recognizing the importance of such basics as fire prevention and incident response.

Fire prevention is often overlooked by information systems security personnel. It is not uncommon to find server rooms full of discarded equipment, packing materials, wiring, and cardboard boxes. This can pose a safety and fire hazard that should be removed. In some cases, it can also be seen that emergency exits from data facilities are blocked by debris or materials waiting for installation. In the event of a fire or other incident, it may not be possible to make a safe exit, not to mention the added risk of providing habitat for rodents.

The next step in environmental security is to ensure that all server rooms have fire extinguishers ready for use if needed. These need regular checks and maintenance and should also be easily accessible—not hidden behind piles of documentation or equipment. Ensuring that all personnel have training and hands-on experience using a fire extinguisher is also a good practice.

In many buildings, the server rooms were built long after the building was completed, resulting in there being no fire alarms or smoke detectors in the server room. It can also be difficult to hear public address systems for the building in many server rooms, meaning that an evacuation order or fire alarm may not be noticed by personnel in the server room. Building server rooms with floor-to-ceiling walls complicates this, but it is necessary to stop fire from spreading through the gap between a false ceiling and the true ceiling. A wall that would only go as high as the false ceiling can, of course, also provide fairly easy entry by crossing over the wall. Some firms, therefore, have begun to install intrusion detection systems in such areas as ventilation ducts, and crawlspaces.

Server rooms also need to be isolated from outside contamination, whether through smoke, dust, or chemicals that could be spread through ventilation systems or insecure access doors or windows. It is preferable for the ventilation system for the server room to be separate from the remainder of the facility. All air conditioners and ventilation systems need to be checked frequently to ensure that the air filters are not clogged and that routine maintenance is being performed. Failure to properly maintain air conditioning systems can lead to the development of harmful bacteria and may result in water leakage into the server room. All ventilation systems should also contain baffles that will close automatically in the event of a fire alarm to prevent the spread of the fire or smoke into the computer areas.

Fire suppression systems should be installed in major data centers. Systems using water, FM200, carbon dioxide, and inert gases have been deployed in various facilities; however, where such systems are in use, care must be taken to train all staff on how to react if an alarm sounds and any special risks related to such systems, such as danger to personnel in case of discharge or protection of equipment through use of an emergency power-off (EPO) switch.

Server rooms are often a hazard area of tangled wiring and tight spaces. This leads to possible damage to cables, accidental disconnection of equipment, and electrical shock from personnel needing to work in confined spaces or on neighboring systems. Securing all cabling and ensuring that the cables are properly tightened onto the equipment can prevent errors or failures that can be very difficult and frustrating to troubleshoot.

The next level of physical security concerns the access to the server room itself. The lists of who has access to the server room must be reviewed on a regular basis—at least once a year if not more—to ensure that access permissions are up to date and personnel that do not require access have such access taken away. Where combination locks or cipher locks that have a set combination to enter are used, it is important to change these combinations on a regular basis; it is not long before contractors, vendors, and half of the office staff seem to learn the code for the server room and have the ability to wander in without proper justification. Where a proximity card is used for access, special care should be taken when revising the permissions of the personnel that formerly had access. Some proximity cards do not properly erase residual data when the permissions are changed and the card will still allow a person access, even though that access has been taken away and the access list does not show them as authorized users.

An effective way to make all staff more security-conscious is to establish work areas that are separated physically from other areas. Even if walls and doors are not used between workgroups, partitioning a work area by locating work groups together can create a sense of ownership of that area. This is sometimes referred to as *territoriality*. This is accomplished by locating each group in their own territory (or "turf") so that they develop an attitude of protecting their area from intruders, safety problems, or disorganization.

Other areas that the information security person must pay heed to include electrical power and backup power supplies. All power into server rooms should be checked to ensure that the power feeds are properly labeled and that the power demands are not exceeding allowable loads. Breaker panels and power rooms should be secured from unauthorized access to ensure that personnel cannot trip breakers or affect power supplies.

The use of UPS (uninterruptible power supplies) for critical systems is required. A UPS also needs maintenance and upkeep. This includes the testing of batteries, checking of the power load on the UPS, and running of backup generators on a monthly basis. The fuel supply for backup generators should also be kept full and checked monthly to ensure that it is not contaminated with water or subject to condensation.

Perhaps the most effective tool in a security person's toolkit is closed-circuit television (CCTV). This technology gives a wide view of many areas to one person and also captures all incidents for later review. CCTV has three functions that make it more valuable then most other alarms; it provides notification of an incident, identification of the personnel or other sources of the incident, as well as recognition of the type of incident. Whereas a fire alarm can notify a security person of a possible incident, it is limited in the amount of information it provides. Really, a fire alarm that triggers is just an event. The responding officer has no idea if it is a false alarm that has just been damaged or malfunctioned, and the officer has limited information about the scope of the event— is it a cigarette, burning toast in the kitchen area, high humidity, or a large fire that requires immediate response. On the other hand, a CCTV system allows the officer to immediately recognize the scope and nature of the alarm. The responding officer may have been alerted to the event by an alarm or movement, and then through observation and analysis can often recognize the incident to respond appropriately. If it turns out to be a fire, call the fire department; if it looks like a medical situation, then call an ambulance; and in the event of theft or an intruder, call the police or a response force.

Another advantage of CCTV is that it records incidents for further follow-up review and analysis. By capturing data related to the incident, it is often possible to learn from the event as the situation unfolded about details or individuals involved in the incident. This may be invaluable for disciplinary action or even prosecution. That requires that all tapes or DVDs related to the incident are protected and procedures are in place for the correct handling and retention of all such materials.

There are many technologies available in CCTV today. Some cameras use a practice called *shadowing* that tracks the movement of an image across a scene. When a person walks through the image of the camera, their presence is captured in a number of images similar to a still camera photo that fades away gradually. This prevents an intruder from being able to "run through" a camera while the monitoring officer was momentarily distracted and not being noticed. In this technology, the images will still be visible for a moment longer.

Other features of some cameras include the ability to pan (move horizontally) across a scene, or tilt (move the camera, up and down), often via remote camera controls. Many cameras also have the ability to zoom in on an image (like a telescope) to extend the focal length of the camera and look more closely at an object that may be quite a distance away. Cameras today can operate in almost any level of light either through adjusting their aperture or the opening for the lens to let in more might in low-light situations, or through features like infrared or low-light sensors. When zooming in on an image or opening the aperture to let in more light, it is important to recognize that, in many cases, this has a negative impact on the depth of field, or the amount of the subject within focus. To be effective for response and follow-up analysis, it is important to be capturing as much of the image in focus as possible.

One newer technology that is being deployed is a capacitance-based wire sensor that is buried around the perimeter of the facility. Whenever any object crosses over the wire, it disturbs the capacitance of the electrical field around the buried wire and triggers an alarm. Many of these technologies can also differentiate between the size of the interruptions, thereby eliminating false positive alarms due to no-adversarial disturbances from small animals or blowing debris.

Finally, one important consideration is providing locking cables or some type of theft-prevention device for all portable equipment. The theft of laptops costs organizations significant amounts of money, as well as lost productivity, every year. All too often it is found that a stolen laptop contained months worth of work that had not been backed up and confidential information that may be difficult to regain.

These are just a few of the many things an information security person must address in today's world—areas that were primarily the responsibility of a physical security department previously.

The physical security people also must learn how to seize computer equipment in the event of an incident, the need to prevent unauthorized access through social engineering attacks, and the importance of ensuring that all equipment is protected from damage or misuse.

The inclusion of increased physical security responsibilities, and often the melding of the physical security groups along with the information systems security personnel, does require each group to have a broader understanding of each group's function, and does provide some advantages through cooperation and better use of personnel. However, it also presents some challenges for two relatively unrelated groups to suddenly learn to work effectively together.

97

Physical Security for Mission-Critical Facilities and Data Centers

Gerald Bowman

97.1 Introduction

In a study of security trends conducted in the summer of 2004, The ASIS Security Foundation, in cooperation with Eastern Kentucky University and the National Institute of Justice, released a report entitled *ASIS Foundation Security Report: Scope and Emerging Trends*. Of the security and information technology professionals surveyed, 46 percent identified computer and network security as their biggest concern. At the heart of concern for network security is the data center or mission-critical information technology facility where architectural, engineering, network, and building systems converge. Data center functionality can assume the traditional role of an enterprise computer room or more specific roles such as an Internet Service Provider (ISP), Application Service Provider (ASP), financial organizations, E-commerce, parcel shippers, government or defense industries, or other specialized purpose.

EXHIBIT 97.1 Hourly Cost of Data Center Downtime

Application	Industry	Hourly Cost ($)
Brokerage	Finance	6,450,000
Credit card services	Finance	2,600,000
Pay-per-view	Media	150,000
Home shopping	Retail	150,000
Catalog sales	Retail	150,000
Airline reservations	Transportation	150,000

Modern data centers are composed of layers of technical, facility, administrative support, and end-user space supporting a large computer room with vast amounts of processing and storage capability. Providing physical and cyber security for a mission-critical facility or data center can encompass a range of types of rooms and security needs. The building shell of the data center might contain the following types of spaces:

- Lobby and meeting rooms
- General offices
- Telecommunications closets
- Equipment rooms
- Electrical and mechanical equipment
- Technical, electrical, and mechanical support
- Storage rooms
- Loading docks
- Computer room

Loss or destruction of property in the typical built environment is typically limited to the value of the property and the costs associated with the actual replacement of the damaged property. As shown in Exhibit 97.1, computer rooms and data centers carry a much higher price tag for loss or damage. The loss of sensitive corporate research and development or financial information can close down an otherwise healthy company. *Disaster Recovery Journal* has reported that, when businesses experience catastrophic data loss, 43 percent never reopen, 51 percent reopen but close within 2 years, and only 6 percent survive longer term. In light of this information, addressing information security (InfoSec) issues becomes mission critical to every business.

97.2 Characterizing Data Center Security

The most frequently benchmarked performance metric for computer rooms and data centers is not an evaluation of the extent of damage or amount of loss that could be incurred by a security breach but rather the amount of time total access to stored data or processed capabilities is available. Although availability is key to cyber security, it is not high on the list of priorities for the physical security professional. The Uptime Institute of Santa Fe, NM, is responsible for a commonly referenced, tiered classification for computer room and data center performance. Exhibit 97.2 shows Uptime's four-tiered, holistic classification, in which measured availability ranges from an expected reliability of "four nines," or 99.995 percent, for tier IV facilities down to just 99.671 percent for tier I facilities. A few points to the right of the decimal do not seem very significant until one computes the downtime and assigns a dollar value to each hour or minute of downtime. Because the difference in downtime between a tier I and tier IV data center can be over 28 hours and because the value of even an hour of downtime can run into the millions of dollars, a strong business case can be made for maintaining the high availability of data.

EXHIBIT 97.2 Four-Tiered, Holistic Classification

Factor	Tier 1	Tier 2	Tier 3	Tier 4
Site availability (%)	99.671	99.749	99.982	99.995
Annual IT downtime (h)	28.8	22.0	1.6	0.4
Construction ($/ft)	450	600	900	1100+
Year first deployed	1965	1970	1985	1995
Months to implement	3	3–6	15–20	15–20
Redundancy	N	$N+1$	$N+1$	$2(N+1)$

When considering the tiered classifications of the Uptime Institute and others, it should be noted that a high rating applies only to the availability of the data and redundancy of the supporting systems. The Uptime Institute's tiered rating does not incorporate the potentially catastrophic effects of failure with the other two foundations of the CIA (confidentiality, integrity, and availability) triad. This chapter deals primarily with the physical security strategies, processes, roles, and equipment necessary to protect the availability of the mission-critical facility and data center; however, much of the text also address one or more areas of physical security, including access control, surveillance, and perimeter protection. The predominant theme for this chapter is prevention.

97.3 Physical Security for Data Centers

The fundamental principles for protecting assets that are used by physical security professionals worldwide apply equally to data centers. Ensuring that the asset is available to its owner, is protected from damage or alteration, and is not taken or copied without permission is universal to both physical and information security. It is generally agreed that the potential for damage or loss can be categorized into seven potential categories of threats to objects, persons, and intellectual property:

- *Temperature*—This category includes sunlight, fire, freezing, and excessive heat.
- *Gases*—This category typically includes war gases, commercial vapors, humidity, dry air, suspended particles, smoke, smog, cleaning fluid, fuel vapors, and paper particles from printers.
- *Liquids*—This category includes water and chemicals, floods, plumbing failures, precipitation, fuel leaks, spilled drinks, and acid.
- *Organisms*—This category includes viruses, bacteria, people, animals, and insects. Examples would be key workers who are sick, molds, contamination from skin oils and hair, contamination from animal or insect defecation, consumption of media and paper, and shorting of microcircuits due to cobwebs.
- *Projectiles*—This category includes tangible objects in motion and powered objects. Examples would be meteorites, falling objects, cars and trucks, bullets and rockets, explosions, and wind.
- *Movement*—This category typically involves collapse, shearing, shaking, vibration, liquefaction, flows, waves, separation, and landslides. Examples would be dropping or shaking fragile equipment, earthquakes, lava flows, sea waves, and adhesive failures.
- *Energy anomalies*—This category includes electric surges or failure, magnetism, static electricity, aging circuitry, radiation, sound, and light, as well as radio, microwave, electromagnetic, and atomic waves. Examples would be electrical utility failures, proximity to magnets and electromagnets, carpet static, decomposition of electrical circuits, cosmic radiation, and explosions.

Regardless of how the threats to data, property, or well-being are classified, identification of the source of potential risk remains key to mitigating these risks. When considering threats to sensitive or mission-critical data, it is easy to envision hacking, identity theft, and corporate espionage as the key threats.

The reality is that physical threats, including natural disasters, interruption of utilities, equipment failure, weather, sabotage, human error, and other seemingly less sinister events, represent a greater likelihood of catastrophic loss of data.

Of the physical threats listed above, the threat from human beings remains the most significant with regard to the reliable operation of the computer room or data center. Even without the impact of sabotage, hacking, and other malicious acts, the risk from the human factor remains high. Some research indicates that up to 80 percent of all unplanned downtime results from people and process issues. This threat can be manifested in failure to perform routine maintenance, ignoring or overriding alarms, or even performing a task out of sequence. In this chapter, the reader will observe that reducing the risk from the human factor is a central theme to data center design and operation.

This chapter evaluates security at four levels:

1. Site
2. Perimeter
3. Building
4. Computer room

It is important to envision layered physical security as being comprised of ring upon ring of concentric circles. Beginning with layer 1 (site security) and ending with layer 4 (computer room security), the security designer addresses issues unique to the potential threats encountered. Although the processes, building attributes, and hardware contribute to a secure IT facility, they are utilized somewhat differently within each successive layer.

97.4 The Site

When selecting a greenfield or existing site with structures, it is important to consider a few key aspects of the proposed location for the construction of a data center or mission-critical facility. The location of a mission-critical facility can have significant impact on a company's ability to restore operations following a natural or manmade disaster. In New York City's financial district, some important lessons were learned following the 9/11 disaster. According to Bruce Fleming, Verizon's Divisional Technology Officer, a number of site-related obstacles challenged restoring services from the central office (CO) located at 140 West Street, within the World Trade Center (WTC) complex. In a 2002 Armed Forces Communications and Electronics Association (AFCEA) presentation, Fleming said that in the CO a major fiber bundle was cut by a falling I-beam, it was flooded by 10 million gallons of water, and it finally lost all electrical power. Attempts to bring in generators, temporary telecommunications and data equipment, fuel, and manpower were all complicated by a number of factors, such as restrictions on the delivery of diesel fuel into an active fire zone and control of credentials changing four times within the first week. Even though the President of the United States had publicly prioritized restoration of service to the crippled financial district, lack of coordination among local authorities delayed Verizon's work. Factors affecting the selection or rating of a potential site for a data center or mission-critical facility include:

- *Crime*—Obtaining and analyzing local crime statistics can provide valuable insight into potential risks specific to the potential site. High incidences of crimes against persons or property could inflate the cost of security countermeasures required to protect the facility's assets, such as employees, visitors, contractors, delivery and mail services, utilities, telecommunications, and the building shell. Discovering a high rate of car theft, kidnapping, sexual assaults, or murders can have a significant effect on the ability to hire and retain key resources, not to mention the impact on insurance rates and client or internal confidence. Any history of arsons, burglaries, and vandalism also should be considered when evaluating a site and when deploying security measures.
- *Emergency services*—The emergency service infrastructure consists of law enforcement, fire, and emergency medical services. Being familiar with the local and regional emergency services and

establishing a strong relationship with each will go a long way toward proactively addressing crime, fire prevention, and reducing downtime in the event of a natural or manmade disaster. Knowing which federal, state, or local agency assumes control in what instances can allow disaster recovery planners to develop adequate strategies to deal with credentialing, access to restricted areas, alternative access or egress options for local highways, early warning systems, and other vital data. In the event of a major incident, the data center will benefit from cooperation by and with the multiple federal, state, and local agencies.

- *Telecommunications*—All public and private users depend on the public switched telephone network (PSTN); the Internet; cellular, microwave, satellite, and private enterprise networks; or a combination of them for voice and data services. In their efforts to maintain over 2 billion miles of copper and optical fiber cable, as well as some 20,000 switches, access tandems, and other network equipment, telecommunications providers face increasing challenges to protect their critical infrastructure. Identifying local telecommunications facilities, available redundancy, and reliability is mandatory when selecting a site for data facilities. Other design considerations include obtaining services from multiple providers or, at a minimum, distinct central offices or points of presence (POPs), using redundant trenches or conduits when on the site, and even installing wireless point-to-point backup circuits.
- *Transportation*—People are necessary for the continuous operation of a data center. Sooner or later employees, contractors, and employees of service companies will need to travel to or from the facility. They will need to use cars, trains, buses, airplanes, boats, or some other form of wheeled, flying, or floating vehicle. The supplies that are required to run a data facility will have to be delivered and, conversely, some items will have to be removed, such as rubbish, backup media to be stored offsite, and equipment being sent out for repair.

In the event of a manmade or natural disaster, local authorities typically use control of the transportation infrastructure to stabilize the affected geographical area. Although this can reduce or prevent looting, rioting, or the escape of criminals, it can also prevent key personnel and resources from reaching an IT facility when they are needed the most. Also, the transportation infrastructure can be the source of threats. Airplanes can become flying missiles, cargo containers can carry dirty bombs, and public transportation can provide easy access for a vandal, thief, or terrorist to travel to and from the data center site after commission of a crime against persons or property.

Another threat to the data center is traffic accidents. As a result of watching the stark images of the Oklahoma City bombing and Middle Eastern attacks, people are aware of the devastation that can be caused by vehicles used as intentional bombs; however, the same risk is present on our highways, where commercial trucks carrying large quantities of fuel or other explosive chemicals travel almost daily. Blast resistance as perimeter design criteria are addressed later in the Building section, but it is important to note that whether the threat is terrorism or accidental explosions, traffic accidents and patterns should be considered when evaluating a potential site, because in some cases the force from a fuel truck 500 feet away could require a 7-inch-thick concrete wall to protect the occupants and assets inside a building.

97.4.1 Utilities

Obtaining statistics on the availability of utilities will help in determining the level of backup systems needed. Frequent rolling blackouts or the occasional loss of water service for chillers can eliminate a potential site due to the dramatic increase in the cost of doing business. In some circumstances it is also advisable to obtain electrical feeds from different substations or even utilities. Although North America's power infrastructure is generally considered to be the most reliable, following New York's power blackout in 1965 the North American Electric Reliability Council (NERC) was commissioned to help prevent blackouts and other electrical problems. The 10 nonprofit regional reliability councils that comprise NERC could provide key empirical data as to regional electrical reliability. Approximately 170,000 public water systems depend on dams, wells, aquifers, rivers, and lakes for their water. If the data center or mission-critical facility depends on water for its operation, then issues such as age and condition of water mains, diverse sources, and capacity become part of the site selection process. It is also important to protect utilities once they have entered the mission-critical site. One way to mitigate risk is to use hardened utility trenches.

97.4.2 Natural Disasters

Although a building code might alert construction and security designers to potential issues, not every potential natural disaster is linked to seismic activity or floods. Although not typically considered as a risk to security, the potential data center site should be evaluated for the likelihood of and its susceptibility to:

- Airborne debris or dust (volcanic ash, dust storms, forest fires)
- Drought
- Earthquakes or tremors
- Extreme hot or cold
- Falling objects (e.g., rocks, trees, hail, ice)
- Flooding
- Forest fires
- Freezing rain
- Hurricanes, tornadoes, and high winds
- Heavy soil erosion
- Landslides
- Medical epidemics
- Snow storms and blizzards
- Tsunamis
- Volcanoes

Natural disasters, in particular storms and flood damage, are said to account for over 20 percent of all downtime. It is not difficult to imagine both the primary and backup site, located 20 miles apart, being impacted by one or more of the effects of nature listed above. A critical component of disaster recovery and business continuity planning involves preparation for natural disasters and their tendency to cause a string of cascading events.

97.5 The Perimeter

Appropriate perimeter security measures provide an often-overlooked layer necessary to protect the physical and cyber security of a data center or mission-critical facility. Perimeter security for facilities where valuable intellectual and physical assets are kept often acts as a bidirectional deterrent, keeping unauthorized or undesirable people out and providing a psychological deterrent for employees, contractors, or visitors who might be considering some sort of malfeasance. The presence of a manned guardhouse through which visitors must pass provides extra psychological and physical fortification. No single security system is foolproof. Providing multiple layers provides four critical benefits:

- They can delay an intrusion attempt long enough to allow alarms or other detection systems to activate.
- They can provide evidence of a successful or attempted intrusion.
- They can serve as a psychological deterrent.
- They can mitigate the damage from the threat.

In many instances, the psychological effect of appearing impermeable is more effective than the countermeasures themselves. The delay or prevention of damage or theft external sources is universally recognized as a benefit of perimeter security. The perimeter can also serve as a way to keep assets from leaving the property. Perimeter security is accomplished using a wide variety of devices, materials, and designs. Allowing outsiders to enter a secure site or facility such as a data center brings with it many risks. These risks can be mitigated through the use of the following methods and devices.

97.5.1 Barriers

Structural barriers are used to limit or discourage penetration from outside of the barrier, inside the barrier, or both. The outermost barriers typically border public space and offer the first line of defense for the secure site. Barriers can be either manmade or natural objects and can limit both accidental and intentional penetration. Some barriers, such as fencing, advertise their purpose, whereas others, such as decorative concrete bollards with planters or lighting, are somewhat less overt but can still stop or damage vehicles operating at high rates of speed. The American Society of Industrial Security (ASIS) identifies three types of penetrations that barriers are used to discourage:

- Accidental
- Force
- Stealth

Some secure IT or telecommunications facilities give the appearance of requiring little or no security. Those familiar with the many central offices constructed over the years came to recognize them by the lack of windows. These typically unremarkable buildings would seem to be the last place one would find a major local communications infrastructure. Barriers can be manmade or natural barriers. The following lists contains some examples of each kind of structural barrier:

- *Manmade barriers*
  Bollards
  Building surface
  Clear zones
  Ditches
  Fences
  Gates
  Walls
- *Natural barriers*
  Deserts
  Hills
  Lakes or ponds
  Mountains
  Rivers
  Rocks
  Swamps or marshes

Factors to consider with regard to the use of barriers include the type of threat, value of asset being protected, number of layers of barriers or protection, number and kind of detection devices such as alarms and surveillance cameras, resilience of the building walls, and potential entry points.

A new generation of electronic and optical barriers is gaining popularity and should be considered for secure data facilities. Perimeter intrusion detection systems and fences with built-in listening or sensing capabilities can be integrated with other perimeter access control devices and alarms to provide temporary perimeters or lower cost primary barriers or to enhance existing perimeters as a second line of defense. The most common types of perimeter devices are (1) traditional fencing with

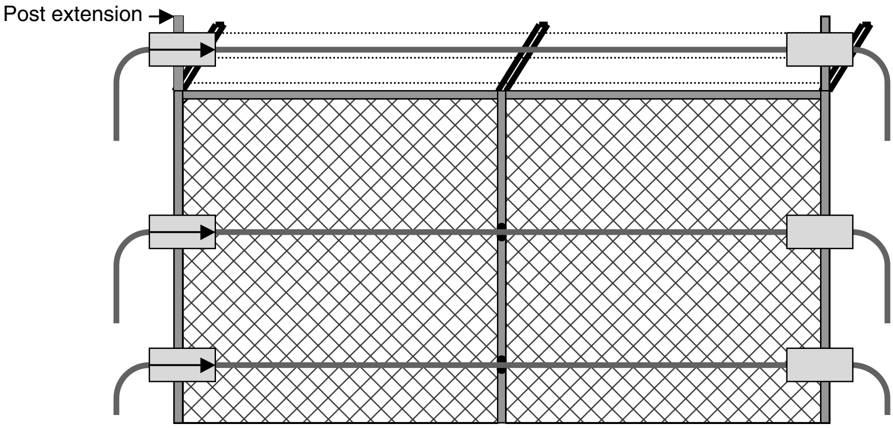


EXHIBIT 97.3 Fiber fence. (Courtesy of Fiber Instrument Sales, Inc.; Oriskany, NY.)

ultrasensitive coaxial cable or optical fiber strands or netting woven or attached to the fence itself (Exhibit 97.3) or (2) logical barriers, which substitute microwaves, infrared, or laser beams in place of fence fabric. Products such as Fiber Instrument Sales' fiber fence (Exhibit 10.1) provide a hybrid deterrent, offering the permanence and psychological deterrence of traditional fencing while incorporating fault and intrusion detection. The totally electronic barriers offer quick installation, portability, and generally lower cost per linear foot; however, the permanence and fortress-like appearance of security fencing is sacrificed for the ability to instantly notify or record intrusion locations. For aesthetic and other reasons, however, the new perimeter intrusion detection systems may be more desirable for a data center or mission-critical facility.

97.5.2 Gatehouse

The use of gatehouses, previously referred to as guard shacks, can incorporate many of the access control devices discussed later in this chapter. It is important to note that channeling vehicle and pedestrian traffic through a single point of entry can reduce the likelihood of site intrusion and provide unique opportunities to record vehicle and human information for later use. For example, surveillance cameras can be placed to record the image of the driver, front license plate, and rear license plate of every vehicle entering and exiting a secure facility. Facial recognition and character recognition would allow nearly real-time comparison of those admitted or requesting entry with databases of known terrorists or those who have previously been involved in domestic or workplace violence. Additionally, if an incident of theft, violence, or damage pointed to a particular time window, then private security or public law enforcement would have a record of every vehicle, driver, passenger, and license number that entered and exited the site during that period.

97.5.3 Lighting

When deployed on the data center site between the buildings and the perimeter, lighting can serve one or more of the following functions: (1) aesthetics, (2) safety from injury, or (3) protection of persons or property. Although architectural lighting can be pleasing to anyone visiting the building or campus, it is secondary to the safety and protection of persons, vehicles, property, and the site itself. Proper lighting will help avoid injuries and accidents due to slipping, falling, or bumping into manmade or natural obstacles. Very specific design criteria exist for safety-related lighting with respect to type of light, mounting height, shadows, and glare. The effect of lighting on closed-circuit television (CCTV) cameras should also be taken into account. Some types of lighting, such as high-pressure sodium lights, do not have the proper color rendering index (CRI) and can actually make proper identification of people and objects more difficult. Considering the dollar value of the equipment and the cost of downtime, the ability to identify intruders might be important enough to avoid moving into a typical warehouse or retail location. The most important benefit of lighting inside the perimeter is that of discouraging assault or intrusion. This protects employees and other personnel who are entering or exiting the facility and provides a psychological deterrent to penetration of any existing barriers. Intruders are less likely to come close to a facility where it is likely that they will be observed.

97.5.4 Private Security Services

Another valuable resource in the perimeter protection of data centers and mission-critical facilities is that of the private security service. Initially known as watchmen, then guards, and now security officers, these personnel were characterized as “aging, white, male, poorly educated, usually untrained, and very poorly paid” in a 1971 RAND report. Today finds the business of private security and loss prevention in somewhat better shape. Typical contract security officers are now in their early 30s, and their training has improved somewhat. Proprietary guards, those hired directly by the company, are typically much better trained and paid. Whether contract or proprietary security is deployed as a perimeter deterrent, the security officer remains a very visible reminder of the organization’s commitment to the protection of physical and cyber assets. The presence of a security guard, whether manning a gate or patrolling the campus, sends a clear message to potential intruders.

97.5.5 Traffic Control

Ideally, employees and visitors must pass through the front entrance, and their movements are limited by the design of the building (the concept of crime prevention through environmental design, or CPTED) and by various types of access control, surveillance, alarm, and personnel-based systems. In some cases, delivery trucks, tractor trailers, fuel trucks, contractors, and other heavy equipment deliveries can arrive at the docks or delivery areas without being subjected to the same security as other visitors. This necessary traffic brings with it a host of security issues. The vehicles that arrive daily at the docks of the data center or IT facility can provide a shield for those who intend to steal, damage, or disrupt the operation of the facility. They also represent a significant risk of fire, explosion, and attack at a point in the building perimeter that is seldom fortified. While the fronts of most buildings contain some sort of barrier to prevent the kind of damage caused recently by truck and car bombs, the loading docks by design cannot block traffic without defeating their ability to function. Some of these risks can be mitigated through interviews at the gatehouse and by under-vehicle and cargo bay inspections for obvious threats; however, the risk will never be completely eliminated.

Parking garages represent another source of threat to the security of an IT facility. The same access control techniques used for pedestrian traffic can be combined with intercoms and gates to control entry and exit from a parking garage. When employees, visitors, or contractors exit their vehicles, their opportunity to be injured or to engage in criminal activity increases until they have entered the building or are once again in their vehicles. Operation of elevators servicing parking areas must be synchronized with the deployment of personnel (receptionists or guards) and with the programming of access control devices. It is also advisable to close the parking garage at night or limit its hours of operation. Keeping the parking garage open 24 hours can trigger a need for additional countermeasures to protect assets and people.

Traffic control devices are also an important consideration when any vehicular traffic is permitted inside of the site. Traffic lights, stop signs, speed limit signs, speed bumps, gates, barriers, painted lines, and other devices help to ensure that the employee, visitor, or service personnel operate their vehicles safely and do not jeopardize key personnel or property while driving inside the perimeter of the site.

97.6 The Building

Preventing theft of or damage to assets and preventing injury to or death of any building occupants are among the most common goals of building security. Although physical damage to a building can only be obstructed, absorbed, or deflected, opportunities to create damage can be reduced through various types of access control, surveillance, and alarms. A combination of these security measures provides the layers of protection necessary to protect the critical IT infrastructure and assets.

97.7 Access Control

Fundamental to the protection of any asset is protecting it from unauthorized access. Information and physical security share the need to both identify and authenticate the user requesting access. Due to the ability to gain access through the unauthorized use of keys or cards, single-factor authentication is often the single point of failure in access control systems. The three generally accepted authentication factors and an additional optional factor are:

- *Type 1*—Something you know (passwords and personal identification numbers [PINs])
- *Type 2*—Something you have (keys, cards, token)
- *Type 3*—Something you are or some physical characteristic (biometrics)
- *Type 4*—Something you do (optional and a less distinct authentication factor)

For a higher level of security, one or more of the authentication factors are often combined to create two-factor or multifactor authentication. An example of two-factor authentication would be an automated teller machine (ATM) card, where both the card (something you have, type 2) is combined with a PIN (something you know, type 1). Multifactor authentication eliminates the likelihood of a single point of failure, such as when a person's ATM card is stolen. The use of individual and combined authentication types is a common access control tactic for both information and physical security. It should also be noted that a poor building design or one not conforming with the design concepts behind CPTED can limit or negate the benefits of a good access control system. Without incorporating the security principles of CPTED during the initial construction of a building, expensive protective measure must be taken later to compensate, which can at times include the need for guard services where none would have otherwise been required. The following text provides an overview of commonly accepted access control methods.

97.7.1 Badging

The role of access control centers on establishing the identity of persons requesting access or egress. Identification must be validated in a couple of ways. First, it must be an authentic form of identification, and, second, it must contain a true likeness of the bearer. Information pertaining to one's identity can also contain information as to that person's functional capabilities. For example, rights and privileges extended to someone who is a police officer will be different from those for someone who is a job applicant. A police officer who needs to enter a data center or computer room to investigate a crime or for other official business would be admitted without a company-issued ID badge, whereas a job applicant would most likely not be allowed to enter.

A solid badging policy and procedure are exceptionally important in light of the value of the assets contained within the data center or mission-critical IT facility. One concern is tampered ID badges or the unauthorized reuse of ID badges issued to visitors and service personnel. Employee and other long-term ID badges should be laminated to prevent tampering in the event they are lost or stolen. When proper lamination techniques and materials are utilized, the ID badge will tear if someone tries to insert a new photograph into the badge. Recently, stick-on temporary badges have become available; they react to light and within a preset period of time (typically about 8 hours) display a word such as "VOID," colored bars, or other visible sign indicating that the badge has expired.

97.7.2 Biometrics

Biometrics can be defined as the statistical analysis of physical characteristics. In security and specifically within access control the term refers to the measurement and comparison of quantifiable physical and physiological human characteristics for the purpose of identification and authorization. From an access control standpoint, biometrics is still relatively new; however, the use of biometrics is gaining ground, because this pattern-recognition system overcomes issues associated with authorized individuals having to carry keys or cards. Biometric systems capture the control data in a process know as enrollment. When the subject's biometric reference data has been collected, it is then stored as a digital template. For the purposes of granting or denying access, submitted biometric samples are compared with the template and not stored images or the enrollment sample. Four technical issues that must be considered prior to selecting biometric technology for use in a data center are:

- *Failure to enroll*—This occurs when the fingerprint or other biometric data submitted during the enrollment process does not have enough unique points of identification to identify the individual.
- *Type 1 error, or false reject*—Just to be confusing, this type of error is also known as "false nonmatch" and occurs when the condition of the biometric data presented for matching to a stored template falls outside of the window of acceptance. In fingerprints, this could be accounted for by the condition of the finger, its placement on the reader, the pressure exerted, or other environmental or injury- or wear-related factors.
- *Type 2 error, or false accept*—Sometimes the selected comparison minutiae on two fingerprints or other biometric data can be identical. Other points of identification may be unique, but the particular sets of characteristics chosen and stored are the same.
- *Crossover error rate (CER)*—This comparison of type 1 and type 2 error rates is potentially the most important measurement of the accuracy of any type of biometric device. Although the CER can be adjusted, a decline in false accepts frequently results in an increase of false rejects, so a biometric device with a crossover error rate of 2 percent is better than one with a rate of 3 percent.

Although the individual criteria that distinguish some biometric factors such as fingerprint and retinal minutiae are decades old, the advances in technology allowing them to become practical for access control purposes are still relatively new. A short list of the biometric technology available that can be used in access control systems for data centers or IT facilities includes the following:

- *Facial recognition* measures unique attributes of the face, including surface features such as geometry, or it can use thermal imaging to map the major veins and arteries under the skin. These types of biometric devices actually capture an image of a face in picture or video format and then convert the image into a template of up to 3000 bytes.
- *Fingerprint recognition* analyzes the patterns found on the tips of the fingers. The use of fingerprint patterns as unique identifiers for criminals has been around for over 100 years; however, the earliest known hand or foot impressions that were used as signatures may date back 10,000 years. Mature methods of identification also spawn mature methods to defeat or bypass identification and authentication. To eliminate the potential removal of the finger of an authorized enrollee and using it to gain access, many manufacturers now measure pulse and temperature as part of the authentication process, although even with these additional metrics fingerprint recognition systems have been spoofed. In 2002, Tsutomu Matsumoto, a Japanese cryptographer, devised a technique that will fool most temperature- and pulse-sensing fingerprint readers. He used various techniques to create gelatin molds of "fingers." When these molds were wrapped around a warm

finger with a pulse, they allowed the unauthorized visitor to gain access, even with a security officer watching—more evidence that multifactor authentication is much more secure than even single-factor biometrics.

- *Hand-scan geometry* compares various hand measurements, including the length, width, thickness, and surface area of the hand. This technology has been around for a few years and is used primarily for access control, but it has also been included in many time and attendance systems. In order to prevent the potentially fatal removal of an authorized user's hand to gain unauthorized access, temperature sensors have been added to the technology included in many commercially available units.
- *Iris and retinal scans* are considered the most secure of the biometric methods; in some studies, the iris scan has been shown to benchmark at a 0 percent crossover error rate. A related technology, the retinal scan, maps the vascular patterns behind the eye, and the iris scan uses the unique pattern formed by the iris for comparison. Biometric data from both iris and retinal scans is internal data and is considered far less subject to tampering or spoofing.
- *Other biometric technology* includes other biometric signatures that can be used to control access to a secure room or site, such as signature dynamics, DNA, signature and handwriting technology, voice recognition, and keystroke dynamics.

Selecting the proper biometric appliance or the number of additional authentication factors or deciding whether biometrics should be used at all should be based upon a number of criteria, including business case, risk, threat, data sensitivity and classification, potential subscribers, and site demographics, among others.

97.7.3 Card Readers

To enhance the use of keys for type 2 authentication, magnetic stripe, watermark magnetic, Wiegend wire, embossing, Hollerith optical, or radiofrequency card readers and cards can be used to control access or egress from a building. These cards can be combined with other access control methods to create a very secure multifactor authentication access control system. Employee, contractor, and visitor ID badges can be printed on the face of the card. Access can also require the additional use of biometrics or passwords to gain entry. In some highly secure sites, access control can be combined with network security to allow users to log onto the network only if they are listed in the access control system as being in the building. With this type of physical and IT security integration, even if intruders forced their way into a secure facility, they would be less likely to gain access to sensitive or proprietary data.

Two special design features that should be considered for implementation within the data center or secure IT facility are anti-passback and the two-man rule. Anti-passback addresses the practice of those who are authorized to enter passing their access card back through or under a door to a waiting employee or other person. The second person then uses the first employee's card to enter the same door. When anti-passback features are installed and activated along with normal access controls, the card can only be used to enter a perimeter door or gate one time. When the user is inside the facility, the card can only be used to enter other doors with readers or to exit the building. When the card is used to exit the building, it cannot be used to open doors inside the facility or secure areas until after it is used to reenter.

This feature prevents both unauthorized persons from entering the facility and the card from being passed back into the facility for use by an unauthorized person. The two-man rule is used for areas where no person is ever permitted to be alone. It is typically used for access to bank vaults, military facilities, and locations with classified documents, objects, or data; however, this technology has potential value for use in mission-critical data facilities. This access control application requires that two persons must have presented valid cards and entered within a given period of time, typically less than a minute, or an alarm sounds. Conversely, if only one of the authorized persons exits and the second one remains inside the secure room, then an alarm sounds, security is notified, and the event is recorded.

97.7.4 Locks and Keys

Of the devices discussed, locks and keys are the most widely deployed method of access control and are not limited to doors. Locks can be found everywhere and protect a wide variety and scale of commercial, government, residential, and industrial assets. Locks are generally classified into one of two categories: (1) mechanical or (2) hybrid (mechanical and electrical). Mechanical locks typically use keys, codes, cards, or combinations to restrict access. Hybrid locks are simply mechanical locks that are controlled or opened using some electrical actuator. These electronic keys include everything from push buttons and motion sensors to panic bars, card readers, radiofrequency identification (RFID), and keypads. Because doors not only protect assets but also require interaction with human beings, fire and life safety concerns must be addressed. Most locking mechanisms are classified as either fail safe or fail secure, and their use should be considered carefully for doors in the egress path during a fire or other emergency when power or command and control is lost. Local building and fire codes will also dictate the allowed complexity of exiting through a door or opening during an emergency. Many codes limit the number of actions required to exit through a door. Exiting through a door almost never involves the use of multi-factor authentication or access control.

Many secure facilities still employ the most common form of type 2 (what you have) authentication—keys. When locks and keys are used, careful management or control of the keys must be maintained. Termination of employees and loaning keys to other employees or service personnel are opportunities for keys to fall into the wrong hands. One way to limit risk in this case is to classify locks and the keys used to open them according to a grand master key system, as shown in Exhibit 97.4. Some rules for key control include:

- Restrict the issuance of keys on a long-term basis to outside maintenance or janitorial personnel. Arrange for employees or guards to meet and admit all contract janitorial and service personnel.
- Keep a record of all issued keys.
- Investigate the loss of all keys. When in doubt, rekey the affected locks.
- Use as few master keys as possible.
- Issue keys based on a need-to-go basis. Review the list periodically to ensure that the various key holders still have a need to access the secured areas for which they hold keys.
- Remember that keys are a single-factor authentication mechanism that can be lost, stolen, or copied. Always consider two-factor or higher authentication mechanisms for computer rooms, sensitive or mission-critical zones in data centers, and any other space where valuable assets are kept.

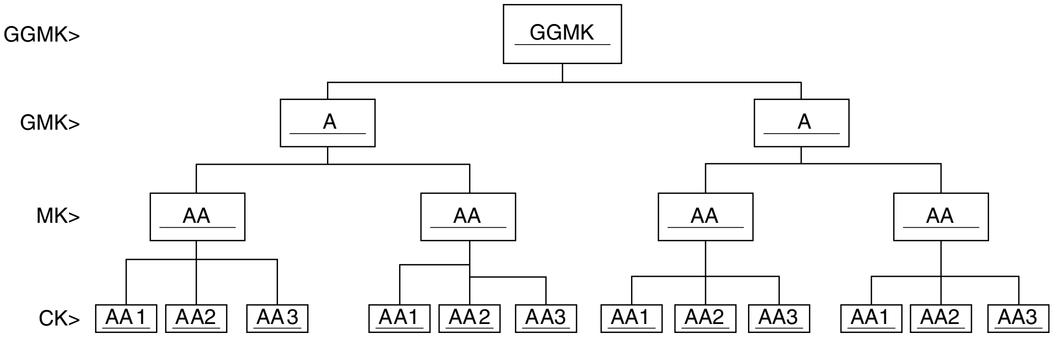

EXHIBIT 97.4 Great grand master key system: four levels of keying.

97.7.5 Special Access Control Devices

Most people are familiar with common access control devices that prevent, limit, or control movement within a building or area, such as door strikes, electromagnetic locks, gates, bollards, walls, and many other devices. Special devices, however, can be used for either higher levels of security or to replace 24/7 private security while still maintaining strict control of entry and exit. Three of those devices are mantraps, sally ports, and turnstiles.

97.7.5.1 Mantraps

Access control portals or mantraps typically consist of two or more doors, spaced and controlled in such a way that (1) no guard or attendant is needed, and (2) only one person can enter at a time; they typically incorporate the use of one or more types of card reader, biometric reader, metal detector, keypad, weight feature, occupant count, or voice recognition. Additionally, the mantrap can include chemical, biological, radiological, nuclear, and explosive (CBRNE) sensors. If an unauthorized individual attempts to enter the facility, if one of the sensors detects any of the CBRNE triggers, or if more than one person enters or piggybacks, then the second door remains locked, trapping the individual. This will trigger an alarm and summon internal security or the police, who can then investigate. In the event that no alarm is triggered, mantraps have intercoms or phones. For low-traffic buildings, a single mantrap may be used for entry and exit, but two or more are generally used for high-traffic facilities. Some manufacturers offer mantraps that look like revolving doors. Others offer bullet-proof and blast-resistant glass as a standard feature to maintain the integrity of the building perimeter. It is not unusual to see mantraps deployed for highly secure data centers, computer rooms, and mission-critical facilities.

97.7.5.2 Sally Ports

Some have described a sally port as a mantrap for vehicles. The material used to build sally ports varies depending on the type of facility where they are installed. Typically, a vehicle is driven to the entrance of a sally port. Through some form of access control (surveillance or intercom), the vehicle requests and is permitted entrance. A pedestrian door with access control is typically located on the inside of the sally port. For facilities with guards that man the sally port, provisions are made for the guards to view the vehicle and its occupants through CCTV or bullet- and blast-resistant windows on the control room.

97.7.5.3 Turnstiles

Similar to mantraps and sally ports, turnstiles typically combine standard access control with a half- or full-height rotating arms. When the person has been authorized to enter, then the arm or arms release and allow access. Turnstiles are typically used for high-traffic facilities such as sports stadiums, public transportation, and other facilities where a blend of accessibility and security is needed. Turnstiles would be best suited for access at the perimeter of a secure IT site.

97.7.5.4 Crime Prevention Through Environmental Design

Through work that began in public housing projects addressing residential security, organizations such as the Law Enforcement Assistance Administration (LEAA) and the American Institute of Architects (AIA) have refined and formalized design concepts addressing the role that building design plays in security. It is easy to identify buildings that were constructed before CPTED became a recognized practice. Many of these buildings were constructed with easy access and virtually no distinction between private spaces, intended only for trusted individuals, and public spaces. Some of the pre-CPTED buildings allowed access and egress through unlocked and unprotected doors and did not funnel foot traffic through a manned secure space such as reception areas or guard desks. Some of the issues addressed by CPTED include:

- Controlling traffic patterns (both vehicular and human)
- Location, height, and number of external windows
- Location and number of external openings and entrances

- Quality and number of locks
- Alarming restricted access and egress points
- Classification of space based on the identification, authorization, and sensitivity of the assets it contains

The practice of crime prevention through environmental engineering defines four types of spaces. In ascending order of their required security, they are:

- *Public space*
  Lobbies
  Public restrooms
  Sidewalks
  Parking lots
- *Semipublic space*
  Conference rooms
  Private restrooms
  Loading docks
  Utility closets
- *Semiprivate space*
  Board rooms
  Offices
  Copy rooms
  Telecom closets
- *Private space*
  Computer rooms
  Network operations centers
  Executive suites
  Human resources and finance

One important aspect of building design and processes is visitor and service personnel management. Providing visitors and service personnel with clear borders and defined boundaries between public and private spaces is critical to maintaining successful traffic control, especially in an unescorted facility. Providing clear directions to restrooms, meeting rooms, mechanical rooms, and electrical closets is a good security practice. Displaying floor and building maps, clearly labeling rooms, and installing information signs all serve to direct visitors and service personnel. Proper building space design, ID badging, access control devices, surveillance, and employee awareness all work together to assist in maintaining the separation between public and private spaces.

If an existing building or site is selected to house a secure IT facility and it was not designed using CPTED design techniques, making the necessary changes can be very expensive and sometimes not worth it. Because site-related issues such as traffic flow, barriers, and other deterrents are typically easier to accomplish than boarding up windows or moving load-bearing walls inside of a building, close attention should be paid when qualifying any existing building for a data center or mission-critical IT facility. A good design using CPTED concepts includes several overlapping strategies, such as natural access control, natural surveillance, territorial enforcement, visitor management, traffic encouragement, maintenance strategies, and reduction of conflicting use. It is important to remember that CPTED is not a target-hardening practice requiring a fortress mentality. It is the study of human and process interaction with the environment and designing the structure and site to encourage desired behavior and discourage undesired behavior.

97.7.5.5 Guards

As noted in our earlier discussion of site selection, guard services or security officers can provide an effective method of access control. Although guards can provide an intuitive and flexible method of determining the identification and authorization of someone requesting access to a secure IT facility, they can also make mistakes in judgment or be subject to other human temptations that jeopardize security.

97.7.5.6 Surveillance and Closed-Circuit Television

Surveillance is one of the oldest forms of security. Originally accomplished through the deployment of sentries or guards, security was labor intensive and required enough personnel to visually monitor the asset, building, or area to be guarded. As technology became available and cost reduction became a driver, a growing number of facilities moved toward more cost-effective surveillance devices to supplement or replace security guards. Surveillance devices can be motion picture cameras, closed-circuit cameras, or sequence cameras, the primary goal of which is to obtain an identifiable image of the subject or asset being monitored. The installation can be covert or hidden, as apprehension is the goal (think “nanny cams”), or the devices can be installed openly so as to discourage any violation of company policy or engaging in criminal activity. Unless continuously monitored, surveillance cameras are limited in their ability to detect crime as it is happening. The primary value offered by cameras is the recording of any theft, violence, damage, or policy violations.

Surveillance plays an important role in both deterrence and detection anywhere within the perimeter of a secure facility; however, advances in the technology can offer incremental benefits to the surveillance industry through the use of artificial intelligence, which provides added benefits compared to strictly watching for intruders or keeping an eye on employees. Many surveillance companies offer the ability to alarm a specific zone or area within the picture sent back to the camera. Using this technology, if a camera is focused on a wall containing both a door and a window, the software would permit recording and alarming of only the target area, the door, while ignoring passing pedestrians, birds, and other potential false alarms. This saves tape or disc storage space as well as time and resources necessary to respond to false alarms. Among other emergency technologies that leverage the surveillance video are those concerned with fire and life safety. The British firm Intelligent Security, Ltd., has developed a product called Video Smoke Detection. It uses the output of common CCTV cameras to detect smoke and fire up to 20 times faster than the best temperature sensors, smoke detectors, or the human eye. In a computer room or data center where the particulate matter from a smoldering fire can do a greater amount of damage than the fire itself, this ancillary benefit of CCTV can provide significant benefit to the overall security without the incremental costs of additional surveillance cameras.

97.7.6 Intrusion Detection

Not every secure facility will need or hire security guards to patrol the perimeter of the site and hallways of the building. Additionally, the chance of catching an intruder when patrolling a facility of any significant size is remote. This fact, plus the cost savings of installing an alarm system, makes it an attractive alternative instead of supplementing guard services. Intrusion detection can involve one of three types of alarms. Fire alarms and special-use alarms (heat, water, and temperature) are common in all commercial buildings systems as well as data centers and computer rooms. Alarms are not necessarily a countermeasure. They do not prevent, funnel, trap, or control anything. Short of some psychological effect as a deterrent, they only detect. Several types of alarms are used for intrusion detection:

- *Audio or sonic systems* depend on intruders creating noise of a sufficient volume that the microphones will detect it and the alarm will be activated.
- *Capacitance alarm systems* detect changes in an induced electromechanical field surrounding containers, fences, or other metal objects.

- *Electromechanical devices* act as switches that provide information to the monitoring person or device regarding the state of some part of the building: The door is open, the window is dosed, or the cover has been removed from a file server or other network device.
- *Motion sensors* use radio, high-frequency sound, or infrared waves to detect movement. The performance of radiofrequency waves is more subject to false alarms because the radiofrequency spectrum can penetrate walls and pick up unintended movement on the other side.
- *Photoelectric devices* monitor for the presence or absence of light. These sensors can detect when a beam has been broken or when a door has been opened on a computer room cabinet.
- *Pressure devices* are also switches that simply respond to pressure. These types of sensors can be placed under carpeting or in some other concealed place.
- *Vibration detectors* sense the movement of objects, surfaces, or vehicles or other assets. When a vibration is detected that is within the preset range of intensity, the alarm sounds.

97.7.7 Walls, Doors, Windows, and Roofs

Security plans often fail to consider the walls, doors, and windows of a building as being integral to security. For many data centers and IT facilities, no perimeter barrier has been established through the use of guards, fencing, or other barriers. In these type of situations, the building shell becomes the perimeter protection. Many times the windows and doors are protected by traditional burglar alarm devices (e.g., glass break sensors, open/closed contacts, motion sensors), but the walls are often ignored as a point of entry. Many police reports are on file that tell the tale of an intruder entering through the outside wall of a business or the inside wall of a poorly hardened or alarmed adjoining space. Deploying alarms and surveillance on interior walls that are adjacent to other businesses and on outside walls where limited or no safe zones exist is recommended. Incidentally, there is also no shortage of incidents where the intruder entered from the roof, so do not forget to include vertical points of entry in the security plan.

97.7.8 Weapons and Explosives Screening

The inspection of persons and property for contraband, weapons, and explosives has become commonplace due to 9/11. Weapons detectors, x-ray machines, and explosives detectors are inescapable when traveling by air. Behind the scenes, dogs and machines are engaged in a constant vigil. The data center or mission-critical IT facility can offer another tempting target for vandals, saboteurs, and terrorists. The following are some suggestions for mitigating the risk of damage or injury due to weapons and explosives:

- Clearly display signs in multiple languages (as appropriate) advising potential entrants of the pending screening procedures, prohibited items, and the company's policy on prosecution if contraband is found.
- In high-risk facilities, install both walk-through and hand-held metal detectors, and hire and train the personnel required to use them for screening.
- Consider the installation of explosives and chemical, biological, radiological, nuclear, or explosives sensors or machines at entry points or inside of mantraps and turnstiles.

97.8 The Computer Room

More than any other place in the enterprise, electrical, mechanical, security, and information technology systems come together to work as one system in support of availability and reliability in the computer room. While many of the alarm systems, access control devices, and surveillance equipment discussed earlier in this chapter apply to computer room security, this section deals with threats to the availability of the systems, applications, and data that comprise this core space. Protecting the computer room, like all other assets, consists of a maintaining a careful balance between the value of what is being protected with the cost of countermeasures. This section deals with direct threats to the cyber health of the facility, critical infrastructure, hardware, software, and occupants of the computer room and how the various systems work together to protect the reliability and availability of the applications and data found there. Many of the seven sources of physical damage referred to earlier in this chapter (i.e., temperature, gases, liquids, organisms, projectiles, movement, and energy anomalies) can also be considered physical threats to the data center.

97.8.1 Risk Assessment

A risk assessment is strongly recommended when designing a computer room. A risk assessment for the computer room will include the following metrics:

- Availability
- Probability of failure/reliability
- Mean time to failure (MTTF)
- Mean time to repair (MTTR)
- Susceptibility to natural disasters
- Fault tolerance
- Single points of failure
- Maintainability
- Operational readiness
- Maintenance programs

Availability and reliability are the overarching objectives of computer room operation. Availability is the long-term average of time that a system is in service and is satisfactorily performing its intended function. Reliability focuses on the probability that a given system will operate properly without failure for a given period of time.

The American Society of Heating, Refrigeration and Air Conditioning Engineers (ASHRAE) has estimated that the average commercial building has 15 building systems. These building systems are divided into the five major groups of office automation (voice, data, video); heating, ventilating, and air conditioning (HVAC); security; fire and life safety (FLS); and energy management. Many of these systems have subsystems. A data center, including the computer room, will average 20 or more of these systems or subsystems. All of these systems must be available and reliable or the rating of the entire data center is reduced. This interdependent group of physical and cyber systems, when combined with human assets and when operating within defined processes, has been identified by the Department of Homeland Security as the *critical infrastructure*. To combat the inevitable failure of a critical infrastructure within the computer room, much attention should be focused on the redundancy, complexity, and operational readiness of each independent system.

97.8.2 System Reliability

It is also important to note the relationship between the number of systems and components in the computer room. Very simply, the more systems and components in the computer room, the less reliable it will be. An additive effect of the MTTF and MTTR of the various systems on the collective performance has been identified. Exhibit 97.5 compares the availability and probability of failure (P_f) over a three-year period for the electrical and mechanical systems that are supporting a computer room. When considered individually, the systems exhibited four or five nines of reliability. The percent probability of failure ranged from 8 to 11.7 percent. When considering the overall combined electrical and mechanical system,

EXHIBIT 97.5 System Reliability

System	Mean Time to Failure (hr)	Availability	Three-Year P_f (%)
Electrical system alone	330,184	0.99999	8.10
Mechanical system alone	178,611	0.999943	11.70
Electrical system supporting mechanical system	108,500	0.999985	21.40
Overall mechanical system	70,087	0.999931	29.20
Combined electrical and mechanical system	57,819	0.999922	36.90

however, the probability of failure escalates to nearly 37 percent over the three-year period. The maximum attainable rating for both systems is slightly under a tier 4 benchmark.

When considering the cumulative effect of multiple systems and human factors on a data center, it is not surprising that only 10 percent of the data centers evaluated by The Uptime Institute ranked at tier 4 levels. Critical failures in the computer room are typically caused by more than one factor or system failure. Most often the failure is caused by a combination of some external event (power failure), followed by some equipment or human failure (the manual override of an alarm). Compounding the contribution of cascading events to downtime are latent failures, where some previously uncorrected minor fault leads to downtime during a disaster (e.g., maintenance personnel leaving a circuit breaker open during the last preventative maintenance of the backup generator). Most critical failures occur during a change of state and are not attributable to system failures. Humans are not all that reliable and tend to cause more downtime than any other factor. When considering the role that the human factor and latent faults play in downtime, it is not surprising that more maintenance does not always mean higher levels of availability. The following five sections address some of the major factors that affect availability in the computer room.

97.8.3 Heating, Ventilation, and Air Conditioning

Many of the performance benchmarks of the modern computer room evolved out of the original Bellcore standards for the telephone company's central offices. Under the standards defined in the Network Equipment Building Systems (NEBS) guidelines, equipment was required to provide the highest possible level of equipment sturdiness and disaster tolerance. The NEBS standards employed a group of tests that put central office equipment under extreme physical and electrical tests, simulating extreme operating conditions such as might be encountered from natural or manmade disasters. NEBS level 3 equipment is required to withstand an earthquake rated at 8.3 on the Richter scale, a direct lightning strike of 15,000 Volts or greater, and extreme fluctuations in temperature ranging from as low as 23°F to as high 131°F These temperatures may not seem all that extreme, but remember that component reliability is reduced by 50 percent for every 18° rise in temperature above 70°F. Temperature is important.

The rigid requirements for HVAC systems in data centers and enterprise computer rooms are derived from what we have learned about other mission-critical facilities. The pending Telecommunications Industry Association Telecommunications Infrastructure Standard for Data Centers (SP-3-0092, to become TIA-942) references the Bellcore standards and goes further to recommend that at a minimum computer room HVAC systems should provide $N+1$ redundancy, or one redundant unit for every three or four systems in service. In addition, computer room air conditioners (CRACs) are required to be able to maintain the temperature at 68 to 77°F and relative humidity within a range of 40 to 55 percent.

Beyond the heating and cooling aspects of a computer room HVAC system are indoor air quality (IAQ) issues, including concerns regarding certain airborne particles and microbes. A number of air filters and filtering systems exist to address indoor air quality and particles. These particle filters offer some protection from chemical, biological, and radiological pollutants and consist of one of four types of basic filtration systems (i.e., straining, impingement, interception, or diffusion).

97.8.4 Fire Detection and Suppression

The National Fire Protection Association (NFPA) *Fire Protection Handbook* identifies a variety of potential results from "thermal-related effects, principally fire," They include thermal injury, injury from inhaled toxic products or oxygen deprivation resulting from fire, injury from structural failure resulting from fire, electric shock, and burns from hot surfaces, steam, or other hot objects and explosions. Nearly 2 million fires are reported each year, which represents only about 5 to 10 percent of unwanted fires. Fires can be classified into the following four categories:

- *Class A*—Fires involving ordinary combustibles (e.g., paper, rags, drapes, furniture)
- *Class B*—Fires that are fueled by gasoline, grease, oil, or other volatile fluids
- *Class C*—Fires in live electrical equipment such as generators and transformers
- *Class D*—Fires that result from chemicals such as magnesium, sodium, or potassium

Fire alarm systems are similar to intrusion alarm systems in that they consist of a sensor and signaling device. The signaling system can be triggered in a number of ways, such as by water-flow switches, manual alarms, and smoke or heat detectors. Sensors are designed to detect fire at different stages of development. For example, ionization detectors are designed for detecting fire at its earliest *incipient stage*. Photoelectric smoke detectors begin to alarm when smoke reaches a concentration of 2–4 percent, which typically occurs during the *smoldering stage*. Infrared flame detectors detect the infrared emissions of active fire during the *flame stage*, and thermal detectors (as their name suggests) react to the heat during the *heat stage* of a fire. Although fire alarm system design is beyond the scope of this chapter, some very important fire-related questions should be asked, including:

- Are smoke and fire detectors located under the raised floor? Above the raised ceiling? Inside of air handling ducts? Inside computer cabinets?
- Are the doors and walls of the computer room fire rated? Do they have a 2-, 3-, or 4-hour rating?
- Is emergency lighting provided in the computer room?
- Are fire extinguishers of the proper class present in the computer room?
- Is fire suppression automatic? What is the temperature rating of the sprinkler system?
- What extinguishing agents are used? Water? Halon? Other?
- How are fires inside of cabinets suppressed?
- Does the air handling or exhaust system activate during a fire to exhaust smoke and steam from the computer room?
- Are portable fire extinguishers available and lit with emergency lighting?
- How close is the fire department? Three miles or less? Is the fire department volunteer or full time? What is their average response time?
- Is a fireproof cabinet or safe located in the computer room for backup media?
- Are the waste receptacles low-fire-risk? Is a metal lid available for each trash can for putting out fires?

97.8.5 General Space Design Issues

Earlier in this chapter we discussed the design of walls, doors, windows, and ceilings with safety and security in mind. It is also important to take a brief look at some often overlooked design issues that could prove to be a threat to the computer room or data center. Most architects and engineers do a good job of avoiding the pitfalls of poor design for IT facilities; however, it is important in both new and existing facilities to examine the floor plan, ceilings, walls, and closets for potential hazards to the computer room and systems that support it.

Water flooding, leakage, and condensation are all security threats to the computer room. It is worth taking a few minutes to make sure that no restrooms, kitchenettes, or janitor closets with water are located adjacent to the computer room walls. Water pipes are frequently located inside walls, and if they leak or rupture the water could spill into the computer room. Similarly, it is important to ensure that no roof drains, water pipes, cooling pipes, or any other pipes carrying liquid are routed directly over or along the computer room.

As a preventative measure, it also makes sense to investigate where water will go if a leak occurs. Does the computer room have a drainage system? What about adjacent rooms or businesses? An inspection of water sources should also include the higher floors in a multistory building. Are drains installed in the floors above the computer room to catch water in the event of a ruptured pipe?

When possible, it makes sense to avoid having doors and windows to the outside in the computer room. If these already exist or the operator is given no choice but to locate the computer room in an existing space with outside doors and windows, several security practices should be considered. Traditional alarm sensors should be installed, and physical barriers such as bars or plates should also be considered, especially if the facility has no perimeter security.

Another consideration is the proximity of the windows and doors to a parking lot, road, or sidewalk. How close can vehicles or pedestrians get to the outside windows and doors? Remember that outside windows in the computer room are the only barrier between that room and the parking lot, street, highway, or walkway. Tempered safety glass, commonly installed in commercial office buildings, only requires about .8 psi of overpressure. In the event of an intentional or accidental explosion, shattered window glass, blast debris, smoke, and fire can all be blown into a computer room from the outside. Fire- and blast-rated doors and strengthened, blast- or bullet-resistant glass are all wise precautions for outside windows and doors. Other considerations for protecting glass windows and doors include the use of window films and fabric screening systems or blast curtains; however, the best solution is to ensure that all computer room walls are inside walls.

Other building design considerations would be the proximity of the computer room to fuel storage tanks (which should ideally be underground), chemical storage, liquid gas tank storage (fork lift and tow motor fuel cells), and other caustic or potentially explosive liquids. A tour of the walls adjacent to the computer room should find them to be clear of any potentially flammable or explosive materials, chemicals, or liquids.

97.8.6 The Human Factor

Human beings should always be considered a risk when analyzing the potential for failure. Human factor risks can include operator error and those caused by poor human interface. Additional considerations would include accidental and intentional damage, such as sabotage and terrorism. Most estimates of the percentage of critical failures due to the human factor exceed the 70 percent mark. The following is a list of people with the potential to cause downtime:

- Base building operations
- Building engineers
- Cafeteria personnel
- Clients
- Delivery personnel
- Design engineering
- Information technology staff
- Messengers
- Other tenants
- Project management
- Property management

- Security guards
- Specialty contractors
- Third-party contractors
- Visitors

Because most security professionals acknowledge that roughly 65 percent of all losses in the enterprise occur at the hands of employees, the first line of defense against the human factor must be the human resources department. The second line of defense would be security design strategies (such as CPTED), access control, traffic control, and alarms. Removing the opportunity to make a mistake or providing audio or visual stimuli to alert employees of mistakes can eliminate many of the mistakes resulting from tasks done out of order, incorrectly, or not at all. In other words, automating or providing feedback during or immediately after the task can help significantly.

Intelligent patching is one application of this idea that is gaining popularity. This approach to physical-layer, structured cabling systems provides the ability to alarm or automate the tasks associated with connecting and disconnecting servers, switches, and other network appliances at the patch panel, as shown in Exhibit 97.6. These devices detect the presence or absence of a patch cable and forward that information to network management software. Intelligent patching systems also have the ability to accept input from a software interface and visually prompt the technician or engineer as to the proper jack or port location for inserting or removing a patch cable. Some intelligent patching systems have the ability to identify the other end of the patch cable that is being removed and can notify the operations center if an incorrect connection or device is terminated. This level of automation and immediate fault detection can significantly reduce accidental disconnects, improper connections, and sabotage. In addition to the automation of tasks, other methods to reduce downtime due to the human factor include:

- Thoroughly screening new hires
- Being on the lookout for unusual work patterns and unscheduled hours
- Providing ongoing training and skills assessment
- Publishing clear and thorough policies, procedures, and guidelines
- Implementing regular security awareness training
- Assess disaster tolerance under a simulated emergency
- Being sure that termination procedures are thorough and remove any chance of future access, retribution, or theft

97.9 Summary

The best practices for data center, mission-critical facility, and computer room design are evolving even as this publication is being written. Many pages have already been devoted to site selection, room design, power, HVAC, fire detection and suppression, network systems, storage, and even cyber security to maximize reliability and availability. It is also important to consider the impact of the escalating value of this corporate asset and how security professionals will protect their systems, components, and occupants. Establishing a secure perimeter and controlling the entrance and exit of employees, visitors, and contractors are important first lines of defense. Controlling and monitoring the movement of vehicles and pedestrians as they move around inside the perimeter can provide a safe environment for those entering and leaving the secure IT site. The use of standard access control methods, surveillance, and CPTED concepts can provide additional countermeasures against intruders, but occupants of the facility must be able to move where they need to move within the walls of the secure IT facility. Finally, emerging standards and performance benchmarks are pushing critical infrastructure and networks systems to new levels of availability. One thing is certain: Because people remain the biggest threat to availability and because the value of data assets and applications continues to soar, providing physical security to critical infrastructures within data centers or secure IT facilities will continue to be necessary.

Physical Security: A Foundation for Information Security

Christopher Steinke

Physical security can be defined as the measures taken to ensure the safety and material existence of something or someone against theft, espionage, sabotage, or harm. In the context of information security, this means about information, products, and people.

Physical security is the oldest form of protection. For ages, people have been protecting themselves from harm and their valuables from theft or destruction. In the past, physical security was all the protection someone needed to have safety. However, with technology, physical security alone is not effective. Information security is an approach that deploys many different layers of security to achieve its goal; hence the phrase "security in layers." With the common acceptance that nothing is 100 percent secure, information security uses the depth of its layers to achieve the highest form of security. A weakness in any one of these layers will cause security to break. Physical protection is the first step in the layered approach of information security. If it is nonexistent, weak, or exercised in malpractice, information security will fail.

98.1 Approaching Physical Security

Physical security is a continuous process that cannot be approached in an unpremeditated manner. The approach must be consistent with the goals of the organization and be applied in accordance with the standards and guidelines set forth in the information security policy.

Because there is little change in the world of physical security (at least not as quickly as the rest of the controls within information security), it is often considered to be boring or unimportant. This misunderstanding often causes physical security to be neglected or practiced haphazardly. Typically, the greatest weakness of any information security control is not the control itself, but the improper application of a control. Physical security must be approached with the same energy, focus, and seriousness as any other information security control. In fact, security controls must be approached and applied in a consistent and predetermined manner to achieve predictable, repeatable, and effective information security.

Locks, guards, surveillance cameras, and identification badges are merely the tools and equipment of physical security. To plan and design physical security, the following questions should be answered:

- What are you protecting?
- How important is the information being protected (in terms of economic, political, or public safety)?
- For whom are you protecting and what is more important to them? Confidentiality, integrity, or availability?
- What and who are you protecting it from?

Granted, not all places need the physical security of Fort Knox (who would want to work there?), but physical security should be applied in proportion to the importance and sensitivity of the people and information it protects. This chapter discusses the risks posed by common threats and vulnerabilities in information security, and how good physical security can provide a foundation for addressing those risks.

98.2 Psychology of Physical Security

When planning and designing physical security, keep in mind that it is as much psychological as it is physical. It is important to consider the advantages that the psychological impact can have. If one can design physical security in such a way as to make it highly visible (while safeguarding the details), one can announce that your organization is well guarded, rendering it less of a target to threatening activity. This is an indirect way to eliminate the desire to commit a crime against that organization. The effectiveness of physical security, as with any security control, is measured in terms of eliminating the opportunity; the psychology of physical security is measured in terms of eliminating the desire.

98.3 Facility Physical Security

The diversity of the modern workplace often makes it impractical to establish universal, rigid physical security standards. Nonetheless, adequate physical security at every location is necessary for achieving a complete, secure environment. This chapter section outlines the types of facilities, how they differ, and ways to approach physical security for each.

98.3.1 Facility Classification

Facilities can be grouped into one of these general classifications:

- *Owned facility.* Owned facilities are probably the simplest structure to maintain physical security. The ease of security management is inherent, due to the occupant having complete administrative control over the facility. This allows the flexibility to implement whatever type of physical security control, in any fashion, the owner/occupant feels will accomplish their protection goals. The main downfall of an owned facility is that the owner/occupant must take complete responsibility if physical security fails. A good example of an owned facility is a large corporate headquarters.
- *Nonowned facility.* Nonowned facilities can be a little more challenging to physically protect. The occupant and the owner will have their own lists of responsibilities that hold them liable if physical security fails. For example, if a water pipe bursts and floods a computer room,

the occupant may hold the owner liable for the damages if it is discovered that the owner did not adequately maintain the plumbing. In this case, nonowned facilities may offer the advantage of legal recourse for failed physical security. Examples of nonowned facilities are buildings an occupant leases but does not own.

- *Shared facility*. Shared facilities are probably the most diverse and threatening of facilities to occupy, yet they account for the majority of structures. These facilities have more than one occupant, with some of the occupants possibly being competitors. Because the facility must provide equal access to all occupants (in certain areas), physical security becomes very challenging. Good examples of shared facilities could be nonowned facilities with multiple occupants, central offices, and co-locations.

When classifying facilities, one takes the first step in developing a strategy for risk mitigation. By understanding the threats that may be inherent to certain facilities, one gains insight into protecting against the risks. Because some facilities may fit more than one classification description, one is not bound by strict adherence to this classification scheme. What one should then be aware of are any new inherent strengths and weaknesses that these hybrid classes might create.

98.3.2 Facility Location

Not only should one be concerned with what kind of facility one occupies, but also the location. A particular location may harbor more threats than another. Below are some location-based threats to consider when choosing an area for one's facility:

- *Vulnerability to crime, riots, and terrorism*. Research crime and terrorism statistics for each location being considered. If the location of the facility is in an area that is frequented by these activities, the chances of physical security being breached increases. For example, frequent demonstrations or riots near a facility could erupt into random acts of violence (e.g., fires, crime, etc.) that may threaten the facility, its employees, and possibly its customers. Even in information security, the protection and safety of people should always come before anything else.
- *Adjacent buildings and businesses*. This issue relates to the previously discussed classification of facilities (particularly shared facilities) and the previous issue of crime and riot vulnerability. It is good practice to know who one's neighbors are and what they do. For example, one may not want to locate a corporate data center next to a competitor, a nuclear power plant, or a freeway or railway that is a route for hazardous chemical transportation. Also, these concerns come to mind about connected buildings. Are their physical security controls as strong as yours? Can someone get into the facility if they break into an adjacent building? What about the roof? These should all be in the forefront of one's mind when choosing a location.
- *Emergency support response*. This is simply defined as the time it takes emergency support (i.e., fire, police, and medical personnel) to reach the facility. Know the mileage and time the driving distance (during the heaviest traffic) from emergency support locations to the facility. This information allows one to implement physical security measures that not only will detect and deter, but also delay and minimize damage or harm until emergency support arrives.
- *Environmental support*. Environmental support is the clean air, water, and power that service the facility. Ensure that the location has room for growth in all of these areas. In particular, for high-availability facilities, look for locations from which to draw from two separate power grids.
- *Vulnerability to natural disasters*. Check local geological and weather statistics for patterns of natural disasters in preferred location(s) for the past 100 years. Granted, natural disasters cannot be predicted or totally avoided, but one can minimize their effect by choosing a location where such disasters are less likely to occur.

98.3.3 Facility Threats and Controls

From the previous discussion, one sees how certain locations can harbor more or fewer threats. What follows here is a list of threats and controls in their basic forms. This is to demonstrate that if one can eliminate a threat at its root, one can effectively eliminate several others at the same time. But also notice that the opposite can happen when one threat manifests another. The controls are simple and basic in nature, but keep in mind that controls, as a whole, should be able to deter, detect, delay, and react to a given threat. There are three classes of threats, those being natural, man-made, and environmental failure.

98.3.4 Natural Threats

Good physical security has a psychological advantage against some threats. Unfortunately, natural threats are not one of them. This threat cannot be deterred or discouraged. At one time or another, Mother Nature will threaten the facility. The only option is to implement controls that will minimize the impact and facilitate a quick recovery. Natural threats and some of their controls include:

- Fire causes the following risks:
  — Heat
  — Smoke
  — Suppression agent (e.g., fire extinguishers and water) damage
- Fire controls include:
  — Installing smoke detectors near equipment
  — Installing fire extinguishers and training employees in their proper use
  — Using gaseous (nonliquid) extinguishing systems near information systems
  — Conducting regular fire evacuation exercises
  — Storing all backup media offsite (with a bonded third party)
  — Developing and exercising a disaster recover plan
- Severe Weather causes the following risks:
  — Lightning
  — Heavy winds
  — Hail
  — Flooding
- Severe weather controls include:
  — Monitoring weather conditions
  — Keeping equipment in areas that are weather-proofed and capable of withstanding strong winds
- Ensuring equipment is properly grounded:
  — Installing surge suppressors and uninterruptible power supplies (UPS) or diesel generators
  — Installing raised flooring
  — Conducting regular weather evacuation exercises
  — Storing all backup media offsite (with a bonded third party)
  — Developing and exercising a disaster recovery plan
- Earthquakes are particularly dangerous because of their ability to spur other natural disasters, such as fires. In addition to collateral damage from quake-induced fires, some additional risks include:
  — Limited or no response from emergency agencies
  — Permanent structural physical damage to facilities and information systems
  — Nullify threat controls (e.g., disables fire-suppression capability)
  — Personnel evacuation is limited
- Earthquake controls include:
  — Keeping information systems equipment off elevated surfaces (without proper mounting)
  — Keeping information systems equipment away from glass windows

- — Installing earthquake-proof or antivibration devices on equipment and infrastructure
- — Conducting routine earthquake drills
- — Storing all backup media offsite (with a bonded third party)
- — Developing and exercising a disaster recovery plan

Natural threats are not always the dramatic events listed above. They can often take a much more subtle and unforeseen form. An example of this is the exposure to dry heat, moisture, and light winds over time. These less-severe threats may not be cause for immediate alarm, yet one should be aware of their potential impact.

98.3.4.1 Man-Made Threats

The second threat class is called man-made. This type of threat is often the most dynamic and challenging, due to ties in human nature. This is drawn from a conclusion that there are three motivating agents of man-made threats, those being malice, opportunity, and accidental. Man-made threats and some of the controls include:

- Theft/fraud causes the following risks:
  - — Reduction or loss of information systems capabilities
  - — Loss of sensitive information or trade secrets
  - — Loss of revenue
- Theft/fraud controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security-and safety-conscious employees
  - — Identification badges
  - — Guards
  - — Minimizing the use of location signs
  - — Routine audits
  - — Good inventory control practices
  - — Good lock and key practices
  - — Insurance
  - — Separation of duties/job rotation
  - — Employee hiring/termination practices
- Espionage causes the following risks:
  - — Loss of sensitive information or trade secrets
  - — Loss of competitive advantage
  - — Loss of revenue
- Espionage controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security-and safety-conscious employees
  - — Identification badges
  - — Minimizing the use of location signs
  - — Guards
  - — Employee hiring/termination practices
  - — Separation of duties/job rotation
  - — Routine audits
- Sabotage causes the following risks:
  - — Reduction or loss of information systems capabilities

- — Loss of sensitive information or trade secrets
  - — Loss of revenue
- Sabotage controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security-and safety-conscious employees
  - — Minimizing the use of location signs
  - — Identification badges
  - — Guards
  - — Insurance
  - — Separation of duties/job rotation
- Workplace violence causes the following risks:
  - — Harm or death to employees
  - — Loss of productivity
  - — Loss of revenue
- Workplace violence controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security-and safety-conscious employees
  - — Awareness of warning signs
  - — Guards
  - — Employee hiring/termination practices

The ingenuity and adaptive nature of the human mind makes man-made threats difficult to control. An organization must maintain vigilance with its protection program by conducting routine assessments on the controls implemented against these threats.

98.3.4.2 Environmental Threats

The third threat class is labeled environmental threats. Environmental controls are important to the operation and safeguarding of information and its systems. Without clean air, water, power, and reliable climate controls, information systems would suffer inconsistent performance or complete failure.

- Climate failure causes the following risks:
  - — Equipment and infrastructure malfunction or failure from overheating
  - — Damage to storage/backup media
  - — Damage to sensitive equipment components
- Climate controls include:
  - — Monitoring temperatures of information systems equipment
  - — Keeping all rooms containing information systems equipment at reasonable temperatures (60–757°F, or 10–25°C)
  - — Maintaining humidity levels between 20 and 70 percent
  - — Considering turning off unnecessary lights in rooms containing information system equipment
  - — Conducting routine preventive maintenance and inspections of climate control system
  - — Storing all backup media offsite (with a bonded third party)
  - — Developing and exercising a disaster recovery plan
- Water and liquid leakage causes the following risks:
  - — Equipment and infrastructure failure from excessive exposure to water or other forms of liquid

  - — Damage to storage/backup media and critical hardcopy information
  - — Damage to critical equipment components

- Water and liquid leakage controls include:
  - — Keeping liquid-proof covers near equipment
  - — Installing drains, water detectors, and raised flooring in rooms that house critical information systems equipment
  - — Conducting routine inspections of plumbing
  - — Using gaseous or dry pipe extinguishing systems near information systems
  - — Storing all backup media offsite (with a bonded third party)
  - — Developing and exercising a disaster recovery plan

- Electrical interruption causes the following risks:
  - — Damage to critical equipment components
  - — Damage to software and storage/backup media
  - — Loss of climate controls
  - — Loss of physical access controls and monitoring devices (i.e., surveillance cameras, door alarms, ID/card readers)

- Electrical interruption controls include:
  - — Installing and testing uninterruptible power supplies (UPS) or diesel generators
  - — Using surge suppressors
  - — Installing electrical line filters to control voltage spikes
  - — Using static guards and antistatic carpeting where applicable
  - — Ensuring that all equipment is properly grounded
  - — Having circuit boxes and wiring routinely inspected
  - — Drawing power from two separate grids (if possible)
  - — Storing all backup media offsite (with a bonded third party)
  - — Developing and exercising a disaster recover plan

Environmental failure, in and of itself, is a threat that can cause considerable damage to information systems. However, it can be also be manifested by natural or man-made threats. Therefore, it is important to approach all threats with a layered approach that has defense-in-depth. This not only ensures that controls cover most of the threats, but that those controls are thorough in their coverage as well.

98.3.5 Facility Protection Strategy

Developing an overall strategy for physical protection is one of the many steps taken toward achieving good information security. One's protection strategy will be comprised of many principles and should center on whether confidentiality, integrity, or availability of the information is of greater importance. Zoning is a strategy that can be used to set a foundation for efficient and effective physical information protection.

98.3.5.1 Zoning

Zoning is not a new concept. Traditionally, zoning refers to a process used for installing fire detection alarms to identify hidden locations of smoke or fire (above ceiling, under floor, etc.). Additionally, a concept called cross-zoning has been used that allows one to reduce false alarms by requiring two or more alarms to be activated before the fire department is notified.

Zoning is sufficiently flexible to facilitate the simplest to the most detailed security model. Because of this, one can apply all other physical security controls to this concept (e.g., motion detectors, physical intrusion detection alarms, CCTVs, etc.). The biggest advantage is with role-based access control models. In role-based access control schemes, users are assigned access to systems, information, and physical areas according to their role in the organization.

Exhibit 98.1 displays a basic example of the use of zoning for role-based access control. In this example, the zones are labeled 1 through 4, 4 being the most restrictive. In this facility, every employee has access to zones 1, 2, and 3; however, the Information Technology Director, IT staff, and Security Manager, have access to zones 1, 2, 3, and 4 because of their roles.

The natural progression of security is obvious; the zones become more restrictive as one moves further into the facility (from left to right). Once this exercise is completed, the next step would be to determine the controls that should be put in place to support access control zones. Keep in mind that the more restrictive the zone, the stronger and more reliable the controls should be.

By combining physical access controls, role-based models, and zoning, one can build a thorough and centralized system to physically protect one's information and assets. Zoning can be a very important part of one's information security strategy. However, prior to conducting a zoning exercise, one should have already conducted a risk analysis (to understand the threats to and vulnerabilities of one's assets), and developed a risk mitigation strategy. Only then will zoning provide for a solid foundation from which an organization can achieve its information security goals.

98.4 Information Systems Physical Security

The second part of physical security is the physical protection of information systems. As discussed, protection should come in layers. If the physical integrity of just one of an organization's computers is compromised, information security could be at risk. If someone were to gain unauthorized physical access to a computer, that person could also gain access to all of the information on that computer and possibly any other resource that computer is connected to (including file servers, mainframes, and e-mail).

98.4.1 Information System Classification

Information systems can be classified into three types:

1. *Servers/mainframes*: Usually the most physically secure class of systems. This is due to the common practice of placing them in a location that has some form of access and environmental control.

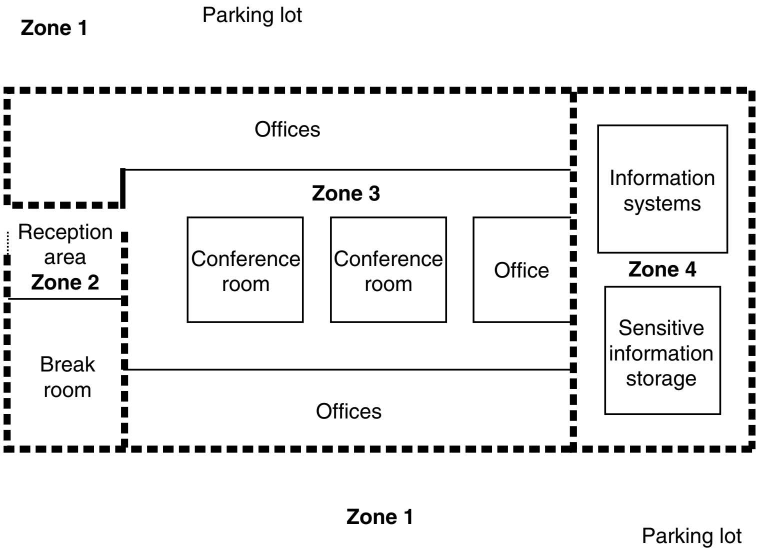

EXHIBIT 98.1 Using zoning for role-based access control.

Although this class may be the most physically secure, their overall security is dependent on the physical security of the workstations and portable devices that access them.

2. *Workstations*: Usually located in more open or accessible areas of a facility. Because of their availability within the workplace, workstations can be prone to physical security problems if used carelessly.
3. *Portable devices*: Can be an organization's security nightmare. Although issuing laptops and PDAs to employees facilitates flexibility and productivity in an organization, it poses several serious risks with regard to physical security. With users accessing the company's internal information systems from anywhere, a breach in physical security on one of these devices could undermine an organization's information security. Extreme care must be taken with this class.

98.4.2 Information Systems Physical Threats and Controls

Classifying information systems helps determine which threats pose a greater risk to which systems. This provides a guideline for applying controls. Probably the biggest threat to information systems is that of the user. Keep in mind that if any user fails to practice due diligence in physically protecting their computing assets, nearly all controls will become ineffective, rendering the device vulnerable. This chapter section outlines the basic threats and controls for information systems.

- Loss/theft/destruction poses the following risks:
  - Loss of sensitive information or trade secrets
  - Loss of productivity
  - Loss of revenue
- Loss/theft/destruction controls include:
  - Physical locks for devices
  - Marking and tagging devices
  - Minimize use of location signs
  - Encryption for sensitive information storage
  - Data classification and handing procedures for sensitive information
  - Insurance
  - Awareness training
  - Visible closed circuit television cameras (CCTVs)
  - Guards
  - Alarm systems
  - Routine audits
- Unauthorized access poses the following risks:
  - Loss of sensitive information or trade secrets
  - Information tampering
  - Malware
  - Loss of revenue
- Unauthorized access controls include:
  - Locking consoles
  - Good password practices
  - Awareness training
  - Data classification and handing procedures for sensitive information
  - Minimizing the use of location signs
  - Visible closed circuit television cameras (CCTVs)
  - Encryption for sensitive information storage
  - Strong authentication and access controls

98.5 Awareness Training

Although information systems are more prevalent in the world today than ever before (and continue to become ever more so), we nonetheless still live in a physical world. All employees affect physical security, which directly impacts their organization's information security. It is common to find that a majority of physical security failures are due to unaware employees circumventing the controls. Ensuring that all employees receive regular awareness training reduces unintentional security bypasses, while providing an economical way to mitigate risks. No matter how well an information security program is designed and implemented, it only takes one unknowing employee to render it ineffective. Physical security must be among the topics presented in an awareness program, which should also include the following:

- Demonstrate to all employees how even the smallest disregard for physical security can quickly develop into an information security incident or loss of life.
- Educate employees on the security standards and guidelines for the organization. Ensure that employees understand the responsibilities expected of them.
- Distribute monthly publications regarding information security to all employees. Include physical security as a regular topic.
- Provide special orientation for upper management, taking them on tours and offering them a behind-the-scenes look at how information security is done. This rallies support.

Taking the time and effort to provide awareness training will boost the effectiveness of not only one's physical security, but also the entire information security program. By making employees cognizant of the their responsibilities, one can instill a sense of ownership and duty. This transforms the human factor from a disadvantage to an advantage.

98.6 Summary

Physical security is more than a niche of information security. In some cases, an organization will have good, strong physical security, but lack many other components of information security. As a practitioner of information security, one must understand the scope and know how to use physical security for protecting assets. Complete physical security will protect all assets, setting a good foundation upon which to build other forms of protection. It is clear that physical security is the foundation for information security.

Physical Security: Controlled Access and Layered Defense

Bruce R. Matthews

> *Security* (si kyoor'e tē) *n*., pl. –ties 1. A feeling secure; freedom from fear, doubt, etc. 2. Protection; safeguard.

The above Webster's definition can be restated for the security practitioner as controlled access. In fact, every aspect of an IT security practitioner's job revolves around the process of defining, implementing, and monitoring access to information. This includes physical access. When to use it, how much, and the best way to integrate it with traditional IT security methods, are concepts the IT security professional must be familiar with. The IT security specialist need not be an expert, someone else will fill that role, but effective policies and strategies should take into account the benefits as well as limitations of physical protection. Success depends on close collaboration with the physical security office; they have more than just IT security on their minds and a mutual respect for each other's duties goes a long way. Thus cross training can prove invaluable, particularly when an incident occurs. In essence, a layered, multidisciplined approach can provide a secure feeling; freedom from fear, doubt, etc. Controlled access is security.

99.1 Security Is Controlled Access

When one thinks of security, one often thinks of it only in terms of implementation. In IT security, one thinks of passwords and firewalls. In personal security, one thinks of avoiding rape and muggers by staying away from dark alleys and suspicious-looking characters. However, to place physical security in the context of IT security, one must examine what security is—not just how one implements it. In the simplest of terms, it boils down to: security is controlled access. Implementing security, therefore, is the process of controlling access. Passwords and firewalls control access to network and data resources. Avoiding dark alleys and suspicious characters control access to our bodies and possessions. Likewise, security in the home generally refers to locks on the doors and windows. With the locks, one is controlling the access of persons into the protected area. Everyone is denied entry unless they can produce the proper key. By issuing keys to only those persons one desires, one is controlling access. Because one normally does not want anyone entering through the windows after-hours (although a teenager may have a different viewpoint), there is typically no key lock on windows and the level of control is total denial of access. Home alarm systems are gaining increased popularity these days. They also control access by restricting the movements of an intruder who is trying to avoid detection.

The definition—security is controlled access—also holds true for the familiar information security concepts of availability, integrity, and confidentiality. Availability is ensuring access to the data when needed. Integrity implies that the data has been unmodified; thus, access to change the data is limited to only authorized persons or programs.

Confidentiality implies that the information is seen only by those authorized. Thus, confidentiality is controlling access to read the data. All of these concepts are different aspects of controlling access to the data. In a perfect world, one could equate assurance with the degree of control one has over access. However, this is not a perfect world, and it may be more appropriate to equate assurance with the level of confidence one has in the controls. A high level of assurance equates to a high level of confidence that the access controls are working and vice versa. For example, locking the window provides only moderate assurance because one knows that a determined intruder can easily break the window. But a degree of access control is gained because the intruder risks detection from the sound of breaking glass.

Bear in mind, and this is important, that more security is not necessarily less access. That is, controlled access does not equal denied access. The locked window is certainly a control that denies access—totally (with respect to intent, not assurance). On the other hand, Social Security provides security by guaranteeing access to a specified sum of money in old age, or should one say the "golden years." (However, the degree of confidence that this access control will provide the requisite security is left as an exercise for the reader.) It is obvious that practically all controls fall somewhere in between providing complete access and total denial. Thus, it is the level of control over access—not the amount of access—that provides security. Confidence in those controls provides assurance.

This leads to the next topic: a layered defense.

99.2 A Layered Defense

A layered defense boosts the confidence level in access controls by providing some redundancy and expanded protection. The details of planning a layered defense for physical security is beyond the scope of this chapter and should be handled by an experienced physical security practitioner. However, the IT security specialist should be able to evaluate the benefits of a layered defense and the security it will and will not provide. When planning a layered defense, the author breaks it into three basic principles: breadth, depth, and deterrence.

Think of applying "breadth" as plugging the holes across a single wall. Each hole represents a different way in or different type of vulnerability. Breadth is used because a single type of control rarely eliminates all vulnerabilities. Relating this first in the familiar IT world, suppose one decides to control read access to data by using a log-on password. But the log-on password does not afford protection if one sends the data over the Internet. A different type of control (i.e., encryption) would therefore provide the additional coverage needed. Physical security works much the same way. For example, suppose one needs to control access to a hot standby site housed in a small one-story warehouse. The facility has a front door, a rear door, a large garage door, and fixed windows that do not open. Locks on the doors control one type of pathway to the inside, but offer no protection for the breakable windows. Thus, bars would be/could be an additional control to provide complete coverage.

The second principle, depth, is commonly ignored yet often the most important aspect for a layered defense. To be realistic with security, one must believe in failure. Any given control is not perfect and will fail, sooner or later. Thus, for depth, one adds layers of additional access controls as a backstop measure. In essence, the single wall becomes several walls, one behind the other. To illustrate on the familiar ground, take a look at the user password. The password will not stay secret forever, often not for a single day, because users have a habit of writing them down or sharing them. Face it; everyone knows that no amount of awareness briefings or admonishments will make the password scheme foolproof. Thus, we embrace the common dictum, "something you have, something you know, and something you are." The password is the "something you know" part; the others provide some depth to the authentication scheme. Depth is achieved by adding additional layers of protection such as a smart card—"something you have." If the password alone is compromised, access control is still in place. But recognize that this too has limitations, so one invokes auditing to verify the controls. Again, physical security works the same way.

For physical security, depth usually works from the outer perimeter, areas far away from the object to be protected, to the center area near the object to be protected. In theory, each layer of access control forms a concentric ring toward the center (although very few facilities are entirely round). The layers are often defined at the perimeter of the grounds, the building entrance and exterior, the building floors, the office suites, the individual office, and the file cabinets or safes.

Deterrence, the third principle, is simply putting enough controls in place that the cost or feasibility of defeating them without getting caught is more than the prize is worth. If the prize to be stolen is a spare $5000 server that could be sold (fenced) in the back alleys for only $1000, it may not be worth it to an employee to try sneaking it out it out a back door with a camera on it when loss of the job and jail time may cost that employee $50,000. Notice here that the deterring factor was the potential cost to the employee, not to the company. A common mistake made even by physical security managers is to equate value only to the owner. Owner value of the protected item is needed for risk analysis to weigh the cost of protection to the cost of recovery/replacement. One does not want to spend $10,000 protecting a $5000 item. However, the principle of deterrence must also consider the value to the perpetrator with respect to their capability—the bad guy's own risk assessment. In this case, maybe an unmonitored $300 camera at the back door instead of a $10,000 monitored system would suffice.

A major challenge is determining how much of the layered defense is breadth and depth in contrast to deterrence. One must examine each layer's contribution to detection, deterrence, or delay, and then factor in a threat's motivation and capabilities. The combined solution is a balancing act called analytical risk management.

99.3 Physical Security Technology

99.3.1 Security Components

99.3.1.1 Locks

Physical security controls are largely comprised of locks (referred to as locking devices by the professionals). In terms of function, there are day access locks, after-hours locks, and emergency egress locks. Day locks permit easy access for authorized persons—such as a keypad or card swipe. After-hours locks are not intended to be opened and closed frequently and are often more substantial. Examples are key locks, locked deadbolts, padlocks, combination padlocks, or high-security combination locks like one would see on safes or vault doors. Emergency egress locks allow easy access in one direction (i.e., away from the fire), but difficult access in the other direction. A common example is the push or "crash" bar style seen at emergency exits in public facilities. Just push the bar to get out, but one needs a key to get back in.

In terms of types, locks can be mechanical or electrical. A mechanical lock requires no electric power. Most of the locks used daily with a key or combination are mechanical. An electric lock requires electricity to move the locking mechanism, usually with a component called a solenoid. A solenoid is a coil of wire around a shaft. The shaft moves in or out when electric current flows through the coil. Another type of electric lock uses a large electromagnet to hold a door closed. The advantage is few moving parts with considerable holding power.

The way people authenticate themselves to a lock (to use an IT term) is becoming more sophisticated each day. Traditionally, people used a key or mechanical combination. Now there are combination locks that generate electricity when one spins the dial to power internal microprocessors and circuits. There are also electronic keypads, computers, biometrics, and card keys to identify people. Although this is more familiar territory to the IT security professional, it all boils down to activating a locking device. Collectively, authentication combined with door locking devices is referred to as a "door control system."

99.3.1.2 Barriers

Barriers include walls, fences, doors, bollards, and gates. A surprising amount of technology and thought goes into the design of barriers. The physics behind barriers can involve calculations for bomb blasts, fire resistance, and forced entry. Installation concerns such as floor loading, wind resistance, and aesthetics can play a role as well. Making sense of the myriad of options requires the answer to the following question: Who or what is the barrier intended to stop, and for how long?

To supply the answer, think of the barrier as an element of access control. It is not a door to the office, but something to control "whom" or "what" is allowed into the office. Is valuable data stored in the office, such as backup tapes, or is the concern with theft of hardware? Is the supposed thief an employee, or is it a small company where a break-in is more likely? Is the office in a converted wooden house where liability for data lost in fire is the primary concern? If so, how long does one need to keep the fire at bay (i.e., what is the fire department response time)? Know these answers.

99.3.1.3 Alarms

Barriers and the locks that secure them directly control access. Alarms are primarily for letting us know if that control is functioning properly—that is, has it been breached? Alarms tell us when some sort of action must be taken, usually by a human. A fire alarm may automatically activate sprinklers as well as the human response by the fire department. In terms of a layered defense, the presence of alarms also adds to the deterrence. Alarms are usually divided into two parts: the controller and the sensors. The sensors detect the alarm condition, such as an intruder's movements or the heat from a fire, and report it to the controller. The controller then initiates the response, such as an alarm bell or dialing the police department. A facility that monitors several control units is referred to as a "central monitoring" facility.

As indicated, sensors usually detect environmental conditions or intrusion. Environmental conditions include temperature, moisture, and vibration. Temperature not only protects against fire, but can alert us to the air conditioner failing in a server room. Moisture may indicate flooding due to rains or broken plumbing. Vibration sensors are used both in environmental sensors, to protect sensitive hardware, and in intrusion detectors such as glass breakage sensors or on fences to detect climbing. Other intrusion sensors detect human motion by measuring changes in heat or ultrasonic sound within a room. In fact, many intrusion sensors are really just environmental sensors configured for human activity. Thus, innocuous items such as coffee pots not turned off or room fans can generate false alarms.

Doors are usually monitored with magnetic switches. A magnet is mounted on the door, and a switch made of thin metal strips is mounted on the doorframe. When the door is shut, the magnet pulls the metal strips closed, completing a circuit (or pushes them open to break a circuit).

The perimeter of an area can be monitored with microwave or infrared beams that are broken when a person passes through them. Cables can be buried in the ground that detect people passing overtop. Animals are a source of false detection for these perimeter sensors.

An important feature of many alarm systems is how the sensors communicate with the controller—wireless or wired. Wireless systems are generally cheaper to install, but can suffer radio frequency interference or intentional jamming. Wired systems can be expensive or impractical to install but can be made quite secure, especially if the wires are in conduit. Whether wired or wireless, the better systems will incorporate some method for the controller to monitor the integrity of the system. The sensors can be equipped with tamper switches and the communication links can be verified through "line monitoring."

The key question for alarms is: who and what is it supposed to detect, and what is the intended response? The "who" will define the sophistication of the alarm system, and the "what" may dictate the sensitivity of the sensors. Provided with this, the alarm specialist can then determine the appropriate mix and placement of sensors.

A major task of the alarm controller is to arm and disarm the system, which really means to act upon or ignore the information from the sensors. With such a vital function, one must have some means to authenticate the person's authority to turn off the alarm system. Like the locks in the previous chapter section, the methods to do this are essentially the same as for authenticating to any information system, ranging from passwords to smart cards to biometrics, with all the same pros and cons.

99.3.1.4 Lights and Cameras

Lights and cameras are combined because they serve essentially the same function: they allow us to see. In addition, lighting is a critical element for cameras. Poor light or too much light, such as glare, can mean not seeing something as big as a truck. Proper camera lighting is a field unto itself; and for high-security situations, data from lighting and camera manufacturers should be consulted. A common misuse of cameras is assuming that they will detect an intruder. With a camera, the possibility certainly exists; in terms of deterrence, both lights and cameras increase the risk to perpetrators that they will be seen. For many low-threat situations, this is sufficient; however, as threat or risk increases, they cannot be relied upon. If a guard's attention is focused elsewhere (and often is), the event will go unnoticed. If ever in doubt, try putting a camera outside an access door without a buzzer for people to ring. People will become rapidly annoyed that the guard does not notice them and open the door fast enough. Cameras are best suited for assessing a situation—a tool to extend the eyes (and sometimes ears) of the guard force.

99.3.1.5 Antitheft, Antitamper, and Inventory Controls

It is obvious that the theft of computers and peripherals can directly affect the availability and confidentiality of data. However, tampering is also an issue, particularly with data integrity. Physical access affords the opportunity to bypass many traditional IT security measures by inserting modems, wireless network cards, or additional hard drives to steal password files, boot up on alternate operating systems, and allow unauthorized network access—the list goes on and on. Physical access to security peripherals such as routers may enable someone to log in locally and modify the settings.

The retail and warehouse industries have created a wide range of products to prevent theft and tampering. Antitamper devices control access to ensure the integrity of the protected asset, whereas antitheft devices and inventory controls are intended to limit movement to a confined area. The technologies behind these products have rapidly spilled over into new product lines designed to protect IT assets.

Antitheft devices include locked cages, cabinets, housings, cables, and anchors. Labels and inventory controls such as barcodes discourage theft. More sophisticated devices include vibration or motion sensors, power line monitoring, and electronic article surveillance (EAS) systems. Power line monitoring alerts us when someone has unplugged the power cord of a computer or other protected asset. EAS systems alert us when a protected asset is moved from a designated area. The most familiar EAS devices are probably those little tags attached to clothes or merchandise in retail stores. They cause that annoying alarm when one departs the store if the clerk forgets to disable it.

Antitamper devices include locked cabinets, locking covers, microswitches, vibration or motion sensors, and antitamper screws.

99.4 The Role of Physical Security

A basic role of physical security is to keep unwanted people out, and to keep "insiders" honest. In terms of IT security, the role is not that much different. One could change "people" to "things" to include fire, water, etc., but the idea is the same. The greatest difference is expanding the assets to be protected. Physical security must not only protect people, paper, and property, but it must also protect data in forms other than paper.

So where does one start? Recall the above descriptions of depth in a layered defense where one countermeasure or barrier backstops the preceding one. In a textbook analysis, sufficient depth is determined by security response time. The physical security practitioners view each control or countermeasure as a delaying action. The amount of the time it takes for the guard force to respond is equivalent to the minimum delay needed. Although a tried and true strategy in the physical security realm, it was only recently proposed as an IT security strategy.[1]

For the physical world, it works like this. Suppose one has an estimated response time of ten minutes by the local police. One discounts the perimeter wall as only a deterrent because there are no alarms there. The first alarm is at the front door, which one estimates will take two minutes to get past. Thus, one needs an additional eight minutes worth of inside layers between the door and the cash for the police to apprehend the thief.

For the IT world, layering brings to mind firewalls backed up by routers, backed up by proxies, etc. Notice that physical controls were backed up by additional physical controls and "cyber" controls were backed up by more cyber controls. This is okay to a point; but for data security, the roles of physical and cyber controls should be to complement one another. They become interleaved in a multidisciplinary defense.

99.5 A Multidisciplinary Defense

In a multidisciplinary defense, more than one skill set or expertise is brought to bear on the security problem. Physical security is comprised of several disciplines, ranging from barrier technology to antitamper devices. Each discipline aids another. Each component has a purpose to be used in concert with another. The basic relationship between components at each layer is the need to prevent a security event, detect a security event, and assess a security event. For example, there is a locked door with alarm contacts and a camera. The door blocks the way to prevent entry. If the door is opened, the alarm alerts the guard. The guard then uses the camera to assess the situation and decide on an appropriate response. Multiple technologies are integrated to prevent, detect, and assess.

Now take a broader view and consider physical security as a single discipline and IT security as a single discipline. Although separate disciplines, one cannot have one without the other. For example, the payroll office is using Windows NT. The administrator has installed the password filter to ensure that users create quality passwords. Auditing is turned on; file and directory permissions are set. The administrator is aware that the passwords, and hence the network, are still vulnerable because the computer can be booted from removable media (i.e., the floppy drive or CD-ROM). Once booted from a floppy, the password files can be stolen and cracked. There are always a number of people working late at the company, with a night shift on the factory floor, but payroll employees are generally gone by 4 p.m. (except before payday).

One solution is to disable the floppy and CD-ROM. But this idea is met with a polite yet firm "not if you value your job…" from management. One could modify the boot function from the bios, install a switch and use the tamper alarm option on the motherboard, and replace the computer case screws with a tamper-resistant type. That is one example of a multidisciplinary approach; but considering the

[1] Winn Schwartau goes into great detail of detection vs. reaction time for network security in his book, *Time Based Security*, Interpact Press, Florida, 1999.

number of clients, one does not relish the extra work—particularly when one is constantly servicing the machines. So think more physical security and back up one layer. Put a high-security deadbolt on the payroll office door. Okay, this example seems fairly intuitive, but are we finished? If one has a guard service, then one would want to brief them on the importance of ensuring that the door is closed after normal hours and to make note of a nonpayroll employee who seems to be rebooting or using a payroll computer. How does the guard know who is an authorized payroll (or systems admin) employee? Provide a list. These "extra" physical security details can be easily forgotten.

Now turn the tables. You are chatting with the guards who are quite happy with the new card-access system (the result of a backroom deal with payroll). They have absolute accountability and control over who enters the various sensitive offices. You are happy; your payroll information is secure. Physical security is quite impressive with this set up-and-forget security wonder. There are fewer guards (okay, not all the guards were so happy) and they no longer wander the hallways all night. But then you begin to wonder, where is this card-access system computer located? You learn it is in a closet down the hall and it too is running Windows NT—with a blank password administrator account and no auditing. Hmm, are your payroll files still safe from a computer-savvy, disgruntled employee? From an ex-guard who is now working in janitorial? Perhaps the remaining guards need some IT security assistance.

The Economic Espionage Act of 1996 brings to bear the importance of protecting data, both physically and electronically. The act makes the theft of trade secrets an act of espionage if the benefactor is a foreign government. However, contained in the definition of "trade secret" is the following statement:

> (A) the owner thereof has taken reasonable measures to keep such information secret; unfortunately, there is no firm legal definition of "reasonable measures," but as a starting point, Mr. Patrick W. Kelley, J.D., LL.M., M.B.A, FBI's chief of the Administrative Law Unit, Office of General Counsel, at FBI Headquarters in Washington, D.C., in 1997 provided the following guidance to their field agents: Advise businesses that "owners must take affirmative steps to mark clearly information or materials that they regard as proprietary, protect the physical property in which trade secrets are stored, limit employees' access to trade secrets to only those who truly have a need to know in connection with the performance of their duties, train all employees on the nature and value of the firm's trade secrets, and so on."[2]

This is good advice to protect any valuable information, trade secret or not. In fact, Mr. Kelley's advice is common-sense security practice. One can capture this common sense with the following tenets: identify it, label it, secure it, track it, and know it. These tenets represent the practical side of controlling access. Below are some common physical security implementations, along with their IT security counterparts.

1. Identify it.
   a. *Physical security.* The U.S. government refers to this as classification guidelines. Decide what needs to be protected, and create guidelines on how to recognize it by subject matter or keywords. The guidelines should enable a company novice to determine, based on content, the sensitivity of a document. For example, perhaps any document that describes the project goal or the name of the client is "company confidential" whereas the project name is not sensitive.
   b. *IT security.* The same as physical security, except create an electronic classification guide. Hyperlink it by subject and keyword so a user can easily determine (by answering a series of questions) the material's sensitivity and what is required in terms of the policies.
2. Label it.
   a. *Physical security.* Use a rubber stamp or stickers to identify sensitive documents. Document folders should be distinctive (color or colored band) and labeled. Labels should indicate special handling requirements, dates for downgrading sensitivity, and who has authorized access to it.

[2] Kelly, Patrick W., J.D., LL.M., MBA, *The Economic Espionage Act of 1996 Law Enforcement Bulletin* (July 1997), FBI Library, Washington, DC, 1997.

   b. *IT security.* Use automatic document headers/footers or cover pages for sensitive data. Automatically print out cover pages.
3. Secure it.
   a. *Physical security.* Create the physical layers of defense based on risk. The following is a list of possibilities for each physical security layer; it does not imply that everyone needs all this stuff. Working from the outer ring inward, these are common options that form layers of physical security that the IT security practitioner should be aware of.
      i. *Perimeter.* Perimeter access controls include physical barriers such as fences, walls, barbed wire, gates, and ID checks. Alarms and cameras are used at the perimeter.
      ii. *Building grounds.* Within the building grounds, cameras, lights, alarms, and roving guards can be deployed, along with physical barriers to control traffic flow (foot or vehicle).
      iii. *Building entrance.* In closer is the facility building where there are doors, locks, barred windows, cameras, alarms, and perhaps another ID check or a card-access system (common in many hotels to gain entry to a room instead of a key).
      iv. *Building floors.* Deeper into the building one might have access limited by floor, with special keys for the elevator as in some hotels and alarmed stairwells. Stairwells and hallways may be monitored with cameras.
      v. *Office suites.* Access controls for the office suite include card-access systems, locks, and keypads that require a code to be entered, human receptionists, and steel or solid-core doors. Wooden doors are typically hollow inside to reduce weight, making them easier to swing and providing less wear-and-tear on the hinges. However, the locks, including deadbolts, do not have much to grab onto and are easily pushed open. Solid cores strengthen the doors considerably. Within the suite may be individual offices with keypads, cards, or regular locks.
      vi. *Office physical security.* Once inside the office, there may be lockable file cabinets, safes, vaults, antitheft/tamper devices, and alarm systems. Lock up any sensitive disks, CD-ROMs, or media. Consider fire/water-resistant storage containers. Use paper shredders.
      vii. *IT security.* Create the IT layers of defense based on risk. Make use of firewalls, proxy servers, routers, network address translation, switches, network monitoring, etc. Use passwords or user authentication, invoke file rights and permissions, anti-virus, data backups, data encryption, or overwrite utilities. Monitors away from observable windows, emergency power source (UPS or generator), spare equipment.
4. Track it.
   a. *Physical security.* Access lists (need-to-know), checkout lists, inventory controls, audits, and registered or insured mail.
   b. *IT security.* Auditing, digital certificates/signatures, file permissions, etc.
5. Know it.
   a. For both physical and IT security, make sure people know what to do and why. Create the policies to implement the protection. Policies should spell out the required access controls and handling procedures. Different jobs have different responsibilities, so vary the presentations and training accordingly.
   b. *Physical security.* Handling procedures should cover issues such as copying, mailing, how long material will be sensitive, and destruction requirements.
   c. *IT security.* Policies for electronic handling, such as copying, e-mailing, posting on Web sites, and deleting files, should be created.

99.6 Integrating Physical Security with IT Security Policy

Policies created to fulfill the "know it" tenet provide the necessary roadmaps to implement the other tenets. Policies instruct us to take the steps outlined in the other tenets. With each tenet, there were physical security examples and corresponding IT security examples. Thus, the policies to protect information must address both physical and IT security requirements. Why protect information in digital form, and then not write policy to protect it in paper form? Policy should cover both. They should be consistent in approach, but not always identical in application. For example, suppose there is a policy to ensure that project confidential information is delivered securely to project partners. For the paper world, a sealed envelope might be sufficient; but for the digital world, robust encryption is needed. So why not encrypt the envelope as well? Certainly, the delivery cyclist is capable of tearing open an envelope; so should it not have the same protection? The reason is the scale of risk. The cyclist can be identified, is probably bonded, and if he or she should drop it, very few people would likely ever see the contents. However, when sending data across the Internet, one has no idea who might come in contact with it, and it can be replicated and redistributed in enormous quantities with amazing speed at virtually no cost to an unethical person. The approach to the "secure it" tenet is the same for digital and nondigital information: deliver it securely; however, the implementations for each are tailored to individual risk.

On the digital side of policy, one cannot divorce oneself from physical access control. For example, a high-level policy states: "Users must be uniquely identified for gain network access." From this emerge standards for passwords, password receipts, and password storage. However, as illustrated previously in the payroll scenario, success for the high-level policy is not assured until one includes standards for protecting physical access to the computer, be it disabling floppy drives or locking the office door. Ensure that IT security policies and standards address avenues of access control in both the physical and digital worlds; this enhances the depth and breadth. Breadth is also improved if standards and policies are applied across the board. If the standards were applied to all networked computing assets in the payroll scenario, the alarm system computer would be covered as well.

99.7 Pitfalls of Physical Security

When implementing physical security, be aware of some common limitations and failings.

1. *Social engineering*. As in IT security, social engineering works quite well to bypass physical security controls. Typically, as long as a person appears to belong, no one will question him. If the person provides a plausible story, a guard may concede. Day-access combination locks and electronic card key systems do not suffer guilt when denying access. However, someone can be conned into sharing the combination or opening the door.
2. *Compromise of combinations*. Like passwords, combinations are often written down or posted. They can be also observed by "shoulder surfing."
3. *Tailgating*. A common practice is to "tailgate" into a facility. To tailgate, just wait until an authorized person enters, then walk in behind that person before the door shuts. Often, that person will even hold the door for the tailgater. Following a group is even easier; just feign impatience with them as they take time to get through in front of you. They might let you go first!
4. *Weather/environmental conditions*. Foul weather, bright sunlight, reflections, fog, etc., can render cameras useless or generate false alarms in the sensors. Like a dirty automobile windshield, dust and dirt on a camera lens compound the glare when looking toward the sun. Excessive heat or cold can cause equipment to malfunction. Trees or branches can interfere with perimeter alarms, as can animals and birds.
5. *Appliances*. Appliances that get hot or cold can affect motion detectors and give unwanted alarms. Therefore, take particular care to turn off coffee pots and hotplates after work hours. Moving appliances (fans) or furnishings (window blinds blowing around) generate unwanted alarms, as can a cold wind blowing into a warm room. Interference from electrical noise, like that generated by faulty refrigerator compressors, or acoustical sound such as steam escaping from heating radiators, can cause false indications in sensors.
6. *Complacency*. Either unwanted alarms or false alarms intentionally induced by bad guys creates a loss of faith in the alarm system. For example, whacking a fence equipped with a vibration sensor

would generate alarms. After repeated checking and finding no one climbing a fence, the alarms are soon ignored. Long periods of inactivity can also cause complacency or slow response. Occasional drills or competitions may help break the monotony.

7. *Notification of video surveillance*. Similar to notifying users of their lack of privacy when on the company computer system, people should be informed that they are under video surveillance. If the camera and view is not in a public area, it may be a legal requirement. Consult an attorney.
8. *User acceptance*. Users might balk at security measures they feel are too intrusive, difficult, or unsafe—whether their concern is justified or not. If they consider something as ugly, it might be vandalized or management might elect to remove it (or not approve it in the first place). One may have to gain approval from a labor union as well. If they will not accept it, despite efforts at education, one might have to rely on a different security layer or become very creative. At times, it may be a risk deemed acceptable.

99.8 IT and Physical Security Teamwork

"Hey! That is the least of my concerns." "Take a number." "Ooh, he is armed and dangerous with a floppy." "⟨sigh⟩, Rent-a-Cops. They just do not get it." "⟨sigh⟩ Computer dweebs. They just do not get it." In fact, none of us ever truly "gets it." If we did, we would be doing the other guy's job. Granted, in small organizations, we probably will be doing the other guy's job; but in larger organizations, with separate physical and IT security personnel, there must be teamwork. Okay, that is a cliché, but teamwork is more than understanding each other's needs and expounding on the virtues of synergy. Teamwork means starting with the understanding that one will never be at the top of another person's priority list. Seek to understand where you *should* fit into each other's priority list. If one works within that framework, then maybe one can achieve some realistic progress.

Well-written policies establish a starting point for teamwork. The policies will identify the specific roles and responsibilities for the physical security team and security officers. A comparison of the physical and IT security requirements articulated in policies may reveal areas of common ground between the two, such as incident response. Whether or not clear policies exist, one can build teamwork on the following triad: education, collaboration, and implementation.

99.8.1 Education

Invite the physical security practitioners, both designers and officers, to attend some computer security courses. Encourage them into the IT world so they can understand where they fit in. A classroom environment is a great place for sharing perceptions and becoming accustomed to the IT practitioner's mindset. Bring them into the courses as mentors, not just as students; they bring a different perspective to the classroom problems. Professional security officers can be quite creative (read "devious") when challenged to think like the opposition; a challenge they frequently engage.

In addition to coursework, educate the physical security crew to in-house IT vulnerabilities that are closely related to their work, such as the susceptibility of outside diskettes to introducing viruses or the potential theft of backup tapes of sensitive data. Do not merely tell them that it is a bad thing and could wipe out the entire corporate profits if taken. Be specific. Show them exactly where the vulnerability exists. If possible, demonstrate it so that they understand the time involved for someone to pull off the crime and what resources they would need. For example, if modems are not permitted in a particular facility, or if breaking into the operating system requires removing the computer case, let them know. Show them what a modem looks like, in comparison to a network interface card. Keep it in their language without being condescending; that is, "You know that little jack on the wall your phone plugs into? Well, a modem card at the rear of a computer will have two of those, one for the telephone and one for the phone line. If it has just one, it is probably the network card, which is okay."

99.8.2 Collaboration

Developing procedures and access controls is enhanced by close collaboration between IT and physical security personnel. If consistency is apparent to users, there will be a greater buy-in on their part. If one labels sensitive documents with a specific color, then labels for diskettes containing the electronic version of those documents should also be the same color. If one requires sensitive documents to be stored in a specific locked file cabinet, perhaps keep the electronic versions in the same or similar locked cabinet.

Collaboration is also helpful for the risk assessments. Applying the principles of a layered defense can become quite complicated and, at times, quite expensive. To design physical protection that is appropriate and creative, a risk management exercise should be completed. In practice, a physical security practitioner may not understand the true value of an item such as a spare server, and the tendency will be to look at the cost of hardware replacement. What if the spare server contained corporate data? What if it was staged for use as a warm standby situation? On the other hand, the IT security practitioner may not recognize creative ways to implement or bypass physical security controls or the extent of insider pilfering. The physical security practitioner generally has a better handle on the costs and practicality of security systems. Maybe a perimeter alarm system sounds great until one finds out too late the additional costs of burying cables under a driveway. Thus, if a company or organization is large enough to have a physical security office or manager, ensure they take part in the process. If hiring a risk assessment company, or providing those services, make sure there is a physical security expert on staff and that they consult with the client security officers. The security officers may have on-site knowledge of vulnerabilities, emergency service response times, and threats unknown to the hired consultant.

During collaboration, do not forget to address issues such as incident response, particularly with respect to laws and statutes, and contingency plans. Agree on what types of incidents will be pursued aggressively and which will be dealt with at a lower level or as time permits. One does not want one office jumping up and down while the other puts it on the back burner. Identifying competing priorities is also important to identify and iron out at this stage. Maybe the theft of a spare server becomes a low-priority incident to the IT office when it confirms the thief did not intrude on the network and the server had no data. But when the physical security office discovers that the thief broke a fire door, rendering the alarm system inoperable, it becomes a huge life-safety issue. The security office needs to let the IT staff know their priority on pursuing an investigation or prosecution because it may affect issues of evidence where the server was stored. Establish a process for communicating these tactical issues.

99.8.3 Implementation

Whatever is decided during collaboration, make it happen. Test it. See what does not work well; then jump back to the education and collaboration steps to resolve it. Fine-tuning the implementation is a continual process.

99.9 Shopping for More Information

A good place to start is with the American Society for Industrial Security (ASIS); it can be found at www.asisonline.org. The ASIS promotes education in security management and offers an ASIS Certified Protection Professional (CPP) Program. At its Web page, one will find an abundance of reference material and publications.

Another organization is the Overseas Security Advisory Council (OSAC). OSAC, established in 1985 by the Department of State, is a joint venture between the U.S. government and the American private sector operating abroad to foster the exchange of security-related information. Administered by the Bureau of Diplomatic Security, the OSAC provides information to organizations to help them protect their investment, facilities, personnel, and intellectual property abroad. Additional information can be found at www.ds-osac.org.

When hiring a physical security consultant, look for the CPP certification combined with experience in the IT sector. A certification that includes expertise in both IT and physical security is the Certified Information Systems Security Professional (CISSP). If a consultant is not professionally certified, look at his or her experience and background. Former law enforcement, military, federal or government investigators, and security engineers are examples of good backgrounds for a consultant. These backgrounds coupled, with professional certification, can make a great package.

The National Center for Education Statistics has some good tips and a checklist for physical security at http://nces.ed.gov/pubs98/safetech/chapter5.html. Although it is intended for schools, which are often strapped for cash and security resources, many of the tips are applicable anywhere.

If one is interested in locks, there is a nice beginner tutorial at http://www.rc3.org/archive/inform/5/4.html. Originally published in a now-defunct hacking zine, *Informatik*, it covers basic lock types and methods of defeating them. It is about ten years old and does not cover high-security locking devices, but it is a quick read and informative.

Infosyssec.org, http://www.infosyssec.org/infosyssec/physfac1.htm, lists a dizzying array of links to physical security companies and information. This should not be the first stop for the physical security novice; but for experienced practitioners, this is a good place to locate a particular vendor or seek specific information.

99.10 Conclusion

When challenged to secure data, a wise IT security manager will heed the contributions of physical security. Understand that security is controlled access and that it is best implemented through a layered defense. The layered defense features breadth, depth, and deterrence to ensure that all areas are covered, and that the coverage has fallback contingencies. There is an abundance of technologies to draw upon for each layer. For small or low-equity assets, the choices may be as simple as a lock on the door; but as the value and associated risk increase, the role of each component becomes more important. Is there a need to detect or assess a situation, or is deterrence the primary objective? If one knows the roles, one can determine how they complement one's IT security strategy and where one's security strategies still fall short or need shoring up. Using the simple tenets—identify it, label it, secure it, track it, and know it—as a template against an existing strategy or to create a new one, will help in assessing how physical and digital security complement each other and help root out those remaining gaps as well. None of the gaps, however, will be adequately filled in practice unless there is detailed collaboration and cooperation between those responsible for physical and digital security. Policies and procedures should establish the relationship, and cross-training should foster it. The benefits and, perhaps more importantly, the limitations of each discipline can be derived from cross-training. Remember: the common goal is to control access. Achieving this, both physically and digitally, gets us much closer to providing a feeling secure; freedom from fear, doubt, etc.

Note

This chapter is dedicated to my father, Floyd V. Matthews, Jr., Professor Emeritus, Cal Poly University, Pomona, California.

100

Computing Facility Physical Security

Alan Brusewitz

Most information security practitioners are experienced in and concentrate on logical issues of computer and telecommunications security while leaving physical security to another department. However, most of us would agree that a knowledgeable person with physical access to a console could bypass most of our logical protective measures by simply rebooting the system or accessing the system that is already turned on with root or administrator access in the computer room. Additionally, an unlocked wiring closet could provide hidden access to a network or a means to sabotage existing networks.

Physical access controls and protective measures for computing resources are key ingredients to a well-rounded security program. However, protection of the entire facility is even more important to the well-being of employees and visitors within the workplace. Also, valuable data is often available in hard copy on the desktop, by access to applications, and by using machines that are left unattended. Free access to the entire facility during or after work hours would be a tremendous asset to competitors or people conducting industrial espionage. There is also a great risk from disgruntled employees who might wish to do harm to the company or to their associates.

As demonstrated in the September 11, 2001 attack on the World Trade Center, greater dangers now exist than we may have realized. External dangers seem more probable than previously thought.

Physical access to facilities, lack of control over visitors, and lack of identification measures may place our workplaces and our employees in danger. Additionally, economic slowdowns that cause companies to downsize may create risks from displaced employees who may be upset about their loss of employment.

Physical security is more important than ever to protect valuable information and even more valuable employees. It must be incorporated into the total information security architecture. It must be developed with several factors in mind such as cost of remedies versus value of the assets, perceived threats in the environment, and protective measures that have already been implemented. The physical security plan must be developed and sold to employees as well as management to be successful. It must also be reviewed and audited periodically and updated with improvements developed to support the business of the organization.

100.1 Computing Centers

Computing centers have evolved over the years, but they still remain as the area where critical computing assets are enclosed and protected from random or unauthorized access. They have varying degrees of protection and protective measures, depending on the perceptions of management and the assets they contain.

Members of the technical staff often demand computing center access during off-hours, claiming that they might have to reboot systems. Members of management may also demand access because their position in the company requires that they have supervisory control over company assets. Additionally, computer room access is granted to nonemployees such as vendors and customer engineers to service the systems. Keeping track of authorized access and ensuring that it is kept to a minimum is a major task for the information security department. Sometimes, the task is impossible when the control mechanisms consist of keys or combination locks.

100.1.1 Computing Center Evolution

In the days of large mainframes, computing centers often occupied whole buildings with some space left around for related staff. Those were the days of centralized computing centers where many people were required to perform a number of required tasks. Operators were required to run print operations, mount and dismount tapes, and manage the master console. Production control staffs were required to set up and schedule jobs. In addition, they required staffs of system programmers and, in some cases, system developers. Computer security was difficult to manage, but some controls were imposed with physical walls in place to keep the functions separate. Some of these large systems still remain; however, physical computer room tasks have been reduced through automation and departmental printing.

As distributed systems evolved, servers were installed and managed by system administrators who often performed all system tasks. Many of these systems were built to operate in office environments without the need for stringent environmental controls over heat and humidity. As a result, servers were located in offices where they might not be placed behind a locked door. That security was further eroded with the advent of desktop computing, when data became available throughout the office. In many cases, the servers were implemented and installed in the various departments that wanted control over their equipment and did not want control to go back to the computing staff with their bureaucratic change controls, charge-backs, and perceived slow response to end-user needs.

As the LANs and distributed systems grew in strategic importance, acquired larger user bases, needed software upgrades and interconnectivity, it became difficult for end-user departments to manage and control the systems. Moreover, the audit department realized that there were security requirements that were not fulfilled in support of these critical systems. This resulted in the migration of systems back to centralized control and centralized computer rooms.

Although these systems could withstand environmental fluctuations, the sheer number of servers required some infrastructure planning to keep the heat down and to provide uninterruptible power and network connectivity. In addition, the operating systems and user administration tasks became more burdensome and required an operations staff to support. However, these systems no longer required the multitudes of specialized staffs in the computer rooms to support them. Print operations disappeared for the most part, with data either displayed at the desktop or sent to a local printer for hard copy.

In many cases, computer centers still support large mainframes but they take up a much smaller footprint than the machines of old. Some of those facilities have been converted to support LANs and distributed UNIX-based systems. However, access controls, environmental protections, and backup support infrastructure must still be in place to provide stability, safety, and availability. The security practitioner must play a part ensuring that physical security measures are in place and effective.

As stated before, the computing center is usually part of a facility that supports other business functions. In many cases, that facility supports the entire business. Physical security must be developed to support the entire facility with special considerations for the computing center that is contained within. In fact, protective measures that are applied in and around the entire facility provide additional protection to the computing center.

100.2 Environmental Concerns

Most of us do not have the opportunity to determine where our facilities will be located because they probably existed prior to our appointment as an information security staff member. However, that does not prevent us from trying to determine what environmental risks exist and taking action to reduce them. If lucky, you will have some input regarding relocation of the facilities to areas with reduced exposure to threats such as airways, earthquake faults, and floodplains.

100.2.1 Community

The surrounding community may contribute to computer room safety as well as risks. Communities that have strong police and fire services will be able to provide rapid response to threats and incidents. Low crime rates and strong economic factors provide safety for the computing facilities as well as a favorable climate for attracting top employees.

It is difficult to find the ideal community, and in most cases you will not have the opportunity to select one. Other businesses in that community may provide dangers such as explosive processes, chemical contaminants, and noise pollution. Community airports may have landing and takeoff flight paths that are near the facility. High crime rates could also threaten the computing facility and its inhabitants. Protective measures may have to be enhanced to account for these risks.

The security practitioner can enhance the value of community capabilities by cultivating a relationship with the local police and fire protection organizations. A good relationship with these organizations not only contributes to the safety of the facilities, but also will be key to safety of the staff in the event of an emergency. They should be invited to participate in emergency drills and to critique the process.

The local police should be invited to tour the facilities and understand the layout of the facilities and protective measures in place. In fact, they should be asked to provide suggested improvements to the existing measures that you have employed. If you have a local guard service, it is imperative that they have a working relationship with the local police officials.

The fire department will be more than happy to review fire protection measures and assist in improving them. In many cases, they will insist with inspecting such things as fire extinguishers and other fire suppression systems. It is most important that the fire department understand the facility layout and points of ingress and egress. They must also know about the fire suppression systems in use and the location of controls for those systems.

100.2.2 Acts of Nature

In most cases we cannot control the moods of Mother Nature or the results of her wrath. However, we can prepare for the most likely events and try to reduce their effects. Earthquake threats may require additional bracing and tie-down straps to prevent servers and peripheral devices from destruction due to tipping or falling. Flooding risks can be mitigated with the installation of sump pumps and locating equipment above the ground floor. Power outages resulting from tornadoes and thunderstorms may be addressed with uninterruptible power supply (UPS) systems and proper grounding of facilities.

The key point with natural disasters is that they cannot be eliminated in most cases. Remedies must be designed based on the likelihood that an event will occur and with provisions for proper response to it. In all cases, data backup with off-site storage or redundant systems are required to prepare for manmade or natural disasters.

100.2.3 Other External Risks

Until the events that occurred on September 11, 2001, physical security concerns related to riots, workplace violence, and local disruptions. The idea of terrorist acts within the country seemed remote but possible. Since that date, terrorism is not only possible, but also probable. Measures to protect facilities by use of cement barriers, no-parking zones, and guarded access gates have become understandable to both management and staff. The cost and inconvenience that these measures impose are suddenly more acceptable.

Many of our facilities are located in areas that are considered out of the target range that terrorists might attack. However, the Oklahoma City bombing occurred in a low-target area. The anthrax problems caused many unlikely facilities to be vacated. The risks of bioterrorism or attacks on nuclear power plants are now considered real and possible, and could occur in almost any city. Alternate site planning must be considered in business continuity and physical security plans.

100.3 Facility

The facilities that support our computing environments are critical to the organization in providing core business services and functions. There are few organizations today that do not rely on computing and telecommunications resources to operate their businesses and maintain services to their customers. This requires security over both the physical and logical aspects of the facility. The following discussion concentrates on the physical protective measures that should be considered for use in the computing center and the facilities that surround it.

100.3.1 Layers of Protection

For many computing facilities, the front door is the initial protection layer that is provided to control access and entry to the facility. This entry point will likely be one of many others such as back doors, loading docks, and other building access points. A guard or a receptionist usually controls front-door access. Beyond that, other security measures apply based on the value of contents within. However, physical security of facilities may begin outside the building.

100.3.1.1 External Protective Measures

Large organizations may have protective fences surrounding the entire campus with access controlled by a guard-activated or card-activated gate. The majority of organizations will not have perimeter fences around the campus but may have fences around portions of the building. In most of those cases, the front of the building is not fenced due to the need for entry by customers, visitors, and staff. These external protective measures may be augmented through the use of roving guards and closed-circuit television (CCTV) systems that provide a 360-degree view of the surrounding area.

Security practitioners must be aware of the risks and implement cost-effective measures that provide proper external protection. Measures to consider are:

- Campus perimeter fences with controlled access gates
- Building perimeter fences with controlled access gates
- Building perimeter fences controlling rear and side access to the building
- Cement barriers in the front of the building
- Restrict parking to areas away from the building
- CCTV viewing of building perimeters

100.3.1.2 External Walls

Facilities must be constructed to prevent penetration by accidental or unlawful means. Windows provide people comforts for office areas and natural light, but they can be a means for unauthorized entry. Ground floors may be equipped with windows; however, they could be eliminated if that floor were reserved for storage and equipment areas. Loading docks may provide a means of unauthorized entry and, if possible, should be located in unattached buildings or be equipped with secured doors to control entry. Doors that are not used for normal business purposes should be locked and alarmed with signs that prohibit their use except for emergencies.

100.3.1.3 Internal Structural Concerns

Critical rooms such as server and telecommunications areas should be constructed for fire prevention and access controls. Exterior walls for these rooms should not contain windows or other unnecessary entry points. They should also be extended above false ceilings and below raised floors to prevent unlawful entry and provide proper fire protection. Additional entry points may be required for emergency escape or equipment movement. These entrances should be locked when not in use and should be equipped with alarms to prevent unauthorized entry.

100.3.1.4 Ancillary Structures (Wiring Cabinets and Closets)

Wiring cabinets may be a source of unauthorized connectivity to computer networks and must be locked at all times unless needed by authorized personnel. Janitor closets should be reserved for that specific purpose and should not contain critical network or computing connections. They must be inspected on a regular basis to ensure that they do not contain flammable or other hazardous materials.

100.3.2 Facility Perils and Computer Room Locations

Computer rooms are subject to hazards that are created within the general facility. These hazards can be reduced through good facility design and consideration for critical equipment.

100.3.2.1 Floor Locations

Historically, computing equipment was added to facilities that were already in use for general business processes. Often, the only open area left for computing equipment was the basement. In many cases, buildings were not built to support heavy computers and disk storage devices on upper floors, so the computer room was constructed on the ground floor. In fact, organizations were so proud of the flashy computer equipment that they installed observation windows for public viewing, with large signs to assist them in getting there.

Prudent practices along with a realization that computing resources were critical to the continued operation of the company have caused computing facilities to be relocated to more protected areas with minimum notification of their special status. Computer rooms have been moved to upper floors to mitigate flooding and access risks. Freight elevators have been installed to facilitate installation and removal of computing equipment and supplies. Windows have been eliminated and controlled doors have been added to ensure only authorized access.

100.3.2.2 Rest Rooms and Other Water Risks

Water hazards that are located above computer rooms could cause damage to critical computing equipment if flooding and leakage occurs. A malfunctioning toilet or sink that overflows in the middle of the night could be disastrous to computer operations. Water pipes that are installed in the flooring above the computer room could burst or begin to leak in the event of earthquakes or corrosion. A well-sealed floor will help, but the best prevention is to keep those areas clear of water hazards.

100.3.2.3 Adjacent Office Risks

Almost all computing facilities have office areas to support the technical staff or, in many cases, the rest of the business. These areas can provide risks to the computing facility from fire, unauthorized access, or chemical spills. Adjacent office areas should be equipped with appropriate fire suppression systems that are designed to control flammable material and chemical fires. Loading docks and janitor rooms can also be a source of risk from fire and chemical hazards. Motor-generated UPS systems should be located in a separate building due to their inherent risks of fire and carbon monoxide. The local fire department can provide assistance to reduce risks that may be contained in other offices as well as the computing center.

100.4 Protective Measures

Entrances to computing facilities must be controlled to protect critical computing resources, but they must also be controlled to protect employees and sensitive business information. As stated before, valuable information is often left on desks and in unlocked cabinets throughout the facility. Desktop computers are often left on overnight with valuable information stored locally. In some cases, these systems are left logged on to sensitive systems. Laptops with sensitive data can be stolen at night and even during business hours.

To protect valuable information resources, people, and systems, various methods and tools should be considered. Use of any of these tools must be justified according to the facility layout and the value of the resources contained within.

100.4.1 Guard Services

There are many considerations related to the use of guard services. The major consideration, other than whether to use them, is employee versus purchased services. The use of employee guards may be favored by organizations with the idea that employees are more loyal to the organization and will be trustworthy. However, there are training, company benefit, and insurance considerations that accompany that decision. Additionally, the location may not have an alternative guard source available. If the guards are to be armed, stringent controls and training must be considered.

There are high-quality guard services available in most areas that will furnish trained and bonded guards who are supervised by experienced managers. Although cost is a factor in the selection of a contract guard service, it should not be the major one. The selection process should include a request for proposal (RFP) that requires references and stringent performance criteria. Part of the final selection process must include discussions with customer references and a visit to at least two customer sites. Obviously, the guard service company should be properly licensed and provide standard business documentation.

The guard service will be operating existing and planned security systems that may include CCTV, card access systems, central control rooms, and fire suppression systems. Before contracting with an organization, that organization must demonstrate capabilities to operate existing and planned systems. It should also be able to provide documented operating procedures that can be modified to support the facility needs.

100.4.2 Intrusion Monitoring Systems

Closed-circuit television (CCTV) systems have been used for years to protect critical facilities. These systems have improved considerably over the years to provide digital images that take up less storage space and be transmitted over TCP/IP-based networks. Their images can be combined with other alarm events to provide a total picture for guard response as well as event history. Digital systems that are activated in conjunction with motion detection or other alarms may be more effective because their activation signals a change to the guard who is assigned to watch them.

CCTV systems allow guards to keep watch on areas that are located remotely, are normally unmanned, or require higher surveillance, such as critical access points. These systems can reduce the need for additional manpower to provide control over critical areas. In many cases, their mere presence serves as a deterrent to unwanted behavior.

They may also contribute to employee safety by providing surveillance over parking areas, low traffic areas, and high-value functions such as cashier offices. A single guard in a central control center can spot problems and dispatch roving manpower to quickly resolve threats. In addition to the above, stored images may be used to assist law enforcement in apprehending violators and as evidence in a court of law.

Security requirements will vary with different organizations; however, CCTV may be useful in the following areas:

- Parking lots for employee and property safety
- Emergency doors where access is restricted
- Office areas during nonworking hours
- Server and telecommunications equipment rooms during nonworking hours
- Loading docks and delivery gates
- Cashier and check-processing areas
- Remote facilities where roving guards would be too costly
- Executive office areas in support of executive protection programs
- Mantrap gates to ensure all entry cards have been entered

Alarms and motion-detection systems are designed to signal the organization that an unusual or prohibited event has occurred. Doors that should not be used during normal business activity may be equipped with local sound alarms or with electronic sensors that signal a guard or activate surveillance systems. Motion detectors are often installed in areas that are normally unmanned. In some systems, motion detection is activated during nonbusiness hours and can be disabled or changed to allow for activities that are properly scheduled in those areas.

Many systems can be IP addressable over the backbone TCP/IP network, and alarm signals can be transmitted from multiple remote areas. It is important to note that IP-based systems may be subject to attack. The vendor of these systems must ensure that these systems are hack-protected against covert activities by unauthorized people.

100.4.3 Physical Access Control Measures

Physical access controls are as important as logical access controls to protect critical information resources. Multiple methods are available, including manual and automated systems. Often, cost is the deciding factor in their selection despite the risks inherent in those tools.

100.4.3.1 Access Policies

All good security begins with policies. Policies are the drivers of written procedures that must be in place to provide consistent best practices in the protection of people and information resources. Policies are the method by which management communicates its wishes. Policies are also used to set standards and assign responsibility for their enforcement. Once policies are developed, they should be published for easy access and be part of the employee awareness training program.

Policies define the process of granting and removing access based on need-to-know. If badges are employed, policies define how they are to be designed, worn, and used. Policies define who is allowed into restricted areas or how visitors are to be processed. There is no magic to developing policies, but they are required as a basic tool to protect information resources.

100.4.3.2 Keys and Cipher Locks

Keys and cipher (keypad) locks are the simplest to use and hardest to control in providing access to critical areas. They do not provide a means of identifying who is accessing a given area, nor do they provide an audit trail. Keys provide a slightly better security control than keypad locks in that the physical device must be provided to allow use. While they can be copied, that requires extra effort to accomplish. If keys are used to control access, they should be inventoried and stamped with the words *Do Not Duplicate*.

Cipher locks require that a person know the cipher code to enter an area. Once given out, use of this code cannot be controlled and may be passed throughout an organization by word of mouth. There is no audit trail for entry, nor is there authentication that it is used by an authorized user. Control methods consist of periodic code changes and shielding to prevent other people from viewing the authorized user's code entry. Use of these methods of entry control could be better protected through the use of CCTV.

100.4.3.3 Card Access Controls

Card access controls are considerably better tools than keys and cipher locks if they are used for identification and contain a picture of the bearer. Without pictures, they are only slightly better than keys because they are more difficult to duplicate. If given to another person to gain entry, the card must be returned for use by the authorized cardholder. Different types of card readers can be employed to provide ease of use (proximity readers) and different card identification technology. Adding biometrics to the process would provide added control along with increased cost and inconvenience that might be justified to protect the contents within.

The most effective card systems use a central control computer that can be programmed to provide different access levels depending on need, time zone controls that limit access to certain hours of the day, and an audit trail of when the card was used and where it was entered. Some systems even provide positive in and out controls that require a card to be used for both entry and exit. If a corresponding entry/exit transaction is not in the system, future entry will be denied until management investigation actions are taken.

Smart card technology is being developed to provide added security and functionality. Smart cards can have multiple uses that expand beyond mere physical access. Additional uses for this type of card include computer access authentication, encryption using digital certificates, and debit cards for employee purchases in the cafeteria or employee store. There is some controversy about multiple-use cards because a single device can be used to gain access to many different resources. If the employee smart card provides multiple access functions as well as purchasing functions, the cardholder will be less likely to loan the badge to an unauthorized person for use and will be more likely to report its loss.

100.4.3.4 Mantraps and Turnstiles

Additional controls can be provided through the use of mantraps and turnstiles. These devices prevent unauthorized tailgating and can be used to require inspection of parcels when combined with guard stations. These devices also force the use of a badge to enter through a control point and overcome the tendency for guards to allow entry because the person looks familiar to them. Mantraps and turnstiles can control this weakness if the badge is confiscated upon termination of access privileges. The use of positive entry/exit controls can be added to prevent card users from passing their card back through the control point to let a friend enter.

100.4.4 Fire Controls

Different fire control mechanisms must be employed to match the risks that are present in protected areas. Fire control systems may be as simple as a hand-held fire extinguisher or be combined with various detection mechanisms to provide automated activation. Expert advice should be used to match the proper system to the existing threats. In some cases, multiple systems may be used to ensure that fires do not reignite and cause serious damage.

100.4.4.1 Detectors and Alarms

Smoke and water detectors can provide early warning and alarm the guards that something dangerous may be happening. Alarms may also trigger fire prevention systems to activate. To be effective, they must be carefully placed and tested by experts in fire prevention.

100.4.4.2 Water-Based Systems

Water-based systems control fires by reducing temperatures below the combustion point. They are usually activated through overhead sprinklers to extinguish fires before they can spread. The problem with water-based systems is that they cause a certain amount of damage to the contents of areas they are designed to protect. In addition, they may cause flooding in adjacent areas if they are not detected and shut off quickly following an event.

Water-based systems may be either dry pipe or wet pipe systems. Wet pipe systems are always ready to go and are activated when heat or accidental means open the sprinkler heads. There is no delay or shut-off mechanism that can be activated prior to the start of water flow. Water in the pipes that connect to the sprinkler heads may become corroded, causing failure of the sprinkler heads to activate in an emergency.

Dry pipe systems are designed to allow some preventive action before they activate. These types of systems employ a valve to prevent the flow of water into the overhead pipes until a fire alarm event triggers water release. Dry pipe systems will not activate and cause damage if a sprinkler head is accidentally broken off. They also allow human intervention to override water flow if the system is accidentally activated.

100.4.4.3 Gas-Based Fire Extinguishing Systems

Halon-type systems are different from water-based systems in that they control fires by interrupting the chemical reactions needed to continue combustion. They replaced older gas systems such as carbon dioxide that controlled fires by replacing the oxygen with a gas (CO_2) that did not support the combustion process. Oxygen replacement systems were effective, but they were toxic to humans who might be in the CO_2-activated room due to the need for oxygen to survive.

Throughout the 1970s and 1980s, halon systems were the preferred method to protect computer and telecommunication rooms from fire damage because they extinguished the fire without damaging sensitive electronic equipment. Those systems could extinguish fires and yet allow humans to breathe and survive in the flooded room. The problem with halon is that it proved unfriendly to the ozone layer and was banned from new implementations by an international agreement (Montreal Protocol). There are numerous Clean Air Act and EPA regulations now in effect to govern the use of existing halon systems and supplies. Current regulations and information can be obtained by logging onto www.epa.gov/docs/ozone/ title6/snap/hal.html. This site also lists manufacturers of halon substitute systems.

Today, halon replacement systems are available that continue to extinguish fires, do not harm the ozone layer, and, most important, do not harm humans who may be in the gas-flooded room. Although these systems will not kill human inhabitants, most system manufacturers warn that people should leave the gas-flooded area within one minute of system activation. Current regulations do not dictate the removal of halon systems that are in place; however, any new or replacement halon systems must employ the newer ozone-friendly gas (e.g., FM 200).

100.4.5 Utility and Telecommunications Backup Requirements

100.4.5.1 Emergency Lighting

As stated before, modern computer rooms are usually lacking in windows or other sources of natural light. Therefore, when a power outage occurs, these rooms become very dark and exits become difficult to find. Even in normal offices, power outages may occur in areas that are staffed at night. In all of these cases, emergency lighting with exit signs must be installed to allow people to evacuate in an orderly and safe manner. Emergency lighting is usually provided by battery-equipped lamps that are constantly charged until activated.

100.4.5.2 UPS Systems

Uninterruptible power supply (UPS) systems ensure that a computing system can continue to run, or at least shut down in an orderly manner, if normal power is lost. Lower cost systems rely on battery backup to provide an orderly shutdown; motor generator backup systems used in conjunction with battery backup can provide continuous power as long as the engines receive fuel (usually diesel). As usual, cost is the driver for choosing the proper UPS system. More enlightened management will insist on a business impact analysis prior to making that decision to ensure that critical business needs are met.

Regardless of the type of system employed, periodic testing is required to ensure that the system will work when needed. Diesel systems should be tested weekly to ensure they work and to keep the engines properly lubricated.

100.4.5.3 Redundant Connections

Redundancy should be considered for facility electrical power, air conditioning, telecommunications connections, and water supplies. Certain systems such as UPS can be employed to mitigate the need for electrical redundancy. Telecommunications connectivity should be ensured with redundant connections. In this E-commerce world, telecommunications redundancy should also include connections to the Internet. Water is important to the staff, but environmental systems (cooling towers) may also depend on a reliable supply. In most cases, this redundancy can be provided with separate connections to the water main that is provided by the supporting community.

100.5 Summary

Physical security must be considered to provide a safe working environment for the people who visit and work in a facility. Although physical access controls must be employed for safety reasons, they also should prevent unauthorized access to critical computing resources.

Many tools are available to provide physical security that continues to be enhanced with current technology. Backbone networks and central control computers can support the protection of geographically separated facilities and operations. IP-supported systems can support the collection of large amounts of data from various sensors and control mechanisms and provide enhanced physical security while keeping manpower at a minimum.

The information security practitioner must become aware of existing physical security issues and be involved. If a separate department provides physical security, coordination with them becomes important to a total security approach. If information security organizations are assigned to provide physical security, they must become aware of the tools that are available and determine where to employ them.

101

Closed-Circuit Television and Video Surveillance

David A. Litzau

In June 1925, Charles Francis Jenkins successfully transmitted a series of motion pictures of a small windmill to a receiving facility over five miles away. The image included 48 lines of resolution and lasted ten minutes. This demonstration would move the television from an engineer's lark to reality. By 1935, *Broadcast* magazine listed 27 different television broadcast facilities across the nation, some with as many as 45 hours of broadcast a week. Although the television set was still a toy for the prosperous, the number of broadcast facilities began to multiply rapidly.

On August 10, 1948, the American Broadcasting Company (ABC) debuted the television show *Candid Camera*. The basis of the show was to observe the behavior of people in awkward circumstances— much to the amusement of the viewing audience—by a hidden camera. This human behavior by surreptitious observation did not go unnoticed by psychologists and security experts of the time. Psychologists recognized the hidden camera as a way to study human behavior, and for security experts it became a tool of observation. Of particular note to both was the profound effect on behavior that the presence of a camera had on people once they became aware that they were being observed.

Security experts would have to wait for advances in technology before the emerging technology could be used. Television was based on vacuum tube technology and the use of extensive broadcast facilities. It would be the space race of the late 1950s and 1960s that would bring the television and its cameras into the realm of security. Two such advances that contributed were the mass production of transistors and the addition of another new technology known as videotape. The transistor replaced bulky, failure-prone vacuum tubes and resulted in television cameras becoming smaller and more affordable. The videotape machine meant that the images no longer had to be broadcast; the images could be collected through one or more video cameras and the data transmitted via a closed circuit of wiring to be viewed on a video monitor or recorded on tape. This technology became known as closed-circuit television, or CCTV.

In the early 1960s, CCTV would be embraced by the Department of Defense as an aid for perimeter security. In the private sector, security experts for merchants were quick to see the value of such technology as an aid in the prevention of theft by customers and employees. Today, unimagined advances in the technology in cameras and recording devices have brought CCTV into the home and workplace in miniature form.

101.1 Why CCTV?

Information security is a multifaceted process, and the goal is to maintain security of the data processing facility and the assets within. Typically, those assets can be categorized as hardware, software, data, and people, which also involves the policies and procedures that govern the behavior of those people. With the possible exception of software, CCTV has the ability to provide defense of these assets on several fronts.

101.1.1 To Deter

The presence of cameras both internally and externally has a controlling effect on those who step into the field of view. In much the same way that a small padlock on a storage shed will keep neighbors from helping themselves to garden tools when the owner is not at home, the camera's lens tends to keep personnel from behaving outside of right and proper conduct. In the case of the storage shed, the lock sends the message that the contents are for the use of those with the key to access it, but it would offer little resistance to a determined thief. Likewise, the CCTV camera sends a similar message and will deter an otherwise honest employee from stepping out of line, but it will not stop someone determined to steal valuable assets. It becomes a conscious act to violate policies and procedures because the act itself will likely be observed and recorded.

With the cameras at the perimeter, those looking for easy targets will likely move on, just as employees within the facility will tend to conduct themselves in a manner that complies with corporate policies and procedures. With cameras trained on data storage devices, it becomes difficult to physically access the device unobserved, thereby deterring the theft of the data contained within. The unauthorized installation or removal of hardware can be greatly deterred by placing cameras in a manner that permits the observation of portals such as windows or doors. Overall, the statistics of crimes in the presence of CCTV cameras is dramatically reduced.

101.1.2 To Detect

Of particular value to the security professional is the ability of a CCTV system to provide detection. The eyes of a security guard can only observe a single location at a time, but CCTV systems can be configured in such a manner that a single pair of eyes can observe a bank of monitors. Further, each monitor can display the output of multiple cameras. The net effect is that the guard in turn can observe dozens of locations from a single observation point. During periods of little or no traffic, a person walking into the view of a camera is easily detected. Placing the camera input from high-security and high-traffic locations in the center of the displays can further enhance the coverage, because an intruder entering the field of view on a surrounding monitor would be easily detected even though the focus of attention is at the center of the monitors. Technology is in use that will evaluate the image field; and if the content of the image changes, an alarm can be sounded or the mode of recording changed to capture more detail of the image. Further, with the aid of recording equipment, videotape recordings can be reviewed in fast-forward or rewind to quickly identify the presence of intruders or other suspicious activities.

101.1.3 To Enforce

The human eyewitness has been challenged in the court of law more often in recent history. The lack of sleep, age of the witness, emotional state, etc., can all come to bear on the validity of an eyewitness statement. On the other hand, the camera does not get tired; video recording equipment is not susceptible to such human frailties. A video surveillance recording can vastly alter the outcome of legal proceedings and has an excellent track record in swaying juries as to the guilt or innocence of the accused. Often, disciplinary action is not even required once the alleged act is viewed on video by the accused, thereby circumventing the expense of a trial or arbitration. If an act is caught on tape that requires legal or disciplinary action, the tape ensures that there is additional evidence to support the allegations.

With the combined abilities of deterrence, detection, and enforcement of policies and procedures over several categories of assets, the CCTV becomes a very effective aid in the process of information security, clearly an aid that should be carefully considered when selecting countermeasures and defenses.

101.2 CCTV Components

One of the many appealing aspects of CCTV is the relative simplicity of its component parts. As in any system, the configuration can only be as good as the weakest link. Inexpensive speakers on the highest quality sound system will result in inexpensive quality sound. Likewise, a poor quality component in a CCTV system produces poor results. There are basically four groups of components:

1. Cameras
2. Transmission media
3. Monitors
4. Peripherals

101.2.1 The Camera

The job of the camera is to collect images of the desired viewing area and is by far the component that requires the most consideration when configuring a CCTV system. In a typical installation, the camera relies on visible light to illuminate the target; the reflected light is then collected through the camera lens and converted into an electronic signal that is transmitted back through the system to be processed.

The camera body contains the components to convert visible light to electronic signals. There are still good-quality, vacuum-tube cameras that produce an analog signal, but most cameras in use today are solid-state devices producing digital signal output. Primary considerations when selecting a camera are the security objectives. The sensitivity of a camera refers to the number of receptors on the imaging surface and will determine the resolution of the output; the greater the number of receptors, the greater the resolution. If there is a need to identify humans with a high level of certainty, one should consider a color camera with a high level of sensitivity. On the other hand, if the purpose of the system is primarily to observe traffic, a simple black-and-white camera with a lower sensitivity will suffice.

The size of cameras can range from the outwardly overt size of a large shoebox to the very covert size of a matchbox. Although the miniaturized cameras are capable of producing a respectable enough image to detect the presence of a human, most do not collect enough reflective light to produce an image quality that could be used for positive identification. This is an area of the technology that is seeing rapid improvement.

There are so many considerations in the placement of cameras that an expert should be consulted for the task. Some of those considerations include whether the targeted coverage is internal or external to the facility. External cameras need to be positioned so that all approaches to the facility can be observed, thereby eliminating blind spots. The camera should be placed high enough off the ground so that it cannot be easily disabled, but not so high that the images from the scene only produce the tops of people's heads and the camera is difficult to service. The camera mount can have motor drives that will permit aiming left and right (panning) or up and down (tilting), commonly referred to as a *pan/tilt drive*. Additionally, if the camera is on the exterior of the facility, it may require the use of a sunshade to prevent the internal temperature from reaching damaging levels. A mount that can provide heating to permit de-icing should be considered in regions of extreme cold so that snow and ice will not damage the pan/tilt drive. Internal cameras require an equal amount of consideration; and, again, the area to be covered and ambient light will play a large part in the placement. Cameras may be overt or covert and will need to be positioned such that people coming or going from highly valued assets or portals can be observed.

Because the quality of the image relies in large part on the reflective light, the lens on the camera must be carefully selected to make good use of available light. The cameras should be placed in a manner that will allow the evening lighting to work with the camera to provide front lighting (lights that shine in the same direction that the camera is aimed) to prevent shadowing of approaching people or objects. Constant adjustments must be made to lenses to accommodate the effects of a constantly changing angle of sunlight, changing atmospheric conditions, highly reflective rain or snowfall, and the transition to artificial lighting in the evening; all affect ambient light. This is best accomplished with the use of an automatic iris. The iris in a camera, just as in the human eye, opens and closes to adjust the amount of light that reaches the imaging surface. Direct exposure to an intense light source will result in blossoming of the image—where the image becomes all white and washes out the picture to the point where nothing is seen—and can also result in serious damage to the imaging surface within the camera.

The single most-important element of the camera is the lens. There are basically four types of lenses: standard, wide-angle, telephoto, and zoom. When compared to human eyesight, the standard lens is the rough equivalent; the wide-angle takes in a scene wider than what humans can see; and the telephoto is magnified and roughly equivalent to looking through a telescope. All are fixed focal length lenses. The characteristics of these three combined are a zoom lens.

101.2.2 The Transmission Media

Transmission media refer to how the video signal from the cameras will be transported to the multiplexer or monitor. This is typically some type of wiring.

101.2.2.1 Coaxial Cable

By far the most commonly used media are coaxial cables. There are varying grades of coaxial cable, and the quality of the cable will have a profound effect on the quality of the video. Coaxial cable consists of a single center conductor with a piezoelectric insulator surrounding it. The insulation is then encased in a foil wrap and further surrounded by a wire mesh. A final coating of weather-resistant insulation is placed around the entire bundle to produce a durable wire that provides strong protection for the signal as it transits through the center conductor. The center conductor can be a single solid wire or a single conductor made up of multiple strands of wire. Engineers agree that the best conductor for a video signal is pure copper. The amount of shielding will determine the level of protection for the center conductor. The shielding is grounded at both ends of the connection and thereby shunts extraneous noise from electromagnetic radiation to ground.

Although 100 percent pure copper is an excellent conductor of the electronic signal, there is still a level of internal resistance that will eventually degrade the signal's strength. To overcome the loss of signal strength, the diameter of the center conductor and the amount of shielding can be increased to obtain greater transmission lengths before an in-line repeater/amplifier will be required. This aspect of the cable is expressed in an industry rating. The farther the distance the signal must traverse, the higher the rating of the coaxial cable that should be used or noticeable signal degradation will occur.

Some examples are:

- RG59/U rated to carry the signal up to distances of 1000 feet
- RG6/U rated to carry a signal up to 1500 feet
- RG11/U rated to carry a signal up to 3000 feet

One of the benefits of coaxial cable is that it is easy to troubleshoot the media should there be a failure. A device that sends a square-wave signal down the wire (time domain reflectometer) can pinpoint the location of excessive resistance or a broken wire. Avoid using a solid center conductor wire on cameras mounted on a pan/tilt drive because the motion of the camera can fatigue the wire and cause a failure; thus, multi-strand wire should be used.

101.2.2.2 Fiber-Optic Cable

Fiber-optic cable is designed to transmit data in the form of light pulses. It typically consists of a single strand of highly purified silica (glass), smaller than a human hair, surrounded by another jacket of lower grade glass. This bundle is then clad in a protective layer to prevent physical damage to the core. The properties of the fiber-optic core are such that the outer surface of the center fiber has a mirror effect, thereby reflecting the light back into itself. This means that the cable can be curved, and it has almost no effect on the light pulses within. This effect, along with the fact that the frequency spectrum that spans the range of light is quite broad, produces an outstanding medium for the transfer of a signal. There is very little resistance or degradation of the signal as it traverses the cable, and the end result is much greater transmission lengths and available communication channels when compared to a metallic medium.

The reason that fiber-optics has not entirely replaced its coaxial counterpart is that the cost is substantially higher. Because the fiber does not conduct any electrical energy, the output signal must be converted to light pulses. This conversion is known as modulation and is accomplished using a laser. Once converted to light pulses, the signal is transferred into the fiber-optic cable. Because the fiber of the cable is so small, establishing good connections and splices is critical. Any misalignment or damage to the fiber will result in reflective energy or complete termination of the signal. Therefore, a skilled technician with precision splicing and connection tools is required. This cost, along with modulators/demodulators and the price of the medium, adds substantial cost to the typical CCTV installation.

For the additional cost, some of the benefits include generous gains in bandwidth. This means that more signals carrying a greater amount of data can be realized. Adding audio from microphones, adjustment signals to control zoom lenses and automatic irises, and additional cameras can be accommodated. The medium is smaller and lighter and can carry a signal measured in miles instead of feet. Because there is no electromagnetic energy to create compromising emanations, and a splice to tap the connection usually creates an easily detected interruption of the signal, there is the additional benefit of a high level of assurance of data integrity and security. In an environment of remote locations or a site containing highly valued assets, these benefits easily offset the additional cost of fiber-optic transmission.

101.2.2.3 Wireless Transmission

The option of not using wiring at all is available for CCTV. The output signals from cameras can be converted to radio frequency, light waves, or microwave signals for transmission. This may be the only viable option for some remote sites and can range from neighboring buildings using infrared transceivers to a satellite link for centralized monitoring of remote sites throughout the globe. Infrared technology must be configured in a line-of-sight manner and has a limited range of distance. Radio frequency and microwaves can get substantial improvements in distance but will require the use of repeaters and substations to traverse distances measured in miles. The more obstacles that must be negotiated (i.e., buildings, mountains, etc.), the greater the degradation of the signal that takes place.

Two of the biggest drawbacks of utilizing wireless are that the signal is vulnerable to atmospheric conditions and, as in any wireless transmission, easily intercepted and inherently insecure. Everything from the local weather to solar activity can affect the quality of the signal. From a security standpoint, the transmission is vulnerable to interception, which could reveal to the viewer the activity within a facility and compromise other internal defenses. Further, the signal could be jammed or modified to render the system useless or to provide false images. If wireless transmission is to be utilized, some type of signal scrambling or channel-hopping technology should be utilized to enhance the signal confidentiality and integrity.

Some of the more recent trends in transmission media have been the use of existing telephone lines and computer networking media. The dial-up modem has been implemented in some installations with success, but the limited amount of data that can be transmitted results in slow image refreshing; and control commands to the camera (focus, pan, tilt, etc.) are slow to respond. The response times and refresh rates can be substantially increased through the use of ISDN phone line technology.

Some recent advances in data compression, and protocols that allow video over IP, have moved the transmission possibilities into existing computer network cabling.

101.2.3 The Monitor

The monitor is used to convert the signal from cameras into a visible image. The monitor can be used for real-time observation or the playback of previously recorded data.

Color or black-and-white video monitors are available but differ somewhat from a standard television set. A television set will come with the electronics to convert signals broadcast on the UHF and VHF frequency spectrums and demodulate those signals into a visible display of the images. The CCTV monitor does not come with such electronics and is designed to process the signals of a standard 75-ohm impedance video signal into visible images. This does not mean that a television set cannot be used as a video monitor, but proper attenuation equipment will be needed to convert the video into a signal that the television can process.

The lines of resolution determine detail and the overall sharpness of the image. The key to reproducing a quality image is matching as closely as possible the resolution of the monitor to the camera; but it is generally accepted that, if a close match is not made, then it is better to have a monitor with a greater resolution. The reason for this is that a 900-line monitor displaying an image of 300 lines of resolution will provide three available lines for each line of image. The image will be large and appear less crisp; but if at a later date the monitor is used in a split-screen fashion to display the output from several cameras on the screen at the same time, there will be enough resolution for each image. On the other hand, if the resolution of the monitor is lower than that of the camera, detail will be lost because the entire image cannot be displayed.

The size of the monitor to be used is based on several factors. The more images to be viewed, the greater the number of monitors. A single monitor is capable of displaying the output from several cameras on the same screen (see multiplexers), but this still requires a comfortable distance between the viewer and monitor. Although not exactly scientific, a general rule of thumb is that the viewer's fist at the end of an extended arm should just cover the image. This would place the viewer farther away from the monitor for a single image and closer if several images were displayed.

101.2.4 The Peripherals

A multiplexer is a hardware device that is capable of receiving the output signal from multiple cameras and processing those signals in several ways. The most common use is to combine the inputs from selected cameras into a single output such that the group of inputs is displayed on a single monitor. A multiplexer is capable of accepting from four to 32 separate signals and provides video enhancement, data compression, and storing or output to a storage device. Some of the additional features available from a multiplexer include alarm modes that will detect a change to an image scene to alert motion and the ability to convert analog video signals into digital format. Some multiplexers have video storage capabilities, but most provide output that is sent to a separate storage device.

A CCTV system can be as simple as a camera, transmission medium, and a monitor. This may be fine if observation is the goal of the system; but if the intent is part of a security system, storage of captured images should be a serious consideration. The output from cameras can be stored and retrieved to provide nearly irrefutable evidence for legal proceedings.

There are several considerations in making a video storage decision. Foremost is the desired quality of the retrieved video. The quality of the data always equates to quantity of storage space required.

The primary difference in storage devices is whether the data will be stored in analog or digital format. The options for analog primarily consist of standard three-quarter-inch VHS tape or higher quality one-inch tape. The measure of quantity for analog is time, where the speed of recording and tape length will determine the amount of time that can be recorded. To increase the amount of time that a recording spans, one of the best features available in tape is time-lapse recording. Time-lapse videocassette recorders (VCRs) reduce the number of frames per second (fps) that are recorded. This equates to greater spans of time on less tape, but the images will appear as a series of sequential still images when played back. There is the potential of a critical event taking place between pictures and thereby losing its evidentiary value. This risk can be offset if the VCR is working in conjunction with a multiplexer that incorporates motion detection. Then the FPS can be increased to record more data from the channel with the activity. Another consideration of analog storage medium is that the shelf life is limited. Usually if there is no event of significance, then tapes can be recorded over existing data; but if there is a need for long-term storage, the quality of the video will degrade with time.

Another option for the storage of data is digital format. There are many advantages to utilizing digital storage media. The beauty of digital is that the signal is converted to binary 1s and 0s, and once converted the data is ageless. The data can then be stored on any data processing hardware, including hard disk drives, tapes, DVDs, magneto-optical disks, etc. By far the best-suited hardware is the digital video recorder (DVR). Some of the capabilities of DVRs may include triplex functions (simultaneous video observation, playback, and recording), multiple camera inputs, multi-screen display outputs, unlimited recording time by adding multiple hard disk drives, hot-swappable RAID, multiple trigger events for alarms, and tape archiving of trigger events. Because the data can be indexed on events such as time, dates, and alarms, the video can be retrieved for playback almost instantly.

Whether analog or digital, the sensitivity of the cameras used, frames recorded each second, whether the signal is in black and white or color, and the length of time to store will impact the amount of storage space required.

101.3 Putting It All Together

By understanding the stages of implementation and how hardware components are integrated, the security professional will have a much higher likelihood of successfully integrating a CCTV system. There is no typical installation, and every site will have its unique characteristics to accommodate; but there is a typical progression of events from design to completion.

- *Define the purpose*. If observation of an entrance is the only goal, there will be little planning to consider. Will the quality of images be sufficient to positively identify an individual? Will there be a requirement to store image data, and what will be the retention period? Should the presence of a CCTV system be obvious with the presence of cameras, or will they be hidden? Ultimately, the question becomes: What is the purpose of implementing and what is to be gained?
- *Define the surveyed area*. Complete coverage for the exterior and interior of a large facility or multiple facilities will require a substantial budget. If there are financial restraints, then decisions will have to be made concerning what areas will be observed. Some of the factors that will influence that decision may be the value of the assets under scrutiny and the security requirements in a particular location.
- *Select appropriate cameras*. At this point in the planning, a professional consultation should be considered. Internal surveillance is comparatively simpler than external because the light levels are consistent; but external surveillance requires an in-depth understanding of how light, lenses, weather, and other considerations will affect the quality of the images. Placement of cameras can make a substantial difference in the efficiency of coverage and the effectiveness of the images that will be captured.
- *Selection and placement of monitors*. Considerations that need to be addressed when planning the purchase of monitors include the question of how many camera inputs will have to be observed at the same time. How many people will be doing the observation simultaneously? How much room space is available in the monitoring room? Is there sufficient air conditioning to accommodate the heat generated by large banks of monitors?

- *Installation of transmission media*. Once the camera locations and the monitoring location have been determined, the installation of the transmission media can then begin. A decision should have already been made on the type of media that will be utilized and sufficient quantities ordered. Technicians skilled in installation, splicing, and testing will be required.
- *Peripherals*. If the security requirements are such that image data must be recorded and retained, then storage equipment will have to be installed. Placement of multiplexers, switches, universal power supplies, and other supporting equipment will have to be planned in advance. Personnel access controls are critical to areas containing such equipment.

101.4 Summary

CCTV systems are by no means a guarantee of security, but the controlling effect they have on human behavior cannot be dismissed easily. The mere presence of a camera, regardless of whether it works, has proven to be invaluable in the security industry as a deterrent.

Defense-in-depth is the mantra of the information security industry. It is the convergence of many layers of protection that will ultimately provide the highest level of assurance, and the physical security of a data processing facility is often the weakest layer. There is little else that can compare to a properly implemented CCTV system to provide security of the facility, data, and people, as well as enforcement of policies and procedures.

102

Types of Information Security Controls

Harold F. Tipton

Security is generally defined as the freedom from danger or as the condition of safety. Computer security, specifically, is the protection of data in a system against unauthorized disclosure, modification, or destruction and protection of the computer system itself against unauthorized use, modification, or denial of service. Because certain computer security controls inhibit productivity, security is typically a compromise toward which security practitioners, system users, and system operations and administrative personnel work to achieve a satisfactory balance between security and productivity.

Controls for providing information security can be physical, technical, or administrative. These three categories of controls can be further classified as either preventive or detective. Preventive controls attempt to avoid the occurrence of unwanted events, whereas detective controls attempt to identify unwanted events after they have occurred. Preventive controls inhibit the free use of computing resources and therefore can be applied only to the degree that the users are willing to accept. Effective security awareness programs can help increase users' level of tolerance for preventive controls by helping them understand how such controls enable them to trust their computing systems. Common detective controls include audit trails, intrusion detection methods, and checksums.

Three other types of controls supplement preventive and detective controls. They are usually described as deterrent, corrective, and recovery. Deterrent controls are intended to discourage individuals from intentionally violating information security policies or procedures. These usually take the form of constraints that make it difficult or undesirable to perform unauthorized activities or threats of consequences that influence a potential intruder to not violate security (e.g., threats ranging from embarrassment to severe punishment).

Corrective controls either remedy the circumstances that allowed the unauthorized activity or return conditions to what they were before the violation. Execution of corrective controls could result in changes to existing physical, technical, and administrative controls. Recovery controls restore lost computing resources or capabilities and help the organization recover monetary losses caused by a security violation.

Deterrent, corrective, and recovery controls are considered to be special cases within the major categories of physical, technical, and administrative controls; they do not clearly belong in either preventive or detective categories. For example, it could be argued that deterrence is a form of prevention because it can cause an intruder to turn away; however, deterrence also involves detecting violations, which may be what the intruder fears most. Corrective controls, on the other hand, are not preventive or detective, but they are clearly linked with technical controls when anti-viral software eradicates a virus or with administrative controls when backup procedures enable restoring a damaged database. Finally, recovery controls are neither preventive nor detective but are included in administrative controls as disaster recovery or contingency plans.

Because of these overlaps with physical, technical, and administrative controls, the deterrent, corrective, and recovery controls are not discussed further in this chapter. Instead, the preventive and detective controls within the three major categories are examined.

102.1 Physical Controls

Physical security is the use of locks, security guards, badges, alarms, and similar measures to control access to computers, related equipment (including utilities), and the processing facility itself. In addition, measures are required for protecting computers, related equipment, and their contents from espionage, theft, and destruction or damage by accident, fire, or natural disaster (e.g., floods and earthquakes).

102.1.1 Preventive Physical Controls

Preventive physical controls are employed to prevent unauthorized personnel from entering computing facilities (i.e., locations housing computing resources, supporting utilities, computer hard copy, and input data media) and to help protect against natural disasters. Examples of these controls include:

- Backup files and documentation
- Fences
- Security guards
- Badge systems
- Double door systems
- Locks and keys
- Backup power
- Biometric access controls
- Site selection
- Fire extinguishers

102.1.1.1 Backup Files and Documentation

Should an accident or intruder destroy active data files or documentation, it is essential that backup copies be readily available. Backup files should be stored far enough away from the active data or documentation to avoid destruction by the same incident that destroyed the original. Backup material should be stored in a secure location constructed of noncombustible materials, including two-hour-rated fire walls. Backups of sensitive information should have the same level of protection as the active files of this information; it is senseless to provide tight security for data on the system but lax security for the same data in a backup location.

102.1.1.2 Fences

Although fences around the perimeter of the building do not provide much protection against a determined intruder, they do establish a formal no-trespassing line and can dissuade the simply curious person. Fences should have alarms or should be under continuous surveillance by guards, dogs, or TV monitors.

102.1.1.3 Security Guards

Security guards are often stationed at the entrances of facilities to intercept intruders and ensure that only authorized persons are allowed to enter. Guards are effective in inspecting packages or other hand-carried items to ensure that only authorized, properly described articles are taken into or out of the facility. The effectiveness of stationary guards can be greatly enhanced if the building is wired with appropriate electronic detectors with alarms or other warning indicators terminating at the guard station. In addition, guards are often used to patrol unattended spaces inside buildings after normal working hours to deter intruders from obtaining or profiting from unauthorized access.

102.1.1.4 Badge Systems

Physical access to computing areas can be effectively controlled using a badge system. With this method of control, employees and visitors must wear appropriate badges whenever they are in access-controlled areas. Badge-reading systems programmed to allow entrance only to authorized persons can then easily identify intruders.

102.1.1.5 Double Door Systems

Double door systems can be used at entrances to restricted areas (e.g., computing facilities) to force people to identify themselves to the guard before they can be released into the secured area. Double doors are an excellent way to prevent intruders from following closely behind authorized persons and slipping into restricted areas.

102.1.1.6 Locks and Keys

Locks and keys are commonly used for controlling access to restricted areas. Because it is difficult to control copying of keys, many installations use cipher locks (i.e., combination locks containing buttons that open the lock when pushed in the proper sequence). With cipher locks, care must be taken to conceal which buttons are being pushed to avoid a compromise of the combination.

102.1.1.7 Backup Power

Backup power is necessary to ensure that computer services are in a constant state of readiness and to help avoid damage to equipment if normal power is lost. For short periods of power loss, backup power is usually provided by batteries. In areas susceptible to outages of more than 15 to 30 minutes, diesel generators are usually recommended.

102.1.1.8 Biometric Access Controls

Biometric identification is a more-sophisticated method of controlling access to computing facilities than badge readers, but the two methods operate in much the same way. Biometrics used for identification include fingerprints, handprints, voice patterns, signature samples, and retinal scans. Because biometrics cannot be lost, stolen, or shared, they provide a higher level of security than badges. Biometric identification is recommended for high-security, low-traffic entrance control.

102.1.1.9 Site Selection

The site for the building that houses the computing facilities should be carefully chosen to avoid obvious risks. For example, wooded areas can pose a fire hazard, areas on or adjacent to an earthquake fault can be dangerous and sites located in a flood plain are susceptible to water damage. In addition, locations under an aircraft approach or departure route are risky, and locations adjacent to railroad tracks can be susceptible to vibrations that can precipitate equipment problems.

102.1.1.10 Fire Extinguishers

The control of fire is important to prevent an emergency from turning into a disaster that seriously interrupts data processing. Computing facilities should be located far from potential fire sources (e.g., kitchens or cafeterias) and should be constructed of noncombustible materials. Furnishings should also be noncombustible. It is important that appropriate types of fire extinguishers be conveniently located for easy access. Employees must be trained in the proper use of fire extinguishers and in the procedures to follow should a fire break out.

Automatic sprinklers are essential in computer rooms and surrounding spaces and when expensive equipment is located on raised floors. Sprinklers are usually specified by insurance companies for the protection of any computer room that contains combustible materials. However, the risk of water damage to computing equipment is often greater than the risk of fire damage. Therefore, carbon dioxide extinguishing systems were developed; these systems flood an area threatened by fire with carbon dioxide, which suppresses fire by removing oxygen from the air. Although carbon dioxide does not cause water damage, it is potentially lethal to people in the area and is now used only in unattended areas.

Current extinguishing systems flood the area with halon, which is usually harmless to equipment and less dangerous to personnel than carbon dioxide. At a concentration of about 10 percent, halon extinguishes fire and can be safely breathed by humans. However, higher concentrations can eventually be a health hazard. In addition, the blast from releasing halon under pressure can blow loose objects around and can be a danger to equipment and personnel. For these reasons and because of the high cost of halon, it is typically used only under raised floors in computer rooms. Because it contains chlorofluorocarbons, it will soon be phased out in favor of a gas that is less hazardous to the environment.

102.1.2 Detective Physical Controls

Detective physical controls warn protective services personnel that physical security measures are being violated. Examples of these controls include:

- Motion detectors
- Smoke and fire detectors
- Closed-circuit television monitors
- Sensors and alarms

102.1.2.1 Motion Detectors

In computing facilities that usually do not have people in them, motion detectors are useful for calling attention to potential intrusions. Motion detectors must be constantly monitored by guards.

102.1.2.2 Fire and Smoke Detectors

Fire and smoke detectors should be strategically located to provide early warning of a fire. All fire detection equipment should be tested periodically to ensure that it is in working condition.

102.1.2.3 Closed-Circuit Television Monitors

Closed-circuit televisions can be used to monitor the activities in computing areas where users or operators are frequently absent. This method helps detect individuals behaving suspiciously.

102.1.2.4 Sensors and Alarms

Sensors and alarms monitor the environment surrounding the equipment to ensure that air and cooling water temperatures remain within the levels specified by equipment design. If proper conditions are not maintained, the alarms summon operations and maintenance personnel to correct the situation before a business interruption occurs.

102.2 Technical Controls

Technical security involves the use of safeguards incorporated in computer hardware, operations or applications software, communications hardware and software, and related devices. Technical controls are sometimes referred to as logical controls.

102.2.1 Preventive Technical Controls

Preventive technical controls are used to prevent unauthorized personnel or programs from gaining remote access to computing resources. Examples of these controls include:

- Access control software
- Antivirus software
- Library control systems
- Passwords
- Smart cards
- Encryption
- Dial-up access control and callback systems

102.2.1.1 Access Control Software

The purpose of access control software is to control sharing of data and programs between users. In many computer systems, access to data and programs is implemented by access control lists that designate which users are allowed access. Access control software provides the ability to control access to the system by establishing that only registered users with an authorized log-on ID and password can gain access to the computer system.

After access to the system has been granted, the next step is to control access to the data and programs residing in the system. The data or program owner can establish rules that designate who is authorized to use the data or program.

102.2.1.2 Anti-Virus Software

Viruses have reached epidemic proportions throughout the microcomputing world and can cause processing disruptions and loss of data as well as significant loss of productivity while cleanup is conducted. In addition, new viruses are emerging at an ever-increasing rate—currently about one every 48 hours. It is recommended that anti-virus software be installed on all microcomputers to detect, identify, isolate, and eradicate viruses. This software must be updated frequently to help fight new viruses. In addition, to help ensure that viruses are intercepted as early as possible, anti-virus software should be kept active on a system, not used intermittently at the discretion of users.

102.2.1.3 Library Control Systems

These systems require that all changes to production programs be implemented by library control personnel instead of the programmers who created the changes. This practice ensures separation of duties, which helps prevent unauthorized changes to production programs.

102.2.1.4 Passwords

Passwords are used to verify that the user of an ID is the owner of the ID. The ID-password combination is unique to each user and therefore provides a means of holding users accountable for their activity on the system.

Fixed passwords that are used for a defined period of time are often easy for hackers to compromise; therefore, great care must be exercised to ensure that these passwords do not appear in any dictionary. Fixed passwords are often used to control access to specific databases. In this use, however, all persons who have authorized access to the database use the same password; therefore, no accountability can be achieved.

Currently, dynamic or one-time passwords, which are different for each log-on, are preferred over fixed passwords. Dynamic passwords are created by a token that is programmed to generate passwords randomly.

102.2.1.5 Smart Cards

Smart cards are usually about the size of a credit card and contain a chip with logic functions and information that can be read at a remote terminal to identify a specific user's privileges. Smart cards now carry prerecorded, usually encrypted access control information that is compared with data that the user provides (e.g., a personal ID number or biometric data) to verify authorization to access the computer or network.

102.2.1.6 Encryption

Encryption is defined as the transformation of plaintext (i.e., readable data) into ciphertext (i.e., unreadable data) by cryptographic techniques. Encryption is currently considered to be the only sure way of protecting data from disclosure during network transmissions.

Encryption can be implemented with either hardware or software. Software-based encryption is the least expensive method and is suitable for applications involving low-volume transmissions; the use of software for large volumes of data results in an unacceptable increase in processing costs. Because there is no overhead associated with hardware encryption, this method is preferred when large volumes of data are involved.

102.2.1.7 Dial-Up Access Control and Callback Systems

Dial-up access to a computer system increases the risk of intrusion by hackers. In networks that contain personal computers or are connected to other networks, it is difficult to determine whether dial-up access is available or not because of the ease with which a modem can be added to a personal computer to turn it into a dial-up access point. Known dial-up access points should be controlled so that only authorized dial-up users can get through.

Currently, the best dial-up access controls use a microcomputer to intercept calls, verify the identity of the caller (using a dynamic password mechanism), and switch the user to authorized computing resources as requested. Previously, call-back systems intercepted dial-up callers, verified their authorization and called them back at their registered number, which at first proved effective; however, sophisticated hackers have learned how to defeat this control using call-forwarding techniques.

102.2.2 Detective Technical Controls

Detective technical controls warn personnel of violations or attempted violations of preventive technical controls. Examples of these include audit trails and intrusion detection expert systems, which are discussed in the following sections.

102.2.2.1 Audit Trails

An audit trail is a record of system activities that enables the reconstruction and examination of the sequence of events of a transaction, from its inception to output of final results. Violation reports present significant, security-oriented events that may indicate either actual or attempted policy transgressions reflected in the audit trail. Violation reports should be frequently and regularly reviewed by security officers and database owners to identify and investigate successful or unsuccessful unauthorized accesses.

102.2.2.2 Intrusion Detection Systems

These expert systems track users (on the basis of their personal profiles) while they are using the system to determine whether their current activities are consistent with an established norm. If not, the user's session can be terminated or a security officer can be called to investigate. Intrusion detection can be especially effective in cases in which intruders are pretending to be authorized users or when authorized users are involved in unauthorized activities.

102.3 Administrative Controls

Administrative, or personnel, security consists of management constraints, operational procedures, accountability procedures, and supplemental administrative controls established to provide an acceptable level of protection for computing resources. In addition, administrative controls include procedures established to ensure that all personnel who have access to computing resources have the required authorizations and appropriate security clearances.

102.3.1 Preventive Administrative Controls

Preventive administrative controls are personnel-oriented techniques for controlling people's behavior to ensure the confidentiality, integrity, and availability of computing data and programs. Examples of preventive administrative controls include:

- Security awareness and technical training
- Separation of duties
- Procedures for recruiting and terminating employees
- Security policies and procedures
- Supervision
- Disaster recovery, contingency, and emergency plans
- User registration for computer access

102.3.1.1 Security Awareness and Technical Training

Security awareness training is a preventive measure that helps users to understand the benefits of security practices. If employees do not understand the need for the controls being imposed, they may eventually circumvent them and thereby weaken the security program or render it ineffective.

Technical training can help users prevent the most common security problem—errors and omissions—as well as ensure that they understand how to make appropriate backup files and detect and control viruses. Technical training in the form of emergency and fire drills for operations personnel can ensure that proper action will be taken to prevent such events from escalating into disasters.

102.3.1.2 Separation of Duties

This administrative control separates a process into component parts, with different users responsible for different parts of the process. Judicious separation of duties prevents one individual from obtaining control of an entire process and forces collusion with others in order to manipulate the process for personal gain.

102.3.1.3 Recruitment and Termination Procedures

Appropriate recruitment procedures can prevent the hiring of people who are likely to violate security policies. A thorough background investigation should be conducted, including checking on the applicant's criminal history and references. Although this does not necessarily screen individuals for honesty and integrity, it can help identify areas that should be investigated further.

Three types of references should be obtained: (1) employment, (2) character, and (3) credit. Employment references can help estimate an individual's competence to perform, or be trained to perform, the tasks required on the job. Character references can help determine such qualities as trustworthiness, reliability, and ability to get along with others. Credit references can indicate a person's financial habits, which in turn can be an indication of maturity and willingness to assume responsibility for one's own actions.

In addition, certain procedures should be followed when any employee leaves the company, regardless of the conditions of termination. Any employee being involuntarily terminated should be asked to leave the premises immediately upon notification, to prevent further access to computing resources. Voluntary terminations may be handled differently, depending on the judgment of the employee's supervisors, to enable the employee to complete work in process or train a replacement.

All authorizations that have been granted to an employee should be revoked upon departure. If the departing employee has the authority to grant authorizations to others, these other authorizations should also be reviewed. All keys, badges, and other devices used to gain access to premises, information, or equipment should be retrieved from the departing employee. The combinations of all locks known to a departing employee should be changed immediately. In addition, the employee's log-on IDs and passwords should be canceled, and the related active and backup files should be either deleted or reassigned to a replacement employee.

Any special conditions to the termination (e.g., denial of the right to use certain information) should be reviewed with the departing employee; in addition, a document stating these conditions should be signed by the employee. All terminations should be routed through the computer security representative for the facility where the terminated employee works to ensure that all information system access authority has been revoked.

102.3.1.4 Security Policies and Procedures

Appropriate policies and procedures are key to the establishment of an effective information security program. Policies and procedures should reflect the general policies of the organization as regards the protection of information and computing resources. Policies should cover the use of computing resources, marking of sensitive information, movement of computing resources outside the facility, introduction of personal computing equipment and media into the facility, disposal of sensitive waste, and computer and data security incident reporting. Enforcement of these policies is essential to their effectiveness.

102.3.1.5 Supervision

Often, an alert supervisor is the first person to notice a change in an employee's attitude. Early signs of job dissatisfaction or personal distress should prompt supervisors to consider subtly moving the employee out of a critical or sensitive position.

Supervisors must be thoroughly familiar with the policies and procedures related to the responsibilities of their department. Supervisors should require that their staff members comply with pertinent policies and procedures and should observe the effectiveness of these guidelines. If the objectives of the policies and procedures can be accomplished more effectively, the supervisor should recommend appropriate improvements. Job assignments should be reviewed regularly to ensure that an appropriate separation of duties is maintained, that employees in sensitive positions are occasionally removed from a complete processing cycle without prior announcement, and that critical or sensitive jobs are rotated periodically among qualified personnel.

102.3.1.6 Disaster Recovery, Contingency, and Emergency Plans

The disaster recovery plan is a document containing procedures for emergency response, extended backup operations, and recovery should a computer installation experience a partial or total loss of computing resources or physical facilities (or of access to such facilities). The primary objective of this plan, used in conjunction with the contingency plans, is to provide reasonable assurance that a computing installation can recover from disasters, continue to process critical applications in a degraded mode, and return to a normal mode of operation within a reasonable time. A key part of disaster recovery planning is to provide for processing at an alternative site during the time that the original facility is unavailable.

Contingency and emergency plans establish recovery procedures that address specific threats. These plans help prevent minor incidents from escalating into disasters. For example, a contingency plan might provide a set of procedures that defines the condition and response required to return a computing capability to nominal operation; an emergency plan might be a specific procedure for shutting down equipment in the event of a fire or for evacuating a facility in the event of an earthquake.

102.3.1.7 User Registration for Computer Access

Formal user registration ensures that all users are properly authorized for system and service access. In addition, it provides the opportunity to acquaint users with their responsibilities for the security of computing resources and to obtain their agreement to comply with related policies and procedures.

102.3.2 Detective Administrative Controls

Detective administrative controls are used to determine how well security policies and procedures are complied with, to detect fraud, and to avoid employing persons that represent an unacceptable security risk. This type of control includes:

- Security reviews and audits
- Performance evaluations
- Required vacations
- Background investigations
- Rotation of duties

102.3.2.1 Security Reviews and Audits

Reviews and audits can identify instances in which policies and procedures are not being followed satisfactorily. Management involvement in correcting deficiencies can be a significant factor in obtaining user support for the computer security program.

102.3.2.2 Performance Evaluations

Regularly conducted performance evaluations are an important element in encouraging quality performance. In addition, they can be an effective forum for reinforcing management's support of information security principles.

102.3.2.3 Required Vacations

Tense employees are more likely to have accidents or make errors and omissions while performing their duties. Vacations contribute to the health of employees by relieving the tensions and anxieties that typically develop from long periods of work. In addition, if all employees in critical or sensitive positions are forced to take vacations, there will be less opportunity for an employee to set up a fraudulent scheme that depends on the employee's presence (e.g., to maintain the fraud's continuity or secrecy). Even if the employee's presence is not necessary to the scheme, required vacations can be a deterrent to embezzlement because the employee may fear discovery during his or her absence.

102.3.2.4 Background Investigations

Background investigations may disclose past performances that might indicate the potential risks of future performance. Background investigations should be conducted on all employees being considered for promotion or transfer into a position of trust; such investigations should be completed before the employee is actually placed in a sensitive position. Job applicants being considered for sensitive positions should also be investigated for potential problems. Companies involved in government-classified projects should conduct these investigations while obtaining the required security clearance for the employee.

102.3.2.5 Rotation of Duties

Like required vacations, rotation of duties (i.e., moving employees from one job to another at random intervals) helps deter fraud. An additional benefit is that as a result of rotating duties, employees are cross-trained to perform each other's functions in case of illness, vacation, or termination.

Physical controls

Preventive

- Backup files and documentation
- Fences
- Security guards
- Badge systems
- Locks and keys
- Backup power
- Biometric access controls
- Site selection
- Fire extinguishers

Detective

- Motion detectors
- Smoke and fire detectors
- Closed-circuit television monitoring
- Sensors and alarms

Technical controls

Preventive

- Access control software
- Anti-virus software
- Library control systems
- Passwords
- Backup power
- Smart cards
- Encryption
- Dial-up access control and callback systems

Detective

- Audit trails
- Intrusion-detection expert systems

Administrative controls

Preventive

- Security awareness and technical training
- Separation of duties
- Procedures for recruiting and terminating employees
- Security policies and procedures
- Supervision
- Disaster recovery and contingency plans
- User registration for computer access

Detective

- Security reviews and audits
- Performance evaluations
- Required vacations
- Background investigations
- Rotation of duties

EXHIBIT 102.1 Information security controls.

102.4 Summary

Information security controls can be classified as physical, technical, or administrative. These are further divided into preventive and detective controls. Exhibit 102.1 lists the controls discussed in this chapter.

The organization's security policy should be reviewed to determine the confidentiality, integrity, and availability needs of the organization. The appropriate physical, technical, and administrative controls can then be selected to provide the required level of information protection, as stated in the security policy.

A careful balance between preventive and detective control measures is needed to ensure that users consider the security controls reasonable and to ensure that the controls do not overly inhibit productivity. The combination of physical, technical, and administrative controls best suited for a specific computing environment can be identified by completing a quantitative risk analysis. Because this is usually an expensive, tedious, and subjective process, however, an alternative approach—referred to as meeting the standard of due care—is often used. Controls that meet a standard of due care are those that would be considered prudent by most organizations in similar circumstances or environments. Controls that meet the standard of due care generally are readily available for a reasonable cost and support the security policy of the organization; they include, at the least, controls that provide individual accountability, auditability, and separation of duties.

103

Workplace Violence: Event Characteristics and Prevention

George Richards

103.1 Introduction

There is little debate that workplace violence is an issue that deserves considerable attention from public and private executives, policy makers, and law enforcement. Homicide, the third-leading cause of workplace fatalities, emphasizes that point. According to the Bureau of Labor Statistics Census of Fatal Occupational Injuries (CFOI), there were 639 homicides in the workplace during 2001 and 8786 total fatalities in the workplace that same year.

When depicted through the electronic media, scenes of workplace violence elicit responses of shock from viewers. There are high-risk occupations in which a certain number of accidents and fatalities, while considered tragic, are accepted. Members of the law enforcement, fire service, and the military communities rank high on this list. However, when we hear of someone in a "civilian" occupation, a secretary, clerk, or factory worker injured by a disturbed co-worker or client, it becomes more difficult to understand the circumstances that led to this type of victimization.

103.2 Environmental Conditions

The daily activities of most people can be separated into three categories: home, community, and work. Victimizations do occur at home. Home intrusions to burglarize or assault residents happen frequently. Consequentially, the specter of domestic violence looms most specifically in residences. However, compared to other locations, the home is a relatively safe place. The chief reason for this is that people are intimately aware of their home environments.

Strangers are recognized and either consciously or subconsciously placed in a category of wariness. Changes to the physical structure of the home that pose security risks, such as a porch light being out or a loose hinge, are noticed and corrected by the homeowner. The time we spend in our homes and neighborhoods gives us a sense of community. Thus, any alterations to that community are noticed.

Interaction with the community is necessary. Shopping for groceries, trips to the bank or pharmacy, and dining out are routine activities. While victimization does occur in every community, it is reduced through a natural wariness we have to unfamiliar and infrequent surroundings. If we see a stranger in a parking lot, it is normal to give that person a wider berth than we would someone with whom we are acquainted. Our protection "antennae" become more attuned to the environment in which we find ourselves.

The work environment, however, differs from both home and community milieus. Few people work in solitude. Managers and co-workers are generally an integral part of our occupations. Depending on the type of job a person has, interaction with clients or customers is a customary part of one's tasks. The difficulty with determining personal risk in the work environment hinges on the time we spend there surrounded by people with whom we are familiar.

Most people spend approximately 40 hours per week at their jobs. This is usually spread over a five-day workweek. Consequently, we may become desensitized to our surroundings from the sheer amount of time we spend there. The people we work with and serve become familiar. That familiarity can breed an assumption of safety that may not be accurate. The question centers on how well we know our co-workers. Work is not the only environment that can create stress. An unhappy marriage, financial pressures, and illness are only a few of the stressors that are common in people's lives. Braverman (1999, p. 21) contends that "Violence is the outcome of unbearable stress." There are work-related stressors as well as the aforementioned personal stressors. Among these is the loss of a job, demotion, reduction in pay, or a poor personal relationship with co-workers or supervisors. A belief that your abilities and job performance are marginalized can result in a poor self-image, which for some people may be unbearable. The desire to strike out at the person whom you blame for this feeling can be overwhelming.

In addition to working with someone who may be volatile, the well-adjusted employee may have relationships with people who are unstable. The dilemma of domestic violence often spills over into the workplace. It is estimated that one out of four women will be physically abused by a romantic partner in her lifetime (Glazer, 1993). While the victim of abuse is the target of the perpetrator's rage, those around that person may also suffer from the assault.

We simply do not know the emotional baggage people bring into the workplace. People have problems. Some know how to deal with these issues; others do not. It is out of concern for the latter that workplace violence poses a concern for law enforcement and public service.

103.3 Typology of Workplace Violence

The most commonly used classification system to categorize incidents of workplace violence is the one constructed by the California Occupational Safety and Health Administration (CalOSHA; State of California Department of Industrial Relations, 1995). According to CalOSHA, there are three types of workplace violence. These categorizations are based on the relationship of the offender to the victim and type of place where the incident occurred.

In Type I incidents, the offender does not have a legitimate relationship with the employees of the business or the business itself. A common motive demonstrated in this category is robbery. For example, the perpetrator enters a convenience store late at night with the intent of robbing the establishment. During the commission of the crime, the clerk on duty is injured or killed. Types of businesses with high rates of Type I incidences include convenience stores and liquor stores. Occupations especially at risk for Type I incidents are security guards, store clerks, custodians, and cab drivers. Other than identifying that a specific type of business such as a liquor store or convenience store is at risk for Type I workplace violence, there is little that can be done to predict victimization. Targets are chosen either because they are convenient or are perceived to be less protected than similar businesses.

Type II acts are commonly attributed to people who have some form of relationship with an employee. According to Braverman (1999), Type II incidents make up the largest proportion of serious, nonfatal injuries. An example of a Type II incident is the assault of a health-care worker. Barab (1996) stated that female health-care workers suffer a higher rate of nonfatal assaults than any other type of occupation. Type II incidents also account for such incidences as women being stalked, harassed, and assaulted in the workplace by romantic or former romantic partners.

Type III covers violence between employee events. Type III events, while serious, account for roughly 6 percent of workplace fatalities (Barab 1996). Consequentially, most incidents of Type III violence come in the form of threats, not actual assaults. The threat of Type III violence usually generates the greatest fear among the workforce. Risk from workplace violence can also be categorized in two forms: external and internal. The external threat is much easier to address. People can be barred from property through protection orders. Additional physical and procedural measures can be taken to insulate workers at risk from clients and the general public. The internal threat is much more difficult to address. The worker who believes he is at risk from a co-worker lives in an environment of fear. The closer the proximity of possible perpetrator to victim increases the convenience and likelihood of victimization.

103.4 Homicide in the Workplace

The image of a sheet-covered body being removed from a factory or office is a powerful one. The mass media plays an important role in informing the public of possible risks of victimization. However, the reporting of especially heinous and sensationalized events may serve to increase attention on the unusual and macabre. Learning from the college courses and workshops I have taught on workplace violence, I have found that the fear of homicide, not assault, is the chief concern of my students. While the fear is real, the actual risk of becoming a fatality in the workplace is a negligible one and is largely dependent on the career choice people make.

Workers most susceptible to homicide in the workplace are those who deal in cash transactions. Other factors that increase the risk of victimization are working alone, employment in high-crime areas, and guarding valuable property (Sygnatur and Toscano, 2000). Police are especially susceptible to workplace homicide because their mission of order maintenance routinely brings them into contact with violent individuals. Of any occupation, it was found in the 1998 Census of Fatal Occupational Injuries (CFOI) that cab drivers and chauffeurs are the most likely to be murdered while performing their work. This was followed by law enforcement, private security officers, managers, and truck drivers. Robbery, not homicide, was the motivation behind truck driver fatalities.

The 1998 CFOI also revealed workplace violence incidents in retail trade and services were responsible for nearly 60 percent of fatalities. Grocery stores, restaurants and bars, and service stations were among those businesses that suffered from this type of victimization. Violence in the public sector accounted for 13 percent of the sample. This category accounted for acts against law enforcement, social workers, and emergency service personnel.

A common misconception about workplace violence is that the majority of workplace homicides are committed late at night or early in the morning. The 1998 CFOI found that there were roughly the same number of homicides committed between 8:00 a.m. and noon as there were between 8:00 p.m. and midnight. The period with the fewest homicides perpetrated was between midnight and 8:00 a.m.

The 1998 CFOI found that men were more likely than women to be victims of homicide in the workplace. While women represent nearly half of the national workforce, they accounted for only 23 percent of the victims of workplace homicide. The CFOI also discovered that minorities faced a higher risk of becoming victims of homicide. Synatur and Toscano (2000) held that this was due to their disproportionate share of occupations in which workplace homicide risk is relatively high, such as cab drivers and small business managers.

103.5 Perpetrator Profile

According to Holmes (1989), profiling the perpetrator of any crime is a dangerous proposition. Not everyone agrees that profiling is a useful weapon in the investigator's arsenal. It is not based on science, but rather on a combination of the profiler's experience, training, and intuition. "That is, he develops a 'feel' for the crime" (Holmes, 1989, p. 14). Using this approach, a criminological profile can better be described as an art, rather than a science.

Braverman (1999) warns against becoming enamored with profiling as a useful predictor of violence. He contends that profiles are generally too broad to be of any utility to the investigator or manager. "What precisely do you do once you have identified all the socially isolated divorced white males in your workforce who are preoccupied with guns and tend to blame other people for their problems?" (Braverman, 1999, p. 2). While it is natural to look for the "quick fix" in identifying risks, dependence on the profile could engender a false sense of security.

Holmes (1989) states there are three goals in the criminal profile. The first goal is to provide a social and psychological assessment of the offender. This section of the profile should discuss the basic elements of the perpetrator's personality. Among these would be predictions as to the race, age, occupation, education, and marital status of the offender. This goal serves to focus the attention of the investigating agency.

The second goal, according to Holmes (1989), is a psychological evaluation of items found in the offender's possession. For example, if a person acted in a particularly violent manner during a sexual assault, items found such as pictures of the victim or pornography could be used to explain the motivations of the subject. The third goal is to provide interviewing strategies. As no two people are alike, no two suspects will respond in the same fashion while being interviewed. A psychological profile of how the suspect will likely respond under questioning will guide investigators in phrasing their questions.

Heskett (1996) agrees with Holmes' (1989) contention that profiling is a risky endeavor. "Stereotyping employees into narrowly defined classifications could establish a propensity to look for employees who fit into the profiles and ignore threats or intimidations made by others" (Heskett, 1996, p. 43). Yet, from case studies of workplace violence incidents, a profile into which a considerable proportion of offenders fit can be constructed.

Heskett (1996) paints a broad picture of the workplace violence offender. They are typically white males between the ages of 25 and 45. Their employment can best be described as long-term. Consequently, it is often found afterward that they have a strong, personal connection with their occupation. Heskett (1996, p. 46) developed the following list of warning signs of possible violent behavior from an analysis of case histories:

- Threats of physical violence or statements about getting even
- History of violence against co-workers, family members, other people, or animals
- History of failed relationships with family members, spouses, friends, or co-workers
- Lack of a social support system (i.e., friends and family)
- Paranoia and distrust of others
- Blaming others for life's failures and problems
- Claims of strange events, such as visits from UFOs
- Alcohol or drug abuse on or off the job
- Frequent tardiness and absenteeism
- Concentration, performance, or safety-related problems
- Carrying or concealing a weapon at work (security officers, police officers, etc. excepted)
- Obsession with weapons, often exotic weapons
- Fascination with stories of violence, especially those that happen at a workplace, such as frequent discussions of the post office slayings

- History of intimidation against other people
- High levels of frustration, easily angered
- Diminished self-esteem
- Inability to handle stressful situations
- Romantic obsession with a co-worker

Once again, the reader must be cautioned that while this profile may help construct a mental image of a possible perpetrator, the majority of items on this list do not constitute criminal behavior. Acting strange or eccentric is not a crime. Likewise, while making people uncomfortable may not contribute to an ideal work environment, it is not a criminal act.

103.6 Strategies for Prevention

Utilizing Crime Prevention Through Environmental Design (CPTED) strategies to alter the physical environment of the business can be an effective means of reducing risk. This could entail changing the location of cash registers or installing bullet-resistant barriers. Other means of physical changes could be measures to improve the visibility of employees to other employees and the general public by taking down signs or posters in the front of stores and improving lighting around the perimeter of the building. Points of ingress and egress from the facility should be controlled. While this is obviously more difficult in a retail setting, persons entering the building should be monitored whenever possible. Security devices for access control include closed-circuit television (CCTV), alarms, biometric identification systems, and two-way mirrors.

Personnel guidelines for screening visitors and notifying security should be developed and the information disseminated throughout the entire facility. Standards of behavior should be articulated. Any deviation from acceptable conduct in the workplace should be addressed as soon as possible. This “zero tolerance” for inappropriate behavior can serve to reassure employees that management is willing to address issues pertaining to their dignity and safety. Training in how to respond to a workplace violence situation may mitigate the harm done by the act.

One of the most effective means of preventing workplace violence is conducting a thorough preemployment background investigation. While former employers are often reticent to discuss specific items in an applicant’s background out of fear of litigation, the seasoned investigator can “ferret out” information pertaining to the applicant’s work ethic and reliability. Criminal records, credit histories, personal references, and school records are excellent resources for determining an applicant’s level of responsibility.

103.7 Conclusion

Workplace violence is a concern for both employees and managers of public and private agencies. While there is no dependable profile of the potential perpetrator, businesses and other organizations are not powerless to reduce the risk of possible victimization. Tragedy can be averted by acting in a proactive manner in order to alert and train employees. Diligence on the part of management in promoting a safe work environment serves to create an environment of greater satisfaction on the part of the employee.

Physical Security: The Threat after September 11, 2001

Jaymes Williams

The day that changed everything began for me at 5:50 a.m. I woke up and turned on the television to watch some news. This was early Tuesday morning, September 11, 2001. My local news station had just interrupted its regular broadcast and switched over to CNN, so right away I knew something important had happened. I learned an airliner had crashed into one of the towers of the World Trade Center in New York.

In disbelief, I made my way to the kitchen and poured myself a cup of coffee. I returned to the television and listened to journalists and airline experts debate the likely cause of this event. I thought to myself, "there isn't a cloud in the sky; how could an aircraft accidentally hit such a large structure?" Knowing, but not wanting to accept the answer, I listened while hoping the television would give me a better one.

While waiting for the answer that never came, I noticed an aircraft come from the right side of the screen. It appeared to be going behind the towers of the Trade Center, or perhaps I was only hoping it would. This was one of those instances where time appeared to dramatically slow down. In the split second it took to realize the plane should have already come out from behind the towers, the fireball burst out the side of the tower instead. It was now undeniable. This was no accident.

Later, after getting another cup of coffee, I returned to the television to see only smoke; the kind of smoke you only see when a building is imploded to make way for new construction. To my horror, I knew a tower had collapsed. Then, while the journalists were recovering from the shock and trying to maintain their on-air composure, they showed the top of the remaining tower. For some reason, it appeared that the camera had started to pan up. I started to feel a bit of vertigo. Then, once again, a horrible realization struck. The camera was not going up; the building was going down. Within the span of minutes, the World Trade Center was no more; and Manhattan was totally obscured by smoke. I was in total disbelief. This had to be a movie; but it was not. The mind's self-defenses take over when things occur that it cannot fathom, and I felt completely numb. I had witnessed the deaths of untold thousands of people on live TV. Although I live 3000 miles away, it might as well have happened down the street. The impact was the same. Then the news of the crash at the Pentagon came, followed by the crash of the aircraft in Pennsylvania.

I tried to compose myself to go to work, although work seemed quite unimportant at the moment. Somehow, I put myself together and made my way out the door. On the way to work, I thought to myself that this must be the Pearl Harbor of my generation. And, I realized, my country was probably at war—but with whom?

The preceding is my recollection of the morning of September 11. This day has since become one of those days in history where we all remember where we were and what we were doing. Although we all have our own individual experiences from that horrible day, some people more affected than others, these individual experiences all form a collective experience that surprised and shocked us all.

Security practitioners around the world, and especially in the United States, have to ask themselves some questions. Can this happen here? Is my organization a potential target? Now that a War on Terrorism has begun as a result of the September 11 attacks, the answer to both of these questions, unfortunately, is "yes." However, there are some things that can be done to lessen the risk. This chapter examines why the risk of terrorism has increased, what types of organizations or facilities are at higher risk, and what can be done to lessen that risk.

104.1 Why Is America a Target?

> Just because you're not paranoid doesn't mean they're not out to get you!
>
> **—From the U.S. Air Force Special Operations Creed**

There are many reasons terrorist groups target America. One reason is ideological differences. There are nations or cultures that do not appreciate the freedom and tolerance espoused by Americans. America is inarguably the world's leading industrial power and capitalist state. There are people in the world who may view America as a robber baron nation and hate Americans because of our perceived wealth. Another reason is religious differences. There are religiously motivated groups that may despise America and the West because of perceived nonconformance with their religious values and faith. A further reason is the perception that the U.S. government has too much influence over the actions of other governments. Terrorists may think that, through acts of terror, the U.S. government will negotiate and ultimately comply with their demands. However, our government has repeatedly stated it will not negotiate with terrorists.

A final reason is that Americans are perceived as easy targets. The "open society" in America and many Western countries makes for easy movement and activities by terrorists. Whether performing in charitable organizations, businesses, in governmental capacities, or as tourists, Americans are all over the world. This makes targeting Americans quite easy for even relatively poorly trained terrorist groups.

U.S. military forces stationed around the world are seen as visible symbols of U.S. power and, as such, are also appealing targets to terrorists.

104.2 Why be Concerned?

Terrorism can be defined as the calculated use of violence, or threat of violence, to inculcate fear; intended to coerce or intimidate governments or societies in the pursuit of goals that are generally political, religious, or ideological. Some examples of terrorist objectives and tactics can be seen in Exhibit 104.1.

The increased threat of terrorism and cyber-terrorism is a new and important consideration for information security practitioners. Previously, physical security threats included such things as unauthorized access, crime, environmental conditions, inclement weather, earthquakes, etc. The events of September 11 have shown us exactly how vulnerable we are. One of the most important lessons we security practitioners can take from that day is to recognize the need to reevaluate our physical security practices to include terrorism. Adding terrorism to the mix necessitates some fundamental changes in the way we view traditional physical security. These changes need to include protective measures from terrorism.

Depending on the type of organization, it is quite possible that terrorists may target it. Whether they target facilities or offices for physical destruction or they select an organization for a cyber-strike, prudent information security practitioners will assume they have been targeted and plan accordingly.

104.3 Is Your Organization a Potential Target?

Many organizations may be potential targets of terrorists and have no idea they are even vulnerable. Government agencies, including federal, state, and local, and infrastructure companies may be primary targets. Other vulnerable organizations may be large multinational companies that market American products around the world and organizations located in well-known skyscrapers. Specific examples of these types of potential targets will not be named to avoid the possibility of placing them at higher risk. See Exhibit 104.2 for different types of potential targets.

EXHIBIT 104.1 Terrorist Objectives and Tactics

Examples of Terrorist Objectives
Attract publicity for the group's cause
Demonstrate the group's power
Show the existing government's lack of power
Extract revenge
Obtain logistic support
Cause a government to overreact
Common Terrorist Tactics
Assassination
Arson
Bombing
Hostage taking
Kidnapping
Hijacking or skyjacking
Seizure
Raids or attacks on facilities
Sabotage
Hoaxes
Use of special weapons
Environmental destruction
Use of technology

EXHIBIT 104.2 Potential Terrorist Targets

Government Agencies
U.S. federal agencies
U.S. military facilities
State governments
County governments
Local governments
Infrastructure
Energy
Transportation
Financial
Water
Internet
Medical
Location Based
Tall office buildings
National landmarks
Popular tourist destinations
Large events
Associated with America
Large corporations synonymous with the Western world
American or *U.S.* in the name
Companies that produce famous American brand products

104.4 Government Agencies

There are many terrorists who hate the U.S. government and those of many Western countries. In the minds of terrorists and their sympathizers, governments create the policies and represent the values with which they vehemently disagree. It does not take a rocket scientist, or an information security practitioner for that matter, to realize that agencies of the U.S. government are prime targets for terrorists. This, of course, also includes the U.S. military. Other Western countries, especially those supporting the United States in the War on Terrorism, may also find themselves targets of terrorists. State and local governments may also be at risk.

- *Infrastructure companies*. Companies that comprise the infrastructure also face an increased risk of terrorism. Not only may terrorists want to hurt the U.S. and Western governments, but they may also want to disrupt normal life and the economies of the Western world. Disrupting the flow of energy, travel, finance, and information is one such way to accomplish this. The medical sector is also included here. One has to now consider the previously unthinkable, look beyond our usual mindsets, and recognize that, because medical facilities have not previously been targeted, it is conceivable they could be targeted in the future.
- *Location-based targets*. There are also those targets that by their location or function are at risk. Just as the towers of the World Trade Center represented the power of the American economy to the September 11 terrorists, other landmarks can be interpreted as representing things uniquely American to those with hostile intent. Such landmarks can include skyscrapers in major cities or any of the various landmarks that represent American or Western interests. Popular tourist destinations or events with large numbers of people in attendance can also be at risk because they are either uniquely American/Western or simply because they are heavily populated.
- *Things that mean America*. There is another category to consider. This category has some overlap with the above categories but still deserves mention. Large corporations that represent America or the West to the rest of the world can also be targeted. This also includes companies whose products are sold around the world and represent America to the people of the world.

If an organization falls into one of the above categories, it may face a greater risk from terrorism than previously thought. If an organization does not fit one of the above categories, information security practitioners are still well-advised to take as many antiterrorism precautions as feasible.

104.5 Paradigm Shift: Deterrence to Prevention

> Business more than any other occupation is a continual dealing with the future; it is a continual calculation, an instinctive exercise in foresight.
>
> **—Henry R. Luce**

The operating paradigm of physical security has been deterrence. The idea of a perpetrator not wanting to be caught, arrested, or even killed has become so ingrained in the way we think that we take it for granted. As we probably all know by now, there are people motivated by fervent religious beliefs or political causes that do not share this perspective; they may be willing or even desiring to die to commit an act they believe will further their cause.

Most security protections considered industry standard today are based on the deterrence paradigm. Security devices such as cameras, alarms, x-ray, or infrared detection are all used with the intent to deter a perpetrator who does not want to be caught. Although deterrence-based measures will provide adequate security for the overwhelming majority of physical security threats, these measures may be largely ineffective against someone who plans to die committing an act of terrorism.

On the morning of September 11, 2001, we learned a painful lesson: that deterrence does not deter those who are willing to die to perpetrate whatever act they have in mind. Unfortunately, this makes physical security much more difficult and expensive. Information security practitioners need to realize that commonly accepted standards such as having security cameras, cipher-lock doors, and ID badges may only slow down a potential terrorist. Instead of working to deter intruders, we now have to also consider the previously unconsidered—the suicidal terrorist. This means considering what measures it will take to prevent someone who is willing to die to commit a terrorist act.

The airline industry appears to have learned that much more stringent security measures are required to prevent a recurrence of what happened on September 11. Previously, an airline's worst nightmare was either a bombing of an aircraft or a hijacking followed by tense negotiations to release hostage passengers. No one had considered the threat of using an airliner as a weapon of mass destruction. Anyone who has flown since then is familiar with the additional delays, searches, and ID checks. They are inconvenient and slow down the traveler; however, this is a small price to pay for having better security.

Although there is still much more to be done, this serves as an example of using the prevention paradigm. The airlines have taken many security measures to prevent another such occurrence. Unfortunately, as with information security, there is no such thing as absolute physical security. There is always the possibility that something not previously considered will occur. Information security practitioners will also likely have to work within corporate/governmental budget constraints, risk assessments, etc. that may limit their ability to implement the needed physical security changes.

104.6 Reducing The Risk of Terrorism

> The determination of these terrorists will not deter the determination of the American people. We are survivors and freedom is a survivor.
>
> **—Attorney General John Ashcroft**
> **Press conference on September 11, 2001**

Now that we have a better understanding of why we face a greater risk of terrorism and who may be a target, the issue becomes how to better protect our organizations and our fellow employees. There are many methods to reduce the risk of terrorism. These methods include reviewing and increasing the physical security of an organization using the previously discussed prevention paradigm; controlling sensitive information through operational security; developing terrorism incident handling procedures; and building security procedures and antiterrorism procedures for employees. Several of these methods rely on employee training and periodic drills to be successful.

104.6.1 Physical Security Assessments

The first step in reducing risk is to control the physical environment. In this section we use the term *standard* to imply industry-standard practices for physical security. The term *enhanced* will refer to enhanced procedures that incorporate the prevention paradigm.

104.6.1.1 Verify Standard Physical Security Practices Are in Place

Conduct a standard physical security assessment and implement changes as required. It is important to have physical security practices at least at current standards. Doing this will also minimize the risk from most standard physical security threats. As the trend toward holding organizations liable continues to emerge in information security, it is also likely to occur with physical security in the foreseeable future.

104.6.1.2 Conduct an Enhanced Physical Security Assessment

Once the standard physical security is in place, conduct another assessment that is much more stringent. This assessment should include enhanced physical security methods. Unfortunately, there is not yet a set of industry standards to protect against the enhanced threat. Many excellent resources are available from the U.S. government. Although they are designed for protecting military or other government facilities, many of these standards can also be successfully implemented in the private sector. At this point, information security practitioners are essentially left to their own initiative to implement standards. Perhaps, in the near future, a set of standards will be developed that include the enhanced threat.

Currently, there are many excellent resources available on the Internet from the U.S. government. However, at the time of this writing, the U.S. government is becoming more selective about what information is available to the public via the Internet for security reasons. It is quite possible that these resources may disappear from the Internet at some point in the near future. Information security practitioners may wish to locate these valuable resources before they disappear. A listing of Internet resources can be found in Exhibit 104.3.

104.6.1.3 Implement Recommended Changes

Again, because there is no uniform set of standards for enhanced physical security for the private sector, we are left to our own devices for enhancing our physical security. Because we are not likely to have unlimited budgets for improving physical security, information security practitioners will have to assess the risk for their organizations, including the potential threat of terrorism, and make recommended changes based on the assessed risk. Ideally, these changes should be implemented in the most expeditious manner possible.

104.7 Controlling Sensitive Information through Operational Security (OPSec)

We have now successfully "circled the wagons" and improved physical access controls to our facilities. The next step is to better control our sensitive information. As illustrated by the famous World War II security poster depicted in Exhibit 104.4, the successful control of information can win or lose wars. The Allied capture of the Enigma encryption device proved a critical blow to the Germans during World War II. The Allies were then able to decipher critical codes, which gave them an insurmountable

advantage. Again, during the Gulf War, the vast technical advantage enjoyed by the Allied Coalition gave them information supremacy that translated into air supremacy.

These lessons of history illustrate the importance of keeping sensitive information out of the hands of those who wish to do harm. In the days since September 11, this means keeping sensitive information from all who do not need access. First, we need to define exactly what information is sensitive. Then we need to determine how to best control the sensitive information.

- *Defining sensitive information*. Sensitive information can easily be defined as information that, if available to an unauthorized party, can disclose vulnerabilities or can be combined with other information to be used against an organization. For example, seemingly innocuous information on a public Web site can provide a hostile party with enough information to target that organization. Information such as addresses of facilities, maps to facilities, officer and employee names, and names and addresses of customers or clients can all be combined to build a roadmap. This roadmap can tell the potential terrorist not only where the organization is and what it does, but also who is part of the organization and where it is vulnerable.
- *Controlling sensitive information*. Prudent information security practitioners will first want to control the information source that leaves them the most vulnerable. There are several methods security practitioners can use to maintain control of their sensitive information: removing sensitive information from Web sites and corporate communications; destroying trash with sensitive

information; having a clean desk policy; and limiting contractor/vendor access to sensitive information.

- *Remove sensitive information from publicly available Web sites*. Removing physical addresses, maps, officer/employee names, etc. from these Web sites is highly advisable. They can either be removed entirely from the site or moved into a secured section of the site where access to this information is verified and logged.
- On January 17, 2002, the National Infrastructure Protection Center released NIPC Advisory 02-001: Internet Content Advisory: Considering the Unintended Audience. See Exhibit 104.5 for a reprint of the advisory. This advisory can function as a set of standards for deciding what and what not to place on publicly available Internet sites. When bringing up the issue with management of removing information from Web sites, the information security practitioner may receive a response that echoes item number seven in the advisory: "Because the information is publicly available in many places, it is not worth an effort to remove it from our site." Although the information does exist elsewhere, the most likely and easiest place for terrorists to find it is on the target organization's Web site. This is also probably the first place they will look. Responsible information security practitioners, or corporate officers for that matter, should make it as difficult as possible for those with hostile intent to gain useful information from their Internet site.

EXHIBIT 104.5 NIPC Advisory 02-001

Internet Content Advisory: Considering the Unintended Audience

January 17, 2002

As worldwide usage of the Internet has increased, so too have the vast resources available to anyone online. Among the information available to Internet users are details on critical infrastructures, emergency response plans and other data of potential use to persons with criminal intent. Search engines and similar technologies have made arcane and seemingly isolated information quickly and easily retrievable by anyone with access to the Internet. The National Infrastructure Protection Center (NIPC) has received reporting that infrastructure related information, available on the Internet, is being accessed from sites around the world. Although in and of itself this information is not significant, it highlights a potential vulnerability.

The NIPC is issuing this advisory to heighten community awareness of this potential problem and to encourage Internet content providers to review the data they make available online. A related information piece on "Terrorists and the Internet: Publicly Available Data should be Carefully Reviewed" was published in the NIPC's *Highlights* 11-01 on December 07, 2001, and is available at the NIPC web site http://www.nipc.gov/. Of course, the NIPC remains mindful that, when viewing information access from a security point of view, the advantages of posting certain information could outweigh the risks of doing so. For safety and security information that requires wide dissemination and for which the Internet remains the preferred means, security officers are encouraged to include in corporate security plans mechanisms for risk management and crisis response that pertain to malicious use of open source information.

When evaluating Internet content from a security perspective, some points to consider include:

1. Has the information been cleared and authorized for public release?
2. Does the information provide details concerning enterprise safety and security? Are there alternative means of delivering sensitive security information to the intended audience?
3. Is any personal data posted (such as biographical data, addresses, etc.)?
4. How could someone intent on causing harm misuse this information?
5. Could this information be dangerous if it were used in conjunction with other publicly available data?
6. Could someone use the information to target your personnel or resources?
7. Many archival sites exist on the Internet, and that information removed from an official site might nevertheless remain publicly available elsewhere.

The NIPC encourages the Internet community to apply common sense in deciding what to publish on the Internet. This advisory serves as a reminder to the community of how the events of September 11, 2001, have shed new light on our security considerations.

The NIPC encourages recipients of this advisory to report computer intrusions to their local FBI office http://www.fbi.gov/contact/fo/fo.htm or the NIPC, and to other appropriate authorities. Recipients may report incidents online at http://www.nipc.gov/incident/cirr.htm, and can reach the NIPC Watch and Warning Unit at (202) 323-3205, 1-888-585-9078, or nipc.watch@fbi.gov

- *Remove sensitive information from all corporate communications*. No corporate communications should contain any sensitive information. If an organization already has an information classification structure in place, this vulnerability should already be resolved. However, if there is no information classification structure in place, this is excellent justification for implementing such a program. And, with such a program, the need for marking documents also exists.
- *Shred/destroy trash with sensitive information*. Do you really know who goes through your trash? Do you know your janitorial staff? Dumpster diving is a widely practiced social engineering method. Shredding is an excellent way to avoid this vulnerability and is already widely practiced. Many organizations have either on-site shredders or bins to collect sensitive documents, which are later shredded by contracted shredding companies.
- *Create a clean desk policy*. Information left unattended on a desktop is a favorite of social engineers. It is easier than dumpster diving (cleaner, too!) and will likely yield better results. Although the definition of clean desk may vary, the intent of such a policy is to keep sensitive information from being left unattended on desktops.
- *Limit contractor/vendor access to sensitive information*. This is a standard physical security practice, but it deserves special mention within the OPSec category because it is fairly easy to implement controls on contractor/vendor access. Restricting access to proprietary information is also a good practice.
- *Verify identity of all building/office visitors*. Many large organizations and office buildings are verifying the identity of all visitors. Some organizations and buildings are checking identification for everyone who enters. This is an excellent practice because it greatly reduces the risk of unauthorized access.
- *Report unusual visitors or activity to law enforcement agencies (LEA)*. Visitors behaving in a suspicious or unusual manner should be reported to building security, if possible, and then to law enforcement authorities. Quick reporting may prevent undesired activities.
- *Exercise safe mail handling procedures*. Mail-handling procedures became of greater importance during the anthrax scare in the autumn of 2001. See Exhibit 104.6 for a list of safe mail handling procedures.

EXHIBIT 104.6 Safe Mail-Handling Checklist

Suspicious Packages or Mail
Suspicious characteristics to look for include:
- An unusual or unknown place of origin
- No return address
- An excessive amount of postage
- Abnormal or unusual size
- Oily stains on the package
- Wires or strings protruding from or attached to an item
- Incorrect spelling on the package label
- Differing return address and postmark
- Appearance of foreign style handwriting
- Peculiar odor (many explosives used by terrorists smell like shoe polish or almonds)
- Unusual heaviness or lightness
- Uneven balance or shape
- Springiness in the top, bottom, or sides

Never cut tape, strings, or other wrappings on a suspect package or immerse a suspected letter or package in water; either action could cause an explosive device to detonate
Never touch or move a suspicious package or letter
Report any suspicious packages or mail to security officials immediately

104.7.1 Develop Terrorism Incident Handling Procedures

104.7.1.1 Security Working Group

Many organizations have established security working groups. These groups may be composed of management, information security practitioners, other security specialists, and safety and facilities management people. Members of the group can also serve as focal points for networking with local, state, and federal authorities and professional organizations to receive intelligence/threat information. The group may meet regularly to review the organization's security posture and act as a body for implementing upgraded security procedures. It may also conduct security evaluations.

104.7.1.2 Establish Terrorism Incident Procedures

Just as it is important to have incident response plans and procedures for computer security incidents, it is also highly advisable to have incident response plans and procedures for terrorist threats or incidents.

An integral part of any terrorism incident response is checklists for bomb threats and other terrorist threats. These checklists should contain numerous questions to ask the individual making the threatening call: where is the bomb, when is it going to go explode, what does it look like, etc. The checklists should also contain blanks to fill in descriptions of the caller's voice—foreign accent, male or female, tone of voice, background noise, etc. Checklists should be located near all phones or, at a minimum, in company telephone directories. Many federal and state agencies have such checklists available for the general public. The Bureau of Alcohol, Tobacco & Firearms has an excellent checklist that is used by many agencies and is shown in Exhibit 104.7.

EXHIBIT 104.7 BATF Bomb Threat Checklist

ATF BOMB THREAT CHECKLIST
Exact time of call:

Exact words of caller:

QUESTIONS TO ASK
1. When is bomb going to explode?
2. Where is the bomb?
3. What does it look like?
4. What kind of bomb is it?
5. What will cause it to explode?
6. Did you place the bomb?
7. Why?
8. Where are you calling from?
9. What is your address?
10. What is your name?

CALLER'S VOICE (circle)

Calm	Slow	Crying	Slurred
Stutter	Deep	Loud	Broken
Giggling	Accent	Angry	Rapid
Stressed	Nasal	Lisp	Excited
Disguised	Sincere	Squeaky	Normal

If voice is familiar, whom did it sound like?
Were there any background noises?

Telephone number call received at:
Date:
Report call immediately to:
(Refer to bomb incident plan)

Again, as with computer incident response teams, training is quite important. Employees need to know how to respond in these types of high-stress situations. Recurring training on how to respond to threatening phone calls and to complete the checklist all contribute to reduced risk.

104.7.1.3 Safety Practices

Here is an excellent opportunity to involve organizational safety personnel or committees. Some practices to involve them with are:

- *Review building evacuation procedures*. This will provide the current and best method for evacuating buildings should the need arise. Also plan for secondary evacuation routes in the event the primary route is unusable.
- *Conduct building evacuation drills*. Periodic building evacuation drills, such as fire drills, provide training and familiarity with escape routes. In an emergency, it is far better to respond with training. These should be conducted without prior notification on all shifts. Drills should not be the same every time. Periodically, vary the drill by blocking an escape route, forcing evacuees to alter their route.
- *Conduct terrorism event drills*. Other drills, such as responding to various terrorism scenarios, may be beneficial in providing the necessary training to respond quickly and safely in such a situation.
- *Issue protective equipment*. Many of the individuals who survived the World Trade Center disaster suffered smoke inhalation, eye injuries, etc. These types of injuries might be avoided if emergency equipment is issued to employees, such as hardhats, dust masks, goggles, flashlights, gloves, etc.

104.7.1.4 Building Security Procedures

A determined terrorist can penetrate most office buildings. However, the presence and use of guards and physical security devices (e.g., exterior lights, locks, mirrors, visual devices) create a significant psychological deterrent. Terrorists are likely to shun risky targets for less protected ones. If terrorists decide to accept the risk, security measures can decrease their chance of success. Of course, if the terrorists are willing to die in the effort, their chance of success increases and the efforts to thwart them are much more complex and expensive. Corporate and government executives should develop comprehensive building security programs and frequently conduct security surveys that provide the basis for an effective building security program. These surveys generate essential information for the proper evaluation of security conditions and problems, available resources, and potential security policy. Only one of the many facets in a complex structure, security policies must be integrated with other important areas such as fire safety, normal police procedures, work environment, and work transactions. The building security checklist found in Exhibit 104.8 provides guidance when developing building security procedures.

104.7.2 Antiterrorism Procedures for Employees

Antiterrorism procedures can be defined as defensive measures used to reduce vulnerability to terrorist attacks. These defensive measures, or procedures, although originated by the U.S. government, are certainly applicable to those living in a high terrorist threat condition. To some security practitioners, many of these procedures may seem on the verge of paranoia; however, they are presented with two intentions: (1) to illustrate the varying dangers that exist and methods to avoid them, and (2) to allow readers to determine for themselves which procedures to use.

Many of the procedures are simply common sense. Others are procedures that are generally only known to those who live and work in high terrorist threat environments. See Exhibit 104.9 for the personnel antiterrorism checklist.

EXHIBIT 104.8 Building Security Checklist

Office Accessibility

- Buildings most likely to be terrorist targets should not be directly accessible to the public.
- Executive offices should not be located on the ground floor.
- Place ingress door within view of the person responsible for screening personnel and objects passing through the door.
- Doors may be remotely controlled by installing an electromagnetic door lock.
- The most effective physical security configuration is to have doors locked from within and have only one visitor access door into the executive office area. Locked doors should also have panic bars.
- Depending on the nature of the organization's activities, deception measures such as a large waiting area controlling access to several offices can be taken to draw attention away from the location and function of a particular office.

Physical Security Measures

- Consider installing the following security devices: burglar alarm systems (preferably connected to a central security facility), sonic warning devices or other intrusion systems, exterior floodlights, deadbolt locks on doors, locks on windows, and iron grills or heavy screens for windows.
- Depending on the nature of the facility, consider installing a 15 to 20-foot fence or wall and a comprehensive external lighting system. External lighting is one of the cheapest and most effective deterrents to unlawful entry.
- Position light fixtures to make tampering difficult and noticeable.
- Check grounds to ensure that there are no covered or concealed avenues of approach for terrorists and other intruders, especially near entrances.
- Deny exterior access to fire escapes, stairway, and roofs.
- Manhole covers near the building should be secured or locked.
- Cover, lock, or screen outdoor openings (e.g., coal bins, air vents, utility access points).
- Screen windows (particularly near the ground or accessible from adjacent buildings).
- Consider adding a thin, clear plastic sheet to windows to degrade the effects of flying glass in case of explosion.
- Periodically inspect the interior of the entire building, including the basement and other infrequently used areas.
- Locate outdoor trash containers, storage bins, and bicycle racks away from the building.
- Book depositories or mail slots should not be adjacent to or in the building.
- Mailboxes should not be close to the building.
- Seal the top of voids and open spaces above cabinets, bookcases, and display cases.
- Keep janitorial closets, service openings, telephone closets, and electrical closets locked at all times. Protect communications closets and utility areas with an alarm system.
- Remove names from reserved parking spaces.
- Empty trash receptacles daily (preferably twice daily).
- Periodically check all fire extinguishers to ensure that they are in working order and readily available. Periodically check all smoke alarms to ensure that they are in working order.

Personnel Procedures

- Stress heightened awareness of personnel working in the building, because effective building security depends largely on the actions and awareness of people.
- Develop and disseminate clear instructions on personnel security procedures.
- Hold regular security briefings for building occupants.
- Personnel should understand security measures, appropriate responses, and should know whom to contact in an emergency.
- Conduct drills if appropriate.
- Senior personnel should not work late on a routine basis. No one should ever work alone.
- Give all personnel, particularly secretaries, special training in handling bomb threats and extortion telephone calls. Ensure a bomb threat checklist and a pen or pencil is located at each telephone.
- Ensure the existence of secure communications systems between senior personnel, secretaries, and security personnel with intercoms, telephones, and duress alarm systems.
- Develop an alternate means of communications (e.g., two-way radio) in case the primary communications systems fail.
- Do not open packages or large envelopes in buildings unless the sender or source is positively known. Notify security personnel of a suspicious package.
- Have mail room personnel trained in bomb detection handling and inspection.
- Lock all doors at night, on weekends, and when the building is unattended.
- Maintain tight control of keys. Lock cabinets and closets when not in use.
- When feasible, lock all building rest rooms when not in use.
- Escort visitors in the building and maintain complete control of strangers who seek entrance.
- Check janitors and their equipment before admitting them and observe while they are performing their functions.

Exhibit 104.8 (Continued)

- Secure official papers from unauthorized viewing.
- Do not reveal the location of building personnel to callers unless they are positively identified and have a need for this information.
- Use extreme care when providing information over the telephone.
- Do not give the names, positions, and especially the home addresses or phone numbers of office personnel to strangers or telephone callers.
- Do not list the addresses and telephone numbers of potential terrorist targets in books and rosters.
- Avoid discussing travel plans or timetables in the presence of visitors.
- Be alert to people disguised as public utility crews who might station themselves near the building to observe activities and gather information.
- Note parked or abandoned vehicles, especially trucks, near the entrance to the building or near the walls.
- Note the license plate number, make, model, year, and color of suspicious vehicles and the occupant's description, and report that information to your supervisor, security officer, or law enforcement agency.

Controlling Entry

- Consider installing a peephole, intercom, interview grill, or small aperture in entry doorways to screen visitors before the door is opened.
- Use a reception room to handle visitors, thereby restricting their access to interior offices.
- Consider installing metal detection devices at controlled entrances. Prohibit non-organization members from bringing boxes and parcels into the building.
- Arrange building space so that unescorted visitors are under the receptionist's visual observation and to ensure that the visitors follow stringent access control procedures.
- Do not make exceptions to the building's access control system.
- Upgrade access control systems to provide better security through the use of intercoms, access control badges or cards, and closed-circuit television.

Public Areas

- Remove all potted plants and ornamental objects from public areas.
- Empty trash receptacles frequently.
- Lock doors to service areas.
- Lock trapdoors in the ceiling or floor, including skylights.
- Ensure that construction or placement of furniture and other items would not conceal explosive devices or weapons.
- Keep furniture away from walls or corners.
- Modify curtains, drapes, or cloth covers so that concealed items can be seen easily.
- Box in the tops of high cabinets, shelves, or other fixtures.
- Exercise particular precautions in public rest rooms.
- Install springs on stall doors in rest rooms so they stand open when not locked. Equip stalls with an inside latch to prevent someone from hiding a device in a locked stall.
- Install a fixed covering over the tops on commode water tanks.
- Use open mesh baskets for soiled towels. Empty frequently.
- Guards in public areas should have a way to silently alert the office of danger and to summon assistance (e.g., foot-activated buzzer).

Discovery of a Suspected Explosive Device

- Do not touch or move a suspicious object. If it is possible for someone to account for the presence of the object, then ask the person to identify it with a verbal description. This should not be done if it entails bringing evacuated personnel back into the area. Take the following actions if an object's presence remains inexplicable:
- Evacuate buildings and surrounding areas, including the search team.
- Evacuated areas must be at least 100 meters from the suspicious object.
- Establish a cordon and incident control point, or ICP.
- Inform the ICP that an object has been found.
- Keep person who located the object at the ICP until questioned.
- Cordon suspicious objects to a distance of at least 100 meters and cordon suspicious vehicles to a distance of at least 200 meters. Ensure that no one enters the cordoned area. Establish an ICP on the cordon to control access and relinquish ICP responsibility to law enforcement authorities upon their arrival. Maintain the cordon until law enforcement authorities have completed their examination or state that the cordon may stand down. The decision to allow reoccupation of an evacuated facility rests with the individual in charge of the facility.

EXHIBIT 104.9 Personnel Antiterrorism Checklist

General Security Procedures

- Instruct your family and associates not to provide strangers with information about you or your family.
- Avoid giving unnecessary personal details to information collectors.
- Report all suspicious persons loitering near your residence or office; attempt to provide a complete description of the person and/or vehicle to police or security.
- Vary daily routines to avoid habitual patterns.
- If possible, fluctuate travel times and routes to and from work.
- Refuse to meet with strangers outside your workplace.
- Always advise associates or family members of your destination when leaving the office or home and the anticipated time of arrival.
- Do not open doors to strangers.
- Memorize key phone numbers—office, home, police, etc. Be cautious about giving out information regarding family travel plans or security measures and procedures.
- If you travel overseas, learn and practice a few key phrases in the native language, such as "I need a policeman, doctor," etc.

Business Travel

- Airport Procedures
  - — Arrive early; watch for suspicious activity.
  - — Notice nervous passengers who maintain eye contact with others from a distance. Observe what people are carrying. Note behavior not consistent with that of others in the area.
  - — No matter where you are in the terminal, identify objects suitable for cover in the event of attack; pillars, trash cans, luggage, large planters, counters, and furniture can provide protection.
  - — Do not linger near open public areas. Quickly transit waiting rooms, commercial shops, and restaurants.
  - — Proceed through security checkpoints as soon as possible.
  - — Avoid secluded areas that provide concealment for attackers.
  - — Be aware of unattended baggage anywhere in the terminal.
  - — Be extremely observant of personal carry-on luggage. Thefts of briefcases designed for laptop computers are increasing at airports worldwide; likewise, luggage not properly guarded provides an opportunity for a terrorist to place an unwanted object or device in your carry-on bag. As much as possible, do not pack anything you cannot afford to lose; if the documents are important, make a copy and carry the copy.
  - — Observe the baggage claim area from a distance. Do not retrieve your bags until the crowd clears. Proceed to the customs lines at the edge of the crowd.
  - — Report suspicious activity to the airport security personnel.
- On-Board Procedures
  - — Select window seats; they offer more protection because aisle seats are closer to the hijackers' movements up and down the aisle.
  - — Rear seats also offer more protection because they are farther from the center of hostile action, which is often near the cockpit.
  - — Seats at an emergency exit may provide an opportunity to escape.
- Hotel Procedures
  - — Keep your room key on your person at all times.
  - — Be observant for suspicious persons loitering in the area.
  - — Do not give your room number to strangers.
  - — Keep your room and personal effects neat and orderly so you will recognize tampering or strange out-of-place objects.
  - — Know the locations of emergency exits and fire extinguishers.
  - — Do not admit strangers to your room.
  - — Know how to locate hotel security guards.

Keep a Low Profile

- Your dress, conduct, and mannerisms should not attract attention.
- Make an effort to blend into the local environment.
- Avoid publicity and do not go out in large groups.
- Stay away from civil disturbances and demonstrations.

Tips for the Family at Home

- Restrict the possession of house keys.
- Change locks if keys are lost or stolen and when moving into a previously occupied residence.
- Lock all entrances at night, including the garage.

Exhibit 104.9 (Continued)

- Keep the house locked, even if you are at home.
- Develop friendly relations with your neighbors.
- Do not draw attention to yourself; be considerate of neighbors.
- Avoid frequent exposure on balconies and near windows.

Be Suspicious

- Be alert to public works crews requesting access to residence; check their identities through a peephole before allowing entry.
- Be alert to peddlers and strangers.
- Write down license numbers of suspicious vehicles; note descriptions of occupants.
- Treat with suspicion any inquiries about the whereabouts or activities of other family members.
- Report all suspicious activity to police or local law enforcement.

Security Precautions when You Are Away

- Leave the house with a lived-in look.
- Stop deliveries or forward mail to a neighbor's home.
- Do not leave notes on doors.
- Do not hide keys outside house.
- Use a timer (appropriate to local electricity) to turn lights on and off at varying times and locations.
- Leave radio on (best with a timer).
- Hide valuables.
- Notify the police or a trusted neighbor of your absence.

Residential Security

- Exterior grounds:
  - — Do not put your name on the outside of your residence or mailbox.
  - — Have good lighting.
  - — Control vegetation to eliminate hiding places.
- Entrances and exits should have:
  - — Solid doors with deadbolt locks
  - — One-way peepholes in door
  - — Bars and locks on skylights
  - — Metal grating on glass doors, and ground-floor windows, with interior release mechanisms that are not reachable from outside
- Interior features:
  - — Alarm and intercom systems
  - — Fire extinguishers
  - — Medical and first-aid equipment
- Other desirable features:
  - — A clear view of approaches
  - — More than one access road
  - — Off-street parking
  - — High (six to eight feet) perimeter wall or fence

Parking

- Always lock your car.
- Do not leave it on the street overnight, if possible.
- Never get out without checking for suspicious persons. If in doubt, drive away.
- Leave only the ignition key with parking attendant.
- Do not allow entry to the trunk unless you are there to watch.
- Never leave garage doors open or unlocked.
- Use a remote garage door opener if available. Enter and exit your car in the security of the closed garage.

On the Road

- Before leaving buildings to get into your vehicle, check the surrounding area to determine if anything of a suspicious nature exists. Display the same wariness before exiting your vehicle.
- Prior to getting into a vehicle, check beneath it. Look for wires, tape, or anything unusual.
- If possible, vary routes to work and home.
- Avoid late-night travel.
- Travel with companions.
- Avoid isolated roads or dark alleys when possible.
- Habitually ride with seatbelts buckled, doors locked, and windows closed.

Exhibit 104.9 (Continued)

- Do not allow your vehicle to be boxed in; maintain a minimum eight-foot interval between you and the vehicle in front; avoid the inner lanes. Be alert while driving or riding.

Know How to React if You Are Being Followed

- Circle the block for confirmation of surveillance.
- Do not stop or take other actions that could lead to confrontation.
- Do not drive home.
- Get description of car and its occupants.
- Go to the nearest safe haven.
- Report incident to police.

Recognize Events that can Signal the Start of an Attack:

- Cyclist falling in front of your car.
- Flagman or workman stopping your car.
- Fake police or government checkpoint.
- Disabled vehicle/accident victims on the road.
- Unusual detours.
- An accident in which your car is struck.
- Cars or pedestrian traffic that box you in.
- Sudden activity or gunfire.

Know What to Do if under Attack in a Vehicle:

- Without subjecting yourself, passengers, or pedestrians to harm, try to draw attention to your car by sounding the horn
- Put another vehicle between you and your pursuer
- Execute immediate turn and escape; jump the curb at 30–45 degree angle, 35 mph maximum
- Ram blocking vehicle if necessary
- Go to closest safe haven
- Report incident to police

Commercial Buses, Trains, and Taxis

- Vary mode of commercial transportation.
- Select busy stops.
- Do not always use the same taxi company.
- Do not let someone you do not know direct you to a specific cab.
- Ensure taxi is licensed and has safety equipment (seatbelts at a minimum).
- Ensure face of driver and picture on license are the same.
- Try to travel with a companion.
- If possible, specify the route you want the taxi to follow.

Clothing

- Travel in conservative clothing when using commercial transportation overseas or if you are to connect with a flight at a commercial terminal in a high-risk area.
- Do not wear U.S.-identified items such as cowboy hats or boots, baseball caps, American logo T-shirts, jackets, or sweatshirts.
- Wear a long-sleeved shirt if you have a visible U.S.-affiliated tattoo.

Actions if Attacked

- Dive for cover. Do not run. Running increases the probability of shrapnel hitting vital organs or the head.
- If you must move, belly crawl or roll. Stay low to the ground, using available cover.
- If you see grenades, lay flat on the floor, with feet and knees tightly together with soles toward the grenade. In this position, your shoes, feet, and legs protect the rest of your body. Shrapnel will rise in a cone from the point of detonation, passing over your body.
- Place arms and elbows next to your ribcage to protect your lungs, heart, and chest. Cover your ears and head with your hands to protect neck, arteries, ears, and skull.
- Responding security personnel will not be able to distinguish you from attackers. Do not attempt to assist them in any way. Lay still until told to get up.

Actions if Hijacked

- Remain calm, be polite, and cooperate with your captors.
- Be aware that all hijackers may not reveal themselves at the same time. A lone hijacker may be used to draw out security personnel for neutralization by other hijackers.
- Surrender your tourist passport in response to a general demand for identification.
- Do not offer any information.
- Do not draw attention to yourself with sudden body movements, verbal remarks, or hostile looks.

Exhibit 104.9 (Continued)

- Prepare yourself for possible verbal and physical abuse, lack of food and drink, and unsanitary conditions.
- If permitted, read, sleep, or write to occupy your time.
- Discretely observe your captors and memorize their physical descriptions. Include voice patterns and language distinctions as well as clothing and unique physical characteristics.
- Cooperate with any rescue attempt. Lie on the floor until told to rise.

104.8 Lessons Learned from September 11

Our plan worked and did what it was supposed to do. Our employees were evacuated safely.

—Paul Honey
Director of Global Contingency Planning for Merrill Lynch

Many well-prepared organizations weathered the disaster of September 11. However, there were also many businesses caught unprepared; of those, many no longer exist. Organizations from around the United States and the world are benefiting from the lessons learned on that fateful day. One large and quite well-known organization that was well prepared and survived the event was Merrill Lynch.

When Paul Honey, director of global contingency planning for Merrill Lynch, arrived for work on the morning of September 11, he was met by the disaster of the collapsed World Trade Center. Honey then went to one of the company's emergency command centers, where his contingency planning staff was hard at work. Within an hour of the disaster, the crisis management team had already established communication with key representatives, and emergency procedures were well underway.

Honey's team was able to facilitate the resumption of critical operations within one day and, within a week, the relocation of 8000 employees. This effort required the activation of a well-documented and robust business continuity program, an enormous communications effort, and a lot of teamwork.

104.9 Business Continuity Plans

Honey has business continuity planning responsibility for all of Merrill Lynch's businesses. He runs a team of 19 planners who verify that the business follows the business continuity plan, or BCP. His team is not responsible for the technology recovery planning, and they do not write the plans. They are the subject matter experts in program management and set the standards through a complete BCP program life cycle. Planning involves many different departments within the company because of the comprehensive nature of the program. Each business and support group (i.e., the trading floor, operations, finance, etc.) assigns a planning manager who is responsible for that area.

Honey's team responds to nearly 70 emergencies, on average, during the course of a year. Facilities and retail branch offices around the globe experience a variety of incidents such as earthquakes, storms, power outages, floods, or bomb threats.

When Honey's team plans for business interruption, the team instructs the business groups to plan for a worst-case scenario of six weeks without access to their facility and, naturally, at the worst possible time for an outage.

The planning also includes having absolutely no access to anything from any building—computers, files, papers, etc. "That's how we force people to think about alternate sites, vital records, physical relocation of staff, and so on, as well as obviously making sure the technology is available at another site," says Honey.

104.10 Upgraded Plans and Procedures after Y2K

Merrill Lynch must comply with standards mandated by regulatory agencies such as the Federal Reserve and the Federal Financial Institutions Examination Council. Honey says, "There's a market expectation that companies such as Merrill Lynch would have very robust contingency plans, so we probably attack it over and above any regulatory requirements that are out there." The BCP team's recent efforts to exceed regulatory standards placed Merrill Lynch in a good position to recover successfully from the September 11 attacks.

104.11 Extensive Testing of Contingency Plans

All plans are tested twice annually, and once a year the large-scale, corporatewide plans are tested. Honey's team overhauled the headquarters evacuation plan earlier in the year. They distributed nearly 8000 placards with the new procedures. These placards proved quite useful on the day of the attacks. Furthermore, the company's human resources database is downloaded monthly into the team's business continuity planning software program. This ensures that the BCP team has a frequently updated list of all current employees within each building. All this preparation resulted in effective execution of the business continuity plans on September 11.

104.12 Recent Test Using Scenario Similar to Terrorist Attacks

In May 2001, Honey's team conducted a two-day planning scenario for the headquarters' key staff. The scenario, although different from September 11, covered an event of devastating impact—a major hurricane in New York City. "While the hurricane scenario doesn't compare to the tragedies of 9/11 in terms of loss of life, we actually put our company through a fairly extensive two-day scenario, which had more impact to the firm in terms of difficulties in transportation and actual damage in the region," says Honey. "So, we were really very well prepared; we had a lot of people who already thought through a lot of the logistical, technology, and HR-type issues."

104.12.1 The Evacuation

The corporate response team was activated at about 8:55 a.m., while Honey was en route to Canal Street. The team, comprised of representatives from all business support groups, is instrumental in assessing the situation, such as building management, physical security personnel, media relations, key technology resources, and key business units. Despite a multitude of telecommunications troubles in the area, the team was finally able to establish a conference call at 9:30 a.m. to communicate with its other command center in Jersey City, New Jersey, to figure out what was happening.

"In hindsight it seems odd, but we really didn't know, apart from the planes hitting the buildings, whether this was an accident or a terrorist attack," says Honey. "So really, the challenge at that time was to account for our employees, and then to try and understand what had happened. The damage to our buildings also was a concern. How were our buildings. Were they still standing? What was the state of the infrastructure in them?"

Call trees were used to contact employees, and employees also knew how to contact their managers to let them know they got out of the area safely. "In a typical evacuation of a building, employees go about 100 yards from the building and wait to get their names ticked off a list," says Honey. "The issue we faced here is that the whole of lower Manhattan was evacuated. So employees were going home or trying to get to other offices—so that was a challenge for us." Honey says the wallet cards key employees carried were extremely beneficial. "Everyone knew who to call and when," he says. "That was a real valuable planning aid to have."

Once the team had the call trees and other communications processes under way, they began to implement the predefined continuity plans and assess what critical business items they wanted to focus on and when.

104.12.2 The Recovery

104.12.2.1 Critical Management Functions Resumed within Minutes

Many of the company's recovery procedures were based on backup data centers at Merrill Lynch facilities outside the area. The data recovery procedures were followed through without incident. The company has a hot site provider, but they did not have to use that service.

The company's preparedness efforts for Y2K resulted in near-routine recovery of critical data. "We had a very large IT disaster recovery program in place," says Honey, "and we've been working for a couple years now with the businesses to really strengthen the business procedures to use it. So backup data centers, mirroring over fiber channels, etc.—that all worked pretty well." Likewise for the recovery personnel at the command centers: "A lot of people already knew what a command center was, why they had to be there, and what they needed to do because we had gone through that during Y2K, and I'm very grateful that we did."

104.12.2.2 8000 Employees Back at Work within a Week

A major challenge for the BCP team was getting the displaced employees back to work. First, the company was able to utilize two campus facilities in New Jersey. The company also had its real estate department itemize every available space in the tri-state area and put it onto a roster. Honey's team collected requirements and coordinated the assignment of available space to each business unit. The company operates a fairly comprehensive alternate work arrangement program, so some employees were permitted to work from home. Finally, the team was able to transfer some work abroad or to other Merrill Lynch offices, which relieved some of the workload from the affected employees.

104.12.2.3 Resuming Normal Operations

By the end of the week, the BCP team's priority shifted to making sure they could communicate with all employees. Workers needed to be assured that the company was handling the crisis and that space was allocated for displaced workers. Messages were sent instructing them on where to go for more information and what human resource hotlines were available for them to call.

Merrill Lynch's chairman, CEO, and senior business and technology managers made prerecorded messages that were sent out automatically to all employees impacted by the incident by use of a special emergency communication system. This accounted for approximately 74,000 phone calls during the first week after the disaster. "That was a very key part," says Honey. "Getting accurate information to our employee base was a real challenge because of a lot of misinformation in the press, which makes the job very challenging. Plus, key business folks made a huge effort to call all our key customers and reassure them with the accurate information that Merrill Lynch was open for business."

A key logistical challenge was getting the thousands of displaced workers to their new work locations. The company ran a series of ferryboats and buses from various points within the city to other points. The company Web site was also used to communicate transportation information to the affected employees.

104.13 Lessons Learned

Honey and his team will be reevaluating certain aspects of their plans in the coming months, even after their success in recovering from such a devastating event, "One of the things I think we'll concentrate on a lot more in the future is region-wide disasters. For example, not so much, 'Your building is knocked out and you can't get in,' but maybe, 'The city you're in is impacted in significant ways.' So, we'll be looking to see how we can make the firm a lot more robust in terms of instances where a city is impacted, rather than just the building."

Honey also believes that many companies will reevaluate their real estate strategies. “Do you really want to have all your operations in one building?” he asks. “Fortunately, for a company like Merrill Lynch, we have a number of real estate options we can utilize.”

104.14 The Work Ahead

The BCP team was busy working on backup plans for the backup facilities by the end of the second week, while primary sites were either cleaned up or acquired. “Many of our operations are in backup mode,” says Honey, “so we did a lot of work to try and develop backup plans for the backup plans. That was a big challenge.”

Now the team is in the planning stages for reoccupying the primary sites, which presents its own set of challenges. Switching back to primary facilities will have to be undertaken only when it is perfectly safe for employees to reoccupy the damaged facilities.

One of the most important things for Honey and his team was that, by the Monday morning following the attack, everything was back to nearly 95 percent of normal operations. Their efforts over the past few years preparing for a disruption of this magnitude appear to have paid off. “Certainly from my perspective, I was very glad that we put the company through the training exercise in May,” says Honey. “It enlightened an awful lot of the key managers on what they would have to do, so we were very prepared for that. Most folks knew what to do, which was very reassuring to me.”

104.15 Conclusion

Reducing vulnerability to physical security threats became immensely more complex after September 11, 2001. Terrorism now needs to be included in all physical security planning. The events of September 11 showed us that procedures designed to deter those with hostile intent might be ineffective against suicidal terrorists. Physical security now needs to change its operating paradigm from that of deterrence to prevention to reduce the risk from terrorism. Taking the additional precautions to prevent hostile acts rather than deter them is much more difficult and costly, but necessary. Protecting one’s organization, co-workers, and family from terrorism is possible with training. Maintaining control of access to sensitive information that could be used by terrorists is paramount. Many government Web sites are awash with information that could be useful in combating terrorism. Unfortunately, many of these Web sites can also provide this information to potential terrorists who could use that information to discover vulnerabilities.

104.15.1 Dedication

This chapter is respectfully dedicated to those whose lives were lost or affected by the events of September 11, 2001. It is the author’s deepest hope that information presented in this chapter will aid in reducing the likelihood of another such event.

Enterprise Assurance: A Framework Explored

Bonnie A. Goins

105.1 Introduction

Your company has made a commitment to security. It’s good for your business, your customers, your staff, your data, and your systems. Senior management is fully on board; you have a budget and are encouraged to spend it. You have spent long days (and some nights) ensuring that your documentation is completed, your patches and configurations are up to date, and you have staff in sufficient number, with sufficient skill sets, to assist you in the effort. Ah, life is good. But, wait (there is always a catch)! Senior management and the Board want you to answer a question (your heart is pounding…): “How confident are you that our security needs have been met? Or, more simply put, how sure are you that everything you’ve done makes us secure? Can we have some assurance?” Gulp…

105.2 What Exactly Does “Assurance” Mean?

According to the Merriam-Webster dictionary, *assurance* is “something that inspires, or tends to inspire, confidence.” In fact, *confidence* is given as a synonym for the word *assurance.* Merriam-Webster defines the word *confidence* as “the quality or state of being certain (i.e., certitude).” Okay, so now you have some idea of what the Board and senior management are asking. The question is, how does that relate to security? Douglas Landoll and Jeffrey Williams stated in their work, *An Enterprise Assurance Framework*, that “there are many definitions of assurance used in security; however, the central theme in these definitions is that assurance is the degree of confidence that security needs are satisfied.” To prove the point made earlier, the National Institute of Standards and Technology (NIST) has defined *assurance* as “grounds for confidence that a system design meets its requirements, or that its implementation satisfies specifications, or that some specific property is satisfied.”

105.3 How Much "Confidence" Is Enough?

Regardless of the rigor used in applying security to an environment, it is not possible to secure an environment completely. Restated, threats, and therefore risks, will always exist in an environment. That said, the people operating within that environment must come to understand that there will *always* be some doubt, and that some flaw or risk will *always* exist in the environment. This notion is sometimes a hard sell to senior management, due mainly to the fact that many of the security activities practiced within an environment are intangible, while the financial implications of implementing security are not.

A reasonable answer to this question of confidence aligns with the concept of risk. It is important for the security practitioner in the environment to determine, as quickly as possible, what tolerance for risk senior management demonstrates. Practitioners can assist themselves by educating senior management early that complete elimination of risk is not possible nor is complete elimination of doubt about the state of security within the environment. Talking candidly with the management chain can help practitioners determine what their level of "reasonable doubt" may be.

When this exercise is completed, you can begin the arduous task of translating this information into criteria to be evaluated as part of the determination of "how much assurance is enough?" You many consider the value of critical business functions, the current state of security and technology within the organization, the cost associated with proper controls, the value of your data, technical and physical assets, and costs associated with an appropriate level of security surrounding each of them.

105.4 Giving "Confidence" a Form

It would seem that at least there is a place to start, but how do you inspire confidence in your enterprise solution? The first step is to recognize that assurance must, as a matter of course, take into account multiple factors within the organization. Is security only provided for information systems or network infrastructure? I would hope not, because, if so, the most serious threat to a secure environment has been neglected—the people within the organization. Also, don't most organizations provide security for their facilities? Before the advent of network intrusion detection, we had closed-circuit televisions and guard stations. Before we were duped by Trojans, worms, viruses, and logic bombs, we had mantraps, PINed, or proximity locks and electronic security methods. Physical security has been present for a very long time. The author is not aware of an organization (other than perhaps a virtual one or one so isolated that only the very strong can reach them) that does not employ physical security measures. So, facilities must also be considered. Assurance can be considered to be a global effort; that is, people, processes, technology, and facilities must all be addressed. In Landoll and Williams' work, they include the following areas for review: people, procedures, environment, and automated information systems (AISs).

105.5 An Assurance Framework for the Enterprise

In *An Enterprise Assurance Framework*, Landoll and Williams introduce a framework for assurance that is designed to be an aid to organizations looking to cut through the complexity of their enterprise security architectures and to produce a clean, clear framework that can answer the assurance questions asked previously in this chapter.

105.5.1 Assurance Components

The authors point out five components that work together to structure what they call an *assurance argument.* As defined in their paper, an assurance argument is "a way of presenting evidence in a clear and convincing manner." Essentially, an assurance argument is a sensible representation of information and analysis (i.e., evidence) that is used to determine whether the organization's assurance expectations are met.

To see how this works we will use our original categories of people, process, facilities, and technology. To put them together in Landoll and Williams' framework, we will place facilities into the "environment" category and technology into "AIS." AIS can be broken down into deliverables (products); the organization's infrastructure, ranging from the network to end-user platforms; configurations for the architecture; development personnel; and the processes for each, as well as the development environment itself. In constructing the AIS assurance argument, all of these aspects must be considered.

According to Landoll and Williams, the five elements that an organization can use to structure its assurance arguments are (1) assurance need, (2) claims, (3) evidence, (4) reasoning, and (5) an assumption zone. *Assurance need* represents the organization's confidence expectation. *Claims* represent statements that something has a particular property. *Evidence* is observable data that is used within the organization to make judgments or decisions. *Reasoning* represents statements that tie evidence together to establish a claim. The *assumption zone* represents the point at which claims made by the organization can no longer be supported by evidence.

105.5.1.1 Assurance Needs

Assurance needs extend throughout the organization and are the expression of confidence in all the parts of the enterprise. These needs should be detailed enough to represent all of the things that the organization is concerned about (the breadth of the need). Activities that help focus an organization's concerns include business impact assessment (i.e., determination of assets), determination of business goals as aligned with the organization's strategic goals (its vision and mission), and risk, vulnerability, and security assessments of the organization's people, processes, data, facilities, and technology using both technical (tool-based) and nontechnical (frameworks such as NIST SP 800:30) (risk) analyses, the National Security Agency Information Assurance Methodology, ISO 17799/BS7799, and the OCTAVE framework (security) means, in order to determine threats, vulnerabilities, and countermeasures. According to Landoll and Williams, assurance needs are typically characterized in an environment as policies. The assurance need also must reflect the level of confidence that the organization maintains in a particular countermeasure, as it relates to the ability of the countermeasure to protect against threat (the depth of the need). To determine the appropriate depth, the organization must prioritize its risks and establish what level of validation will be required to measure the success of the countermeasure.

105.5.1.2 Claims

To properly analyze assurance, we must look to appropriate security properties. Examples of security properties, as provided in *An Enterprise Assurance Framework*, include:

- Properties that are capable of being validated, such as structure, complexity, and modularity. This is the property of being *analyzable.* An example could include a software package (i.e., complexity, modularity).
- Properties possessing desired or required skills. This is the property of being *capable.* An example could include a sufficiently skilled human resource within the enterprise.
- Properties that are without defect, based on a particular higher level specification. This is the property of being *correct.* An example could include validated data input.
- Properties that can be utilized, implemented, managed, and maintained easily. This is the property of being *easy to use.* An example could include an appropriately designed human interface for intrusion detection or other security tools.
- Properties that create a minimum of waste. This is the property of being *efficient.* An example could include a streamlined process within the enterprise.
- Properties that demonstrate a task or activity that has been repeated. This is the property of being *experienced.* An example could include a highly experienced, long-term human resource within the enterprise.
- Properties that possess essential information. This is the property of being *knowledgeable.* See the example for the experienced property.

- Properties that can be reproduced. This is the *repeatable* property. An example of this could include an appropriate calculation, conducted millions of times, by an automated information system (AIS).
- Properties that can be defended, that are difficult to break or are resistant to attacks. This is the property of being *strong*. An example of this could include a properly secured enterprise architecture.
- Properties of confidence that promote the character (truth) of a person. This is the *trustworthy* property. An example could include an ethical professional or a lifelong friend.

105.5.1.3 Evidence

Evidence can be defined as anything that can assist in validating a claim. Examples of evidence include deliverables or documentation, assessment reports (such as risk or vulnerability assessments, SAS 70s), corroborated interviews, and so on. Evidence can be aggregated if doing so makes its digestion easier (as long as the aggregation can still be validated). Evidence, like claims, has properties, including *correctness*, *analyzability*, and *completeness*. In fact, as Landoll and Williams point out, claims about evidence can be supported by collection and presentation of additional evidence. This evidence is called *circumstantial* and can contribute to the believability of a claim, even though it is not directly related to other evidence for the claim. It is important to note that the relationship between claims and evidence is not one to one. A single piece of evidence may have many properties and support many claims. A good example of this is an assessment or audit deliverable, such as a SAS 70, risk assessment, or vulnerability analysis. A large amount of evidence does not necessarily validate claims. In order to do so, the evidence must be compelling. This is also true of complex systems or environments, where many pieces of evidence must be placed together to create a validation of the entire system or environment. This is fourth category of assurance, known as *reasoning*.

105.5.1.4 The Assumption Zone

Remember what was stated earlier in this chapter—that there is no such thing as perfect security? Remember also that a discussion ensued that stated that senior management could report the point at which they felt comfortable they could accept this "doubt." The "Assumption Zone" is that threshold where the assurance claims are presented, with evidence minimal or absent, with the outcome being that the claims are still accepted by the organization, Examples include elements that do not have direct or significant impact on the security of the organization. This could include documentation surrounding non-critical functions or personnel.

105.6 Enterprise Assurance, through the Security Practitioner's Eyes

Now that we have reviewed the assurance components, we must now translate them into security terms. Imagine that we represent a healthcare provider that has determined it has die following security needs:

- Critical business functions must be available 24/7, 365 days per year.
- Electronic protected health information (ePHI) must carry the maximum protection to achieve compliance and prevent unauthorized disclosure.
- Data assets must be catalogued and reviewed periodically to ensure data integrity.
- All compliance objectives within the Health Insurance Portability and Accountability Act (HIPAA) security rule must be met with at least the minimum necessary protection.

As stated, these security needs could be detailed in a corporate or compliance security policy, along with the requisite procedures. It is important that these deliverables also include measurable expectations (i.e., depth).

According to Landoll and Williams, the properties most relevant to security include analyzability, correctness, completeness, and strength. These four properties translate to the enterprise as follows:

- The property of *analyzability* indicates that complexity is properly managed within the enterprise.
- The property of *correctness* indicates that all functions within the enterprise perform correctly as advertised.
- The property of *completeness* attests to the enterprise completing its due diligence by identifying all known threats (that is, those that can be found) and ensuring that policies and procedures are created, implemented, maintained, monitored, and enforced for the expressed purpose of mitigating, transferring, or accepting risk.
- The property of *strength* indicates the enterprise's ability to stave off, or minimize the impact from, an attack.

Now, it is essential for the enterprise to gather and present its evidence to support its assurance claims. Evidence that applies to the entire enterprise is preferred to evidence that relates only to a subset of the enterprise. Appropriate evidence can include the following:

- Information security documentation, such as a corporate security program, business continuity plan, security incident response plan, or corporate security policies and procedures
- Corporate strategic documentation, such as the business plan or information technology or security strategy documents
- Risk, vulnerability, or security assessments
- Audits
- Interview results
- Satisfaction surveys
- Metrics (such as service levels)
- Contractual agreements

In our example of the healthcare provider, collected evidence could include:

- Business associate agreements
- Information about service levels, both internal and external
- Mandatory HIPAA risk assessment (with appropriate findings generalized to the entire organization)
- Vulnerability scanning results
- Penetration testing results
- Patching and configuration management plans
- Security incident response plan, including the tracking of occurrences and their reporting
- Business continuity plan
- HIPAA policies and procedures, utilized throughout the organization
- Staff security awareness training results
- Compliance walkthroughs
- Internal audits

The provision of supporting, or *circumstantial*, evidence can also support assurance claims made by the organization. Such claims can include the property of trustworthiness or effectiveness. For example, trustworthy and effective people may have a lesser chance of creating security issues for the enterprise. Processes that include intrusion detection, access control activities, logging and monitoring, appropriate media handling, protection against malware, and others augment enterprise protection, lessening the exposure of the environment to vulnerability, particularly if the processes are easy to use and correct.

Strong environments can protect the enterprise from many vulnerabilities, including unauthorized access, terrorism, or a catastrophic event that threatens business continuance, such as a weather emergency. The strong environments do so through appropriately designed facilities (blueprints), physical access controls, and biometric devices, among others. Analyzable, complete, correct, strong, and easy-to-use systems can reduce inadvertent errors that introduce risk or can thwart an attack from a malicious outsider.

When the enterprise has collated its evidence, the hard work begins of evaluating whether the security mechanisms in place meet the stated enterprise assurance needs. To perform this reasoning, claims, evidence, and supporting (circumstantial) evidence are tied together and linked to the appropriate assurance argument. This process should be repeated for all identified assurance needs.

To revisit the question of "How much is enough?" we will now apply it to the evidence we have gathered. No security analog for rating the amount of evidence collected exists, but a legal analog does. This analog was used by Landoll and Williams in the construction of their enterprise framework. These standards include:

- *Evidence beyond a reasonable doubt*—In this standard, evidence cannot be rejected by a reasonable person.
- *Clear and convincing evidence*—In this standard, evidence is presented that a reasonable person could believe.
- *Preponderance of evidence*—In this standard, more evidence exists for than against.
- *Substantial evidence*—In this standard, a significant amount of evidence exists and is available for review.

It is apparent that the issue with these standards is that no terms have been defined, so it leaves them open to interpretation; that is, what is reasonable and what is significant? As metrics in the area of assurance mature, it is likely that more quantifiable standards will be introduced.

105.7 Conclusion

It takes a great deal of effort and diligence for an organization to come to an assurance judgment. Inspecting security implementations in a vacuum, piece by piece, will not guarantee that an enterprise is appropriately secured. Every part of the enterprise must be examined before a judgment can be made about the state of security. After proper evaluation and measurement, and with a little luck, you can go back to the senior management and the Board and emphatically state, "I am confident that we are on the right track!"

Creating a Secure Architecture

Christopher A. Pilewski

Bonnie A. Goins

106.1 What Is Network Security?

As discussed in the chapter entitled “Network Security Overview,” network security may be thought of as the mechanism for providing consistent, appropriate access to confidential information across an organization and ensuring that information’s integrity.

106.2 Why Is Network Security Essential?

An organization cannot leave itself open to any attack on any front; exposures, left unattended, may prove fatal to business continuance. In many cases, the government requires appropriate security controls. In the cases where there is no government mandate, business partners, vendors, and other entities may preclude conducting business with the organization unless it employs appropriate security mechanisms. This also extends to the creation and maintenance of a secure architecture.

106.3 Security Is a Process

Many organizations view security as a technology. This can be seen by the number of organizations that expect all security initiatives, as well as their planning, design, execution, and maintenance, to be carried out solely by technical departments, such as Information Systems, Application Development, or others. This is an incorrect perception. Technology most certainly plays a part in protecting an organization against attack or loss; however, the diligent provision of a secure architecture involves all aspects of the organization. *People* must be educated regarding their responsibilities for security and then enabled by the organization to properly carry out these responsibilities. *Processes* must be reviewed across the entire organization, to determine where assets reside, how they interact, the results produced from interactions, threats that may be present in the environment, and the mechanisms that protect organizational assets. *Facilities* must be evaluated to ensure that they are constructed and maintained appropriate to function. Security considerations must also be taken into account when evaluating a facility.

As if the resources necessary to properly address all the aspects listed above were not enough, all of these aspects must be evaluated periodically, over time. Why? Let us say an organization mustered a team to address all of these aspects, with the requirement that it detail any discovered exposures and fix them, as appropriate. Once completed, the organization is confident that it has done its work for the long term. Six months down the road, the government enacts legislation that requires executives to sign off on a document indicating that the organization has done its job and provided a secure environment in which to do business. The government gives all organizations six months to comply prior to audit. Any organizations failing to meet regulatory requirements will be fined, at minimum; at maximum, litigation and possible jail terms for personnel will also ensue.

Sound familiar? Organizations that will be bound by Sarbanes–Oxley legislation in July 2005 face this very scenario. Healthcare and financial organizations are enmeshed in meeting security and privacy regulations at this writing, through the enactment of the Health Insurance Portability and Accountability Act of 1996 (HIPAA) and the Gramm–Leach–Bliley Act (GLBA).

Now go back to the scenario described above. Would it be prudent, as a senior executive, to sign an affidavit asserting that the organization is rock-solid from a security perspective with the information available from an assessment conducted six months ago? Perhaps the executive is not aware that the Information Technology department has performed a major network redesign over the past six months. Perhaps she has just been informed that Applications Development has completed and integrated a world-class data warehouse, developed entirely in-house. Human Resources has also informed her that the updates to employee job descriptions, as well as the personnel policy additions that commenced a year ago, are now complete and awaiting her signature. Would it be prudent, as a senior executive, to attest to the organization's security state using information that appears to be outdated?

This scenario, although it may seem unlikely at first inspection, happens daily in the business world. A static organization is one that has ceased to function. Because the natures of business and technology are dynamic, security must be periodically evaluated, as well as diligently documented and reported. A discussion of the security cycle follows.

106.3.1 Assess

As stated in the chapter entitled "Network Security Overview," an assessment is a snapshot, or a point-in-time view of the current state of security within an organization. While it is never possible to identify and neutralize all risks and threats to an organization and its function, the assessment process goes a long way toward identifying exposures that could impact the organization.

Some organizations argue that the moment an assessment is completed, it is out-of-date. While this argument may seem sound on its merits, and while the authors would concur that periodic assessment plays an important role in obtaining current information about an organization's state of security, organizations typically do not experience major changes on a daily basis, every day, for an extended period of time. Organizations that find themselves in a chaotic state of change, on a major scale and on a daily basis, may indeed require assessment on a more frequent basis, in order to accurately depict the changing environment.

106.3.2 Nonintrusive Assessment Methods

Nonintrusive security assessments provide a "snapshot" of the organization's current state. The final analysis relies on accurate and truthful representation by the organization and its interviewees. No assessment can discover 100 percent of the exposures within an environment and, as such, it is highly recommended that organizations review their current states of security periodically and diligently to minimize risk and threat.

It is important to note that nonintrusive assessments are very important to the health of the network. Based on the fact that network security is driven, as discussed, by people, processes, technology, and facilities, all these aspects must be appropriately assessed in order to provide a holistic view of network security.

106.3.2.1 Document Review

Documentation present within the organization is obtained and reviewed to provide background information for the security assessment. Documents evaluated vary, and typically include information security documentation, such as results from previous assessments and audits; security policies and procedures, disaster and incident response plans; service level, nondisclosure vendor and business partner agreements; insurance carried by the organization that relates to the network environment; network architecture designs and drawings; configurations of network devices, servers, and workstations; facilities blueprints; human resources policies; job descriptions; etc.

106.3.2.2 Interviews

Interviews are conducted with representation from each role in the organization as they fulfill the scope of the assessment. Roles typically interviewed include senior management, line or technical management, departmental management, full-time technical and business resources, and casual employees, such as part-time employees, temporaries, and interns. Sample size can be kept low, such as one to two appropriate interviewees per role, if the information obtained from the interviews can be generalized across the role for the organization.

106.3.2.3 System Demonstrations

System demonstrations are conducted with selected interviewees. This is done to verify information obtained during the interview, but also to gain insight into the technical operations of the organization, without intrusion, so that a determination can be made whether it is possible for users to bypass existing security controls. The assessor makes no attempt to access the organization's network; the interviewee is the "driver" and the assessor merely an interested observer.

106.3.2.4 Site Visits

Site visits, or "walkthroughs," fulfill a number of objectives during a security assessment. First, they provide the assessor with information relative to the physical security of the facility. Aspects observed can include appropriate, conspicuously posted evacuation instructions for personnel in the event of emergency; appropriate, conspicuously posted hazardous materials handling procedures; appropriate fire suppression equipment, such as extinguishers and FM-200 systems in any resident data center; appropriate climate controls; the presence of an access-controlled data or network operations center; appropriate facility construction (i.e., can the building withstand weather-related or catastrophic disasters?); "clean" workspaces (i.e., sensitive material is obscured from public view on walkthrough); inappropriate posting or otherwise public display of access credentials, such as user IDs or passwords; proper orientation of monitors and other display devices; any individuals inspecting visitors to the facility (i.e., receptionists, guards) and the methods by which they track facility access; etc.

Many organizations are distributed among multiple sites. It is important for assessors to determine whether it is prudent to visit each facility separately or whether there are sufficient and justifiable grounds for aggregating sites for reporting purposes. If aggregation for reporting does occur, it is still important to conduct the documentation and interviewing components of the assessment at these sites, either through standard telephone or video conferencing, or by another appropriate method. Substantiation of the information obtained should occur as soon as possible after the initial remote meeting.

106.3.2.5 Business Impact Analysis (BIA)

This method is often associated with the organization's business continuance efforts. As the method's title suggests, this assessment is conducted to determine how the loss of a particular asset or collection of assets impacts an organization.

The inventory and classification of assets in the organization is critical to the successful application of this method. Potentially, this is one of the most difficult tasks an organization can undertake. Where to start? A starting point for many organizations is to identify and document information assets, or data, present in the environment. This initiative can begin with any data that is sensitive within the environment. Unfortunately, many organizations do not have a data classification scheme in place; this makes determination of whether data is "sensitive" more difficult; fortunately, however, organizations can apply some common-sense rules to start this process. For example, healthcare organizations are bound by regulations that stipulate that all personally identifiable healthcare information must be kept strictly confidential; therefore, it follows that this information would be classified at the highest sensitivity level. The organization would then proceed to identify and classify data at the next level, and so on, until the task is completed. Many organizations choose to undertake this activity at a departmental level, so that it can be completed in a timely manner.

Threats to the assets, as well as countermeasures to those assets, are also evaluated in the method. This allows the organization to determine the impact of an asset or assets' loss to the organization. Data is then collated and presented to the organization for analysis and dissemination, as appropriate.

106.3.2.6 Risk Assessment

A risk assessment, or risk analysis, is a method that utilizes metrics to characterize exposures in the environment, as well as the probability of their occurrence. These assessments can be quantitative or qualitative in nature. If the organization has a significant amount of data it can employ in analysis, as well as a sufficient amount of time and resources, the analysis can be made more quantitative, or metric driven. If time, resources, and historic (or trend) data is not readily available, a qualitative (but still metric) analysis can be undertaken. Organizations interested in researching risk assessment will find a wealth of information on the Internet and in reference books, including this book. The Society for Risk Analysis is also a good site to visit for this information.

106.3.2.7 Auditing

Auditing is an assessment against the controls present to protect an organization. Control methodologies include COBIT; details on this method can be viewed through the ISACA (Information Systems Audit and Control Association).

106.3.3 Intrusive Assessment Methods

Intrusive methods are used in conjunction with data gathering to provide a more complete view of exposures to the environment. The following are some of the activities conducted during intrusive testing.

106.3.3.1 Footprinting and Enumeration

It is useful during the data-gathering process for the intrusive assessor to evaluate information that may be publicly available about the organization. Web sites, listservs, chat rooms, and other Web sources may contain information that has been illicitly obtained or has been posted by staff. Personnel may have a technology question that can be legitimately answered through the Internet; however, it is important to remember that the Internet is also mined for information by attackers. While the intent of the staff member may be good, posting too much information, or sensitive information, can give an attacker a leg up into the organization.

106.3.3.2 Social Engineering

It is highly impractical for an attacker to attempt a technological means of entry into an organization when tricking a staff member or obtaining sensitive information through "dumpster diving" or "shoulder surfing" is available and effective. Attackers using this method to obtain information prey upon people's desire to assist and their lack of understanding of security responsibilities, in order to gain access to an organization's resources. Social engineering is an activity that directly tests an organization's processes and its security awareness. Social engineers attempt to gain access to information or to restricted premises by means of distraction, misdirection, impersonation, or other means. Although social engineering is often performed anecdotally, it is a surprisingly effective activity. A common social engineering technique is to acquire an organization's phone directory and call its help desk impersonating a manager or an employee and demand that the target's password be changed to a simple word or phrase. Although it is a simple deception, it often works, particularly when shifts are ending. Other, more imaginative methods might employ social engineers disguised as package or food delivery persons, or as the organization's own uniformed staff.

106.3.3.3 Password Cracking

While many organizations provide guidance to staff regarding the construction and maintenance of passwords, many others do not. Intrusive assessors often use software tools to attempt to "crack," or break, passwords. These tools make multiple attempts to force the discovery of passwords used in the environment. This method is called "brute force." The majority of passwords can be discovered in an organization in a very short period of time.

106.3.3.4 Network Mapping

Network mapping is a technique used by intrusive assessors to "draw" the current network architecture. This "map" is used by the assessor and network administrators or information technology resources to review devices that are able to access the organization's resources. If there are any devices on the network that are unfamiliar to, or not approved by, the organization, they may belong to an attacker and, as such, should be disconnected from the architecture pursuant to the organization's security incident response plan.

106.3.3.5 Vulnerability Scanning

Vulnerability scanning uses open source or commercially available software to "scan" (probe) its target for specific technical vulnerabilities. The target may be a server, workstation, switch, router, firewall, or an entire network range. The information returned by the scanner can be quite extensive. It represents specific information about the target(s), such as the IP and MAC addresses, the operating system and version, and a list of that target's technical vulnerabilities.

The exact quantity and types of vulnerabilities that the scanner detects is the product of two factors: (1) the set of vulnerabilities that the scanner is instructed to look for (often called its profile), and (2) the vulnerabilities present on the target(s). It is possible for the target to have vulnerabilities that the scanner's profile does not instruct it to look for, and therefore are not found. Scanning profiles are often restricted to contain the time that the scan will take, or to help minimize the impact on the target device. It is also possible for a scanner to reveal vulnerabilities that the target does not have. These are called false positives. As scanning software evolves, false positives are becoming increasingly rare.

Common vulnerabilities discovered during scanning include detection of specific information that would lead, if exploited, to unrestricted access to the target device (an administrator account without password protection, for example, or anonymous read or read/write access to network objects). Other vulnerabilities reveal detection of services or protocols that permit or facilitate denial-of-service attacks or simply additional information gathering that could make further attacks possible.

While extremely valuable, data from vulnerability scanning should not be evaluated in isolation. Vulnerability scans frequently reveal information that requires further investigation to clarify. Most of all, vulnerability scanning should not be considered a substitute for security awareness and other measures.

106.3.3.6 Attack and Penetration

Attack and penetration can be thought of as the exploitation of a specific vulnerability, or a set of vulnerabilities, located by vulnerability scanning. The intent of attack and penetration is typically to determine the impact that successful exploitation would have. It may have a specific goal, such as a particular file or piece of information, or it may be more general. In a hypothetical example, successful penetration of a firewall could lead to successful access to an open service, or an openly writable directory on a server. This, in turn, may allow a keystroke logger to be surreptitiously installed where a variety of account names and passwords may be acquired and used later.

106.3.3.7 War Dialing and War Driving

Additional assessment activities may benefit an organization, depending on the environment. War dialing uses software programs to dial large blocks of phone numbers in an effort to locate modems on computers (or on other devices) that can be exploited later. Although war dialing can be time consuming, many commercially available programs can use multiple modems at a time to dial huge blocks of phone numbers in little time.

War driving is similar to war dialing. War driving uses commercial or publicly available software and hardware to detect wireless LANs, determine their characteristics, and break applicable encryption if detected. The war driver can "drive" from location to location looking for random wireless LANs, or use antennas to pinpoint and gain access to a predetermined wireless LAN from a great distance.

106.3.4 Remediate

When assessment activities have been completed and the data has been analyzed to determine where the organization is exposed, those exposures are then prioritized so that they can be appropriately addressed. Addressing and correcting exposures in an environment is called remediation. These fixes are typically activities resulting in a deliverable, such as a policy, procedure, technical fix, or facility upgrade, that satisfactorily addresses the issue created by the exposure.

106.3.5 Remediation Planning

Like any organizational initiative, remediation must be carefully planned for prior to its execution if it is to be successful. Given that resources, time, and dollars are finite, it is prudent to ensure from the onset that they are being utilized in a way that brings maximum benefit to the organization. Nonintrusive and intrusive assessment results must be carefully reviewed; exposures must be prioritized by severity level. This prioritization tells the organization how seriously it would be impacted if an exposure were successfully exploited. An organization might choose to remediate all of its "High" severity exposures as a precaution, or it might remediate exposures across the results. A good rule of thumb is never to fix something if it costs more than leaving it alone. For example, if an organization loses ten cents on a particular transaction that would cost twenty dollars to fix, dollars would be lost in the exposure's remediation. An exception would be any exposure that results in injury or loss of life; these exposures must always be corrected. Finally, if there is an exposure that costs little or nothing to fix, do so, even if it has a lower priority. If it costs nothing to fix, it will reap a benefit for the organization. Remember to calculate both resource time and dollars in the cost of remediation.

106.3.6 Remediation Activities

Remediation activities for organizations vary but may include recommendation of templates to serve as the foundation of a corporate security policy; recommendations for creation of appropriate targeted security procedures; review of an organization's business continuity, disaster, or incident response plans; review and implementation of the organization's technologies and architectures, from a security standpoint; identification of an appropriate scope of responsibilities and skill level for the security professionals; provision of ongoing executive-level security strategy consulting; high-level identification of educational processes and ongoing training required to support the organization's implemented security program; and other remediation activities, as pursued by the organization to meet its business, regulatory, and technology goals.

106.4 Layered Security for Network Architecture

Securing the architecture can be a complicated and confusing task. The network must first be properly assessed and documented in terms of its physical locations, links, and topologies. After a network itself has been properly assessed and documented, the constituent components should be known and indexed. The network perimeter can be clearly identified as the set of all entry and exit points into and out of the network. These also should be identified and indexed.

Typical entry and exit points include portals (or gateways) to the Internet, remote access servers, network connections to business partners, and virtual private networks (VPNs). Entry and exit points that are often unconsidered include the physical server rooms and wiring closets, unrestricted network wall ports, certain types of wide area network (WAN) links, and exposed computer workstations.

Technical safeguards can now be identified and discussed to help ensure controlled access to each entry and exit point. It may be tempting to address only the most obvious or convenient entry and exit points. This can be a serious mistake. While the relative priorities of different network perimeter entry points may be debatable, their importance is not. Locking a door is a sound security measure, but this practice is more efficacious when the window next to the door is not standing open.

A wide variety of technical safeguards and practices exist. Due to the inherent nature of networking technologies, the applicable safeguards are often less than completely effective. A layered approach is indicated in a secure network architecture where technologies and processes work together.

106.4.1 Perimeter Connection Security

Network perimeter connections can be thought of as the first layer of a comprehensive approach to secure network architecture. These connections should be listed individually and appropriate safeguards should be designed and implemented for each.

106.4.1.1 Internet Service Provider (ISP) Connections

An expanding universe of threats exists on the Internet. Attacks from sources on the Internet can be subtle and targeted at precise information that the attacker wants. Attacks can also be dramatic and highly destructive with motives that are unclear or esoteric. Many organizations already protect portals to the Internet with one or more network firewalls. Network firewalls can protect an organization from threats originating from other sources as well. A firewall is a network device that filters and logs network traffic based on a predetermined set of rules, typically called a rule base. Incoming network traffic can be forwarded or dropped. It can be logged in either case.

The correct use of network firewalls represents one of the most useful technical safeguards in a secure network architecture. Correct use, however, is critical. The firewall itself must be located in a secure location, such as a data center, where access is restricted and monitored. The firewall must be properly maintained. Its software operating system must be updated regularly, and it must be configured with a sufficient processor and sufficient memory to effectively use its rule base. The rule base itself must be aligned with the organization's security policies, which must clearly define the network traffic that is permitted to be forwarded in and out of the organization.

An organization might have one ISP in a single physical location or it might have several ISPs in different locations around the world. Each connection must be identified and protected by a firewall. Properly used, network firewalls can be a highly effective safeguard to address threats originating from connections to the Internet and from a number of entry and exit points to the network.

106.4.1.2 Remote Access Connections

A variety of remote access technologies exist. These include dedicated phone lines, dial-up servers, wireless LANs, and others. Remote access connections must be listed completely and described with their individual business needs. This will allow for matching the appropriate safeguards to each connection identified.

Common remote access connections include two general types of connections: (1) those intended for end users and (2) those intended for use by an organization's Information Technology department. In both cases, the permitted use of these connections must be clearly identified. Specifically, this means that remote access connections must be described in terms of the information assets that they are intended and permitted to access. Dial-up lines or a dial-up server for end-user application or document access would be one example of remote access for end users. A modem connected to the serial port of a router would be an example of remote access for IT uses. In each case, the remote access connection should be configured to permit access only to the intended resources. The organization's security policies must make these information assets clear. Unrestricted forms of remote access should be avoided. Unrestricted forms of remote access can allow a remote computer that has been compromised (by a virus or a Trojan horse, for example) to compromise the organization's computer environment as well.

Access to remote access connections can be restricted by several means. As with connections to ISPs, remote access servers can be placed behind a network firewall (in a segregated network segment called a DMZ) so that only predefined network traffic that matches the firewall's rule base will be forwarded. Network firewalls are particularly effective at segregating network traffic. Other safeguards include thin-client or remote management solutions that access information indirectly. There are advantages to each approach, depending on business goals.

106.4.1.3 Business Partner Connections

Connections to business partners (usually vendors or customers) represent another type of connection that requires definition, examination, and appropriate safeguards. Business partners can connect to the organization with leased circuits, with VPNs, with modems connected directly to servers, or by other means. This type of connection requires similar measures as connections to ISPs and remote access connections. Many organizations will deploy safeguards on connections to their ISP but neglect to employ similar safeguards on connections to other organizations. There are numerous risks associated with unrestricted connections to business partners. If the networks of business partners are connected without the protection of a network firewall, a malicious party that manages to penetrate the partner's network has also penetrated yours.

Connections to business partners must first be fully listed. This may not always be a simple task. Connections to business partners can be confused with other WAN connections. Once they are

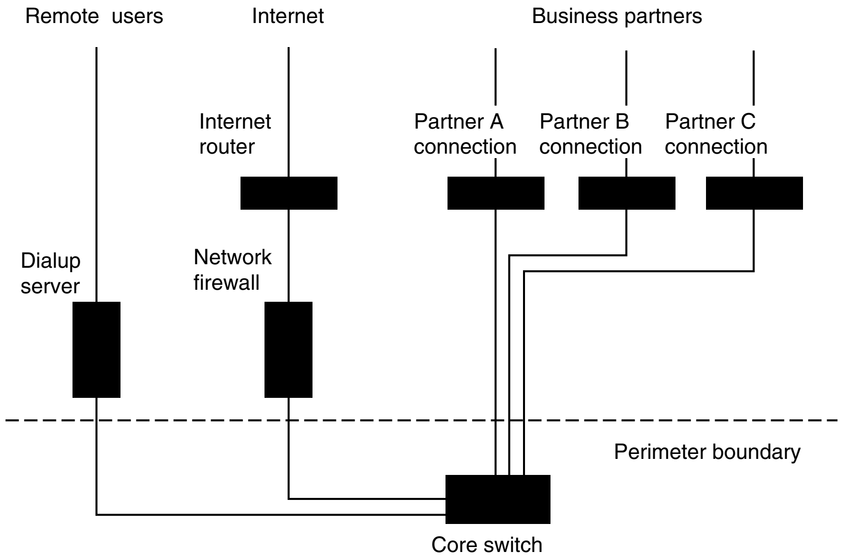

EXHIBIT 106.1 Network perimeter with protected internet connection only.

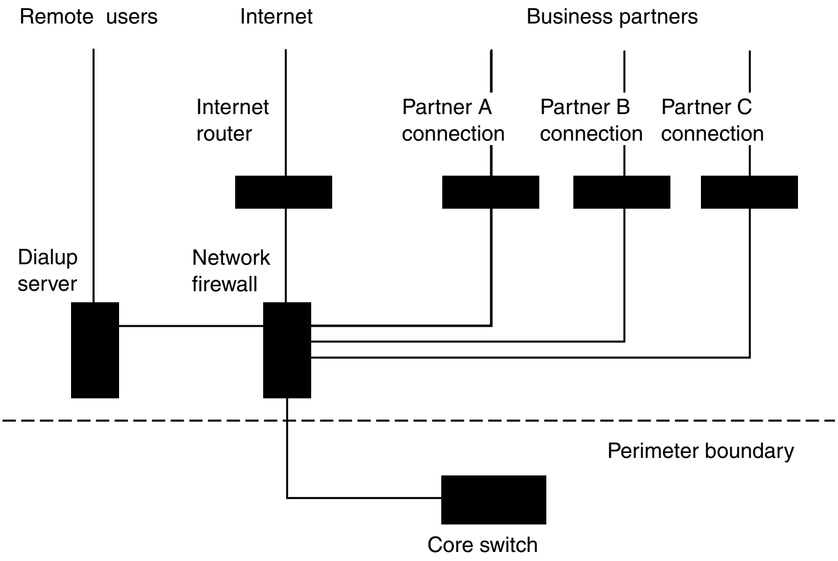

EXHIBIT 106.2 Network perimeter with protected connections.

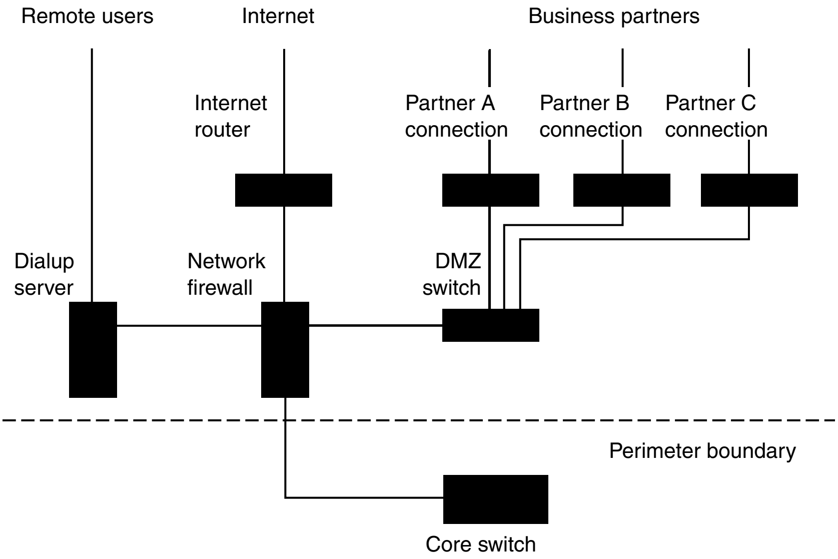

EXHIBIT 106.3 Network perimeter utilizing DMZ switch.

identified, permitted network traffic into and out of the organization must be explicitly defined in the security policy. For each connection, the intended far-end parties, the files transferred, and the applications used must all be identified and documented. This information will be used to construct an effective rule base for the firewall.

106.4.1.4 Perimeter Connection Security Examples

The typical network perimeter configuration shown in Exhibit 106.1 restricts access on some perimeter connections. The firewall protects the connection to the Internet but the dial-up server and business partners bypass the firewall and connect to the network around it.

The network perimeter configuration shown in Exhibit 106.2 restricts access on all perimeter connections. The connection to the Internet is protected by the firewall. The other dial-up servers and business partners connect through the firewall on separate DMZ ports. The firewall can filter and log network traffic with an appropriate set of rules for each connection.

The network perimeter configuration shown in Exhibit 106.3 also restricts access on all perimeter connections, but it employs another device in addition to the firewall. The connection to the Internet and the connection to the dial-up server are protected by the firewall. Business partners connect to the firewall through a separate DMZ switch.

This approach can make connecting business partners easier if the network firewall does not have enough ports for each external source to connect individually. This configuration is preferable to connecting business partners directly to the internal network (without protection), but certain considerations apply. Each business partner must be placed on ports belonging to separate virtual LANs (VLANs). If they are not connected in separate VLANs, two or more business partners could eavesdrop or interfere with each other's network traffic. Further, the firewall rule base must be configured to properly filter and log all the traffic sources connected to the DMZ switch.

106.5 Reassess

It is highly recommended that organizations revisit their environments post-remediation to ensure that the corrections have not created new exposures, and to identify any additional exposures that exist in the environment.

106.6 Summary

It is clear that securing a network, and indeed, network security itself, is process oriented and cyclic. To begin, a determination must be made as to the organization's current state of security. Multiple security assessment frameworks are available to facilitate the assessment process and should be selected based on alignment with the organization's business case and security objectives.

Once that determination has been made, it is possible to prioritize and to address the exposures present. A "layered security" approach permits the organization to correct the exposures by priority and to construct multiple barriers to delay or prevent attackers from exploiting network resources. This concept supports the notion that people, processes, data, technology, and facilities must be addressed during the creation and maintenance of a secure environment.

107

Common Models for Architecting an Enterprise Security Capability

Matthew J. Decker

107.1 Introduction

Enterprise security architecture (ESA) comprises all aspects of a security program, including corporate leadership, strategy, organizational structure, policies, procedures, standards, and technical components. The purpose of this chapter is to present a road map for achieving an effective ESA, via implementation of common security models, standards, and practices.

107.2 System Security Models

The three system security models briefed in this section are well known, and have formed the basis for the development of secure systems, pursuant to the needs of the entities that employed them. Each offers a different definition for a secure system. This drives home the point, at a most fundamental level, that an organization must clearly define security in terms of what makes sense for them. The models are presented in the order that they were published, from earliest to most recent.

107.2.1 Bell and LaPadula Model

The Bell and LaPadula (BLP) Model is most commonly associated with the classification policy used by the military, which is more concerned with the confidentiality of data at higher levels of sensitivity than the ability of users to modify that data, intentionally or not. The BLP is a finite-state machine model that employs the following logic: if a machine starts in a secure state and all possible transitions between states within the machine result in secure states, then the machine is secure.

There are four components to the BLP Model, as follows:

1. *Subjects* are the users and system executable processes.
2. *Objects* are the data elements.
3. *Modes of access* include read, write, execute, and combinations thereof.
4. *Security levels* are essentially security classification levels.

These four components are used to establish three security principles to formulate the basis for the BLP Model. The three principles are as follows:

1. *Simple security property*, which states that the level of the subject must be at least the level of the object if the mode of access allows the level to be read.
2. *Confinement property* (a.k.a. "*star*" *property, or *-property*), which states that the level of the object must be at least the level of the subject if the mode of access allows the subject to write.
3. *Tranquility principle*, which states that the operation may not change the classification level of the object.

Confidentiality of data is protected, but the fact that users with lower privileges are permitted to write data to objects with a higher sensitivity level does not sit well in many environments. Biba developed a model to address this integrity issue.

107.2.2 Biba Model

The Biba Integrity Model was published at Mitre after Biba noticed that the BLP Model did not address data integrity. The problem was that lower-level security users could overwrite classified documents that they did not have the authority to read. Although the Biba Model has not been widely implemented, it is well known. The Biba Model is based on a hierarchy of integrity levels. Integrity levels (a hierarchy of security classifications) are assigned to subjects (e.g., users and programs) and objects (data elements), and are based on axioms (rules) that define the integrity policy to follow.

The Biba Model supports five different integrity policies, including:

1. *Low Water Mark Policy* permits the integrity level of a subject to change. The new integrity level is set to the lower of the integrity levels for the object, or for the subject that last performed an operation on the object.
2. *Low Water Mark Policy for Objects* adds permission to permit the integrity level of an object to change.
3. *Low Water Mark Integrity Audit Policy* adds axioms to measure the possible corruption of data.
4. *Ring Policy* enforces a static integrity level for the life of both subjects and objects. Subjects cannot write to objects with higher integrity levels, or read objects with lower integrity levels. Further, subjects cannot invoke other subjects with higher integrity levels or write to objects with a higher integrity level, but can read objects at a higher integrity level.
5. *Strict Integrity Policy* adds to the Ring Policy the axiom that a subject cannot read objects with a higher integrity level.

The BLP Model works well for military environments, although it is not well suited to commercial entities because it does not address data integrity. The Biba Model addresses this integrity issue but is still not sufficient in commercial environments to prevent a single individual with a high level of authority from manipulating critical data, unchecked. The Clark–Wilson Model, discussed next, addresses both of these issues.

107.2.3 Clark–Wilson Model

The Clark–Wilson Model is most commonly used in a commercial environment because it protects the integrity of financial and accounting data, and reduces the likelihood of fraud. This model defines three goals of integrity, as follows:

1. Unauthorized subjects cannot make any changes.
2. Authorized subjects cannot make any unauthorized changes.
3. Internal and external consistency is maintained.

In a commercial environment, these goals are well suited to ensuring the integrity of corporate financial and accounting data. Not only are unauthorized individuals prohibited access to protected data, but even individuals authorized to access this data are prohibited from making changes that might result in the loss or corruption of financial data and records.

Clark–Wilson introduced an integrity model employing two mechanisms to realize the stated integrity goals, as follows:

1. *Well-formed transactions*, which introduces the concept of duality for each transaction. Each transaction is recorded in at least two places such that a duplicate record exists for each transaction. This is not necessarily a copy of the transaction, but a separate record that is used to validate the accuracy and validity of the original transaction.
2. *Separation of duty*, which prohibits one person from having access to both sides of a well-formed transaction, and also prohibits one individual from having access to all steps of a complete transaction process. This reduces the likelihood of fraud by forcing collusion between multiple users if the fraud is to go undetected.

This integrity model does not apply classification levels to data, or users. Instead, it places strict controls on what programs have permission to manipulate certain data, and what users have access to these various programs.

107.3 Common Standards and Practices

Common security standards and practices are tools used in conjunction with modeling techniques and should be adopted by organizations as a matter of policy. In fact, although they are called "standards," they are actually guidelines until they are adopted by an organization as its standard. Publications addressed in this section include ISO 17799, COBIT, Common Criteria (ISO 15408), and NIST's Generally Accepted Principles and Practices for Securing Information Technology Systems. The first three are internationally accepted standards, whereas the fourth one is exactly what it states to be, which is a statement of generally accepted principles and practices. Each of these shares a number of common characteristics, including:

- They are all reasonable and practical.
- Where they overlap, they are generally consistent with one another.
- They are applicable for use in any organization, or any industry.
- Tuning to the organization and culture by adopting only those focus areas relevant to the business or mission is expected for an effective implementation.
- They can be employed in parallel; thus, selection of one does not preclude use of the others.

Of course, for these statements to be true, it is clear that all aspects of these common standards and practices are not utilized by every organization. Every organization, especially from different lines of business, should select its own standard(s), and then the components of the standard(s) with which it intends to comply. Each of the standards presented in this section is well known, and has been thoroughly implemented in practice.

107.3.1 BS 7799 and ISO 17799

BS 7799 Parts 1 and 2, and ISO 17799 are addressed together in this chapter because they are so closely related. BS 7799 Part 1 has essentially been adopted as ISO 17799, and thus warrants no further discussion for our immediate purposes. We discuss ISO 17799 shortly; thus, providing highlights of BS 7799 Part 1 would prove redundant. So why mention BS 7799 in this chapter at all? There are two reasons for this. The first objective is to make clear the origins of the ISO standard. The second and more significant point is that BS 7799 Part 2 establishes the concept of an Information Security Management System (ISMS), which is not addressed in the ISO standard and is not likely to be adopted by ISO any time in the near future.

BS 7799 Part 2 (BS 7799-2:2002) was published on September 5, 2002. It provides the framework for an ISMS establishing monitoring and control of security systems, thereby providing a framework to minimize business risk. The concept of an ISMS may be of greater importance than the original Code of Practice (Part 1) because it enables a security program to continue to fulfill corporate, customer, and legal requirements.

BS 7799-2:2002 provides for the following:

- Guidance on creating an ISMS
- A Plan-Do-Check-Act (PDCA) Model for creating and maintaining an effective ISMS
- Critical success factors to successfully implement information security
- Ability to continually improve the security management process
- Ability to continually assess security procedures in the light of changing business requirements and technology threats

ISO 17799 (ISO/IEC 17799:2000) is essentially BS 7799 Part 1, with minor revisions. The purpose of the standard is to establish a Code of Practice for Information Security Management. This standard establishes a hierarchy of 127 controls, within 36 control objectives, within 10 security domains.

The ten security domains that form the framework of the standard are as follows:

1. Security Policy
2. Organizational Security
3. Asset Classification and Control
4. Personnel Security
5. Physical & Environmental Security
6. Communications and Operations Management
7. Access Control
8. Systems Development and Maintenance
9. Business Continuity Management
10. Compliance

Within these ten domains lies the set of 36 control objectives, which are further broken down to reveal 127 more detailed controls. An organization should select those controls that are important to achieving their security goals, and set aside the others. Organizations choosing to adopt this standard need not attempt to comply with every aspect of the standard. Like every other standard, it should be applied in accordance with the needs of the organization.

ISO 17799 maintains a focus on IT security. It is specific in terms of what constitutes sound security practices, yet does not recommend technology specific guidelines. Certification to the standard can be made an organizational goal but most organizations simply use the standard to benchmark their security capability against sound practices.

BS 7799-2:2002 and ISO/IEC 17799:2000 are available online (http://www.iso-standards-international.com/bs-7799.htm) or via CD-ROM for a nominal fee.

107.3.2 COBIT®

COBIT (Control Objectives for Information and related Technology) was developed jointly by the IT Governance Institute and the Information Systems Audit and Control Association (ISACA) as a generally applicable standard for sound information technology (IT) security and control practices, and is now in its third edition (COBIT® 3rd edition©). This widely accepted standard provides a reference framework for management, users, auditors, and security practitioners.

COBIT is a mature standard that continues to be updated and improved. The COBIT IT processes, business requirements, and detailed control objectives define what needs to be done to implement an effective control structure. The IT control practices provide the more detailed how and why needed by management, service providers, end users, and control professionals to implement highly specific controls based on an analysis of operational and IT risks.

COBIT provides an IT governance and objectives framework, stated in business terms. Broader than just security, this is a six-volume work containing an IT governance guideline, and an entire volume of management guidelines that provide management tools to use for evaluating the status and effectiveness of the enterprise. This standard establishes a hierarchy of 318 detailed control objectives within 34 high-level control objectives (IT processes), and are organized within 4 domains.

The framework for these four domains, and the number of IT processes addressed within each, is as follows:

- Planning and Organization (PO) contains 11 high-level control objectives.
- Acquisition and Implementation (AI) contains six high-level control objectives.
- Delivery and Support (DS) contains 13 high-level control objectives.
- Monitoring (M) contains four high-level control objectives.

It is beyond the scope of this chapter to delve into the details of the detailed control objectives; however, it is worthwhile to tie in how this standard can be used to assist with establishing an overall ESA. A break-out of one of the 34 high-level control objectives is used to emphasize this point. The sample below is taken from the COBIT Framework document, Planning and Organization domain, Objective 8 (PO8), ensuring compliance with external requirements. COBIT structures this high-level control objective as follows:

Control over the IT process of

ensuring compliance with external requirements

that satisfies the business requirement

to meet legal, regulatory, and contractual obligations

is enabled by

identifying and analyzing external requirements for their IT impact, and taking appropriate measures to comply with them

and takes into consideration

- Laws, regulations and contracts
- Monitoring legal and regulatory developments
- Regular monitoring for compliance

- Safety and ergonomics
- Privacy
- Intellectual property

This sample illustrates several points related to establishing an overall ESA:

- *That IT controls are driven by external factors, not within the control of the organization.* Other high-level control objectives address internal factors as well.
- *That controls placed into operations are there to satisfy a specific business requirement.* All of the high-level control objectives identify the business requirement for the stated control.
- *A clear indication that a legal representative should play a key role in the overall security program and architecture.* Other high-level control objectives bring out the need for involvement of additional non-security, non-IT functions, each of which should have a say in the overall security scheme.

The majority of COBIT 3rd edition is available for complimentary download, as an open standard, from www.isaca.org/cobit.htm. The entire COBIT 3rd edition print and CD-ROM, six-volume set can be purchased for a nominal fee, and is discounted to ISACA members.

107.3.3 Common Criteria (ISO 15408)

Version 2.1 of the Common Criteria for Information Technology Security Evaluation (Common Criteria) is a revision that aligns it with International Standard ISO/IEC 15408:1999. This standard largely supersedes the Trusted Computer System Evaluation Criteria (5200.28-STD—Orange Book, also known as TCSEC), dated December 26, 1985. TCSEC is one of the best-known documents comprising the rainbow series, which is a library of documents that addressed specific areas of computer security. Each of the documents is a different color, which is how they became to be referred to as the Rainbow Series. If the reader is interested in further information about the Rainbow Series, most of the documents can be found online at http://www.radium.ncsc.mil/tpep/library/rainbow/.

The objective of the Common Criteria is to provide a standard approach to addressing IT security during the processes of development, evaluation, and operation of targeted systems. Common Criteria can thus be adopted as a standard for use within an organization's system development life cycle (SDLC). It is sound practice to reduce the risk of project failure by adopting an SDLC to guide developers throughout development projects. Common SDLC methodologies generally fall into either "Heavy" or "Agile" camps, and there are literally dozens of widely known and accepted methodologies within each camp. Some common examples include Waterfall Methodology, Rapid Application Development (RAD), Spiral/Cyclic Methodology, Microsoft Solutions Framework (MSF), Scrum, and Extreme Programming (XP). One of the critical success factors met by the Common Criteria is the fact that it does not mandate any specific development methodology or life-cycle model; thus, it can be used by developers without forcing them into a methodology not suitable to their approach to system development.

Security specifications written using Common Criteria, and IT products or systems shown to be compliant with such specifications, are considered ISO/IEC 15408:1999 compliant, although certification of compliance can only be achieved through accredited evaluation facilities known as Common Criteria Testing Laboratories (CCTLs). It is important to note that Common Criteria is not applied as a whole to any particular system, or target of evaluation (TOE), as the standard is very large and complex. A security target (ST) is created using elements of the Common Criteria in an effort to provide the basis for evaluation and certification against the standard. Protection profiles (PPs) are developed and used to provide implementation-independent statements of security requirements that are shown to address threats that exist in specified environments.

PPs are needed when setting the standard for a particular product type, or to create specifications for systems or services as the basis for procurement. Numerous validated protection profiles have been created and approved, and are available online at http://niap.nist.gov/cc-scheme/. This site also contains information regarding validated products, accredited CCTLs, and other useful information.

107.3.4 NIST SP 800-14

NIST (National Institute of Standards and Technology) is a U.S. Government organization whose mission is to develop and promote measurement, standards, and technology to enhance productivity, facilitate trade, and improve the quality of life. NIST has a Computer Security Division (CSD) that is dedicated to improving information systems security by:

- Raising awareness of IT risks, vulnerabilities, and protection requirements
- Researching, studying, and advising agencies of IT vulnerabilities
- Devising techniques for the cost-effective security and privacy of sensitive federal systems
- Developing standards, metrics, tests, and validation programs
- Developing guidance to increase secure IT planning, implementation, management, and operation

NIST Special Publication 800–14, *Generally Accepted Principles and Practices for Securing Information Technology Systems*, is an excellent resource for providing a baseline that organizations can use to establish and review their IT security programs. The document gives a foundation that organizations can reference when conducting multi-organizational business as well as internal business. The intended audience for the guideline includes management, internal auditors, users, system developers, and security practitioners. The following 14 common IT security practices are addressed in this publication:

1. Policy
2. Program management
3. Risk management
4. Life-cycle planning
5. Personnel/user issues
6. Preparing for contingencies and disasters
7. Computer security incident handling
8. Awareness and training
9. Security considerations in computer support and operations
10. Physical and environmental security
11. Identification and authentication
12. Logical access control
13. Audit trails
14. Cryptography

The entire 800 series of NIST documents provides a wealth of information to the security practitioner. Some of the documents are tuned to securing federal systems, but most are largely applicable to both the public and private sectors. These documents are freely available online at http://csrc.nist.gov/publications/nistpubs/.

107.4 Security Governance Model

The purpose of the Security Governance Model is to assist in marrying existing corporate organizational structures and cultures with new security program development activities, which are usually brought about by changing business needs. This is accomplished by identifying and classifying the existing organizational structure as a specific security governance type, and determining if the business needs of the organization can be met by achieving a security capability within this type. Dramatic changes to organizational structures can have a negative impact on a business, and most business leaders will find it preferable to interject security into the existing corporate culture, rather than change the corporate culture to achieve a specific security capability.

The Security Governance Model addresses the way information security is mandated, implemented, and managed across the enterprise. Governance is generally categorized as being either centralized or decentralized, but these labels are oversimplified for practical modeling purposes. This is because many entities must apply both attributes to achieve their security goals in a cost-effective manner; thus, they are often both centralized and decentralized at the same time. We can model this by first recognizing that security governance has two primary components—control and administration—each of which can be centralized or decentralized. The following definitions for control, administration, centralized, and decentralized are used for this model:

- *Control* refers to the authority to mandate how security will be managed for an organization. Primary objectives are to develop policy and provision budget for security initiatives.
- *Administration* refers to the authority to apply, manage, and enforce security, as directed. Primary objectives include the plan, design, implementation, and operation of security in accordance with policy, and within the confines of budget.
- *Centralized* indicates a single authority, which can be a person, committee, or other unified body.
- *Decentralized* indicates multiple entities with a common level of authority.

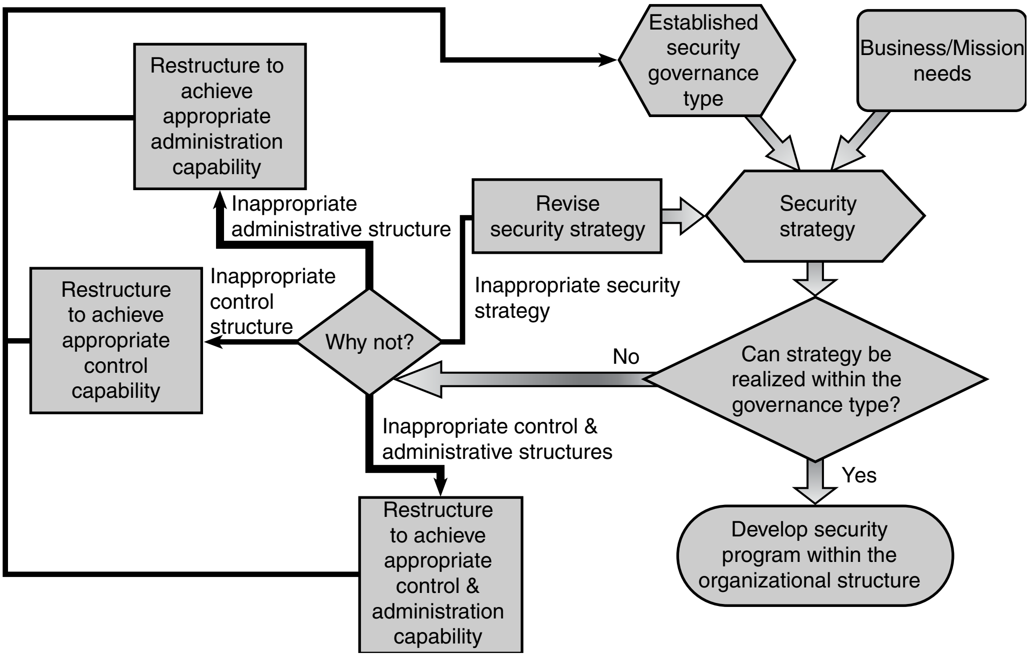
Combining the above definitions provides the standard terminology used for this model. The terms "centralized" and "decentralized" no longer stand by themselves, but are coupled with the two primary components of security governance. This yields the following four terms, which form the basis for the Security Governance Model:

1. *Centralized control* (CC) is indicative of an organization where the authority for policy and budget decisions is granted to a representative person or assembly, and is applicable throughout the organization.
2. *Decentralized control* (DC) is indicative of an organization where no one person or body has been authorized to formulate security policy and develop budget for security initiatives.
3. *Centralized administration* (CA) grants authority to apply and manage security policy to security or system administrative personnel who share a common reporting chain.
4. *Decentralized administration* (DA) grants authority to apply and manage security policy to security or system administrative personnel who have multiple reporting chains.

Given an understanding of the terminology, the reader is now in a position to pair each of these control and administration components to formulate the four basic types of security governance:

1. *Centralized control/centralized administration (CC/CA)*: one central body is responsible for developing policies that apply across the entire organization, and all administration is performed by personnel within a single chain of command.
2. *Centralized control/decentralized administration (CC/DA)*: one central body is responsible for developing policies that apply across the entire organization, yet administration is performed by personnel within multiple chains of command.
3. *Decentralized control/centralized administration (DC/CA)*: several entities are responsible for developing policies that apply within their areas of responsibility, yet all administration is performed by personnel working within a single chain of command.
4. *Decentralized control/decentralized administration (DC/DA)*: several entities are responsible for developing policies that apply within their areas of responsibility, and administration is performed by personnel within multiple chains of command.

To utilize this model (Exhibit 107.1), an organization first defines the security needs of the business or mission, and classifies the type of security governance currently in place. A security strategy for the organization is then developed, taking into account the governance type and business needs. Once



Established security governance type
Business/Mission needs
Restructure to achieve appropriate administration capability
Inappropriate administrative structure
Revise security strategy
Security strategy
Restructure to achieve appropriate control capability
Inappropriate control structure
Why not?
Inappropriate security strategy
No
Can strategy be realized within the governance type?
Inappropriate control & administrative structures
Yes
Restructure to achieve appropriate control & administration capability
Develop security program within the organizational structure

EXHIBIT 107.1 Security governance model.

a strategy is realized that can be effectively accomplished within the governance type, it is reasonable to proceed with further development of the ESA within the existing organizational structure. If the strategy cannot be realized within the governance type, then one is forced to change something. Assuming the main drivers have been properly identified as the business needs, there remain four areas of focus. The easiest approach is to revisit the security strategy. If the strategy can be revised such that an effective security capability can be achieved within the existing governance type, then the process is greatly simplified. If not, then the organizational structure must be modified to achieve the best cost/benefit security governance type for the organization.

This model does not mandate a specific organizational structure. Rather, the model associates aspects of the organizational structure to align business needs with the security capability desired by the organization by identifying the governance type that will best achieve the security strategy for the organization.

To assist with clarifying the four types of governance, organizational structure examples are provided for each type. The following should be noted when reviewing the samples provided:

- All of the examples with a CIO (Chief Information Officer) or CSO (Chief Security Officer) show them reporting to a COO (Chief Operating Officer). This is for example purposes only and is not intended as a recommended reporting structure. The CIO and CSO might report to any number of executives, including directly to the CEO (Chief Executive Officer).
- The CIO and CSO are intentionally identified as peers. If a CSO exists in the organization, then the CIO and CSO should report to the same executive officer, primarily to resolve their inherent conflicts of interest and to ensure unbiased appropriation of budgets.
- There are almost as many different organizational charts as there are organizations. The examples provided herein are intended to help clarify why an organizational structure fits a particular security governance type.

107.4.1 Centralized Control/Centralized Administration (CC/CA)

CC/CA identifies a truly centralized security capability (Exhibit 107.2). One central body is responsible for developing policies that apply across the entire organization, and personnel within a single chain of command perform all administration. Representatives for each department are assigned to a steering committee that ensures that each has appropriate influence over the policy-making process. This influence is depicted by the arrows in Exhibit 107.2, versus traditional organizational structure reporting.

In this case, the CEO has designated that the COO is responsible for a security program. The COO has delegated this responsibility by creating a CSO position. The steering committee exists to ensure that each department is given appropriate input to the policy-making process, because each department has security issues that must be addressed. Legal and regulatory issues such as the PATRIOT Act, Gramm–Leach–Bliley, Sarbanes–Oxley, HIPAA, and Safe Harbor, just to name a few, must also be addressed. The CSO typically chairs the security steering committee. Although the CSO must maintain proper control and administration over security, it is a function that impacts the entire organization.

Security operations and IT operations have been completely separated. The CSO is responsible for all things security, while the CIO is responsible for IT operations. There is no overlapping of responsibility, although both groups will have responsibilities on the same devices. Firewalls provide a good example. IT operations must be able to reboot, or restore a firewall if a failure occurs, but need not be authorized to make changes to the rule set. Authority to make changes to the rule set falls to the security operations group, but this group must not be permitted to interrupt traffic or adversely affect operations except during scheduled maintenance periods. These groups work together to support organizational needs, but do not share operational tasks.

107.4.2 Centralized Control/Decentralized Administration (CC/DA)

CC/DA (Exhibit 107.3) is the most commonly implemented governance model type for mid- to large-sized organizations. One central body is responsible for developing policies that apply across the entire organization, yet personnel within multiple chains of command perform administration.

As in the prior example, the CEO has designated that the COO is responsible for a security program, the COO has delegated this responsibility by creating a CSO position, and the steering committee exists to ensure that each department is given appropriate input to the policy-making process. Again, the influence of each department over the security development process is depicted in Exhibit 107.3 by arrows. The aspects of centralized control have not changed.

The relationship between security operations and IT operations has changed dramatically. This organizational structure passes greater responsibility to IT managers located at remote facilities by permitting each to manage security and IT operations, inclusively. The CSO may have dotted-line control over security personnel at some remote facilities, as noted in the diagram, but there is not one central point of control for all security operations.

107.4.3 Decentralized Control/Centralized Administration (DC/CA)

DC/CA (Exhibit 107.4) is appropriate for some small organizations that do not have the resources to justify a steering committee. Several entities are responsible for developing policies that apply within their areas of responsibility, and these policies are pushed to operations managers for implementation and enforcement. This influence is depicted in the Exhibit 107.4 by arrows, versus traditional organizational structure reporting. Personnel within a single chain of command, in this case the COO, perform all administration.

Note that remote location IT managers might include co-location arrangements, where IT operations are outsourced to a third party, while ownership and some measure of control of the IT assets are maintained by the organization.

107.4.4 Decentralized Control/Decentralized Administration (DC/DA)

DC/DA (Exhibit 107.5) identifies a truly decentralized security capability. This structure is appropriate for some small organizations that neither have the resources to justify a steering committee nor keep their critical

IToperations in-house. In this example, the CFO manages a contract for outsourcing company financials, HR manages the contract for outsourcing human resources, and IT operations has little or nothing to do with either. The outsourced companies are responsible for the policies and procedures that apply to the systems within their control, and the customer either accepts these policies, or takes its business elsewhere.

The administration portion of the above example, under the COO, is indicative of a CA structure, yet the organization is classified as DA because the COO has no control over security administration for the

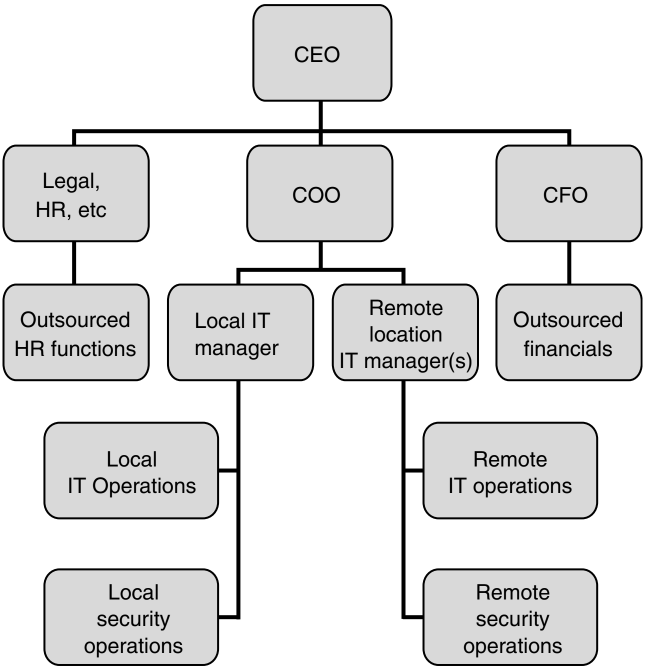

EXHIBIT 107.5 Decentralized control/decentralized administration (DC/DA).

outsourced IT capabilities. In this case, the responsibility for ensuring adequate controls over the security of company financial data is relegated to the outsourcing provider.

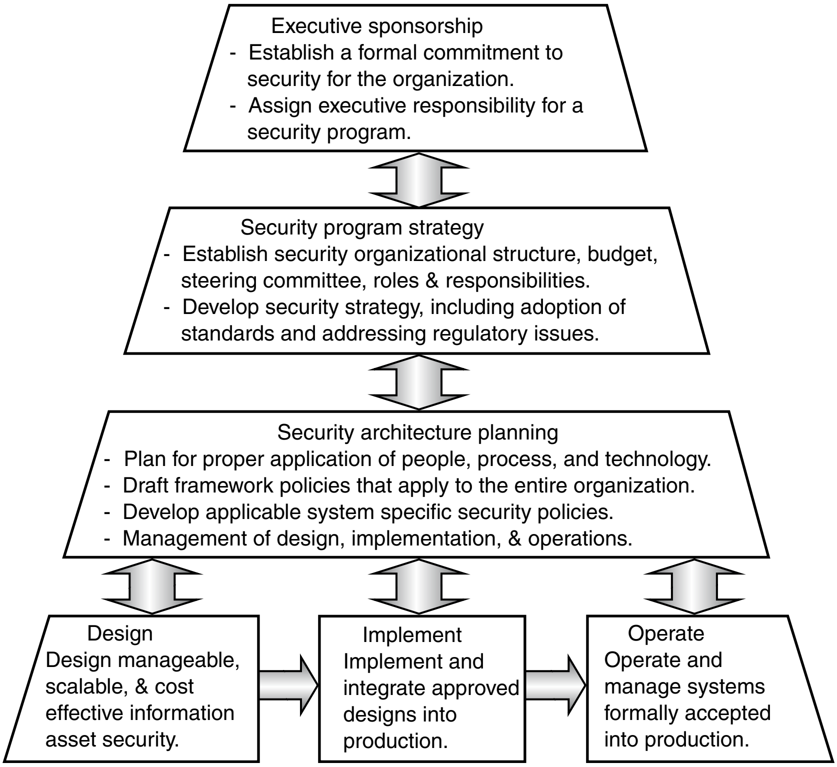
The advantages and disadvantages of each governance type will differ from organization to organization. One that is more expensive to implement in one organization may prove cheaper to implement in another. The fundamental objective is to achieve organizational security goals as effectively and painlessly as possible.

107.5 Enterprise Security Architecture Model

Enterprise security architecture (ESA) incorporates all aspects of security for an organization, including leadership, strategy, organizational structure, planning, design, implementation, and operations. It encompasses the people, processes, and technology aspects of security. Numerous models have been developed, and those that communicate sound security practices share a common approach to enterprise security. The ESA Model shown in Exhibit 107.6 is an open source model that this author has developed to communicate this approach.

107.5.1 Executive Sponsorship

Organizations should elicit executive sponsorship for developing a corporate security program; otherwise, the program leader will lack buy-in from other departments and will not have the ability to enforce compliance with the program. A brief policy statement, typically issued in the form of a formal corporate memo, should be presented from the highest corporate level in order to authorize the existence



Executive sponsorship
- Establish a formal commitment to security for the organization.
- Assign executive responsibility for a security program.

Security program strategy
- Establish security organizational structure, budget, steering committee, roles & responsibilities.
- Develop security strategy, including adoption of standards and addressing regulatory issues.

Security architecture planning
- Plan for proper application of people, process, and technology.
- Draft framework policies that apply to the entire organization.
- Develop applicable system specific security policies.
- Management of design, implementation, & operations.

Design
Design manageable, scalable, & cost effective information asset security.

Implement
Implement and integrate approved designs into production.

Operate
Operate and manage systems formally accepted into production.

EXHIBIT 107.6 Enterprise security architecture (ESA).

of a corporatewide security program. This directive will justify development of the security program, thus establishing the requirement to develop a security program charter.

The security program charter authorizes development of a formal security program, and delegates an authority appropriate for the organization (e.g., the Chief Operating Officer [COO]). This executive would then typically delegate this responsibility by creating a CSO or equivalent position. Note that without executive sponsorship, the CSO will likely have difficulty applying and enforcing security directives that impact other departments.

107.5.2 Security Program Strategy

The CSO then formulates a formal policy statement in response to the corporate directive. This broad policy document will define the goals of the security program, as well as the organizational structure. These must generally be approved by the corporate Board of Directors. In this example, the CEO has designated that the COO is responsible for the security program, and the COO has delegated this responsibility to a CSO. Many organizations have appropriately created a CSO position that reports directly to the Board of Directors, which is preferable for organizations that face significant risks to their business from security breaches.

A security program strategy is drafted to meet the business or mission needs of the organization. The CSO drafts the overall security program strategy by aligning the organizational approach to security with sound industry practices, and by leveraging common standards and practices such as the ISO 17799, COBIT, Common Criteria (ISO 15408), and NIST publications mentioned previously in this chapter. Application of the Security Governance Model can be applied in this layer to assist in marrying an effective strategy with an appropriate organizational structure.

In many organizations, sound practices suggest that the CSO formulate a security steering group, or intra-organizational policy board, comprising representatives from each functional business area. Customer Operations, Engineering, Finance, Internal Communications, HR, IT, Legal, Marketing, and Sales are examples of departments that might be represented in this group. This steering group will oversee most security policy development for the company in order to establish the organization's overall approach to computer security.

107.5.3 Security Architecture Planning

Planning the architecture refers to planning that takes place within an established security organization. Planning to execute security initiatives is an exercise in futility if executive sponsorship and security program strategy have *not* been established. Planning encompasses the people, processes, and technology aspects of security, and thus addresses policy, procedure, and technical implementation. Having established executive sponsorship and security program strategy for the organization, one can continue to develop the ESA.

If COBIT has been determined to be the standard to be used by the organization, then guidance offered within the Planning and Organization domain falls primarily within this layer of the model, and the other three COBIT domains will each be spread across the design, implementation, and operations components of the lowest layer of this model. The model is scalable such that existing standards can and should be used, yet sufficiently flexible that no one standard must be used. Developing security policies is a critical component of this layer of the ESA Model. Again, selection of one standard does not preclude the use of other well-known and accepted publications. A sample approach to developing security policies in accordance with the guidance from NIST Special Publication 800-14 follows.

Program-framework policies can now be drafted to establish the organization's overall approach to computer security. This is a set of corporatewide policy statements that establish a framework for the security program. Board-level direction is recommended for establishing most program policy statements because these policies provide organizationwide direction on broad areas of program implementation. This board-level direction is the fundamental function of the steering group, because representatives of the board are included in this committee. Policy statements at this level reflect high-level decisions about priorities given to the protection of corporate data. Board-level direction is recommended for acceptable use, remote access, information protection (a.k.a. data management), data retention, special access (root level), network connection, system acquisition and implementation, and other policies, as required. Program policy is usually broad enough that it does not require much modification over time. Additional policies will need to be developed, and are categorized as issue specific and system specific.

Board-level direction is also recommended for development of *issue-specific policies*, which address specific issues of concern to the organization. Whereas program-framework policy is intended to address the broad, organizationwide computer security program, issue-specific policies are developed to focus on areas of current relevance, concern, and possible controversy to an organization. Issue-specific policies are likely to require frequent revision as changes in technology and related factors take place. An example of an issue-specific policy is one that addresses peer-to-peer file sharing via programs such as Kazaa and Morpheus.

System owners, versus board-level representatives, are responsible for systems under their control, and as such should establish *system-specific policies* for these systems. System-specific policies focus on decisions taken by management to protect a particular system. Program policy and issue-specific policy both address policies from a broad level, usually encompassing the entire organization. However, they do not provide sufficient information or the direction, for example, to be used in establishing an access control list or in training users on what actions are permitted. A system-specific policy fills this need. It is much more focused because it addresses only one system.

In general, for issue-specific and system-specific policies, the issuer is a senior official. The more global, controversial, or resource intensive the policy statement, the more senior the policy issuer should be.

Many security policy decisions will apply only at the system level and will vary from system to system within the same organization. While these decisions might appear to be too detailed to be policy, they can be extremely important, with significant impacts on system usage and security. A management official should make these types of decisions, as opposed to a technical system administrator. Technical system administrators, however, often analyze the impacts of these decisions.

Once a policy structure is in place, the overall planning and management of the security life cycle is maintained at this layer of the ESA Model.

107.5.4 Security Architecture Design, Implementation, and Operations

Security architecture planning establishes how an organization will realize its security strategy. Security architecture design, implementation, and operations are where the “rubber meets the road.” Planned activities are realized and executed, usually in phases and with interim planning steps conducted throughout the cycle.

Support, prevention, and recovery occur in a continuous cycle at the foundation of this model. These activities can be effective when they occur as part of a well-structured security program. As an example, a qualitative risk assessment for the organization is among the activities to be executed. This includes identifying major functional areas of information, and then performing a risk assessment on those assets. The output of this process includes tables detailing the criticality of corporate systems and data in terms of confidentiality, integrity, and availability. Additional services or capabilities that are likely addressed include, but are certainly not limited to, the following:

- Firewall architecture
- Wireless architecture
- Router and switch security

- Network segmentation and compartmentalization
- Intrusion detection systems
- Business continuity
- Anti-spam and malicious code protection
- Incident response and digital forensics
- Vulnerability assessments and penetration testing
- Patch management

Additional models can be employed to address the technical security services associated with the design, implementation, and operations components comprising this foundational layer of the ESA Model. The model presented to address this issue is the Security Services Model.

107.6 Security Services Model

One model that should be considered in the design, implementation, and operations of technical security capabilities is detailed in NIST Special Publication 800–33, *Underlying Technical Models for Information Technology Security.*

This publication defines a specific security goal, which can be met through achievement of five security objectives. The stated goal for IT security is to:

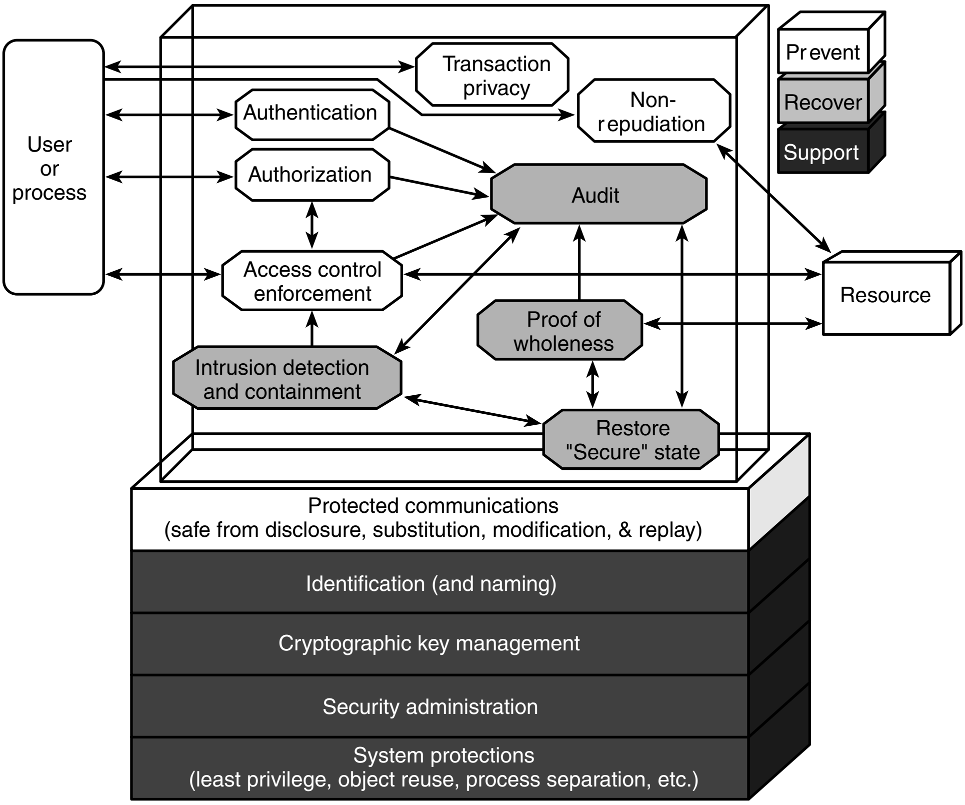
> Enable an organization to meet all of its mission/business objectives by implementing systems with due care consideration of IT-related risks to the organization, its partners and customers.

The five security objectives are generally well understood by security professionals, and are as follows:

1. Availability (of systems and data for intended use only)
2. Integrity (of system and data)
3. Confidentiality (of data and system information)
4. Accountability (to the individual level)
5. Assurance (that the other four objectives have been adequately met)

This model next identifies and classifies 14 primary services that can be implemented to satisfy these security objectives. The 14 services are classified according to three primary purposes: support, prevent, and recover. Definitions of each of the primary purposes, as well as the 14 primary services classified within each, are as follows:

- *Support*. These services are generic and underlie most information technology security capabilities.
  - Identification (and naming)
  - Cryptographic key management
  - Security administration
  - System protections
- *Prevent*. These services focus on preventing a security breach from occurring.
  - Protected communications
  - Authentication
  - Authorization
  - Access control enforcement
  - Non-repudiation
  - Transaction privacy



Prevent
Recover
Support
User or process
Transaction privacy
Authentication
Non-repudiation
Authorization
Audit
Access control enforcement
Resource
Proof of wholeness
Intrusion detection and containment
Restore "Secure" state
Protected communications (safe from disclosure, substitution, modification, & replay)
Identification (and naming)
Cryptographic key management
Security administration
System protections (least privilege, object reuse, process separation, etc.)

EXHIBIT 107.7 Security services model. (*Source*: Security Services Model, NIST Special Publication 800–33, *Underlying Technical Models for Information Technology Security*, p. 5.)

- *Recover*. The services in this category focus on the detection and recovery from a security breach.
  – Audit
  – Intrusion detection and containment
  – Proof of wholeness
  – Restore “secure” state

The underlying technical Security Services Model is depicted in Exhibit 107.7. This shows the primary services and supporting elements used in implementing an information technology security capability, along with their primary relationships.

Remember that we endeavor to meet a specific security goal by achieving five security objectives. It stands to reason that the above model must be broken out five different ways—one for each objective—in order to allow us to effectively implement a comprehensive technical security capability. The NIST publication does this, and it can be found at http://csrc.nist.gov/publications/nistpubs/800-33/sp800-33.pdf if the reader is interested in delving into the further details of this model.

107.7 Conclusion

This chapter presented a number of security models that were brought together to form a road map to achieving an effective enterprise security architecture (ESA). The ESA Model provides this road map at a high level, and additional models have been introduced that can be applied within the layers of this model. System Security Models have been presented; these help to form the basis for the development of secure systems. Common standards and practices were presented that assist in the development and realization of the security strategy. The Security Governance Model assists with categorizing and developing an organizational structure for the security program, and the Security Services Model details the primary services and supporting elements used in implementing an information technology security capability.

The models, standards, and practices presented in this chapter neither constitute a complete collection, nor is it the intent of this chapter to suggest that this is the only approach to an ESA. Numerous additional models and suggested standards exist, and can likely be substituted for those presented herein.

108
The Reality of Virtual Computing

Chris Hare

A major issue in many computing environments is accessing the desktop or console display of a different graphical-based system than the one you are using. If you are in a homogeneous environment, meaning you want to access a Microsoft Windows system from a Windows system, you can use applications such as Timbuktu, pcAnywhere, or Remotely Possible.

In today's virtual enterprise, many people have a requirement to share their desktops or allow others to view or manipulate it. Many desktop-sharing programs exist aside from those mentioned, including Microsoft Net Meeting and online conferencing tools built into various applications.

The same is true for UNIX systems, which typically use the X Windows display system as the graphical user interface. It is a simple matter of running the X Windows client on the remote system and displaying it on the local system.

However, if you must access a dissimilar system (e.g., a Windows system from a UNIX system) the options are limited. It is difficult to find an application under UNIX that allows a user to view an online presentation from a Windows system using Microsoft PowerPoint. This is where Virtual Network Computing, or VNC, from AT&T's United Kingdom Research labs, enters the picture.

This chapter discusses what VNC is, how it can be used, and the security considerations surrounding VNC. The information presented does get fairly technical in a few places to illustrate the protocol, programming techniques, and weaknesses in the authentication scheme. However, the corresponding explanations should address the issues for the less technical reader.

108.1 What Is VNC?

The Virtual Network Computing system, or VNC, was developed at the AT&T Research Laboratories in the United Kingdom. VNC is a very simple graphical display protocol allowing connections from heterogeneous or homogeneous computer systems.

VNC consists of a server and a viewer, as illustrated in Exhibit 108.1. The server accepts connection requests to display its local display on the viewer.

The VNC services are based on what is called a *remote framebuffer* or RFB. The framebuffer protocol simply allows a server to update the framebuffer or graphical display device on the remote viewer. With total independence from the graphical device driver, it is possible to represent the local display from the server on the client or viewer. The portability of the design means the VNC server should function on almost any hardware platform, operating system, windowing system, and application.

Support for VNC is currently available for a number of platforms, including:

- Servers:
  - UNIX (X Window system)
  - Microsoft Windows
  - Macintosh

- Viewers:
  - UNIX (X Window System)
  - Microsoft Windows
  - Macintosh
  - Java
  - Microsoft Windows CE

VNC is described as a thin client protocol, making very few requirements on the viewer. In this manner, the client can run on the widest range of hardware. There are a number of factors distinguishing VNC from other remote display systems, including:

- VNC is stateless, meaning you can terminate the session and reconnect from another system and continue right where you left off. When you connect to a remote system using an application such as a PC X Server and the PC crashes or is restarted, the X Window system applications running terminate. Using VNC, the applications remain available after the reboot.

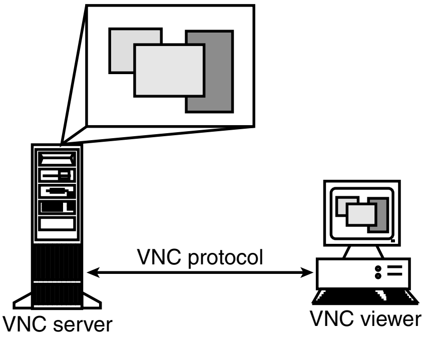

EXHIBIT 108.1 The VNC components.

- The viewer is a thin client and has a very small memory footprint.
- VMC is platform independent, allowing a desktop on one system to be displayed on any other type of system, including Java-capable Web browsers.
- It can be shared, allowing multiple users the ability to view and share a single desktop at the same time. This can be useful when needing to perform presentations over the network.
- And, best of all, VNC is free and distributed under the standard GNU General Public License (GPL).

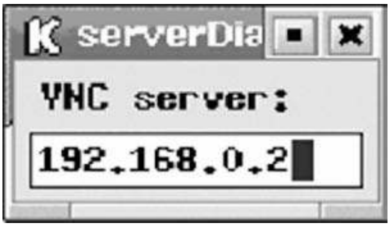
These are some of the benefits available with VNC. However, despite the clever implementation to share massive amounts of video data, there are a few weaknesses, as presented in this chapter.

108.2 How It Works

Accessing the VNC server is done using the VNC client and specifying the IP address or node name of the target VNC server as shown in Exhibit 108.2.

The window shown in Exhibit 108.2 requests the node name or IP address for the remote VNC server. It is also possible to add a port number with the address. The VNC server has a password to protect unauthorized access to the server. After providing the target host name or IP address, the user is prompted for the password to access the server, as seen in Exhibit 108.3.

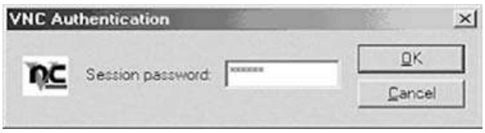
The Microsoft Windows VNC viewer does not display the password when the user enters it, as shown in Exhibit 108.4. However, the VNC client included in Linux systems does not hide the password when the user enters it. This is an issue because it exposes the password for the server to public view. However, because there is no user-level authentication, one could say there is no problem. Just in case you missed it, *there is no user-level authentication*. This is discussed again later in this chapter in the section entitled "Access Control."



VNC server:

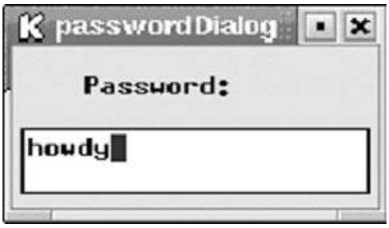
192.168.0.2

EXHIBIT 108.2 The X Windows VNC client.



Session password: ******

EXHIBIT 108.3 Entering the VNC server password.



Password:

howdy

EXHIBIT 108.4 The UNIX VNC client displays the password.

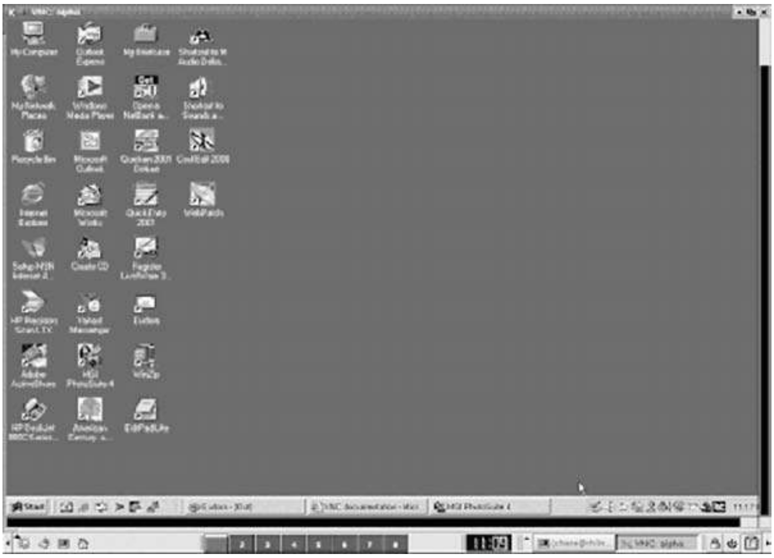


EXHIBIT 108.5 The Windows desktop from Linux.

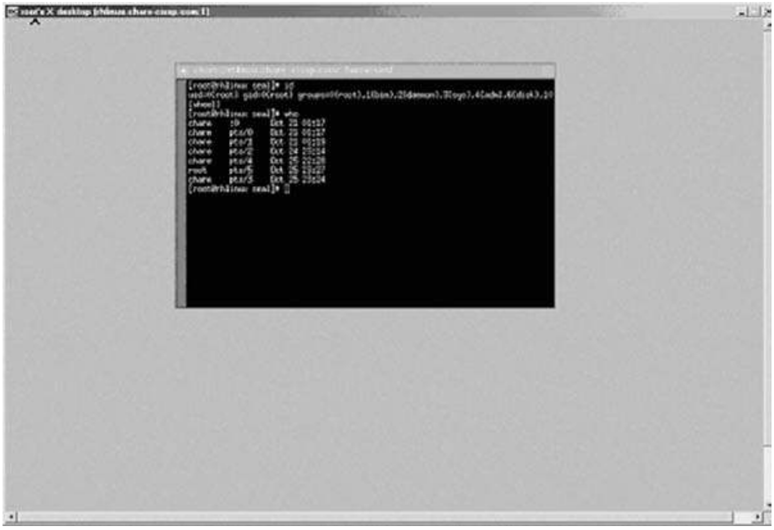
The VNC client prompts for the password after the connection is initiated with the server and requests authentication using a challenge–response scheme. The challenge–response system used is described in the section entitled "Access Control."

Once the authentication is successful, the client and server then exchange a series of messages to negotiate the desktop size, pixel format, and the encoding schemes. To complete the initial connection setup, the client requests a full update for the entire screen and the session commences. Because the client is stateless, either the server or the client can close the connection with no impact to either the client or server.

Actually, this chapter was written logged into a Linux system and using VNC to access a Microsoft Windows system that used VNC to access Microsoft Word. When using VNC on the UNIX- or Linux-based client, the user sees the Windows desktop as illustrated in Exhibit 108.5.



```
[root@rhlinux seal]# id

chare    pts/3   Oct 25 23:24
[root@rhlinux seal]# 
```

EXHIBIT 108.6 The TWM Window Manager from Windows.

The opposite is also true—a Windows user can access the Linux system and see the UNIX or Linux desktop as well as use the features and functionality offered by the UNIX platform (see Exhibit 108.6). However, VNC is not limited to these platforms, as mentioned earlier and demonstrated later.

However, this may not be exactly what the Linux user was expecting. The VNC sessions run as additional displays on the X server, which on RedHat Linux systems default to the TWM Window Manager. This can be changed; however, that is outside the topic area of this chapter.

108.3 Network Communication

All network communication requires the use of a network port. VNC is a connection-based TCP/IP application requiring the use of network ports. The VNC server listens on two ports. The values of these ports depend on the access method and the display number.

The VNC server listens on port 5900 plus the display number. WinVNC for Microsoft Windows defaults to display zero, so the port is 5900. The same is true for the Java-based HTTP port, listening at port 5800 plus the display number. This small and restrictive Web server is discussed more in the section entitled "VNC and the Web."

If there are multiple VNC servers running on the same system, they will have different port numbers because their display number is different, as illustrated in Exhibit 108.7.

There is a VNC server executed for each user who wishes to have one. Because there is no user authentication in the VNC server, the authentication is essentially port based. This means user chare is running a VNC server, which is set up on display 1 and therefore port 5901. Because the VNC server is running at user chare, anyone who learns or guesses the password for the VNC server can access chare's VNC server and have all of chare's privileges.

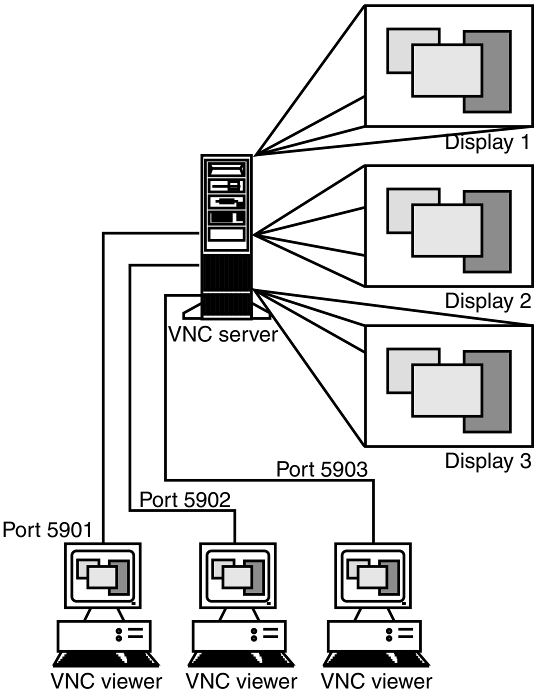

EXHIBIT 108.7 Multiple VNC servers.

Looking back to Exhibit 108.6, the session running on the Linux system belonged to root as shown here:

```
[chare@rhlinux chare]$ ps -ef | grep vnc
root20368 10 23:21 pts/100:00:00 Xvnc :
     1 -desktop X -httpd/usr/s
chare20476204360 23:25 pts/300:00:00 grep vnc
[chare@rhlinux chare]$
```

In this scenario, any user who knows the password for the VNC server on display 1, which is port 5901, can become root with no additional password required. Because of this access control model, good-quality passwords must be used to control access to the VNC server; and they must be kept absolutely secret.

As mentioned previously, the VNC server also runs a small Web server to support access through the Java client. The Web server listens on port 58xx, where xx is the display number for the server. The HTTP port on the Web server is only used to establish the initial HTTP connection and download the applet. Once the applet is running in the browser, the connection uses port 59xx. The section entitled “VNC and the Web” describes using the VNC Java client.

There is a third mode, where the client listens for a connection from the server rather than connecting to a server. When this configuration is selected, the client listens on port 5500 for the incoming connection from the server.

108.4 Access Control

As mentioned previously, the client and server exchange a series of messages during the initial connection setup. These protocol messages consist of:

- ProtocolVersion
- Authentication
- ClientInitialization
- ServerInitialization

Once the ServerInitialization stage is completed, the client can send additional messages when it requires and receive data from the server.

The protocol version number defines what level of support both the client and server have. It is expected that some level of backward compatibility is available because the version reported should be the latest version the client or server supports. When starting the VNC viewer on a Linux system, the protocol version is printed on the display (standard out) if not directed to a file.

Using a tool such as tcpdump, we can see the protocol version passed from the client to the server (shown in bold text):

```

With the protocol version established, the client attempts to authenticate to the server. The password prompt shown in Exhibit 108.3 is displayed on the client, where the user enters the password.

There are three possible authentication messages in the VNC protocol:

1. *Connection Failed.* The connection cannot be established for some reason. If this occurs, a message indicating the reason the connection could not be established is provided.
2. *No Authentication.* No authentication is needed. This is not a desirable option.
3. *VNC Authentication.* Use VNC authentication.

The VNC authentication challenge–response is illustrated in Exhibit 108.8.

The VNC authentication protocol uses a challenge–response method with a 16-byte (128-bit) challenge sent from the server to the client. The challenge is sent from the server to the client in the clear. The challenge is random, based on the current time when the connection request is made. The following packet has the challenge highlighted in bold.

```
14:36:08.908961 < alpha.5900 > rhlinux.chare-cissp.com.
2058: P 17:33(16) ack 13 win 17508 <nop,nop,timestamp

         ^Y] ..
```

The client then encrypts the 16-byte challenge using Data Encryption Standard (DES) symmetric cryptography with the user-supplied password as the key. The VNC DES implementation is based upon a public domain version of Triple-DES, with the double and triple length support removed. This means VNC is only capable of using standard DES for encrypting the response to the challenge. Again, the following packet has the response highlighted in bold.

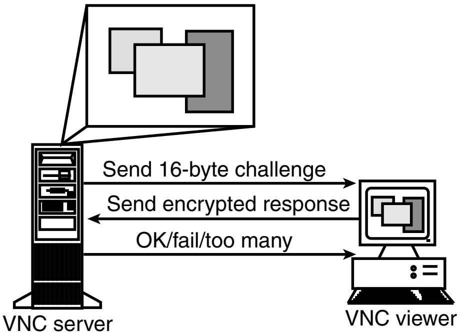

EXHIBIT 108.8 The VNC authentication challenge–response.

```

The server receives the response and, if the password on the server is the same, the server can decrypt the response and find the value issued as the challenge. As discussed in the section “Weaknesses in the VNC Authentication System” later in this chapter, the approach used here is vulnerable to a man-in-the-middle attack, or a cryptographic attack to find the key, which is the password for the server.

Once the server receives the response, it informs the client if the authentication was successful by providing an *OK, Failed*, or *Too Many* response. After five authentication failures, the server responds with *Too Many* and does not allow immediate reconnection by the same client.

The *ClientInitialization* and *ServerInitialization* messages allow the client and server to negotiate the color depth, screen size, and other parameters affecting the display of the framebuffer.

As mentioned in the “Network Communication” section, the VNC server runs on UNIX as the user who started it. Consequently, there are no additional access controls in the VNC server. If the password is not known to anyone, it is safe. Yes and no. Because the password is used as the key for the DES-encrypted response, the password is never sent across the network in the clear. However, as we will see later in the chapter, the challenge–response method is susceptible to a man-in-the-middle attack.

108.4.1 The VNC Server Password

The server password is stored in a password file on the UNIX file system in the ~/.vnc directory. The password is always stored using the same 64-bit key, meaning the password file should be protected using the local file system permissions. Failure to protect the file exposes the password, because the key is consistent across all VNC servers.

The password protection system is the same on the other supported server platforms; however, the location of the password is different.

The VNC source code provides the consistent key:

```
/*
•We use a fixed key to store passwords, because we assume
•that our local file system is secure but nonetheless
•don't want to store passwords as plaintext.
*/
unsigned char fixedkey[8]={23,82,107,6,35,78,88,7};
```

This fixed key is used as input to the DES functions to encrypt the password; however, the password must be unencrypted at some point to verify authentication.

The VNC server creates the ~/.vnc directory using the standard default file permissions as defined with the UNIX system's umask. On most systems, the default umask is 022, making the ~/.vnc directory accessible to users other than the owner. However, the password file is explicitly set to force read/write permissions only for the file owner; so the chance of an attacker discovering the password is minimized unless the user changes the permissions on the file, or the attacker has gained elevated user or system privileges.

If the password file is readable to unauthorized users, the server password is exposed because the key is consistent and publicly available. However, the attacker does not require too much information, because the functions to encrypt and decrypt the password in the file are included in the VNC source code. With the knowledge of the VNC default password key and access to the VNC server password file, an attacker can obtain the password using 20 lines of C language source code.

A sample C program, here called attack.c, can be used to decrypt the VNC server password should the password file be visible:

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/types.h>
#include <sys/stat.h>
#include <vncauth.h>
#include <d3des.h>
main(argc, argv)
     int argc;
     char **argv;
{
     char *passwd;
     if (argc <=1)
     {
       printf ("specify the location and name of a VNC
          password file\n");
       exit(1);
       }
       /* we might have a file */
       passwd = vncDecryptPasswdFromFile(argv[1]);
       printf ("password file is%s\n," argv[1]);
```

```
        printf ("password is%s\n," passwd);
        exit(0);
  }
```

Note: Do not use this program for malicious purposes. It is provided for education and discussion purposes only.

Running the attack.c program with the location and name of a VNC password file displays the password:

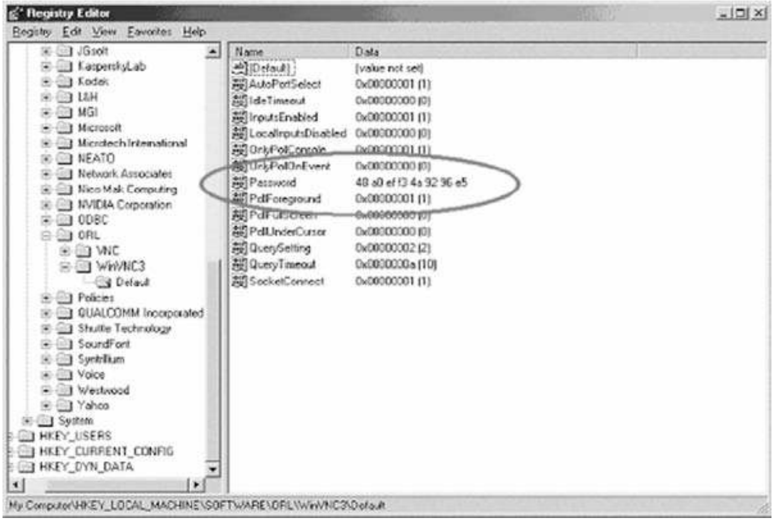
```
[chare@rhlinux libvncauth]$./attack $HOME/.vnc/passwd
passowrd file is/home/chare/.vnc/passwd
password is holycow
```

The attacker can now gain access to the VNC server. Note, however, this scenario assumes the attacker already has access to the UNIX system.

For the Microsoft Windows WinVNC, the configuration is slightly different. Although the methods to protect the password are the same, WinVNC uses the Windows registry to store the server's configuration information, including passwords. The WinVNC registry entries are found at:

- *Local machine-specific settings:*
  HKEY_LOCAL_MACHINE\Software\ORL\WinVNC3\
- *Local default user settings:*
  HKEY_LOCAL_MACHINE\Software\ORL\WinVNC3\Default
- *Local per-user settings:*
  HKEY_LOCAL_MACHINE\Software\ORL\WinVNC3\<*username*>
- *Global per-user settings:*
  HKEY_CURRENT_USER\Software\ORL\WinVNC3

The WinVNC server password will be found in the local default user settings area, unless a specific user defines his own server. The password is stored as an individual registry key value as shown in Exhibit 108.9.



Name	Data
(Default)	(value not set)
AutoPortSelect	0x00000001 (1)
IdleTimeout	0x00000000 (0)
InputsEnabled	0x00000001 (1)
LocalInputsDisabled	0x00000000 (0)
OnlyPollConsole	0x00000001 (1)
OnlyPollOnEvent	0x00000000 (0)
Password	48 a0 ef f3 4a 92 96 e5
PollForeground	0x00000001 (1)
PollFullScreen	0x00000000 (0)
PollUnderCursor	0x00000000 (0)
QuerySetting	0x00000002 (2)
QueryTimeout	0x0000000a (10)
SocketConnect	0x00000001 (1)

My Computer\HKEY_LOCAL_MACHINE\SOFTWARE\ORL\WinVNC3\Default

EXHIBIT 108.9 WinVNC Windows registry values.

Consequently, access to the registry should be as controlled as possible to prevent unauthorized access to the password.

The password stored in the Windows registry uses the same encryption scheme to protect it as on the UNIX system. However, looking at the password shown in Exhibit 108.9, we see the value:

```
48 a0 ef f3 4a 92 96 e5
```

and the value stored on UNIX is:

```
a0 48 f3 ef 92 4a e5 96
```

Comparing these values, we see that the byte ordering is different. However, knowing that the ordering is different, we can use a program to create a binary file on UNIX with the values from the Windows system and then use the attack.c program above to determine the actual password. Notice that because the password values shown in this example are the same, and the encryption used to hide the passwords is the same, the passwords are the same.

Additionally, the VNC password is limited to eight characters. Even if the user enters a longer password, it is truncated to eight. Assuming a good- quality password with 63 potential characters in each position, this represents only 63^8 possible passwords. Even with this fairly large number, the discussion thus far has demonstrated the weaknesses in the authentication method.

108.5 Running a VNC Server under UNIX

The VNC server running on a UNIX system uses the X Window System to interact with the X-based applications on UNIX. The applications are not aware there is no physical screen attached to the system. Starting a new VNC server is done by executing the command:

```
vncserver
```

on the UNIX host. Because the vncserver program is actually written in Perl, most common problems with starting vncserver are associated with the Perl installation or directory structures.

Any user on the UNIX host can start a copy of the VNC server. Because there is no user authentication built into the VNC server or protocol, running a separate server for each user is the only method of providing limited access. Each vncserver has its own password and port assignment, as presented earlier in the chapter.

The first time a user runs the VNC server, he is prompted to enter a password for the VNC server. Each VNC server started by the same user will have the same password. This occurs because the UNIX implementation of VNC creates a directory called.vnc in the user's home directory. The.vnc directory contains the log files, PID files, password, and X startup files. Should the user wish to change the password for the VNC servers, he can do so using the vncpasswd command.

108.5.1 VNC Display Names

Typically the main display for a workstation using the X Window System is display 0 (zero). This means on a system named *ace*, the primary display is ace:0. A UNIX system can run as many VNC servers as the users desire, with the display number incrementing for each one. Therefore, the first VNC server is display ace:1, the second ace:2, etc. Individual applications can be executed and, using the DISPLAY environment variable defined, send their output to the display corresponding to the desired VNC server.

For example, sending the output of an xterm to the second VNC server on display ace:2 is accomplished using the command:

```
     xterm -display ace:2 &
```

Normally, the vncserver command chooses the first available display number and informs the user what that display is; however, the display number can be specified on the command line to override the calculated default:

```
vncserver:2
```

No visible changes occur when a new VNC server is started, because only a viewer connected to that display can actually see the resulting output from that server. Each time a connection is made to the VNC server, information on the connection is logged to the corresponding server log file found in the $HOME/.vnc directory of the user executing the server. The clog file contents are discussed in the "Logging" section of this chapter.

108.5.2 VNC as a Service

Instead of running individual VNC servers, there are extensions available to provide support for VNC under the Internet Super-Daemon, inetd and xinetd. More information on this configuration is available from the AT&T Laboratories Web site.

108.6 VNC and Microsoft Windows

The VNC server is also available for Microsoft Windows, providing an alternative to other commercial solutions and integration between heterogeneous operating systems and platforms. The VNC server under Windows is run as a separate application or a service. Unlike the UNIX implementation, the Windows VNC server can only display the existing desktop of the PC console to the user. This is a limitation of Microsoft Windows, and not WinVNC. WinVNC does not make the Windows system a multi-user environment: if more than one user connects to the Windows system at the same time, they will all see the same desktop.

Running WinVNC as a service is the preferred mode of operation because it allows a user to log on to the Windows system, perform his work, and then log off again.

When running WinVNC, an icon as illustrated in Exhibit 108.10 is displayed. When a connection is made, the icon changes color to indicate there is an active connection.

The WinVNC properties dialog shown in Exhibit 108.11 allows the WinVNC user to change the configuration of WinVNC. All the options are fully discussed in the WinVNC documentation.

With WinVNC running as a service, a user can connect from a remote system even when no user is logged on at the console. Changing the properties for WinVNC when it is running as a service has the effect of changing the service configuration, also known as the default properties, rather than the individual user properties. However, running a nonservice mode WinVNC means a user must have logged in on the console and started WinVNC for it to work correctly. Exhibit 108.12 illustrates accessing WinVNC from a Linux system while in service mode.

Aside from the specific differences for configuring the WinVNC server, the password storage and protocol-level operations are the same, regardless of the platform. Because there can be only one WinVNC server running at a time, connections to the server are on ports 5900 for the VNC viewer and 5800 for the Java viewer.

EXHIBIT 108.13 A VNC connection using a Java-capable Web browser.

108.7 VNC and the Web

As mentioned previously, each VNC server listens not only on the VNC server port but also on a second port to support Web connections using a Java applet and a Web browser. This is necessary to support Java because a Java applet can only make a connection back to the machine from which it was served.

Connecting to the VNC server using a Java-capable Web browser to:

```
http://ace:5802/
```

loads the Java applet and presents the log-in screen where the password is entered. Once the password is provided, the access controls explained earlier prevail. Once the applet has connected to the VNC server port, the user sees a display resembling that shown in Exhibit 108.13.

With the Java applet, the applications displayed through the Web browser can be manipulated as if they were displayed directly through the VNC client or on the main display of the workstation.

108.8 Logging

As with any network-based application, connection and access logs provide valuable information regarding the operation of the service. The log files from the VNC server provide similar information for debugging or later analysis. A sample log file resembles the following. The first part of the log always provides information on the VNC server, including the listing ports, the client name, display, and the URL.

```
26/10/01 23:25:47 Xvnc version 3.3.3r2

     vnc for information on VNC
26/10/01 23:25:47 Desktop name ‘X’ (rhlinux.chare-cissp.com:1)
```

```
26/10/01 23:25:47 Protocol version supported 3.3
26/10/01 23:25:47 Listening for VNC connections on TCP port 5901
26/10/01 23:25:47 Listening for HTTP connections on TCP port 5801
26/10/01 23:25:47 URL http://rhlinux.chare-cissp.com:5801
```

The following sample log entry shows a connection received on the VNC server. We know the connection came in through the HTTPD server from the log entry. Notice that there is no information regarding the user who is accessing the system—only the IP address of the connecting system.

```
26/10/01 23:28:54 httpd: get `` for 192.168.0.2
26/10/01 23:28:54 httpd: defaulting to 'index.vnc'
26/10/01 23:28:56 httpd: get 'vncviewer.jar' for 192.168.0.2
26/10/01 23:29:03 Got connection from client 192.168.0.2
26/10/01 23:29:03 Protocol version 3.3
26/10/01 23:29:03 Using hextile encoding for client 192.168.0.2
26/10/01 23:29:03 Pixel format for client 192.168.0.2:
26/10/01 23:29:03 8 bpp, depth 8
26/10/01 23:29:03 true colour: max r 7 g 7 b 3, shift r 0 g 3 b 6
26/10/01 23:29:03 no translation needed
26/10/01 23:29:21 Client 192.168.0.2 gone
26/10/01 23:29:21 Statistics:
26/10/01 23:29:21 key events received 12, pointer events 82
26/10/01 23:29:21 framebuffer updates 80, rectangles 304,
   bytes 48528
26/10/01 23:29:21 hextile rectangles 304, bytes 48528
26/10/01 23:29:21 raw bytes equivalent 866242, compression ratio
   17.850354
```

The log file contains information regarding the connection with the client, including the color translations. Once the connection is terminated, the statistics from the connection are logged for later analysis, if required.

Because there is no authentication information logged, the value of the log details for a security analysis are limited to knowing when and from where a connection was made to the server. Because many organizations use DHCP for automatic IP address assignment and IP addresses may be spoofed, the actual value of knowing the IP address is reduced.

108.9 Weaknesses in the VNC Authentication System

We have seen thus far several issues that will have the security professional concerned. However, these can be alleviated as discussed later in the chapter. There are two primary concerns with the authentication. The first is the man-in-the-middle attack, and the second is a cryptographic attack to uncover the password.

108.9.1 The Random Challenge

The random challenge is generated using the rand(3) function in the C programming language to generate random numbers. The random number generator is initialized using the system clock and the current system time. However, the 16-byte challenge is created by successive calls to the random number generator, decreasing the level of randomness on each call. (Each call returns 1 byte or 8 bits of data.)

This makes the challenge predictable and increases the chance an attacker could establish a session by storing all captured responses and their associated challenges. Keeping track of each challenge–response pair can be difficult and, as discussed later, not necessary.

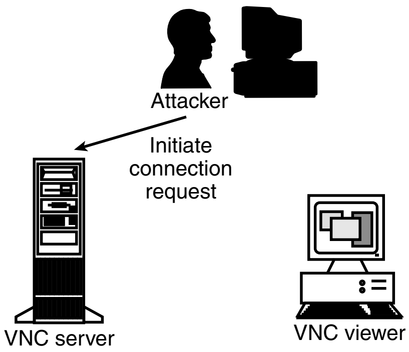

EXHIBIT 108.14 Attacker opens connection to VNC server.

108.9.2 The Man-in-the-Middle Attack

For the purposes of this illustration, we will make use of numerous graphics to facilitate understanding this attack method. The server is system S, the client is C, and the attacker, or man in the middle, is A. (This discussion ignores the possibility the network connection may be across a switched network, or that there are ways of defeating the additional security provided by the switched network technology.)

The attacker A initiates a connection to the server, as seen in Exhibit 108.14. The attacker connects, and the two systems negotiate the protocols supported and what will be used. The attacker observes this by sniffing packets on the network.

We know both the users at the client and server share the DES key, which is the password. The attacker does not know the key. The password is used for the DES encryption in the challenge–response.

The server then generates the 16-byte random challenge and transmits it to the attacker, as seen in Exhibit 108.15. Now the attacker has a session established with the server, pending authorization.

At this point, the attacker simply waits, watching the network for a connection request to the same server from a legitimate client. This is possible as there is no timeout in the authentication protocol; consequently, the connection will wait until it is completed.

When the legitimate client attempts a connection, the server and client negotiate their protocol settings, and the server sends the challenge to the client as illustrated in Exhibit 108.16. The attacker captures the authentication request and changes the challenge to match the one provided to him by the server.

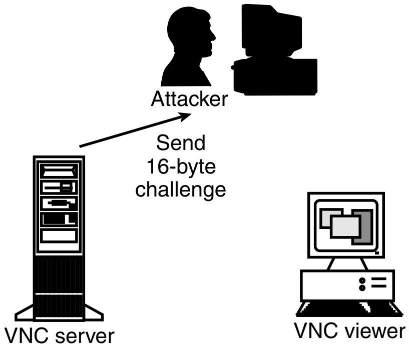

EXHIBIT 108.15 Server sends challenge to attacker.

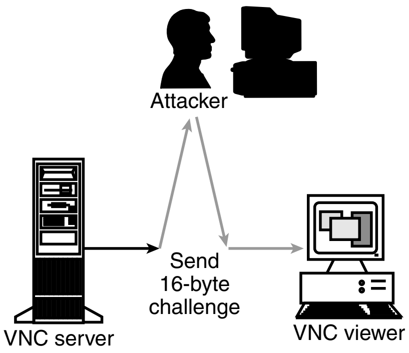

EXHIBIT 108.16 Attacker captures and replaces challenge.

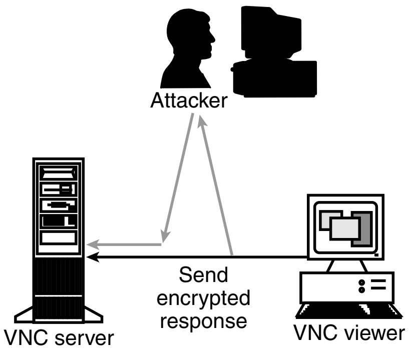

EXHIBIT 108.17 Attacker and client send encrypted response.

Once the attacker has modified the challenge, he forges the source address and retransmits it to the legitimate client. As shown in Exhibit 108.17, the client then receives the challenge, encrypts it with the key, and transmits the response to the server.

The server receives two responses: one from the attacker and one from the legitimate client. However, because the attacker replaced the challenge sent to the client with his own challenge, the response sent by the client to server does not match the challenge. Consequently, the connection request from the legitimate client is refused.

However, the response sent does match the challenge sent by the server to the attacker; and when the response received from the attacker matches the calculated response on the server, the connection is granted. The attacker has gained unauthorized access to the VNC server.

108.9.3 Cryptographic Attacks

Because the plaintext challenge and the encrypted response can both be retrieved from the network, it is possible to launch a cryptographic attack to determine the key used, which is the server's password. This is easily done through a brute-force or known plaintext attack.

A brute-force attack is the most effective, albeit time-consuming method of attack. Both linear cryptanalysis, developed by Lester Mitsui, and differential cryptanalysis, developed by Biham and Shamir, are considered the two strongest analytic (shortcut) methods for breaking modern ciphers; and even these have been shown as not very practical, even against Single-DES.

The known plaintext attack is the most advantageous method because a sample of ciphertext (the response) is available as well as a sample of the plaintext (the challenge). Publicly available software such as *crack* could be modified to try a dictionary and brute-force attack by repeatedly encrypting the challenge until a match for the response is found. The nature of achieving the attack is beyond the scope of this chapter.

108.9.4 Finding VNC Servers

The fastest method of finding VNC servers in an enterprise network is to scan for them on the network devices. For example, the popular nmap scanner can be configured to scan only the ports in the VNC range to locate the systems running it.

```
[root@rhlinux chare]# nmap -p “5500,5800-5999” 192.168.0.1-5
Starting nmap V. 2.54BETA29 (www.insecure.org/nmap/)
All 201 scanned ports on gateway (192.168.0.1) are: filtered
Interesting ports on alpha (192.168.0.2):
(The 199 ports scanned but not shown below are in state: closed)
Port    State    Service
5800/tcp    open    vnc
5900/tcp    open    vnc
Interesting ports on rhlinux.chare-cissp.com (192.168.0.3):
(The 199 ports scanned but not shown below are in state: closed)
Port    State    Service
5801/tcp    open    vnc
5901/tcp    open    vnc- 1
Nmap run completed---5 IP addresses (3 hosts up) scanned in 31
   seconds
[root@rhlinux chare]#
```

There are other tools available to find and list the VNC servers on the network; however, nmap is fast and will identify not only if VNC is available on the system at the default ports but also all VNC servers on that system.

108.9.5 Improving Security through Encapsulation

To this point we have seen several areas of concern with the VNC environment:

- There is no user-level authentication for the VNC server.
- The challenge–response system is vulnerable to man-in-the-middle and cryptographic attacks.
- There is no data confidentiality built into the client and server.

Running a VNC server provides the connecting user with the ability to access the entire environment at the privilege level for the user running the server. For example, assuming root starts the first VNC server on a UNIX system, the server listens on port 5901. Any connections to this port where the remote user knows the server password result in a session with root privileges.

We have seen how it could be possible to launch a man-in-the-middle or cryptographic attack against the authentication method used in VNC. Additionally, once the authentication is completed, all the session data is unencrypted and could, in theory, be captured, replayed, and watched by malicious users. However, because VNC uses a simple TCP/IP connection, it is much easier to add encryption support with Secure Sockets Layer (SSL) or Secure Shell (SSH) than, say, a telnet, rlogin, or X Window session.

Secure Shell (SSH) is likely the more obvious choice for most users, given there are clients for most operating systems. SSH encrypts all the data sent through the tunnel and supports port redirection; thus, it can be easily supported with VNC. Furthermore, although VNC uses a very efficient protocol for carrying the display data, additional benefits can be achieved at slower network link speeds because SSH can also compress the data.

There are a variety of SSH clients and servers available for UNIX, although if you need an SSH server for Windows, your options are very limited and may result in the use of a commercial implementation. However, SSH clients for Windows and the Apple Macintosh are freely available. Additionally, Mindbright Technology offers a modified Java viewer supporting SSL.

Because UNIX is commonly the system of choice for operating a server, this discussion focuses on configuring VNC with SSH using a UNIX-based system. Similar concepts are applicable for Windows-based servers, once you have resolved the SSH server issue. However, installing and configuring the base SSH components are not discussed in this chapter.

Aside from the obvious benefits of using SSH to protect the data while traveling across the insecure network, SSH can compress the data as well. This is significant if the connection between the user and the server is slow, such as a PPP link. Performance gains are also visible on faster networks, because the compression can make up for the time it takes to encrypt and decrypt the packets on both ends.

A number of extensions are available to VNC, including support for connections through the Internet superserver inetd or xinetd. These extensions mean additional controls can be implemented using the TCP Wrapper library. For example, the VNC X Window server, Xvnc, has been compiled with direct support for TCP Wrappers.

More information on configuring SSH, inetd, and TCP Wrappers is available on the VNC Web site listed in the “References” section of this chapter.

108.10 Summary

The concept of thin client computing will continue to grow and develop to push more and more processing to centralized systems. Consequently, applications such as VNC will be with the enterprise for some time. However, the thin client application is intended to be small, lightweight, and easy to develop and transport. The benefits are obvious—smaller footprint on the client hardware and network, including support for many more devices including handheld PCs and cell phones, to name a few.

However, the thin client model has a price; and in this case it is security. Although VNC has virtually no security features in the protocol, other add-on services such as SSH, VNC, and TCP Wrapper, or VNC and xinetd provide extensions to the basic VNC services to provide access control lists limited by the allowable network addresses and data confidentiality and integrity.

Using VNC within an SSH tunnel can provide a small, lightweight, and secured method of access to that system 1000 miles away from your office. For enterprise or private networks, there are many advantages to using VNC because the protocol is smaller and more lightweight than distributing the X Window system on Microsoft Windows, and it has good response time even over a slower TCP/IP connection link. Despite the security considerations mentioned in this chapter, there are solutions to address them; so you need not totally eliminate the use of VNC in your organization.

Formulating an Enterprise Information Security Architecture

Mollie E. Krehnke
David C. Krehnke

109.1 Introduction

Ours is a connected world, and a dependent world. The condition and livelihood of any organization is dependent on the integrity, availability, and confidentiality of information obtained from or protected from other sources. Today, organizations are at greater risk and their security stance against malicious actors, in the form of individuals, criminal cartels, terrorists, or nation-states, will affect the well-being of many persons, other companies, and perhaps the nation. These organizations often depend upon cyberspace—hundreds of millions of interconnected computers, servers, routers, switches, and fiber-optic cables that allow our critical infrastructures to work.[1]

109.1.1 Threat Opportunities Abound

Individuals and organizations with malicious intent will use any means to disrupt business processes; obtain the data the information systems create, maintain, and transmit; and acquire the power that the information systems and associated networks possess for other unauthorized acts. Malicious actors have the intent (political, economic, national security), the tools (widely available), and the targets (many and well-known vulnerabilities). Malicious actors also have the time and the financial resources necessary to implement attacks. These attacks can have serious consequences, such as disruption of critical operations, causing loss of revenue and intellectual property, or loss of life. Such attacks could use any available cyber resources, including computers located in homes or small businesses to initiate attacks on critical infrastructure organizations—exploiting weaknesses, disrupting communications, hindering defensive or offensive responses, or delaying emergency responders.

Vulnerabilities result from weaknesses in technology and improper implementation and oversight of technological products.[2] The majority of vulnerabilities can be mitigated through good security practices, although such practices must go beyond mere installation, and include proper training, operation, regular patching, and virus updates. The vulnerabilities within an organization can be used to mount an attack against that organization or against other organizations.

109.1.2 Responding to an Increasing Threat

The cyberspace vulnerabilities must be addressed at an individual level and an organizational level. “Each American who depends on cyberspace must secure the part that they own or for which they are responsible.”[3] Likewise, each organization must establish and maintain an effective enterprise information security architecture that contributes to its own security, its employees, customers, business partners—and that of the nation.

The effective deployment of security for an enterprise is dependent on the business functions of the enterprise. To gain business commitment, the security functions determined to be necessary must support the business functions of the organization and provide “added value.” The provision of added value in the form of enterprise information security is dependent upon many factors: accurate identification of business functions; configuration and management of the existing and planned resources (e.g., networks and technologies); business and security infrastructures; enterprise business processes; people (employees, business partners, and vendors); physical security of facilities, equipment, and remote sites; and associated security or security-supporting policies and processes. The mere presence of certain security mechanisms will not guarantee an acceptable level of risk for the enterprise. Therefore, an enterprise information security architecture must be defined, installed, monitored, assessed, and upgraded on a periodic basis to ensure that the security architecture is appropriate for the enterprise. The major key to successful implementation of security is the commitment of upper management.

109.2 Architectural Design Concepts

109.2.1 Association of Business Functions to Security Services

To add value to an organization's business functions, those functions must be understood. A business will have documentation that presents an overview of those functions. Certain individuals will be good resources as well, and should be delighted to discuss security from an added-value standpoint. Business unit managers who oversee specific lines of business (business domains) and subject matter experts can support the documentation of business functions and provide the business perspective to the sequencing of automated and nonautomated processes to address the business mission. The business functions to be addressed also have to be viewed in light of capital planning, enterprise engineering, and program management.

Exhibit 109.1 presents an approach for enterprise architecture development. If such an architecture exists for the enterprise, then the creation of a security architecture has a firm foundation. Business functions and associated business processes, data and data flows, applications and associated functionality, present technology architecture, business locations, business partners and vendors, and strategic goals to support the business mission may already exist—in some form.

The three-to-five-year target enterprise architecture is a good resource for determining future goals of the organization that will have to be addressed from a security standpoint. Any goals beyond that timeframe will not be as useful for the establishment of an effective information

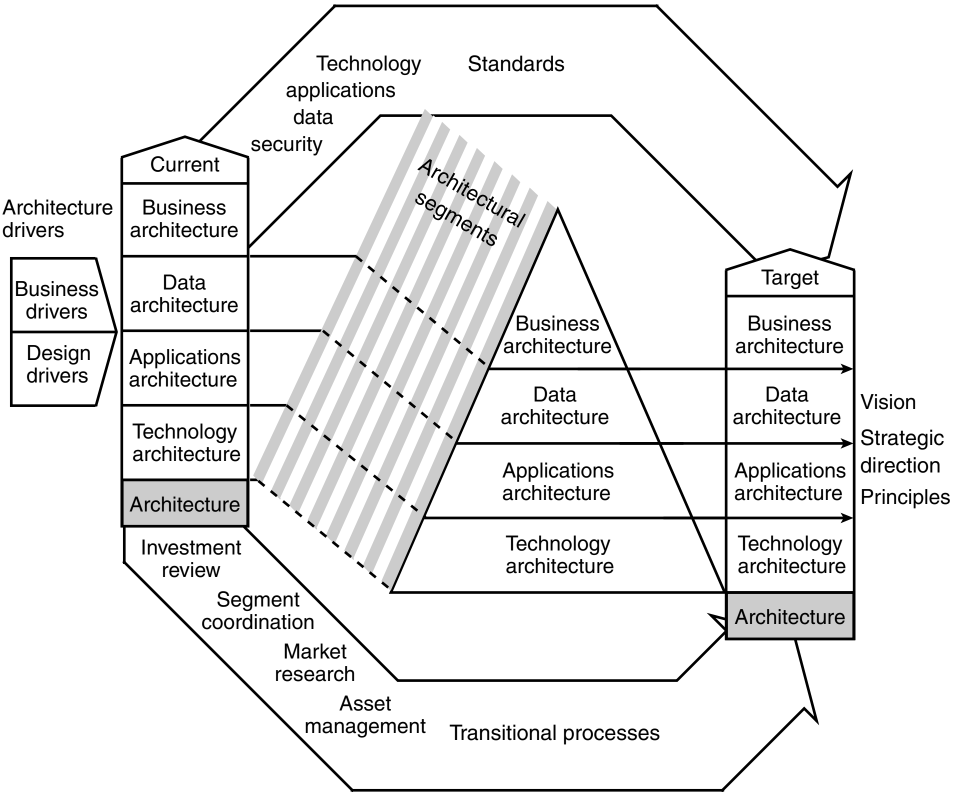

EXHIBIT 109.1 Structure of the federal enterprise architecture framework. (*Source*: A Practical Guide to Federal Enterprise Architecture, Chief Information Officer Council, Version 1.0, February 2001, Figure 6, Structure of the FEAF Components.)

security architecture—technology, customer focus, and external requirements are key drivers in this architecture and they are not easily defined beyond that time with any accuracy.

109.2.2 Association of Enterprise Architecture to Information Security Architecture

The target enterprise architecture can provide answers to the following questions that will be invaluable to the enterprise security architecture initiative:

- What are the strategic business objectives of the organization?
- What information is needed to support the business?
- What applications are needed to provide information?
- What technology is needed to support the applications?
- What is the needed level of interoperability between the data sources and the users of the data?
- What information technology is needed to support the enterprise's technical objective?
- What systems are going to be replaced in the near term? In the long term? What systems are going to be migrated to the new enterprise architecture?
- What risks are associated with the current sequencing plan?
- What alternatives are currently available if funding or resources are delayed?
- What are the budgetary and territorial concerns?

The enterprise architecture can be managed as "a program that facilitates systematic agency [business] change by continuously aligning technology investments and projects with agency mission needs."[4] There are going to be areas in which the enterprise architecture information, such as data information and flows, can move directly into an enterprise information security architecture as factors in establishing processes and functionality. There will be others, such as the identification of the business areas or information needs with the greatest potential payoff for the enterprise, which will have to be tempered with other security considerations. Although an organization certainly wants to address these high payoff areas in terms of information availability, integrity, and confidentiality, there may be other less "visible" areas that have higher areas of risk that will also have to be appropriately addressed in order to ensure the security of all business functions.

109.2.3 General Enterprise Architecture Principles

Federal agencies are now required to establish an enterprise architecture that will be used to streamline the collection, storage, and analysis of information, and the provision of applicable information to the general public. The process for the identification and documentation of information required to establish a federal enterprise architecture has aspects that can be applied to private industry as well.

Excerpts from the Chief Information Officer (CIO) Council guide[5] provide principles that help in the establishment of a enterprise architecture and, for our purposes, the establishment of an enterprise information security architecture:

- Architectures must be appropriately scoped, planned, and defined based on the intended use of the architecture.
- Architectures must be compliant with the law.
- Architectures facilitate change.
- Architectures must reflect the organization's strategic plan.

[4] A Practical Guide to Federal Enterprise Architecture, Chief Information Officer Council, Version 1.0, February 2001,p. 40.

[5] A Practical Guide to Federal Enterprise Architecture, Chief Information Officer Council, Version 1.0, February 2001.

- Architectures continuously change and require transition toward the target architecture.
- Target architectures should project no more than three to five years into the future.
- Architectures provide standard business processes and common operating environments.
- The quality of the associated architecture documentation is dependent upon the information obtained from subject matter experts and business owners.
- Architectures minimize the burden of data collection, streamline data storage, and enhance data access.
- Target architectures should be used to control the growth of technical diversity.[6]

Although the CIO architecture model mentions security as a concept[7] that "overlies" the enterprise life cycle, and the Interoperability Clearinghouse, a nonprofit organization that develops architectures,[8] includes security as a domain architecture, the impact that security should have in the establishment of the architecture is not fully presented. The implementation of an enterprise information security architecture requires the establishment of strong, far-reaching business practices that ensure system compliance with the security architecture and needs continuous assessment to enforce compliance (with the full support of senior management). Otherwise, there is no way to assure that the enterprise information security architecture meets the established business needs and functions at an acceptable level of risk.

109.2.4 General Enterprise Information Security Architecture Principles

Objectives of an enterprise information security architecture, in support of the business mission, must include the following:

- Not impede the flow of authorized information or adversely affect user productivity
- Protect information at the point of entry into the enterprise
- Protect the information throughout its useful life
- Enforce common processes and practices throughout the enterprise
- Be modular to allow new technologies to replace existing ones with as little impact as possible
- Be virtually transparent to the user
- Accommodate the existing infrastructure[9]

109.2.5 Inputs to the Security Architecture

Exhibit 109.2 depicts the inputs to the initial process in formulating an enterprise information security architecture. The process should, at a minimum, consider the following inputs:

- Business-related inputs:
  - Business goals and objectives for protecting the organization's business interests, assets, personnel, and the public; and the future direction of the business and supporting information systems
  - Business operational considerations of how the business will operate day to day (e.g., centralized or decentralized approach to security administration)
  - Current business directions and initiatives for the installed information systems and those under development

Current business directions and initiatives
Business operational considerations
Business information systems requirements
Business goals and objectives
Business policies and processes
Business risk tolerance
Business assets
Legal and regulatory requirements
Enterprise information security architecture
Existing IT infrastructure
Security goals and objectives
Threats
System use considerations
Vulnerabilities
Information sensitivity and criticality
Security requirements
Security policies

EXHIBIT 109.2 Considerations for formulating an enterprise information security architecture.

- — Business information system requirements (e.g., access requirements, availability requirements, business partner connectivity)
- — Business policies and processes defining what is acceptable and what is not acceptable business behavior
- — Business assets to be protected by the architecture
- — Existing infrastructure including a characterization of the current technical environment and what may help or negatively affect information security
- — Business risk tolerance for information disclosure, unauthorized modification and loss, unavailability, downtime due to hackers and viruses, and defaced Web pages
- — Legal and regulatory requirements including laws and regulations such as privacy, basic due care and due diligence, and sentencing guidelines
- — Threats to the existing infrastructure or business operations
- — Vulnerabilities associated with the existing infrastructure or computing operations

- Security-related inputs:
  - — Security goals and objectives (e.g., safeguard information assets from unauthorized and inappropriate use, loss, or destruction; protect sensitive information from unauthorized disclosure and manipulation; and protect the availability of critical information)
  - — System use considerations including who will use the information systems (employees, contractors), what level of background screening, when (time of day, days of the week), where (office, home, travel), why (inquiries, file updating, research), etc.

- — Sensitivity and criticality of the information to be protected, including the impact due to unavailability or loss
- — Security requirements to protect information, applications, platforms, and networks based on the sensitivity and criticality of the information (e.g., label sensitive media, back up information, store backups off site, encrypt information stored in nonsecure locations or transmitted over untrusted networks)

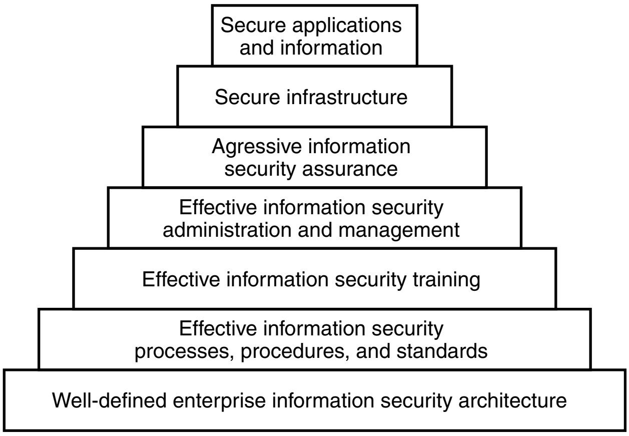
- Security policies on what is and what is not acceptable security behavior

109.3 Moving from Design to Deployment

109.3.1 Building a Secure Computing Environment

As depicted in Exhibit 109.3, a well-defined enterprise information security architecture provides the foundation for a secure infrastructure and a secure computing environment. The building blocks of a secure computing environment include:

- Well-defined enterprise information security architecture, with accountability, deployment strategies, technology, and security services
- Effective information security processes, procedures, and standards, derived from policies, but dealing with specific components and technologies and providing detailed specifications that can be audited
- Effective information security training, including new-hire training; job-related operational training for executives, managers, supervisors, privileged users, and general users; and periodic awareness training
- Effective information security administration and management, including configuration management, information resources management (IRM), hardened platforms with the latest security patches and virus signature files, virus scanning, vulnerability scans, intrusion detection, penetration testing, logging, alarms, and reviews of common vulnerabilities and exposures (CVEs)
- Aggressive information security assurance, including certification, accreditation, self-assessments, inspections, audits, and independent verification and validation (IV&V)



Secure applications and information
Secure infrastructure
Agressive information security assurance
Effective information security administration and management
Effective information security training
Effective information security processes, procedures, and standards
Well-defined enterprise information security architecture

EXHIBIT 109.3 Building blocks of a secure computing environment.

- Secure infrastructure, including DMZ, routers, niters, firewalls, gateways, air gaps, protected distribution systems (PDSs), virtual private networks (VPNs), secure enclaves, and separate test environments
- Secure applications, including well-designed, structured, and documented modules; software quality assurance code review; file integrity checking of change detection software, including products such Tripwire and Advanced Intrusion Detection Environment (AIDE); and access based on the principles of clearance, need-to-know, and least privilege
- Secure information, including encryption, backups, and integrity checking software.

109.3.2 Information Security Life Cycle

Exhibit 109.4 indicates how the information security life cycle interacts with the foundation and core components of an information security program. As the outer ring illustrates, organizations should continuously perform the following functions during the information security life cycle:

- Assess business security needs and the risks to the organization
- Design security solutions to appropriately address the assessed risks
- Acquire or develop security solutions
- Integrate and test security solutions

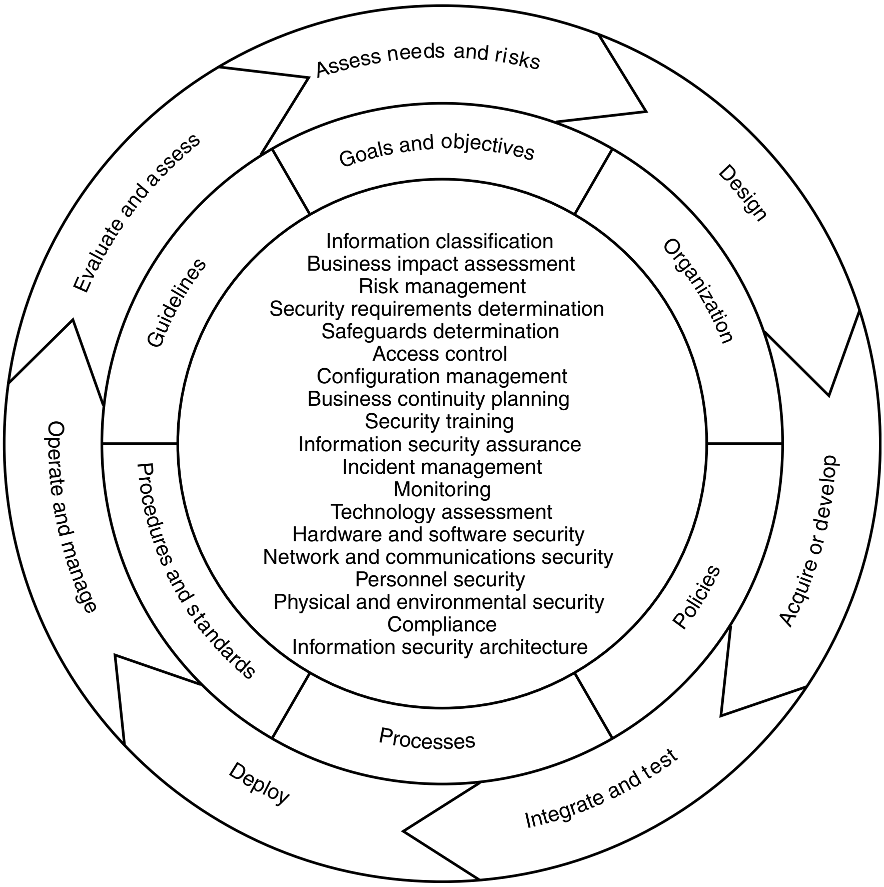


EXHIBIT 109.4 Information security lifecycle and the information security program.

- Deploy security solutions
- Operate and manage security solutions
- Evaluate and assess security solutions to assure their effectiveness

The organization can perform these functions directly or outsource them, and ensure they are implemented effectively. These functions should be performed continuously because security is an ongoing process, not a one-time destination. Business, technology, risk, and organization structure are not static.

The inner ring illustrates the foundation or essential ingredients of an information security program:

- *Goals and objectives*: Confidentiality and possession, integrity and authenticity, availability and utility, accountability, non-repudiation, and assurance
- *Organization*: Full-time and *ad hoc* personnel identified to implement the information security programs
- *Policies*: High-level management instructions that support an enterprisewide information security program that incorporates prudent practices from industry and government
- *Processes*: Methodologies that support the information security policies and cost effectively implement information security in the enterprise
- *Procedures and standards*: Detail components, technologies, and step-by-step actions that support the policies and processes
- *Guidelines*: Recommended activities to provide a more secure environment

The inner elements are the functional core components of an information security program:

- *Information classification*: The process and consulting support by which the sensitivity of each application is determined.
- *Business impact assessment*: The process and consulting support by which the criticality of each application is determined.
- *Risk management*: The process and consulting support for the identification and assessment of assets, threats, vulnerabilities, and the resulting risks and their successful mitigation, transfer, or acceptance.
- *Security requirements determination*: The process and consulting support for identifying the information security requirements given the sensitivity, criticality, and risks.
- *Safeguards determination*: The process and consulting support for identifying information security safeguards or controls that will satisfy the security requirements.
- *Access control*: The process of identification and authentication of users, maintaining audit records of their access, and enforcing individual accountability that prevents unauthorized access to information systems.
- *Configuration management*: The rigorous management of the change process that provides hardware and software integrity, and change and version control.
- *Business continuity planning*: The process and consulting support that implements effective planning for continued business operations under all conditions and situations.
- *Security training*: The operational and awareness guidance that ensures all employees are trained in the security aspects of their jobs and their associated security responsibilities, and the secure, appropriate use of information systems and data.
- *Information security assurance (also known as certification and accreditation)*: The formal security evaluation and management approval process that ensures the information system is protected at a level appropriate to its sensitivity and criticality classifications; identifies the controls that satisfy the security requirements, and are documented in a security plan. Determines the residual risk before the information system is put into production as it is, and periodically reviewed over the

life of the information system. Periodically tests and evaluates the effectiveness of protection mechanisms, based on current threats and vulnerabilities.

- *Incident management*: The process and consulting support that ensures appropriate actions for detecting, reporting, and responding to information security incidents. Receives and tracks information security incident reports through resolution, escalates serious incidents, and incorporates "lessons learned" into ongoing security awareness and operational training programs.
- *Monitoring*: The monitoring of logs and activities to verify the security stance, ensure appropriate resource use, and defend resources from attack.
- *Technology assessment*: The review, evaluation, and recommendation of advanced security technologies. Evaluates infrastructure and commercial-off-the-shelf (COTS) products for common vulnerabilities and exposures (CVEs).
- *Hardware and software security*: The procurement, configuration, installation, operation, and maintenance of hardware and software in a manner that ensures information security. Includes platform hardening and software integrity checking.
- *Network and communications security*: Perimeter protection, intrusion detection, vulnerability scans, penetration testing, remote access management, and control of modems. Determines the criteria for the evaluation of firewalls, recommends encryption solutions, determines when secure enclaves are required, and provides consulting support for the review of network connectivity requests.
- *Personnel security*: Identifies sensitive positions and ensures individuals assigned to those positions have an appropriate clearance. Includes information security in job descriptions, and through performance appraisals holds individuals accountable for carrying out their information security responsibilities and for their actions.
- *Physical and environmental security*: Protects hardware, software, and information through physical and environmental controls.
- *Compliance*: Administrative inspections, reviews, evaluations, audits, and investigations for the purpose of maintaining effective information security. Consulting support on best practices from industry and government on remedial action to address any significant deficiencies. Confiscation and removal of unauthorized hardware and software, and hardware, software, and data required for use as evidence of wrongdoing.
- *Information security architecture*: The framework for information security and the road map for implementation to ensure the confidentiality, integrity, and availability of applications and information.

109.3.3 Defense-in-Depth for a Secure Computing Environment

Exhibit 109.5 depicts the requirements for a secure computing environment. The lack of security in any one of these components is going to negatively impact the security of the computing environment. If there is no policy, there can be no uniform management direction on how to protect the business, its operations, its people, and its information. If there are no processes and procedures with associated standards, implementation of policy will be based on an individual's interpretation of policy—which is likely to vary from person to person. If there is no physical security, then logical and administrative controls can be easily circumvented without being discovered. The lack of environmental controls can bring down the enterprise and cause more destruction than a malicious agent. If there is inadequate personnel security, the likelihood of insider threat increases dramatically and the impact may not be detected for a significant period of time. The need for communications and network security is obvious; we live in a connected world. However, the unapproved use and unknown presence of a modem or wireless network access points will circumvent firewall protection. Hardware controls must be in line with the equipment functionality, e.g., servers must be hardened before deployment if it is going to be effective.

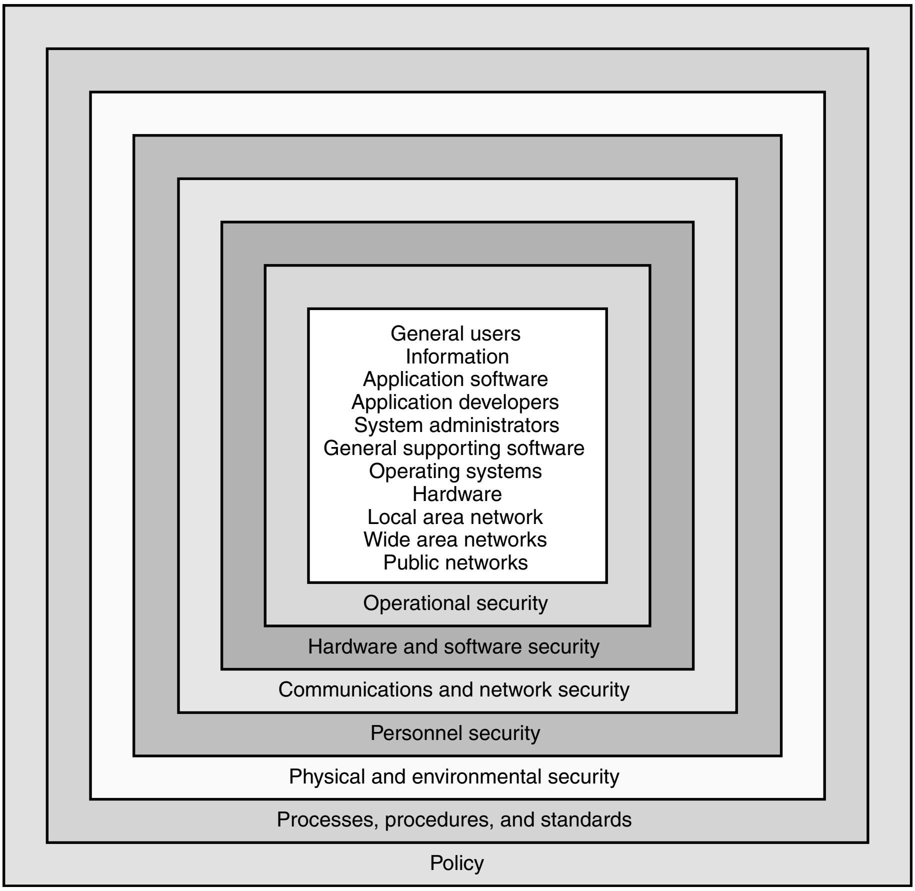

EXHIBIT 109.5 Defense-in-depth.

Software and its associated controls must be up to date, including patches and updated virus signature files. Employees, contractors, vendors, and visitors must know what is expected of them to support enterprise information security. Public networks, although vital to many business operations, must be viewed as untrusted components of the enterprise architecture and handled appropriately. Wide area networks (WANs) and local area networks (LANs) have certain operational requirements that must be implemented to ensure information confidentiality, integrity, and availability. Hardware must be assessed on its ability to perform the required functions, and must be protected so it cannot be reconfigured to perform unauthorized functions. Software must be licensed, purchased from a trusted source, and assessed to ensure it does not contain malicious code even if it is shrink-wrapped. System administration and application developers must be trusted personnel with the appropriate clearances who have been trained to perform their job responsibilities accurately and effectively. Application software must be accurately designed, developed, and implemented to protect information and the business environment. Information is the lifeblood of the organization and must be protected from unauthorized disclosure, while being made available when required in an accurate, usable, and complete format. General users represent a significant threat to the secure computing environment, accidentally or with malicious intent. The actions of users must be controlled, and users must be trained in secure operations and use of information and computing and communications resources. The user is the weakest component of the secure computing environment, and carelessness or social engineering can result in established controls being circumvented. Therefore, defense-in-depth must also include checks and balances, with multiple security functions and associated components to address the security requirements. The standardization of security components is represented in this chapter as information security services.

109.4 Defining the Enterprise Information Security Architecture

109.4.1 Information Security Services

Information security services provide the enterprise information security architecture with standard methods to support the integration and implementation of information security across the organization infrastructure. These services must be standardized, shareable, and reusable. Information security services include people and technology services.

- *Accountability*: Associates each unique identifier (e.g., user account or log-on ID) with one and only one user or process to enable tracking of all actions of that user or process.
- *Assurance*: Provides a formal information security evaluation and management approval process to ensure information applications and the supporting infrastructure are protected at a level appropriate to their sensitivity and criticality.
- *Authentication*: Verifies the claimed identity of an individual, workstation, or process.
- *Authorization*: Determines whether and to what extent access should be granted to specific information, applications, and information systems.
- *Availability*: Ensures information, applications, and information systems will be accessible by authorized personnel or other information resources when required.
- *Confidentiality*: Ensures that information is not made available or disclosed to unauthorized individuals, entities, or processes.
- *Identification*: Associates a user with a unique identifier by which that user or process is held accountable for the actions and events initiated by that identifier.
- *Integrity*: Ensures the correct operation of applications and information systems, consistency of data structures, and accuracy of the stored information.

109.4.2 Information Security Functions

Each information security service consists of one or more security functions that further identify and define the security action or process needed to secure the information and information systems. Examples of such information security functions include, but are not limited to, authorization, identification, authentication, accountability, risk assessment, confidentiality, encryption, physical access control, logical access control, digital signatures, integrity, intrusion protection, virus protection, non-repudiation, availability, security administration, audit logging and reviews, information security assurance, incident handling, monitoring, and compliance.

109.4.3 Enterprise Information Security Services Matrix

Exhibit 109.6 summarizes information security services and their related security functions. The exhibit is organized as follows:

- *Information Security Service*. Names the information security service that addresses one or more specific security needs or requirements identified to secure information and information systems and comply with applicable laws, statutes, regulations, policies, and best industry practices. Securing information and information systems may require the use of one or more information security services.

EXHIBIT 109.6 Enterprise Information Security Services

Information Security Service	Security Function	Security Function Description	Vehicle
Accountability	Non-repudiation	Assures the sender cannot deny he sent the message and recipient cannot claim that he received a different message	Digital signature and certificates
	User deterrence	Places restraint on deviant activities by increasing the likelihood of identification and prosecution of personnel conducting such activities	Security awareness training Operational security training Policy, processes, and procedures
Assurance	Data designation	Determines the sensitivity and criticality of information and information systems	Data element assessment
	Monitoring	Provides surveillance of the activity being performed within the information systems as well as at its boundaries; the surveillance service is carried out on networks and on servers/hosts: network monitoring and host/server-based monitoring	Intrusion detection systems (IDS) Host-based IDS
	Intrusion detection	Detects attempts at system break-ins, behavior patterns, and anomalies with respect to activities at the boundaries of the information system (e.g., network, mainframe, or other device)	IDS
	Malicious code protection	Security code review provides assurance that the information system does and will only execute authorized operations that ensure, preserve, and maintain the integrity of the system and all the information systems accessed	Security coda review
		Virus protection monitors, analyzes, and protects the information resource from possible virus attacks	Virus scanning Pattern distribution
	Security administration	Implements management constraints, operational procedures, and supplemental controls established to provide adequate protection of an information system	Configuration management Information resource life cycle Database administration
	Acceptable use monitoring	Ensures information resources will be used in an approved, ethical, and lawful manner to avoid loss or damage to operations, image, or financial interests	Audit logging Monitoring Content filtering
	Compliance	Reviews and examines the records, procedures, and activities to assess the information system security posture and ensure adherence with established criteria	Audit logging Monitoring Content filtering Inspection Independent assessment Penetration testing
	Audit	Provides the information systems with reviews as well as examination of records and activities to test for adequacy of the security controls, compliance with established policies, and operational procedures, and possibly recommends changes to policies and procedures	Audit logging Inspection Independent assessment
	Assessment of business impact	Determines the level of sensitivity, criticality, recovery time objective (RTO); the potential consequences due to information and information system unavailability or loss; and the identification of security requirements	Business impact assessment

EXHIBIT 109.6 (continued)

Information Security Service	Security Function	Security Function Description	Vehicle
	Assessment of risk	Identifies vulnerabilities, threats, likelihood of occurrence, potential loss or impact, expected effectiveness of security measures, and residual risk for an information resource	Risk assessment COTS vulnerability assessment
	Security testing and evaluation	Provides support for testing to determine if all the required security controls and countermeasures described in the security plan are in place and functioning correctly	Security test and evaluation plan
	Certification	Establishes the extent to which the information system meets a specified set of security requirements	C&A process
	Accreditation	Provides support to management in their formal acceptance of the residual risk for operating the information system and approval to deploy	C&A process
	Enclaving	Allows for configuration of special network areas that provide additional protections and access controls to secure information resources	Enclaving process Firewalls IDS Vulnerability scans
	Network connectivity	Protects network and communications infrastructure by managing network connectivity	Network connectivity process
	Penetration testing and vulnerability scans	Checks the robustness and effectiveness of the boundary countermeasures implemented for a given information resource	Vulnerabilities test plan
	Physical security	Identifies specific physical weaknesses, vulnerabilities, and threats for a facility, network, enclave, and information system and implements countermeasures	Site security review System security plan Locks, mantraps, locking turnstiles Guards Fences Lighting CCTV Motion detectors
	Environmental security	Identifies specific environmental weaknesses, vulnerabilities, and threats to a facility, network, enclave, and information system and implements countermeasures	Redundant power UPS Backup diesel generators Redundant telecommunications Backup HVAC
	Personnel security	Identifies sensitive positions and provides the structure to ensure personnel are cleared and their information security responsibilities are defined and included in their performance evaluation	Personnel clearances Job descriptions Performance appraisals Sanctions Conditions of continued employment Job rotation
	Incident management	Provides security incident handling and analysis	Incident reporting process
Authentication	Authentication	Verifies the claimed identity of an individual, workstation, or originator	Passwords and PINs Biometrics Smart cards Tokens Digital certificates
Authorization	Authorization	Determines whether and to what extent personnel should have access to specific information and information systems	User registration and authorization management
Availability	Fault isolation	Hardware: Allows the detection of hardware malfunction and the identification of the component that caused it Software: Allows the detection of software malfunction and the identification of the component that caused it	System alerts Network management systems/protocols Audit logging Network management systems/protocols

EXHIBIT 109.6 (continued)

Information Security Service	Security Function	Security Function Description	Vehicle
	Contingency planning	Provides contingency planning for information and information systems, personnel, and the facilities that house them	Emergency plan Contingency plan Facility recovery plan Personnel evacuation plan
Confidentiality	Confidentiality	Ensures information is not disclosed to unauthorized Individuals, entitles, or processes; confidentiality applies to hardcopy and electronic media in storage, during processing, and while in transit	Eradicate media Encryption Secure storage Key management Information classification Screen savers Physical access controls Physical access controls Public key infrastructure Logical access controls Separation of duties
Identification	Trusted identification	Associates a user with a unique identifier (e.g., user account or log-on ID) by which that user is held accountable for the actions and events initiated by that identifier	Unique user identifier
Integrity	Data integrity	Ensures the consistency of data structures and accuracy of transmitted or stored information	Hashing Checksum Digital signature
	Information system integrity	Ensures the correct operation of information system	System development methodology Independent security testing and evaluation Configuration management Session management Screen savers Test environment restrictions Server hardening

- *Security Function*. Lists the security functions that comprise an information security service.
- *Security Function Description*. Provides a brief description of the security function.
- *Vehicle*. Enumerates the mechanisms, processes, controls, and technologies that support, contribute, and implement the named information security service. Each information security service may be implemented through multiple processes and technologies.

109.5 Assessing the Enterprise Information Security Architecture

109.5.1 Controlling the Growth of Technical Diversity

The priorities established for the enterprise architecture will have to address all enterprise information security considerations. On the flip side, security projects, like business projects, will have to be reviewed in light of several considerations:

- *Business alignment*: Does the project support established strategic plans, goals, and objectives?
- *Business case solution*: What is the impact on the organization's information technology and business environments?

- *Sequencing plan*: Is the proposed investment consistent with the sequence (plan) and priorities established to reach the target architecture?
- *Technical plan compliance*: Does the proposed project comply with the enterprise standards and the architecture levels?

109.5.2 Ensuring Continued Support by Addressing Design Principles

The establishment of an enterprise security architecture is a significant undertaking. The perceived (or actual) complexity of the product could entice the viewer to assume that the architecture can successfully support the design, development, operation, and retirement of an information system. Periodically throughout the implementation of the architecture, it is good to look at the model in light of a system that supports a business function and see if it complies with security principles that support the system throughout its life cycle: initiation, development or acquisition, implementation, operation and maintenance, and disposal. Have the following design principles been addressed?

- Establish a sound security policy as the “foundation” for design.
- Treat security as an integral part of the overall system design.
- Clearly delineate the physical and logical security boundaries governed by associated security policies.
- Reduce risk to an acceptable level.
- Assume that external systems are insecure.
- Identify potential trade-offs between reducing risks and increased costs and decreases in other aspects of operational effectiveness.
- Implement layered security (ensure no single point of vulnerability).
- Implement tailored system security measures to meet organizational security goals.
- Strive for simplicity.
- Design and operate an information technology system to limit vulnerability and to be resilient in response.
- Minimize the system elements to be trusted.
- Implement security through a combination of measures distributed physically and logically.
- Provide assurance that the system is, and continues to be, resilient in the face of expected threats.
- Limit or contain vulnerabilities.
- Formulate security measures to address multiple overlapping information domains.
- Isolate public access systems from mission-critical resources (e.g., data, processes).
- Use boundary mechanisms to separate computing systems and network infrastructures.
- Where possible, base security on open standards for portability and interoperability.
- Use common language in developing security requirements.
- Design and implement audit mechanisms to detect unauthorized users and to support incident investigations.
- Design security to allow for regular adoption of new technology, including a secure and logical technology upgrade process.
- Authenticate users and processes to ensure appropriate access control decisions both within and across domains.
- Use unique identities to ensure accountability.
- Implement least privilege.
- Do not implement unnecessary security mechanisms.

- Protect information while it is being processed, in transit, and in storage.
- Strive for operational ease of use.
- Develop and exercise contingency or disaster recovery procedures to ensure appropriate availability.
- Consider custom products to achieve adequate security.
- Ensure proper security in the shutdown or disposal of a system.
- Protect against all likely classes of "attacks."
- Identify and prevent common errors and vulnerabilities.
- Ensure that developers are trained in how to develop secure software.[10]

109.6 Conclusion

109.6.1 Benefits of Architectures

The profit margin for most businesses is small, and the reduction of costs is vital to the success of the business. The enterprise security architecture can "reduce the response time for impact assessment, trade-off analysis, strategic plan redirection, and tactical action" with regard to security.

Some additional benefits are:

- Support for capital planning and investment management.
- Capturing a "snapshot in time" of business and technology assets.
- Provision of a strategy for systems and business migration.
- Help to mitigate risk factors in enterprise modernization.
- Identification of possible sites for innovative technology deployment.
- Support for key management decision making throughout the organization.[11]

Some direct cost-saving benefits include:

- Discounts on new products through bulk purchasing.
- Capital planning assistance from department CIO offices to ease the paperwork burden on division CIOs.
- Better career opportunities for information technology and security workers because their skill sets can be used on any of the standard systems that will be deployed throughout the department (enterprise).
- Increased ability to provide standardized training with a higher return on investment, because the number of people being trained by the same curriculum is greater for all levels of training, including users, technical support, and administrators.
- Ability to allocate human resources to areas other than their usual assignments to address key security concerns or incidents.

109.6.2 Helpful Hints from a Security Architecture Practitioner

The security architect is becoming a key function in many organizations, and functions as "the 'corporate clutch,' providing an interface between the security policy-makers and those tasked with providing

[10] Zyskowski, J., 2002. Building for the future: Enterprise architecture emerges as a blueprint for better IT management, *Federal Computer Week*, January 2.

[11] Scammell, T. 2003. Security architecture: One practitioner's view. *Information Systems Control Journal*, 1, 24–28.

information systems solutions to businesses." Concepts supporting a successful deployment and utilization of an enterprise security architecture include:

- Available architectural frameworks will have to be modified to adequately address security at the enterprise level.
- Avoid product focus (and resulting product wars) in the establishment of the security architecture.
- Deviations from initial security requirements must be managed to ensure compensating controls are used to minimize risk.
- Architectural documentation must be current and complete, or decisions will be made on obsolete information and ultimately require reworking.
- Documentation is a key deliverable of the architecture team; the lack of it can be costly—more so than the personnel costs associated with creating and maintaining the documentation.
- Project management supports the timely completion of tasking and deliverables.
- Publish all the information that can be provided to all members of the architectural team to facilitate their understanding of the security target architecture.
- Risk assessments are a valuable tool for any security architecture initiative and help to support a responsive architecture that avoids obsolescence and addresses business needs.
- Use business cases as a forum to assign costs to risks, focus the team on providing cost-effective solutions, and to contrast the costs of alternative (less desirable) solutions.
- Make presentation of architectural concepts and associated requests to senior management.
- Architecture supports policy and serves as a policy advocate, working to shape security requirements into practical solutions.[11]

109.6.3 The Bottom Line

The enterprise information security architecture is a complex model that incorporates business functions, technology, security policy, physical security, configuration management, risk management, contingency planning, users, and business partners and vendors. Generally speaking, all of these concepts will have to be applied to every business function or application, and the justification for the associated resources will have to be presented to senior management. Business functions have to be linked to security functions, and then added value has to be presented in a way that makes sense to senior management and positively affects the business bottom line.

110

Security Architecture and Models

Foster J. Henderson
Kellina M. Craig-Henderson

> He is like a man who built a house, and digged deep, and laid the foundation on a rock: and when the flood arose, the stream beat vehemently upon that house, and could not shake it; for it was founded upon a rock. But he that heareth, and doeth not is like a man that without a foundation built a house upon the earth; against which the stream did beat vehemently, and immediately it fell and the ruin of that house was great.
>
> **—Luke 6:48–49, The Bible, King James Version**

As this passage illustrates, a strong foundation has been akin to protection from adversity since the beginning of time. It should not be surprising then that information security professionals must have a good foundation to implement successful security architecture. Following are the areas designated as the cement for our "virtual foundation." A commitment to successful security architecture requires a clear understanding of issues involving:

- Technology
- Environment
- Software

What follows is initially a brief description of the components to this "tripartite" conceptualization of the virtual foundation. This in turn is followed by a more detailed discussion of exactly what the information security professional must know about each component, as well as the interactive effects of each.

Sounds easy; so why are more people *not* implementing successful security architecture? There are probably a number of reasons, but when one considers that architecture involves "the manner in which the components of a computer or computer system are organized and integrated,"[1] the answer should be fairly obvious. Security involves a very fine synergy that represents the interaction between software, technology, and the environment.

No IT system can be secured unless you unplug it and have "Fort Knox" security protecting it. Security is not only anti-virus software (insert your favorite vendor name) and a firewall. Importantly, people and policy must be factored in as well. And, with respect to the latter, a policy that is too strict, or that does not integrate seamlessly, or is not transparent to its user, is one that will be circumvented, ignored, or not supported.

Technology is multifaceted, and can be thought of as Intel, AMD, Motorola, and RISC chip architectures, wireless standards, Voice-over-IP, biometrics, smart card, IPv4, IPv6, etc. Each one has it advantages, disadvantages, and unique limitations. For example, a few years ago it was common knowledge among IT professionals that if your business operations required performing graphic-intensive work (such as computer-aided design), then you chose the Motorola chip (found in Apple computers) over the Intel chips (found in IBM-compatible personal computers [PCs]).

Environment is the second bullet in our initial outline. However, it is arguably the hardest one to tackle. Here, "environment" refers to the people, business operations, and risks, as well as the threats to your security architecture or model. We incorporate policy to change our business environment. If the policy is properly implemented, we can expect that the people in the environment will be influenced and guided by it. For example, think of the way in which the air conditioner (AC) modifies the environment of the office, the home, or the car. Here, the AC represents a "policy" to the extent that it changes the environment. The best way to ensure that the environment is up to par is to perform an information security (InfoSec) risk assessment. By not performing one, you cannot or will not understand the environment in which a business operates. You will also be able to identify what environmental threats are lurking out there, such as insiders (i.e., disgruntled employees), hackers, and social engineers. Performing a business impact analysis will enable you to identify the critical practices and tasks essential to a business' survival.

110.1 Information Assurance

Information assurance is a term you now see a lot in publications, or job postings on the Internet or in newspapers—or you may even have heard it tossed around at professional meetings. So, what is information assurance? Information assurance consists of the following five areas:

1. *Integrity*: This refers to the quality or condition of being complete or unaltered, i.e., protecting information from unauthorized alterations or destruction.
2. *Confidentiality*: This has to do with having the assurance that the information is not disclosed to unauthorized persons, processes, or devices.
3. *Availability*: Information resources must be available and accessible to its user(s) in a timely manner.
4. *Authentication*: This entails validation and verification of the user and involves determining whether the user should be granted access.
5. *Non-repudiation*: This occurs when the sender is provided with proof of delivery, and the recipient is provided with proof of the sender's identity. It assures that neither party can deny possession of the data at a later time.

Not surprisingly, information assurance should be considered a requirement for all systems used to enter, process, store, display, or transmit national security information.[2] What is perhaps the easiest way to think about information assurance is to think of it as the process that ensures that the correct, unaltered information always gets delivered to its intended and authorized recipient(s) at the correct

[1] Merriam-Webster Dictionary, http://www.m-w.com.

[2] National Security Telecommunications and Information Systems Security Policy (NSTISSP) 11, January 2000, available at NIST.gov.

place and time. The U.S. government, it could be argued, is more concerned with confidentiality, integrity, and availability than is the commercial sector, whose primary focus is availability and integrity. An understanding of the information assurance concept will enable you to determine which solution is best for your environment.

110.1.1 Software Applications

Software refers to the set of instructions that cause the hardware to carry out specific physical tasks. Within this context, "software applications" refers not only to the obvious, but it also refers to "anti-virus," "mobile code," "malicious logic," as well as the various popular operation systems and more. Hopefully, you get the picture.

If you are thinking that what we have just outlined to discuss in this section is daunting, you are correct. But do not despair. At the end of this section you should have a firm grasp of the requisite concepts and ideas to successfully implement security architecture. We will discuss concepts, security practices, preventive, detective, and corrective controls (i.e., the environment), equipment, platforms, networks (i.e., technology), and applications (i.e., software) necessary to ensure information assurance. At various points you will note that the discussion will necessarily reflect the interactive nature of technology, environment, and software. For example, although we begin by discussing aspects of technology, this invariably entails a discussion of software.

110.2 Technology

110.2.1 Address Space

Address space refers to the set of all legal addresses in memory for a given application. The address space represents the amount of memory available to a program.[3] By using a technique called *virtual memory* or *virtual storage*, address space can be made larger than primary storage (i.e., RAM; primary storage is the main memory assessed by the CPU).[4] Think of it this way: FJH is a National Football League fan who plans to see his favorite team, the Dallas Cowboys, at Texas Stadium, which has 65,846 seats.[5] Think of each seat as representing an address in memory. In his fantasy, FJH purchases an entire row of seats in section 28A, directly behind the Cowboys' bench. Think of the actual purchase of the row of seats as a program running in physical memory, which is the stadium. Imagine that, after a sensational season (yes, we said "imagine"), the Cowboys host the NFC Championship game at Texas Stadium, and tickets are sold out. So FJH goes to the local sports bar to watch the televised game on the big screen. The sports bar has a seating capacity of 200. Taking this metaphor a step further, this is represented by the hard drive. To tie all of this together, think of the combination of seating at Texas Stadium (i.e., the physical memory) and that of the sports bar (i.e., the hard drive) as making up virtual storage.

To understand when this process is used, its helpful to describe some related terms. To begin with, keep in mind that an operating system accesses virtual memory when it detects that physical RAM is close to being depleted. Once that limit has been reached, swapping—the process whereby information is transferred from RAM to secondary storage—begins. In contrast, paging is the process of moving information from the input/output device to primary storage. The operating system (OS) has to keep track of all of this movement. A good metaphor for an OS is the conductor of a symphony orchestra. Just as the conductor must account for and direct the movements of each musician, so too must the operating system keep track of all movement between primary, secondary, and virtual storage. Consequently,

[3] Available at http://www.webopedia.com.

[4] In contrast, secondary storage refers to the floppy disk, tape drives, hard disk, and optical media we are so familiar with handling. You know the terms: terabytes, gigabytes, megabytes, or kilobytes.

EXHIBIT 110.1 Interrupt Request Lines (IRQ)

IRQ 0	System timer
IRQ 1	Keyboard
IRQ 2	Cascade interrupt for IRQ 8–15
IRQ 3	COM 2: 2nd serial port
IRQ 4	COM 1: 1st serial port
IRQ 5	Sound card
IRQ 6	Floppy disk controller
IRQ 7	1st parallel port
IRQ 8	Real-time clock
IRQ 9	Open interrupt
IRQ 10	Open interrupt
IRQ 11	Open interrupt
IRQ 12	Mouse
IRQ 13	Coprocessor
IRQ 14	Primary IDE channel
IRQ 15	Secondary IDE channel[a]

[a] See broadbandreports.com.

address space, which can consist of virtual storage, "includes the range of addresses that a processor or process[6] can access, or at which a device can be accessed."[7] Each process will have its own address space, which may be all or a part of the processor's address space. For example, to better understand address space, below is a list of common devices that should look familiar to you to demonstrate address space. It is a list of the most common interrupt request lines (IRQs [i.e.]) and includes the items listed in Exhibit 110.1.

110.2.2 Types of Addressing

The Texas Stadium example of address space pertains to physical addressing. It is an actual location. Relative addressing involves an expressed location from a known point. For example, imagine that you have ordered something from Amazon.com that will be shipped via United Parcel Service (UPS) to your address at 1 Main Street. You know that you will not be home for the delivery, so you leave a message for the driver to deliver the package to your next-door neighbor (3 Main Street). So the address to which the package is actually delivered is 3 Main Street.

Logical addressing is a little more complicated. It is the opposite of physical addressing; its location involves the translation of the physical address. Keep in mind that addressing does not apply to memory only, as is the case in programming, but it can also refer to mass storage as well. Examples include the file allocation table (FAT), the new technology file system (NTFS), or the compact disc file system (CDFS).

As you probably know, a central processing unit (CPU) is the heart of the computer. Although CPUs are made by various manufacturers, a few commonly known ones include Intel's Pentium 4, AMD's Athlon, and the PowerPC G4 chips.[8] Both the CPU and bus (the internal components of the CPU that are wired to the primary storage) are physical assets. Consequently, we say that physical addressing is used.[9] Because software is virtual or logical, relative and logical addressing is used. For example, think of using Excel to run a large spreadsheet. The phone rings; after the call has terminated, you return to your spreadsheet and ask yourself, "Which cell am I currently working in?"

[6] A process is a program being executed, and is discussed in more detail in the section on machine types.

[7] Denis Howe. 1993–2001. The Free Online Dictionary of Computing.

[8] According to information available at Apple.com, the PowerPC G4 is a collaborative effort between Apple, Motorola, and IBM.

[9] Harris, S. 2002. *All in One CISSP Certification*. Osborne/McGraw-Hill, Berkeley, California.

110.2.3 Memory

RAM was discussed briefly in the section on address space, and it refers to volatile memory. The term "volatile" is an apt one given that once the power is turned off, all information held in RAM is lost. Nonvolatile memory is the opposite—when power is turned off, the information contained in the memory space is still there. A good example of nonvolatile memory is read-only memory (ROM), which is used in laser printers (the fonts are actually stored in ROM), in calculators, and in portions of the PC that boots the computer.[10] In addition, there is programmable read-only memory (PROM), erasable-programmable read-only memory (EPROM), as well as electrically erasable-programmable read-only memory (EEPROM).

What is the difference between the different types of memory? PROM is blank memory where a set of instructions that have been recorded cannot be used again; EPROM is like PROM, but with instructions that are erased by ultraviolet light. In contrast, EEPROM is PROM with an electric charge that is used to erase the set of instructions.

By the way, have you ever performed an update for a basic input/output system (i.e., BIOS) from a vendor with the latest update, or upgraded your modem with the latest vendor software? Or, have you changed the personal identification number (i.e., PIN) on a smart card? If you have answered "yes" to any of these questions, then you have most certainly had some experience with flash memory. And, guess what? Another name for EEPROM is flash memory. When programs are stored in them, this family of ROM products is also called *firmware*, which refers to the combination of hardware and software.

While we are still discussing the many aspects of memory, it is worth mentioning cache. Cache refers to the reserved section of main memory for high-speed reading and writing of instructions. When data is found, it is called a "hit" and a "miss," depending on whether the information is maintained in cache.

Why are we spending so much time discussing memory and addressing? The easy answer is that some viruses propagate in memory. The more complex answer has to do with the fact that buffer overflow attacks involve sending a set or block of instructions that overflows the set address space of the memory. A few blocks of a malicious code slip in at the tail end of a program being executed, for example, in a privileged state. Buffer overflows occur when programs do not adequately check for the appropriate length in value, and consequently, the malicious code gets executed. Because there is more input than expected, it spills into another program waiting to be executed by the CPU.[11]

For example, Sun Microsystems' Java Virtual Machines executes in memory or in temporary files in various operating systems. Java will run on just about anything that has storage space and a powerful enough CPU. Java applets are on some smart cards and cell phones, so the CPU required is not as large or as powerful as you may have thought. It is when those applets (i.e., Java programs) execute outside the sandbox (i.e., address space limitations) within your browser, or in temp folders on the hard drive, or in allocated memory space, that the trouble usually begins. A note of advice: Be aware of the environment!

We have discussed memory and the various kinds of memory, whether it is physical or symbolic. Now we will consider the importance of machine types.

110.2.4 Machine Types

We have briefly discussed one machine type—the virtual machine, which is the case when a program is being executed in memory (for example, Java Virtual Machine [VM], anti-virus heuristics technology). Symantec's white papers explain the basic principle behind heuristic technology. In a nutshell, Symantec's program, in addition to emulating the program in a virtual machine, is also monitoring requests being made to the operating system (OS).[12] The conceptual opposite of a virtual machine is the common

[10] See www.webopedia.com.

[11] For a more-detailed discussion of this process, see McClure, S., Scambray, J., and Kurtz, G. 2001. *Hacking Exposed, 3rd Ed.*, Osborne/McGraw-Hill, Berkeley, California.

[12] For more information, see Understanding Heuristics: Symantec's Bloodhound Technology.

three-dimensional, physical PC, which is "real." There are at least three other types of machines that we will discuss here: (1) the multistate, (2) the multitasking, and (3) the multiprogramming machines.

A multistate machine actually processes different classification levels at the same time. Think of it as a system enabling users with different authorized classifications to access information from the same workstation rather than using two workstations. For example, with classified documents a user would turn a switch on a box representing nonclassified information on the display screen. Think of it as maintaining confidential, public, and proprietary information.[13] In contrast, a multitasking machine exists when the OS slices out CPU time to different programs to execute specific tasks, or when each program can control the CPU as long as it needs to. For example, Windows 95, Windows NT, and UNIX workstations switch back and forth to give the appearance of executing tasks at the same time. An example of a multitasking machine is best demonstrated by the Windows 3.1 OS. By the way, this explains why 3.1 "locked" more than NT: it did not incorporate memory protection.[14]

The multiprogramming machine is similar to the multitasking machine. However, rather than switch between tasks, it involves execution of two or more programs by one processor. This should not be confused with the multiprocessor, which refers to the number of CPUs used to execute tasks or programs. With a multiprocessor, more than one CPU is being used; Novell's and Microsoft's various server application products support multiprocessors.

110.2.5 Operating Modes

Following a recent house move, we unpacked and I was happy to find a Netware 4.1 reference book. Do not laugh! The principles are still the same today. UNIX, Windows NT, and Novell Netware all use memory protection.

Consider the following example. Imagine a dartboard. Do you have the image in your mind? The smallest circle is a red area or "bull's eye." This circle is ring "0" (or ground zero for you military folks). There are four rings (0 to 3), and each circle gradually radiates outward, getting larger. Now, think of ring 0 as the area where operating systems such as UNIX, NT, and Novell operate. Netware 4.1 servers use this area as a default, although the system administrator could of course change the default setting. Whereas ring 0 is for the OS kernel and provides the least restriction to the CPU, ring 3 (i.e., the outermost ring for Netware 4.1) provides the most restrictions to the CPU. Ironically, although ring 0 is the smallest ring, it offers the fastest performance. As you move from the center outwards (that is, from ring 0 to ring 3), you take a hit in performance. As for the other rings, ring 1 is for the operating system (not the security portion), ring 2 is for the various drivers, and ring 3 is where the programs are executed.

Personally, I have always preferred Novell's security approach over the other OSs. The reason I developed this preference has to do with a little bit of history. Back then, Netware 4.1 would place things in ring 3 as a test or trial area. The process might run a little slower, but at least it did not crash the server! How is that possible? Because Netware 4.1 is operating in ring 0 memory address space, as noted earlier. For example, if the OS receives a request from a process or program to use the memory space in ring 0, the request is blocked; this process is called memory protection.[15] Data may be accessed on the same ring or from a less privileged ring by a program. Resources may be requested in the opposite manner; at the same ring level or from a higher-privileged ring. Processes operating in the inner ring are called "supervisor" or "privileged" state, and those working on the outer rings are called "user" state.[16]

[13] Further discussion of multistate machines is found in the section on Security Models.

[14] This is explained further in the section on Operating Modes.

[15] Lawrence, B. 1996. *Using Netware 4.1. 2nd Ed.*, Que, Indianapolis.

[16] Harris, S. 2002. *All in One CISSP Certification*. Osborne/McGraw-Hill, Berkeley, California.

EXHIBIT 110.2 Process States

1	Ready	Ready to run on the next available processor
2	Running	Program currently being executed
3	Standby	Assigned a queue and about to run
4	Terminated	Finished executing the program
5	Waiting	Not ready for the processor
6	Transition	Ready, waiting on resources other than the CPU (e.g., input from the user, completing a print job, etc.)[a]

[a] See http://support.microsoft.com/support/ntserver/serviceware/nts40y60.asp.

110.2.6 CPU States

CPUs exist in two types of states. Supervisory state exists when a program can access an entire system (i.e., meaning the OS on the mainframe). It is in the supervisory state where both privileged and nonprivileged instructions can be executed. In contrast, a problem state is where nonprivileged instructions and application instructions are executed. For example, telecommunications, ports, and protocols were discussed in Domain 2. The more well-known ports—1024 and below—operate in a privileged state.[17] As it happens, Microsoft defines eight process states for NT. However, we have cut down the first and last states to come up with a series that looks a lot like the four more commonly known states. This results in a total of six states and includes those listed in Exhibit 110.2.

To summarize, in this section on resource management we have discussed addressing, as well as swapping, paging, caching, storage types, and memory protection.

110.3 Environment

Now that we have discussed memory, CPUs, buses, logical and physical organizations, the basic technology concepts, and a little sprinkling on software, we will address the environment and software applications. In Domain 1, Access Control Systems and Methodology, control types were discussed. As a reminder, the control categories mentioned were "PAT." This is, of course, the easiest way to remember the following:

- Physical: Refers to locks, guards, alarms, badge systems, lights, etc.
- Administrative: Refers to policies and procedures, security awareness, auditing, etc.
- Technical: Refers to anti-virus, firewalls, intrusion detection systems (IDS), etc.

As stated before, it is important to know your environment. Consider the fact that Internet stock fraud is estimated at $10 billion per year, or $1 million per hour,[18] or as the FBI's Deputy Assistant Director recently stated, "Cyber crime continues to grow at an alarming rate, and security vulnerabilities contribute to the problem."[19] As evidence of this, results of the Seventh Annual 2002 Computer Crime and Security Survey revealed that:

- 94 percent detected security intrusions within the last year.
- 80 percent acknowledge financial loss.
- Financial losses caused by theft of proprietary information cited as the most severe cases again.
- 74 percent indicated their Internet connection as the most frequent point of attack.

[17] RFC 793, Internet Assigned Numbers Authority (IANA).

[18] According to Louis J. Freeh, Director of the FBI, March 28, 2000, Congressional Statement on Cyber Crime.

[19] Farnan, J. E., Deputy Assistant Director, 4/3/03, Congressional Statement on Fraud: Improving Information Security.

- 78 percent detected employee abuse.
- 85 percent detected computer viruses.

As a result of findings like these and others, it should be clear that protection mechanisms are required now more than ever. Keep in mind that no system can be totally secured. Sooner or later an incident will occur. However, it is those actions and responses used to mitigate damage combined with corrective actions to ensure the same incident does not reoccur that distinguishes the superior (i.e., more secure) system from the others.

110.3.1 Layering

Layering is a concept that is important to understand when designing a security architecture. Remember the earlier discussion of memory protection as it was associated with Netware 4.1? That was actually layering in that the kernel is located in the center with programs located on the outer edge; drivers (for secondary storage) are located in between. Layering refers to the organization of separate functions that interact in a hierarchal sequence or order.[20] A good example for layering is the OSI model: there are seven component layers stacked upon each other. Whether you start from the bottom layer and work up, or the reverse order, there is an interaction among those layers.

110.3.2 Abstraction

Abstraction is something system administrators and programmers should be familiar with in their normal duties. Object-oriented programming uses abstraction. Abstraction (as the definition implies) involves the removal of characteristics from an entity in order to easily represent its essential properties. For example, it is easier for a system administrator to grant group rights to a group of 25 people called "Human Resources" than to grant 25 individual rights to each HR member. Windows 2000 Professional provides six built-in local groups straight from the "jewel box," including:

- Administrators
- Backup operators
- Power users
- Users
- Guest
- Replicator

Each local group has a set of predefined rights for the user group. If you are "security smart," you have disabled the guest account and renamed the administrator group!

110.3.3 Data Hiding

This also has to do with object-oriented programming. Graphical user interfaces (GUIs) use object-oriented programming. For example, I am using the 2000 Professional OS. The printer icon, which is an object, contains information related to a specific printer. The information on this specific object is predefined. The object only needs to know certain information to complete its task. Think of the items recently learned in this section. Which IRQ, port, and protocol should be used to execute this task? What is the memory space address? Does the user have sufficient rights to print? In other words, anything not specifically needed to carry out the print task is hidden from the printer object.

[20] See http://www.whatis.com.

110.3.4 Principle of Least Privilege

This brings us to the principle of least privilege that applies to programs as well as people. Programs and people should only be given access to those resources necessary to complete a specific task, execute a program, or accomplish their job. Once a process has been accomplished, depending on the circumstances, access to privileged resources should be removed. For example, your organization's work hours are from 7 A.M. to 6 P.M. You have decided to restrict outgoing fax calls between 6:30 P.M. and 7 A.M., preventing the cleaning crew or security guard from abusing the system. Data hiding, abstraction, and hardware segmentation each fall under the principle of least privilege. This principle is critical to understand to properly secure Novell Directory Services (NDS), Microsoft's Active Directory, Lightweight Directory Access Protocol (LDAP), and file, fax, server, and printer access within an organization. Failure to implement the correct assignation of administrative properties to objects, users, and resources, or to properly understand how inheriting rights are transferred, will lead to a security incident each and every time.

Now, as Emeril Lagasse says, "Let's take it up a few notches…." Bam! Remember the PAT acronym? We will begin focusing on a few additional concepts to tie it all together.

110.3.5 Security Practices

Remember that no system is totally secured unless you unplug it. Consequently, a secure system needs preventive, detective, and corrective controls in place in order to take proper action when incidents occur.

110.3.5.1 Preventive Controls

Preventive controls are measures carried out to block anticipated aggression from hostile forces. Locks, fences, alarms, guards, lighting, access control lists (ACL), IDS, anti-virus software, firewalls, logical access controls (smart cards, biometrics, PINs), demilitarized zones, and policies and procedures are all used to do the job so that those "hostile forces" are less likely to impact the operations. Just how can policy and procedures help? Consider that when an employee is terminated, resigns, or transfers positions, the user's profile must be removed from the network. This means that the third or at least the fourth person who should be notified within the organization is the senior IT security professional, who should remove that person's log-in account.

Exhibit 110.3 shows a list of preventive control tips, though not inclusive of all possible ones, which should provide you with an understanding of what is being discussed.

110.3.5.2 Detective Controls

Sooner or later someone will try to breach your security. As network professionals, we need to be vigilant about employing effective methods to catch cyber crooks. Below is a listing of a few detective controls:

- Enable logging for system changes, unsuccessful log-ins, system policy changes, access to files.
- Review those logs, outsource logging tasks, or automate the process (few good automated tools available).
- Conduct incident investigations.
- Use an IDS.
- Use anti-virus software. (*Note*: Can also be called preventive.)
- Make sure to have supervision oversight, job rotations, mandatory vacations.[21]

[21] Consider the fact that most large banks require forced vacations. It is harder, for example, to keep an embezzlement scam running while a person is away on vacation and another employee is filling his/her position during the absence.

EXHIBIT 110.3 Preventive Control Tips

- Audit active employee names against user accounts or profiles currently assigned network file access privileges
  - — Remove/disable those accounts where there are discrepancies
- Use incremental and full backups and test backups
- Prepare contingency plans and test regularly
- System administrators should not access personal e-mail while logged into networks with system administration privileges (create a regular user profile to perform this task)
- Harden an operating system prior to placing it online
- Use standard integrated desktops for users
- Use log-in restrictions when it is feasible
- Develop educational and awareness programs for users and system administrators
- Clearly mark and label files (both soft and hard copies, and secondary storage devices)
  - — Sanitize electronic media (reminiscence security) and properly dispose of classified documents whether you are in the private or government sector[a]
- Apply critical patches (software bug fixes) to affected systems (automated tools are available)
- Use a test LAN (certification and accreditation process)[b]
- Use external connectivity controls
- Practice configuration management control
  - — Configure firewalls to allow only those services required for users to accomplish their tasks; restrict all other services or protocols
  - — Change default user passwords, disable guest, and rename administrator group accounts
  - — Set servers to retrieve anti-virus updates at least weekly[c]
- Use a mobile code software tool to complement anti-virus software (layering technique)
  - — Use a trusted computing base (TCB) model (sorry, Millennium 9x or earlier does not qualify)
  - — Discourage placing Web server software running on top of e-mail server (double ouch!)

[a] This entails proper disposal of classified documents, whether private or federal. Keep in mind it also means proper sanitization of electronic media/equipment before turning it over to schools, charities, etc.

[b] We strongly encourage you to develop a test LAN that is representative of your local network (enclave) environment. Why? Would you want to install something on your main system network and then have to wait for the software interactions and trouble in having it impact the operational network? Instead, would you rather prefer the alternative of having problems on the test LAN segment and being able to work through the problems without impacting the operational network? A certification and accreditation process will minimize the potential for these sorts of problems. If your resources are scarce, do not throw away those old computers, routers, etc. Instead, place them in your test LAN.

[c] Anti-virus alone is not good enough to protect servers/clients, nor does it stop all malicious code. Anti-virus should be used in conjunction with mobile code software, because anti-virus is only as good as the installed definitions.

110.3.5.3 Corrective Controls

Zero-day incidents are here to stay and will probably increase in the near future. Zero-day incidents are attacks that are exploited in the wild before they are reported to the rest of the security community by groups such as the National Infrastructure Protection Center (NIPC), the Computer Emergency Response Team (CERT), or the Common Vulnerability Exposures (CVE) list. Not surprisingly, hackers exploit those exposed vulnerabilities. What can a network security professional do? Our recommendation: Develop work-arounds and apply the patches as they become available. Addressing audit deficiencies (company or government auditors) and incident investigations will allow the update of security policies and updating IDS databases.

110.3.6 Trusted Computing Base (TCB)

At this point, it is useful to restate that security involves a very fine synergy that represents the interaction between software, technology, and the environment. It should be clear to you that security is not only of the utmost importance, but it is multifaceted. Consider the following point from the National Information Systems Security Glossary on TCB:

> The totality of protection mechanisms within a computer system, including hardware, firmware, and software, the combination of which is responsible for enforcing a security policy. The ability of

> a trusted computing base to enforce correctly a unified security policy depends on the correctness of the mechanisms within the trusted computing base, the protection of those mechanisms to ensure their correctness, and the correct input of parameters related to the security policy.[22]

The tips we have suggested for preventive and detective controls fall under trusted computing base (TCB). Think of the TCB as a baseline model to obtain a level of trust. Newton's third law of motion states, "For every reaction there is an equal and opposite reaction."[23] Although Newton was discussing physics, the same case can be made for the various configuration and security policy settings a person can make to the hardware, software, and firmware of a system. We now turn to yet another aspect of security related issues.

110.3.7 Social Engineering

> People are the weakest link. You can have the best technology, firewalls, intrusion detection systems, biometric devices—and somebody can call an unsuspecting employee. That's all she wrote, baby. They got everything.
>
> **—Kevin Mitnick**[24]

Today, almost everyone who has at least a passing familiarity with the Internet and Internet-linked systems knows that the integrity of any good system lies in its ability to protect itself from intruders or would-be attackers. As a way of responding to the threat that computer hackers pose, organizations with public and private networks have implemented a variety of strategies ranging from static authentication—whereby a would-be intruder can gain access only by guessing at a legitimate user's authentication data, to more sophisticated intrusion detection systems that effectively discover unauthorized activity and in some cases identify intruders.[25] Although each of the different strategies varies in complexity and component parts, they are similar in that they each represent a deliberate attempt to discourage or at least minimize the threat of potential intruders.

Yet, there is an additional threat to which even the most secure systems are vulnerable. This additional threat, as illustrated by the above quote, has a decidedly human aspect to it, and occurs when would-be attackers try to access a system by manipulating and deceiving company employees or other legitimate system users. In its most egregious form, "social engineering" practices permit intruders to gain unrestricted access to closed systems by talking and interacting with company employees. In a slightly more benign form, it involves intruders gaining unauthorized information about employees or company business practices. In short, hackers[26] and would-be intruders use their "social skills" (e.g., persuasion, coercion, deception) to feign legitimacy in order to obtain compliance from unsuspecting employees. When this occurs, employees find themselves on the receiving end of an earnest request for information from what is ostensibly a legitimate user or company employee. Oftentimes the intruder poses as a senior executive of the company whose power and prestige make compliance with the intruder's request (however unusual) especially likely.

Consider the scenario in which a would-be intruder poses as a company executive and asks a help-desk employee to provide an access code he or she claims to have accidentally left in the office. Alternatively, imagine the hacker who telephones the CEO's executive secretary with an elaborate ruse that concludes

[22] National Information Systems Security (InfoSec) Glossary, NSTISSI No. 4009, June 5, 1992.

[23] Sir Isaac Newton, Laws of Motion, 1686.

[24] Kevin Mitnick, the notorious computer hacker, was arrested for computer crimes in 1995, and is one of the first people to be convicted and jailed for unauthorized access of someone else's computer.

[25] Tipton, H.F. and Krause, M. 2000. *Information Security Management Handbook, 4th Ed.*, Auerbach Publications, Boca Raton, Florida.

[26] For ease of discussion, the term "hacker" is used throughout this section. However, it is acknowledged that this discussion also applies to the efforts of crackers, coders, and cyber punks.

with a request for the CEO's password. Although neither employee can be certain of the legitimacy of the request, they will feel a personal sense of obligation to comply with the actual request. Here, compliance occurs when the employee does what he or she is asked to do (by providing the unknown person with privileged information) even though he or she might prefer not to do so. In cases like these, successful computer hackers and intruders are able to influence company employees in a way that brings about compliance.

Social engineering represents a form of persuasive manipulation. Use of social engineering techniques involves the exploitation of common and basic human attributes—namely, that of helpfulness and trustworthiness. Although the term "social engineering" is specific to the computing industry, the techniques involved are common to a host of situations and industries. Across all settings in which people are dependent on the compliance of others, social engineering techniques are at work. For example, the parent who wishes to influence a child to brush its teeth, the husband who seeks to convince his wife of the necessity of an expensive purchase, and the panhandler who requests money from passers-by each use social engineering skills to bring about compliance.

There are a number of well-known cases in the computer industry in which intruders have succeeded at social engineering. To be sure, the actual mediums through which these manipulative techniques are transmitted are varied, and include the telephone, e-mail, trash pilferage, in-person site visits, and, of course, snail mail. Regardless of the medium employed, would-be intruders intent on accessing a system hone their social skills to gain information, manipulate policies, and acquire resources, all with the unwitting assistance and compliance of company employees.

Students of human behavior know well the tendency for people to be compliant with requests emanating from people who they believe to be legitimate authority figures. Researchers in social psychology,[27] for example, have conducted numerous empirical studies investigating the conditions under which compliance is most likely, as well as those circumstances or factors that may limit its occurrence. Research findings pertaining to the latter would seem to be most relevant for computer professionals who are committed to ensuring the security of their network systems.

What does the research tell us about the effectiveness of efforts to resist social pressure? In other words, how can network administrators inoculate employees against the social engineering efforts of would-be intruders? Can anything be done to combat the would-be intruder and keep systems users and data safe and secure? The answer is "yes."

Fortunately, research on best business practices has revealed that there are important limitations to social engineering techniques. Knowledge of the limitations to social engineering schemes can significantly enhance a network administrator's ability to ensure the integrity of a system. Although network administrators cannot eliminate the problem of computer hackers, they can take specific steps to reduce the effectiveness of their influence schemes. What follows is a brief discussion of at least three prescriptions for network systems administrators who are vulnerable to social engineering schemes.

110.3.8 Risk Awareness Training

First and foremost, employees must be made aware of the potential problems posed by computer hackers. Only when employees and other system users know about the existence and pervasiveness of social engineering schemes can they act against them. According to some writers in this area,[28] when it comes to user suspicion, "paranoia is good!" Whether this occurs in the context of new employee orientation training or specific security awareness training for users, individuals must be informed about the potential risk for social engineering schemes. Far too often, individuals assume that their systems are invincible, and that requests for information come from legitimate users.

[27] There are many different studies in this area investigating the effectiveness of a host of compliance techniques. They have included studies of car salespeople, professional fundraisers, and con artists.

[28] See p. 587 in McClure et al. (2001).

System users and employees must realize the role that they personally play in the security of a company's information. Any information awareness session should be focused on getting people to appreciate the fact that there are people out there who are trying to access companies' networks, and that their role as employees or legitimate users of the system is to be both proactive and reactive in making it as hard as possible for would-be intruders to succeed. Proactively, this means that users must be cautious about whose requests they comply with, and reactively, when users encounter unusual or outrageous requests for information either in-person or online they should immediately alert their network administrator.

The theory of psychological reactance may be particularly useful for those most apt to encounter hackers employing social engineering schemes. This theory is most relevant in situations where employees are sensitized to the potential risk of social engineering schemes, and would-be intruders employ high-pressure tactics. According to the theory, too much pressure to comply with a request can actually have the opposite intended effect.[29] The idea that forms the basis of the theory is that people are motivated to maintain their sense of personal freedom and when they suspect that they are being pressured or feel that their freedom is being threatened, they will act so as to protect their freedom by refusing to comply. Hence, they react against the pressure to comply by doing the exact opposite of what they are being asked to do. Employees who are aware of the risk of social engineering schemes and who confront would-be intruders using high-pressure tactics are especially likely to experience the phenomenon of reactance. Consequently, in these situations, by being less willing to comply, they are more apt to thwart the would-be intruder's efforts. Network administrators should work to ensure that the risk of social engineering schemes remains salient for employees and other legitimate users with access to company information.

110.3.9 Formulate a Written Policy for Procedures

Sometimes employees who are approached with a request for information may suspect that something is amiss, but because they are unsure about what to do about their suspicions, they wind up complying with the would-be intruder's request. Even the most conscientious employees who are usually vigilant about information distribution may encounter a situation in which they are faced with a novel request. They may simply be at a loss to know the appropriate procedure. Although written policy cannot possibly speak to every potential request that a world-be intruder can come up with, existing policy should inform employees that "when in doubt, be conservative, do not comply."

The policy that is ultimately formulated with the help of users should be comprehensive and clear. Employees and others who are approached for information should clearly be able to distinguish a legitimate request for information from an illegitimate one, whether the person requesting the information is a legitimate user or not. What is more, employees must be able to feel that they can ask questions about the request in an environment in which they do not appear silly or ignorant. In some cases, network operators have initially failed to take users' requests for information seriously enough and in the end are burned. One way of ensuring that this does not happen is to create a policy that permits, indeed encourages, employees who are uncertain about information requests to verify the legitimacy of the request with a network operator. This may take more time up front, but in the long run it may prove to be extremely beneficial.

110.3.10 Eliminating Paper Trails and Staying Connected

The final set of prescriptions aimed at securing network systems from would-be intruders employing social engineering schemes has to do with the elimination of company documents and materials, and maintaining contact with organizations specializing in security. With respect to the former, although

[29] For a classic discussion of psychosocial work investigating this, see Brehm, J. W. 1996. *A Theory of Psychological Reactance*, Academic Press, New York.

there has been considerable discussion about trash pilferage in the popular press, with the exception of a few highly secure federal agencies, people in general are lax about discarding their trash. Organizations must provide employees with convenient ways of discarding sensitive documents and material. Finally, companies should keep in touch with those organizations and agencies that can be trusted to provide up-to-date, dependable information about security issues.

110.3.11 Certification and Accreditation (C&A)

Remember the admonition to know your environment? Understanding which laws, policies, and service-level agreement contracts are in place is critical to effective implementation and testing of a security policy or architecture. Although there is no law that formally requires companies to perform a C&A, shareholders enforce policies within the private sector. Conversely, within the federal arena, Congress ultimately regulates such practices. But the question remains as to why C&A is important, and perhaps more importantly, what are its implications and impact for the network administrator?

The National Institute of Standards and Technology (NIST) defines certification as

> the comprehensive evaluation of the technical and nontechnical security controls of an IT system to support the accreditation process that establishes the extent to which a particular design and implementation meets a set of specified security requirements.[30]

What are the implications of this for private industry and the federal government? What motivates each to comply? For the private sector it may be argued that the primary motive is an economic one; in other words, "the wallet." When companies fail to do so, the consequences can be grave. Consider the following statement made by one attorney:

> We have seen several recent incidents where our clients have threatened legal action against trading partners who have been the cause of a security breach or virus infection. All of these cases have been settled out of court, primarily because of the unwanted publicity connected with court cases.[31]

Thus, having a C&A package that has demonstrated effective implementation is one manner of showing the courts due diligence.

As for the federal government, it is mandated by laws such as the Health Insurance Portability and Accountability Act of 1996 (HIPAA), Clinger–Cohen, and the Federal Information Security Management Act of 2002 (FISMA), to name a few. Although it depends on which part of the federal government you are referring to, the major policies are DoDD 8500.1, DoDD 5200.40, and NIST's Special Publication 800-37.

110.3.12 Accreditation

Accreditation refers to

> the authorization of an IT system to process, store, or transmit information, granted by a management official. Accreditation, which is required under OMB Circular A-130, is based on an assessment of the management, operational, and technical controls associated with an IT system.[32]

Simply stated, this amounts to management's formal approval of the certification process that essentially says that it can live with the risks to the IT system and the mitigation of those risks. It also means that

[30] NIST Special Publication 800-37, Guidelines for the Security Certification and Accreditation of Federal Information Technology Systems, October 2002.

[31] Kitt Burden, http://computerweekly.com, February 14, 2002.

[32] From NIST SP 800-37.

there is help to assist someone through the process. Admittedly, this is a complicated process, but there are automated tools available from appropriate vendors. Just ensure that the information entered is valid and not "pencil-whipped."

110.3.13 Security Models

Taking the principle of trust further, we will discuss the more commonly used security models, including:

- Bell–LaPadula
- Biba
- Clark–Wilson

110.3.13.1 The Bell–LaPadula Model

In 1973, Drs. Bell and LaPadula from the MITRE Corporation developed a security model for the Department of Defense. (As you may recall, mainframes were common during this period.) The Bell–LaPadula model controls information flow. For example, Novell's and Microsoft's training literature discuss access rights to objects and resources. Those various access privileges (read, write, delete, modify, etc.) form a "woven lattice." One concept of the model states that a user cannot read an object of a higher classification than granted.

For example, if you have a government security clearance of Secret, you are allowed to read Secret and below classification level documents; accordingly, you have no access to Top Secret information. The Bell–LaPadula model incorporates the "* property," i.e., it states that a user cannot write from a higher classification level to a lower one. Using the previous example, Secret e-mail messages or documents cannot be sent to recipients who do not have a Secret or higher clearance or written or stored to file servers designated for Unclassified information. It is for this reason that the Bell–LaPadula model is considered a confidentiality model.

110.3.13.2 Biba Model

This model, developed in the late 1970s, uses a process similar to the Bell–LaPadula model (i.e., the subject cannot write to a higher integrity source). However, the Biba model is an integrity model. Whereas the Bell–LaPadula model was concerned with protecting the release of information to unauthorized users, the Biba model was developed strictly for the developing computer systems of that period. With this model, unauthorized objects are blocked from making modifications. The "* property" is used to block subjects from writing to objects of higher integrity, the "read property" keeps subjects from corruption by objects of lower integrity, and subjects cannot request services from objects maintaining a higher integrity model.[33]

For example, imagine that you work for the CIA as a low-level analyst with a Secret clearance. You do the leg work for a report to gather raw intelligence from various sources addressing sonar technology. You take your proposal to your supervisor for review; your supervisor makes further input to the report and hands it off to ex-Naval officers and an expert who has published extensively on bats' acute hearing techniques. They further refine the report to a finished product that lands on the Secretary of the Navy's desk. Although the Secretary would never read your report in its raw state, he would read the finished CIA product. Although you may wish to update the report in its finished form, you are actually blocked from write access to it because you are now at a lower level of integrity than the report. However, you would be allowed to read the report in accordance with Biba. The same principle could be used for a database recognized as the authoritative source such as that produced by the Bureau of the Census.

[33] We have borrowed this from http://www.cccure.org/Documents/HISM/023-026.html.

110.3.13.3 Clark–Wilson Model

This is another model developed to address integrity and uses a broader approach than the Biba model, which addressed only subjects and objects. Clark–Wilson addresses a special type of program called a "well-formed transaction." In this case, changes to a process or to data can be made only through this trusted program because the subject can access the object through the trusted program only. This concept binds the subject to the program and the program to the object, creating a "triple" instead of the subject-object "tuple" used in Biba. The trusted program is constructed to only make authorized changes. Think of it as incorporating a program to complete transactions, and one that incorporates the policy of separation of duties as well. Separation of duty involves breaking a task or operations into parts where no one person can complete a process. For example, this would prevent someone in Acquisition from cutting a check to purchase office furniture for use in a private home. Access control prevents unauthorized personnel from making alterations or changes to data. Separation of duty helps prevent authorized personnel from making unauthorized modifications.

110.4 Software Applications

At this point, it is worth asking, "How does a person know how to distinguish between the good, the bad, and the ugly software in order to develop a valid C&A package? What is the TCP based on?" These are good questions that you may already have considered asking. The answers have to do with the efforts of the federal government, which has provided a number of valuable resources to IT professionals through the National Information Assurance Partnership (NIAP). NIAP is an initiative to increase information technology security by collaborating with industry in security testing, research, and the development of information assurance methodologies.[34] From NIAP came the Common Criteria Evaluation and Validations Scheme (CCEVS), which is jointly managed by the National Security Agency and NIST. The CCEVS established a national program for the evaluation of information technology products. This program is known as Common Criteria (CC) and it is identified as International Standards Organization (ISO) 15408. Under CC there are seven protection profiles. A firm understanding of the CC's protection profiles, which also include seven evaluation assurance levels (EAL), is important for various reasons. If you are working in the federal government sector, following CC is a requirement mandated by policy. For evidence of this, see the reference cited in Note 2.

110.4.1 Minimizing the Need for Applying Patches

Why make life difficult? By using an enterprisewide architecture, which employs a layered approach, you will minimize the need to apply patches. Keep this in mind as your organization begins to perceive a shortage of resources and starts looking to cut resources from somewhere. Rather than being on the short end of the stick, be progressive: pitch the use of an enterprise architecture. Incidentally, this has been the direction in which the federal government is moving.

For example, using the Command, Control, Communications, Computers, Intelligence, Surveillance, Reconnaissance (C4ISR) architecture model, which applies to the federal government and to some extent carries over to the private sector, you can minimize a lot of the work down the road through detailed planning (for patches). The enterprise architecture can list software by version (i.e., an interim technical reference) for approving software prior to placing it on the desktop or network. The approval can include supporting the software, training, life cycle, etc. For example, imagine instituting a standardized integrated desktop configuration that includes the minimum standard for clients and network connectivity. For the desktop (as an example), you would only support Windows NT 4.0 Service Pack 6a. This minimizes the need to support the previous service packs as well as the time required for installing patches. The architecture would detail setting retirement dates (for applications

[34] See NIAP brochure for 2003.

and operating system) and planning for new technology insertion dates, thus minimizing the "software zoo."[35] This in turn reduces legacy applications, vendors' support (for phased-out software, much like NT 4.0 now), the associated security vulnerabilities, and time mitigating those vulnerabilities (applying patches, policy, etc.).

Not surprisingly, there are at least two cost-saving benefits associated with this effort. First, minimized desktop support is achieved by narrowing various operating system platforms to a few (even within the Microsoft family there are various versions of Office for the same OS). Second, by narrowing the software applications supported, you reduce manpower needs and patches to be maintained or applied. In this way, organizations can arrange individuals into groups (power user, standard user, sys-admin/support, as an example for software applications) and apply the manpower to group configurations rather than the individual desktop zoo.

We conclude by listing the benefits of using an enterprise architecture, which are numerous:

- Capturing facts on operations and functions in an understandable manner to drive better planning and decision-making
- Supporting analyses of alternatives, risks, and trade-offs for the investment-management process, which reduces the risk of:
  —Building systems that do not meet operational needs
  —Expending resources on developing unnecessary duplicative functionality
- Improving consistency, accuracy, and timeliness of information shared collaboratively across the enterprise[36]

[35] For example, for your architecture, you would support either Microsoft Office, Corel's Office Suite, or Sun's office package. To do so, you would probably have to migrate the majority to one or the other if you were not currently supporting it.

[36] Air Force (C4ISR) architecture plan, November 2002.

111

The Common Criteria for IT Security Evaluation

Debra S. Herrmann

This chapter introduces the Common Criteria (CC) by:

- Describing the historical events that led to their development
- Delineating the purpose and intended use of the CC and, conversely, situations not covered by the CC
- Explaining the major concepts and components of the CC methodology and how they work
- Discussing the CC user community and stakeholders
- Looking at the future of the CC

111.1 History

The Common Criteria, referred to as "the standard for information security,"[1] represent the culmination of a 30-year saga involving multiple organizations from around the world. The major events are discussed below and summarized in Exhibit 111.1.

A common misperception is that computer and network security began with the Internet. In fact, the need for and interest in computer security or COMPUSEC have been around as long as computers. Likewise, the *Orange Book* is often cited as the progenitor of the CC; actually, the foundation for the CC was laid a decade earlier. One of the first COMPUSEC standards, DoD 5200.28-M,[2] *Techniques and Procedures for Implementing, Deactivating, Testing, and Evaluating Secure Resource-Sharing ADP Systems*, was issued in January 1973. An amended version was issued June 1979.[3] DoD 5200.28-M defined the purpose of security testing and evaluation as:[2]

EXHIBIT 111.1 Timeline of Events Leading to the Development of the CC

Year	Lead Organization	Standard/Project	Short Name
1/73	U.S. DoD	DoD 5200.28M, ADP Computer Security Manual—Techniques and Procedures for Implementing, Deactivating, Testing, and Evaluating Secure Resource Sharing ADP Systems	—

- To develop and acquire methodologies, techniques, and standards for the analysis, testing, and evaluation of the security features of ADP systems
- To assist in the analysis, testing, and evaluation of the security features of ADP systems by developing factors for the Designated Approval Authority concerning the effectiveness of measures used to secure the ADP system in accordance with Section VI of DoD Directive 5200.28 and the provisions of this Manual
- To minimize duplication and overlapping effort, improve the effectiveness and economy of security operations, and provide for the approval and joint use of security testing and evaluation tools and equipment

As shown in the next section, these goals are quite similar to those of the Common Criteria.

The standard stated that the security testing and evaluation procedures "will be published following additional testing and coordination."[2] The result was the publication of CSC-STD-001-83, the *Trusted Computer System Evaluation Criteria* (TCSEC),[4] commonly known as the *Orange Book*, in 1983. A second version of this standard was issued in 1985.[5]

The *Orange Book* proposed a layered approach for rating the strength of COMPUSEC features, similar to the layered approach used by the Software Engineering Institute (SEI) Capability Maturity Model (CMM) to rate the robustness of software engineering processes. As shown in Exhibit 111.2, four evaluation divisions composed of seven classes were defined. Division A class A1 was the highest rating, while division D class D1 was the lowest. The divisions measured the extent of security protection provided, with each class and division building upon and strengthening the provisions of its predecessors. Twenty-seven specific criteria were evaluated. These criteria were grouped into four categories: security policy, accountability, assurance, and documentation. The *Orange Book* also introduced the concepts of a reference monitor, formal security policy model, trusted computing base, and assurance.

The *Orange Book* was oriented toward custom software, particularly defense and intelligence applications, operating on a mainframe computer that was the predominant technology of the time. Guidance documents were issued; however, it was difficult to interpret or apply the *Orange Book* to networks or database management systems. When distributed processing became the norm, additional standards were issued to supplement the *Orange Book*, such as the Trusted Network Interpretation and the Trusted Database Management System Interpretation. Each standard had a different color cover, and collectively they became known as the Rainbow Series. In addition, the Federal Criteria for Information Technology Security was issued by NIST and NSA in December 1992, but it was short-lived.

At the same time, similar developments were proceeding outside the United States. Between 1990 and 1993, the Commission of the European Communities, the European Computer Manufacturers Association (ECMA), the Organization for Economic Cooperation and Development (OECD), the U.K. Communications-Electronics Security Group, and the Canadian Communication Security Establishment (CSE) all issued computer security standards or technical reports. These efforts and the

EXHIBIT 111.2 Summary of *Orange Book* Trusted Computer System Evaluation Criteria (TCSEC) Divisions

Evaluation Division	Evaluation Class	Degree of Trust
A—Verified protection	A1—Verified design	Highest
B—Mandatory protection	B3—Security domains	
	B2—Structured protection	
	B1—Labeled security protection	
C—Discretionary protection	C2—Controlled access protection	
	C1—Discretionary security protection	
D—Minimal protection	D1—Minimal protection	Lowest

evolution of the Rainbow Series were driven by three main factors:[6]

1. The rapid change in technology, which led to the need to merge communications security (COMSEC) and computer security (COMPUSEC)
2. The more universal use of information technology (IT) outside the defense and intelligence communities
3. The desire to foster a cost-effective commercial approach to developing and evaluating IT security that would be applicable to multiple industrial sectors

These organizations decided to pool their resources to meet the evolving security challenge. ISO/IEC Joint Technical Committee One (JTC1) Subcommittee 27 (SC27) Working Group Three (WG3) was formed in 1990. Canada, France, Germany, the Netherlands, the United Kingdom, and the United States, which collectively became known as the CC Sponsoring Organizations, initiated the CC Project in 1993, while maintaining a close liaison with ISO/IEC JTC1 SC27 WG3. The CC Editing Board (CCEB), with the approval of ISO/IEC JTC1 SC27 WG3, released the first committee draft of the CC for public comment and review in 1996. The CC Implementation Management Board (CCIMB), again with the approval of ISO/IEC JTC1 SC27 WG3, incorporated the comments and observations gained from the first draft to create the second committee draft. It was released for public comment and review in 1997. Following a formal comment resolution and balloting period, the CC were issued as ISO/IEC 15408 in three parts:

- ISO/IEC 15408-1(1999-12-01), Information technology—Security techniques—Evaluation criteria for IT security—Part 1: Introduction and general model
- ISO/IEC 15408-2(1999-12-01), Information technology—Security techniques—Evaluation criteria for IT security—Part 2: Security functional requirements
- ISO/IEC 15408-3(1999-12-01), Information technology—Security techniques—Evaluation criteria for IT security—Part 3: Security assurance requirements

Parallel to this effort was the development and release of the Common Evaluation Methodology, referred to as the CEM or CM, by the Common Evaluation Methodology Editing Board (CEMEB):

- CEM-97/017, Common Methodology for Information Technology Security Evaluation, Part 1: Introduction and General Model, v0.6, November 1997
- CEM-99/045, Common Methodology for Information Technology Security Evaluation, Part 2: Evaluation Methodology, v1.0, August 1999
- CEM-2001/0015, Common Methodology for Information Technology Security Evaluation, Part 2: Evaluation Methodology, Supplement: ALC_FLR—Flaw Remediation, v1.0, August 2001

As the CEM becomes more mature, it too will become an ISO/IEC standard.

111.2 Purpose and Intended Use

The goal of the CC project was to develop a standardized methodology for specifying, designing, and evaluating IT products that perform security functions which would be widely recognized and yield consistent, repeatable results. In other words, the goal was to develop a full life-cycle, consensus-based security engineering standard. Once this was achieved, it was thought, organizations could turn to commercial vendors for their security needs rather than having to rely solely on custom products that had lengthy development and evaluation cycles with unpredictable results. The quantity, quality, and cost effectiveness of commercially available IT security products would increase; and the time to evaluate them would decrease, especially given the emergence of the global economy.

There has been some confusion that the term *IT product* only refers to plug-and-play commercial off-the-shelf (COTS) products. In fact, the CC interprets the term *IT product* quite broadly, to include a single product or multiple IT products configured as an IT system or network.

The standard lists several items that are not covered and considered out of scope:[7]

- Administrative security measures and procedural controls
- Physical security
- Personnel security
- Use of evaluation results within a wider system assessment, such as certification and accreditation (C&A)
- Qualities of specific cryptographic algorithms

Administrative security measures and procedural controls generally associated with operational security (OPSEC) are not addressed by the CC/CEM. Likewise, the CC/CEM does not define how risk assessments should be conducted, even though the results of a risk assessment are required as an input to a PP.[7] Physical security is addressed in a very limited context—that of restrictions on unauthorized physical access to security equipment and prevention of and resistance to unauthorized physical modification or substitution of such equipment.[6] Personnel security issues are not covered at all; instead, they are generally handled by assumptions made in the PP. The CC/CEM does not address C&A processes or criteria. This was specifically left to each country and/or government agency to define. However, it is expected that CC/CEM evaluation results will be used as input to C&A. The robustness of cryptographic algorithms, or even which algorithms are acceptable, is not discussed in the CC/CEM. Rather, the CC/CEM limits itself to defining requirements for key management and cryptographic operation. Many issues not handled by the CC/CEM are covered by other national and international standards.

111.3 Major Components of the Methodology and How They Work

The three-part CC standard (ISO/IEC 15408) and the CEM are the two major components of the CC methodology, as shown in Exhibit 111.3.

111.3.1 The CC

Part 1 of ISO/IEC 15408 provides a brief history of the development of the CC and identifies the CC sponsoring organizations. Basic concepts and terminology are introduced. The CC methodology and how it corresponds to a generic system development life cycle are described. This information forms the foundation necessary for understanding and applying Parts 2 and 3. Four key concepts are presented in Part 1:

- Protection Profiles (PPs)
- Security Targets (STs)
- Targets of Evaluation (TOEs)
- Packages

A Protection Profile, or PP, is a formal document that expresses an *implementation-independent* set of security requirements, both functional and assurance, for an IT product that meets specific consumer needs.[7] The process of developing a PP helps a consumer to elucidate, define, and validate their security requirements, the end result of which is used to (1) communicate these requirements to potential developers and (2) provide a foundation from which a security target can be developed and an evaluation conducted.

A Security Target, or ST, is an *implementation-dependent* response to a PP that is used as the basis for developing a TOE. In other words, the PP specifies security functional and assurance requirements, while an ST provides a design that incorporates security mechanisms, features, and functions to fulfill these requirements.

A Target of Evaluation, or TOE, is an IT product, system, or network and its associated administrator and user guidance documentation that is the subject of an evaluation.[7–9] A TOE is the physical implementation of an ST. There are three types of TOEs: monolithic, component, and composite. A monolithic TOE is self-contained; it has no higher or lower divisions. A component TOE is the lowest-level TOE in an IT product or system; it forms part of a composite TOE. In contrast, a composite TOE is the highest-level TOE in an IT product or system; it is composed of multiple component TOEs.

A package is a set of components that are combined together to satisfy a subset of identified security objectives.[7] Packages are used to build PPs and STs. Packages can be a collection of functional or assurance requirements. Because they are a collection of low-level requirements or a subset of the total requirements for an IT product or system, packages are intended to be reusable. Evaluation assurance levels (EALs) are examples of predefined packages.

Part 2 of ISO/IEC 15408 is a catalog of standardized security functional requirements, or SFRs. SFRs serve many purposes. They[7–9] (1) describe the security behavior expected of a TOE, (2) meet the security objectives stated in a PP or ST, (3) specify security properties that users can detect by direct interaction with the TOE or by the TOE's response to stimulus, (4) counter threats in the intended operational environment of the TOE, and (5) cover any identified organizational security policies and assumptions.

The CC organizes SFRs in a hierarchical structure of security functionality:

- Classes
- Families

EXHIBIT 111.3 Major components of the CC CEM.

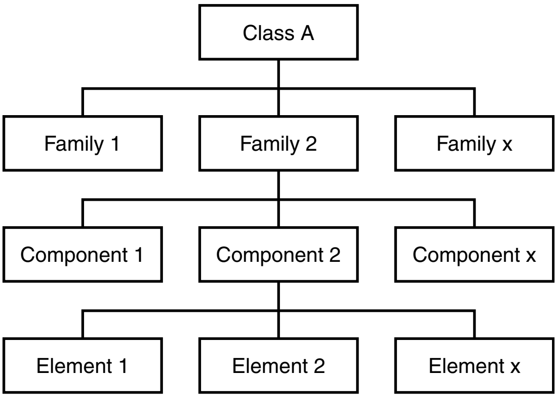

EXHIBIT 111.4 Relationship between classes, families, components, and elements.

- Components
- Elements

Eleven security functional classes, 67 security functional families, 138 security functional components, and 250 security functional elements are defined in Part 2. Exhibit 111.4 illustrates the relationship between classes, families, components, and elements.

A class is a grouping of security requirements that share a common focus; members of a class are referred to as families.[7] Each functional class is assigned a long name and a short three-character mnemonic beginning with an "F." The purpose of the functional class is described and a structure diagram is provided that depicts the family members. ISO/IEC 15408-2 defines 11 security functional classes. These classes are lateral toone another; there is no hierarchical relationship among them. Accordingly, the standard presents the classes in alphabetical order. Classes represent the broadest spectrum of potential security functions that a consumer may need in an IT product. Classes are the highest-level entity from which a consumer begins to select security functional requirements. It is not expected that a single IT product will contain SFRs from all classes. Exhibit 111.5 lists the security functional classes.

EXHIBIT 111.5 Functional Security Classes

Short Name	Long Name	Purpose[8]
FAU	Security audit	Monitor, capture, store, analyze, and report information related to security events
FCO	Communication	Assure the identity of originators and recipients of transmitted information; non-repudiation
FCS	Cryptographic support	Management and operational use of cryptographic keys
FDP	User data protection	Protect (1) user data and the associated security attributes within a TOE and (2) data that is imported, exported, and stored
FIA	Identification and authentication	Ensure unambiguous identification of authorized users and the correct association of security attributes with users and subjects
FMT	Security management	Management of security attributes, data, and functions and definition of security roles
FPR	Privacy	Protect users against discovery and misuse of their identity
FPT	Protection of the TSF	Maintain the integrity of the TSF management functions and data
FRU	Resource utilization	Ensure availability of system resources through fault tolerance and the allocation of services by priority
FTA	TOE access	Controlling user session establishment
FTP	Trusted path/channels	Provide a trusted communication path between users and the TSF and between the TSF and other trusted IT products

A functional family is a grouping of SFRs that share security objectives but may differ in emphasis or rigor. The members of a family are referred to as components.[7] Each functional family is assigned a long name and a three-character mnemonic that is appended to the functional class mnemonic. Family behavior is described. Hierarchics or ordering, if any, between family members is explained. Suggestions are made about potential OPSEC management activities and security events that are candidates to be audited.

Components are a specific set of security requirements that are constructed from elements; they are the smallest selectable set of elements that can be included in a Protection Profile, Security Target, or a package.[7] Components are assigned a long name and described. Hierarchical relationships between one component and another are identified. The short name for components consists of the class mnemonic, the family mnemonic, and a unique number.

An element is an indivisible security requirement that can be verified by an evaluation, and it is the lowest-level security requirement from which components are constructed.[7] One or more elements are stated verbatim for each component. Each element has a unique number that is appended to the component identifier. If a component has more than one element, all of them must be used. Dependencies between elements are listed. Elements are the building blocks from which functional security requirements are specified in a protection profile. Exhibit 111.6 illustrates the standard CC notation for security functional classes, families, components, and elements.

Part 3 of ISO/IEC 15408 is a catalog of standardized security assurance requirements or SARs. SARs define the criteria for evaluating PPs, STs, and TOEs and the security assurance responsibilities and activities of developers and evaluators. The CC organize SARs in a hierarchical structure of security assurance classes, families, components, and elements. Ten security assurance classes, 42 security assurance families, and 93 security assurance components are defined in Part 3.

A class is a grouping of security requirements that share a common focus; members of a class are referred to as families.[7] Each assurance class is assigned a long name and a short three-character mnemonic beginning with an "A." The purpose of the assurance class is described and a structure diagram is provided that depicts the family members. There are three types of assurance classes: (1) those that are used for Protection Profile or Security Target validation, (2) those that are used for TOE conformance evaluation, and (3) those that are used to maintain security assurance after certification. ISO/IEC 15408-3 defines ten security assurance classes. Two classes, APE and ASE, evaluate PPs and STs, respectively. Seven classes verify that a TOE conforms to its PP and ST. One class, AMA, verifies that security assurance is maintained between certification cycles. These classes are lateral to one another; there is no hierarchical relationship among them. Accordingly, the standard presents the classes in alphabetical order. Classes represent the broadest spectrum of potential security assurance measures that a consumer may need to verify the integrity of the security functions performed by an IT product. Classes are the highest-level entity from which a consumer begins to select security assurance requirements. Exhibit 111.7 lists the security assurance classes in alphabetical order and indicates their type.

An assurance family is a grouping of SARs that share security objectives. The members of a family are referred to as components.[7] Each assurance family is assigned a long name and a three-character

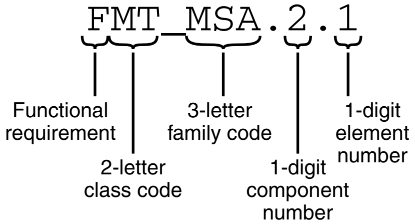

EXHIBIT 111.6 Standard notation for classes, families, components, and elements.

EXHIBIT 111.7 Security Assurance Classes

Short Name	Long Name	Type	Purpose
APE	Protection profile evaluation	PP/ST	Demonstrate that the PP is complete, consistent, and technically sound
ASE	Security target evaluation	PP/ST	Demonstrate that the ST is complete, consistent, technically sound, and suitable for use as the basis for a TOE evaluation
ACM	Configuration management	TOE	Control the process by which a TOE and its related documentation is developed, refined, and modified
ADO	Delivery and operation	TOE	Ensure correct delivery, installation, generation, and initialization of the TOE
ADV	Development	TOE	Ensure that the development process is methodical by requiring various levels of specification and design and evaluating the consistency between them
AGD	Guidance documents	TOE	Ensure that all relevant aspects of the secure operation and use of the TOE are documented in user and administrator guidance
ALC	Lifecycle support	TOE	Ensure that methodical processes are followed during the operations and maintenance phase so that security integrity is not disrupted
ATE	Tests	TOE	Ensure adequate test coverage, test depth, functional and independent testing
AVA	Vulnerability assessment	TOE	Analyze the existence of latent vulnerabilities, such as exploitable covert channels, misuse or incorrect configuration of the TOE, the ability to defeat, bypass, or compromise security credentials
AMA	Maintenance of assurance	AMA	Essure that the TOE will continue to meet its security target as changes are made to the TOE or its environment

PP/ST—Protection Profile or Security Target evaluation.
TOE—TOE conformance evaluation.
AMA—Maintenance of assurance after certification.

mnemonic that is appended to the assurance class mnemonic. Family behavior is described. Unlike functional families, the members of an assurance family only exhibit linear hierarchical relationships, with an increasing emphasis on scope, depth, and rigor. Some families contain application notes that provide additional background information and considerations concerning the use of a family or the information it generates during evaluation activities.

Components are a specific set of security requirements that are constructed from elements; they are the smallest selectable set of elements that can be included in a Protection Profile, Security Target, or a package.[7] Components are assigned a long name and described. Hierarchical relationships between one component and another are identified. The short name for components consists of the class mnemonic, the family mnemonic, and a unique number. Again, application notes may be included to convey additional background information and considerations.

An element is an indivisible security requirement that can be verified by an evaluation, and it is the lowest-level security requirement from which components are constructed.[7] One or more elements are stated verbatim for each component. If a component has more than one element, all of them must be used. Dependencies between elements are listed. Elements are the building blocks from which a PP or ST is created. Each assurance element has a unique number that is appended to the component identifier and a one-character code. A “D” indicates assurance actions to be taken by the TOE developer. A “C” explains the content and presentation criteria for assurance evidence, that is, what must be demonstrated.[7] An “E” identifies actions to be taken or analyses to be performed by the evaluator to confirm that evidence requirements have been met. Exhibit 111.8 illustrates the standard notation for assurance classes, families, components, and elements.

Part 3 of ISO/IEC 15408 also defines seven hierarchical evaluation assurance levels, or EALs. An EAL is a grouping of assurance components that represents a point on the predefined assurance scale.[7] In short, an EAL is an assurance package. The intent is to ensure that a TOE is not over- or underprotected by

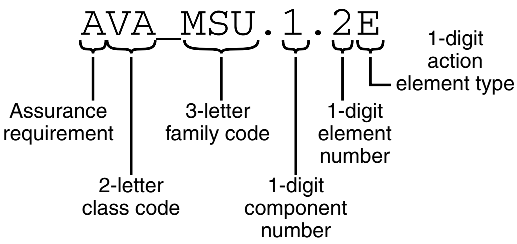

EXHIBIT 111.8 Standard notation for assurance classes, families, components, and elements.

balancing the level of assurance against cost, schedule, technical, and mission constraints. Each EAL has a long name and a short name, which consists of "EAL" and a number from 1 to 7. The seven EALs add new and higher assurance components as security objectives become more rigorous. Application notes discuss limitations on evaluator actions and/or the use of information generated. Exhibit 111.9 cites the seven standard EALs.

111.3.2 The CEM

The Common Methodology for Information Technology Security Evaluation, known as the CEM (or CM), was created to provide concrete guidance to evaluators on how to apply and interpret SARs and their developer, content and presentation, and evaluator actions, so that evaluations are consistent and repeatable. To date the CEM consists of two parts and a supplement. Part 1 of the CEM defines the underlying principles of evaluations and delineates the roles of sponsors, developers, evaluators, and national evaluation authorities. Part 2 of the CEM specifies the evaluation methodology in terms of evaluator tasks, subtasks, activities, subactivities, actions, and work units, all of which tie back to the assurance classes. A supplement was issued to Part 2 in 2001 that provides evaluation guidance for the ALC_FLR family. Like the CC, the CEM will become an ISO/IEC standard in the near future.

111.4 CC User Community and Stakeholders

The CC user community and stakeholders can be viewed from two different constructs: (1) generic groups of users, and (2) formal organizational entities that are responsible for overseeing and implementing the CC/CEM worldwide. (See Exhibit 111.10.)

ISO/IEC 15408-1 defines the CC/CEM generic user community to consist of:

- Consumers
- Developers
- Evaluators

EXHIBIT 111.9 Standard EAL Packages

Short Name	Long Name	Level of Confidence
EAL 1	Functionally tested	Lowest
EAL 2	Structurally tested	
EAL 3	Methodically tested and checked	
EAL 4	Methodically designed, tested, and reviewed	Medium
EAL 5	Semi-formally designed and tested	
EAL 6	Semi-formally verified design and tested	
EAL 7	Formally verified design and tested	Highest

EXHIBIT 111.10 Roles and Responsibilities of CC/CEM Stakeholders

Category	Roles and Responsibilities
I. Generic Users[a]	
Consumers	Specify requirements Inform developers how IT product will be evaluated Use PP, ST, and TOE evaluation results to compare products
Developers	Respond to consumer's requirements Prove that all requirements have been met
Evaluators	Conduct independent evaluations using standardized criteria
II. Specific Organizations[b]	
Customer or end user	Specify requirements Inform vendors how IT product will be evaluated Use PP, ST, and TOE evaluation results to compare IT products
IT product vendor	Respond to customer's requirements Prove that all requirements have been met Deliver evidence to sponsor
Sponsor	Contract with CCTL for IT product to be evaluated Deliver evidence to CCTL
Common Criteria Testing Laboratory (CCTL)	Request accreditation from National Evaluation Authority Receive evidence from sponsor Conduct evaluations according to CC/CEM Produce Evaluation Technical Reports Make certification recommendation to National Evaluation Authority
National Evaluation Authority	Define and manage national evaluation scheme Accredit CCTLs Monitor CCTL evaluations Issue guidance to CCTLs Issue and recognize CC certificates Maintain Evaluated Products Lists and PP Registry
Common Criteria Implementation Management Board (CCIMB)	Facilitate consistent interpretation and application of the CC/CEM Oversee National Evaluation Authorities Render decisions in response to Requests for Interpretations (RIs) Maintain the CC/CEM Coordinate with ISO/IEC JTC1 SC27 WG3 and CEMEB

[a] ISO/IEC 15408-1(1999-12-01), Information technology—Security techniques—Evaluation criteria for IT security—Part 1: Introduction and general model; Part 2: Security functional requirements; Part 3: Security assurance requirements.

[b] Arrangement on the Recognition of Common Criteria Certificates in the Field of Information Technology Security, May 23, 2000.

Consumers are those organizations and individuals who are interested in acquiring a security solution that meets their specific needs. Consumers state their security functional and assurance requirements in a PP. This mechanism is used to communicate with potential developers by conveying requirements in an implementation-independent manner and information about how a product will be evaluated.

Developers are organizations and individuals who design, build, and sell IT security products. Developers respond to a consumer's PP with an implementation-dependent detailed design in the form of an ST. In addition, developers prove through the ST that all requirements from the PP have been satisfied, including the specific activities levied on developers by SARs.

Evaluators perform independent evaluations of PPs, STs, and TOEs using the CC/CEM, specifically the evaluator activities stated in SARs. The results are formally documented and distributed to the appropriate entities. Consequently, consumers do not have to rely only on a developer's claims—they are privy to independent assessments from which they can evaluate and compare IT security products.

As the standard[7] states:

> The CC is written to ensure that evaluations fulfill the needs of consumers—this is the fundamental purpose and justification for the evaluation process.

The Common Criteria Recognition Agreement (CCRA),[10] signed by 15 countries to date, formally assigns roles and responsibilities to specific organizations:

- Customers or end users
- IT product vendors
- Sponsors
- Common Criteria Testing Laboratories (CCTLs)
- National Evaluation Authorities
- Common Criteria Implementation Management Board (CCIMB)

Customers or end users perform the same role as consumers in the generic model. They specify their security functional and assurance requirements in a PP. By defining an assurance package, they inform developers how the IT product will be evaluated. Finally, they use PP, ST, and TOE evaluation results to compare IT products and determine which best meets their specific needs and will work best in their particular operational environment.

IT product vendors perform the same role as developers in the generic model. They respond to customer requirements by developing an ST and corresponding TOE. In addition, they provide proof that all security functional and assurance requirements specified in the PP have been satisfied by their ST and TOE. This proof and related development documentation is delivered to the Sponsor.

A new role introduced by the CCRA is that of the Sponsor. A Sponsor locates an appropriate CCTL and makes contractual arrangements with them to conduct an evaluation of an IT product. They are responsible for delivering the PP, ST, or TOE and related documentation to the CCTL and coordinating any pre-evaluation activities. A Sponsor may represent the customer or the IT product vendor, or be a neutral third party such as a system integrator.

The CCRA divides the generic evaluator role into three hierarchical functions: Common Criteria Testing Laboratories (CCTLs), National Evaluation Authorities, and the Common Criteria Implementation Management Board (CCIMB).

CCTLs must meet accreditation standards and are subject to regular audit and oversight activities to ensure that their evaluations conform to the CC/CEM. CCTLs receive the PP, ST, or TOE and the associated documentation from the Sponsor. They conduct a formal evaluation of the PP, ST or TOE according to the CC/CEM and the assurance package specified in the PP. If missing, ambiguous, or incorrect information is uncovered during the course of an evaluation, the CCTL issues an Observation Report (OR) to the sponsor requesting clarification. The results are documented in an Evaluation Technical Report (ETR), which is sent to the National Evaluation Authority along with a recommendation that the IT product be certified (or not).

Each country that is a signatory to the CCRA has a National Evaluation Authority. The National Evaluation Authority is the focal point for CC activities within its jurisdiction. A National Evaluation Authority may take one of two forms—that of a Certificate Consuming Participant or that of a Certificate Authorizing Participant. A Certificate Consuming Participant recognizes CC certificates issued by other entities but, at present, does not issue any certificates itself. It is not uncommon for a country to sign on to the CCRA as a Certificate Consuming Participant, then switch to a Certificate Authorizing Participant later, after it has established a national evaluation scheme and accredited some CCTLs.

A Certificate Authorizing Participant is responsible for defining and managing the evaluation scheme within its jurisdiction. This is the administrative and regulatory framework by which CCTLs are initially accredited and subsequently maintain their accreditation. The National Evaluation Authority issues guidance to CCTLs about standard practices and procedures and monitors evaluation results to ensure their objectivity, repeatability, and conformance to the CC/CEM. The National Evaluation Authority issues official CC certificates, if they agree with the CCTL recommendation, and recognizes CC certificates issued by other National Evaluation Authorities. In addition, the National Evaluation Authority maintains the Evaluated Products List and PP Registry for its jurisdiction.

The Common Criteria Implementation Management Board (CCIMB) is composed of representatives from each country that is a party to the CCRA. The CCIMB has the ultimate responsibility for facilitating the consistent interpretation and application of the CC/CEM across all CCTLs and National Evaluation Authorities. Accordingly, the CCIMB monitors and oversees the National Evaluation Authorities. The CCIMB renders decisions in response to Requests for Interpretations (RIs). Finally, the CCIMB maintains the current version of the CC/CEM and coordinates with ISO/IEC JTC1 SC27 WG3 and the CEMEB concerning new releases of the CC/CEM and related standards.

111.5 Future of the CC

As mentioned earlier, the CC/CEM is the result of a 30-year evolutionary process. The CC/CEM and the processes governing it have been designed so that CC/CEM will continue to evolve and not become obsolete when technology changes, like the *Orange Book* did. Given that and the fact that 15 countries have signed the CC Recognition Agreement (CCRA), the CC/CEM will be with us for the long term. Two near-term events to watch for are the issuance of both the CEM and the SSE-CMM as ISO/IEC standards.

The CCIMB has set in place a process to ensure consistent interpretations of the CC/CEM and to capture any needed corrections or enhancements to the methodology. Both situations are dealt with through what is known as the Request for Interpretation (RI) process. The first step in this process is for a developer, sponsor, or CCTL to formulate a question. This question or RI may be triggered by four different scenarios. The organization submitting the RI:[10]

1. Perceives an error in the CC or CEM
2. Perceives the need for additional material in the CC or CEM
3. Proposes a new application of the CC or CEM and wants this new approach to be validated
4. Requests help in understanding part of the CC or CEM

The RI cites the relevant CC or CEM reference and states the problem or question.

The ISO/IEC has a five-year reaffirm, update, or withdrawal cycle for standards. This means that the next version of ISO/IEC 15408, which will include all of the final interpretations in effect at that time, should be released near the end of 2004. The CCIMB has indicated that it may issue an interim version of the CC or CEM, prior to the release of the new ISO/IEC 15408 version, if the volume and magnitude of final interpretations warrant such an action. However, the CCIMB makes it clear that it remains dedicated to support the ISO/IEC process.[1]

111.5.1 Acronyms

ADP—Automatic Data Processing equipment
C&A—Certification and Accreditation
CC—Common Criteria
CCEB—Common Criteria Editing Board
CCIMB—Common Criteria Implementation Board
CCRA—Common Criteria Recognition Agreement
CCTL—accredited CC Testing Laboratory
CEM—Common Evaluation Methodology
CESG—U.K. Communication Electronics Security Group
CMM—Capability Maturity Model
COMSEC—Communications Security
COMPUSEC—Computer Security

CSE—Canadian Computer Security Establishment
DoD—U.S. Department of Defense
EAL—Evaluation Assurance Level
ECMA—European Computer Manufacturers Association
ETR—Evaluation Technical Report
IEC—International Electrotechnical Commission
ISO—International Organization for Standardization
JTC—ISO/IEC Joint Technical Committee
NASA—U.S. National Aeronautics and Space Administration
NIST—U.S. National Institute of Standards and Technology
NSA—U.S. National Security Agency
OECD—Organization for Economic Cooperation and Development
OPSEC—Operational Security
OR—Observation Report
PP—Protection Profile
RI—Request for Interpretation
SAR—Security Assurance Requirement
SEI—Software Engineering Institute at Carnegie Mellon University
SFR—Security Functional Requirement
SSE-CMM—System Security Engineering CMM
ST—Security Target
TCSEC—Trusted Computer Security Evaluation Criteria
TOE—Target of Evaluation

112
Common System Design Flaws and Security Issues

William Hugh Murray

This chapter identifies and describes many of the common errors in application and system design and implementation. It explains the implications of these errors and makes recommendations for avoiding them. It treats unenforced restrictions, complexity, incomplete parameter checking and error handling, gratuitous functionality, escape mechanisms, and unsafe defaults, among others.

In his acceptance of the Turing Award, Ken Thompson reminded us that unless one writes a program oneself, one cannot completely trust it. Most people realize that although writing a program may be useful, even necessary, for trust, it is not sufficient. That is to say, even the most skilled and motivated programmers make errors. On the other hand, if one had to write every program that one uses, computers would not be very useful. It is important to learn both to write and recognize reliable code.

Historically, the computer security community has preferred to rely on controls that are external to the application. The community believed that such controls were more reliable, effective, and efficient. They are thought to be more reliable because fewer people have influence over them and those people are farther away from the application. They are thought to be more effective because they are more resistant to bypass. They are thought to be more efficient because they operate across and are shared by a number of applications.

Nonetheless, application controls have always been important. They are often more granular and specific than the environmental controls. It is usually more effective to say that those who can update the vendor name and address file cannot also approve invoices for payment than it is to say that Alice cannot see or modify Bob's data. Although it sometimes happens that the privilege to update names and addresses maps to one data object and the ability to approve invoices maps to another data object, this is not always true. Although it can always be true that the procedure to update names and addresses is in a different program from that to approve invoices, and although this may be coincidental, it usually requires intent and design.

However, in modern systems, the reliance on application controls goes up even more. Although the application builder may have some idea of the environment in which his program will run, his ability to specify it and control it may be very low. Indeed, it is increasingly common for applications to be written in cross-platform languages. These languages make it difficult for the author to know whether his program will run in a single-user system or a multi-user system, a single application system or a multi-application system. Historically, one relied on the environment to protect the application from outside interference or contamination; in modern systems one must rely on the application to protect itself from its traffic. In distributed systems, environmental controls are far less reliable than in traditional systems. It has become common, not to say routine, for systems to be contaminated by applications.

The fast growth of the industry suggests that people with limited experience are writing many programs. It is difficult enough for them to write code that operates well when the environment and the inputs conform to their expectation, much less when they do not.

The history of controls in applications has not been very good. Although programs built for the marketplace are pretty good, those built one-off specifically for an enterprise are often disastrous. What is worse, the same error types are manifesting themselves as seen 20 years ago. The fact that they get renamed, or even treated as novel, suggests that people are not taking advantage of the history. "Those who cannot remember the past are condemned to repeat it."[1]

This chapter identifies and discusses some of the more common errors and their remedies in the hope that there will be more reliable programs in the future. Although a number of illustrations are used to demonstrate how these errors are maliciously exploited, the reader is asked to keep in mind that most of the errors are problems *per se*.

112.1 Unenforced Restrictions

In the early days of computing, it was not unusual for program authors to respond to error reports from users by changing the documentation rather than changing the program. Instead of fixing the program such that a particular combination of otherwise legitimate input would not cause the program to fail, the programmers simply changed the documentation to say, "Do not enter this combination of inputs because it may cause unpredictable results." Usually, these results were so unpredictable that, while disruptive, they were not exploitable. Every now and then, the result was one that could be exploited for malicious purposes.

It is not unusual for the correct behavior of an application to depend on the input provided. It is sometimes the case that the program relies on the user to ensure the correct input. The program may tell the user to do A and not to do B. Having done so, the program then behaves as if the user will always do as he is told. For example, the programmer may know that putting alpha characters in a particular field intended to be numeric might cause the program to fail. The programmer might even place a caution on the screen or in the documentation that says, "Put only numeric characters in this field." What the programmer does not do is check the data or constrain the input such that the alpha data cannot cause an error.

Of course, in practice, it is rarely a single input that causes the application to fail. More often, it is a particular, even rare, combination of inputs that causes the failure. It often seems to the programmer as if such a rare combination will never occur and is not worth programming for.

[1] Georage Santayana, *Reason in Common Sense.*

112.2 Complexity

Complexity is not an error *per se*. However, it has always been one of the primary sources of error in computer programs. Complexity causes some errors and may be used to mask malice. Simplicity maximizes understanding and exposes malice.

Limiting the scope of a program is necessary but not sufficient for limiting its complexity and ensuring that its intent is obvious. The more one limits the scope of a program, the more obvious will be what it does. On the other hand, the more one limits the scope of all programs, the more programs one ends up with.

Human beings improve their understanding of complex things by subdividing them into smaller and simpler parts. The atomic unit of a computer program is an instruction. One way to think about programming is that it is the art of subdividing a program into its atomic instructions. If one were to reduce all programs to one instruction each, then all programs would be simple and easy to understand, but there would be many programs and the relationship between them would be complex and difficult to comprehend.

Large programs may not necessarily be more complex than short ones. However, as a rule, the bigger a program is, the more difficult it is to comprehend. There is an upper bound to the size or scope of a computer program that can be comprehended by a human being. As the size of the program goes up, the number of people that can understand it approaches zero and the length of time required for that understanding approaches infinity. Although one cannot say with confidence exactly where that transition is, neither is it necessary. Long before reaching that point, one can make program modules large enough to do useful work.

The issue is to strike a balance in which programs are large enough to do useful work and small enough to be easily understood. The comfort zone should be somewhere between and 10 and 50 verbs and between one complete function and a page.

Another measure of the complexity of a program is the total number of paths through it. A simple program has one path from its entry at the top to its exit at the bottom. Few programs look this way; most will have some iterative loops in them. However, the total number of paths may still be numbered in the low tens as long as these loops merely follow one another in sequence or embrace but do not cross. When paths begin to cross, the total number of possible paths escalates rapidly. Not only does it become more difficult to understand what each path does, it becomes difficult simply to know if a path is used (i.e., is necessary) at all.

112.3 Incomplete Parameter Check and Enforcement

Failure to check input parameters has caused application failures almost since Day One. In modern systems, the failure to check length is a major vulnerability. Although modern databases are not terribly length sensitive, most systems are sensitive to input length to some degree or another.

A recent attack involved giving an e-mail attachment a name more than 64 kb in length. Rather than impose an arbitrary restriction, the designer had specified that the length be dynamically assigned. At lengths under 64 kb, the program worked fine; at lengths above that, the input overlaid program instructions. Neither the programmer, the compiler, nor the tester asked what would happen for such a length. At least two separate implementations of the function failed in this manner.

Yes, there really are people out there that are stressing programs in this way. One might well argue that one should not need to check for a file name greater than 64 kb in length. Most file systems would not even accept such a length. Why would anyone do that? The answer is to see if it would cause an exploitable failure; the answer is that it did.

Many compilers for UNIX permit the programmer to allocate the size of the buffer statically at execution time. This makes such an overrun more likely but improves performance. Dynamic allocation of the buffer is more likely to resist an accidental overrun but is not proof against attacks that deliberately use excessively long data fields.

These attacks are known generically as “buffer-overflow” attacks. More than a decade after this class of problem was identified, programs vulnerable to it continue to proliferate.

In addition to length, it is necessary to check code, data type, format, range, and for illegal characters. Many computers recognize more than one code type (e.g., numeric, alphabetic, ASCII, hexadecimal, or binary). Frequently, one of these may be encoded in another. For example, a binary number might be entered in either a numeric or alphanumeric field. The application program must ensure that the code values are legal in both code sets—the entry and display set and the storage set. Note that because modern database managers are very forgiving, the mere fact that the program continues to function may not mean that the data is correct. Data types (e.g., alpha, date, currency) must also be checked. The application itself and other programs that operate on the data may be very sensitive to the correctness of dates and currency formats. Data that is correct by code and data type may still not be valid. For example, a date of birth that is later than the date of death is not valid although it is a valid data type.

112.4 Incomplete Error Handling

Closely related to the problem of parameter checking is that of error handling. Numbers of employee frauds have their roots in innocent errors that were not properly handled. The employee makes an innocent error; nothing happens. The employee pushes the envelope; still nothing. It begins to dawn on the employee that she could make the error in the direction of her own benefit—and still nothing would happen.

In traditional applications and environments, such conditions were dangerous enough. However, they were most likely to be seen by employees. Some employees might report the condition. In the modern network, it is not unusual for such conditions to be visible to the whole world. The greater the population that can see a system or application, the more attacks it is likely to experience. The more targets an attacker can see, the more likely he is to be successful, particularly if he is able to automate his attack.

It is not unusual for systems or applications to fail in unusual ways when errors are piled on errors. Programmers may fail to program or test to ensure that the program correctly handles even the first error, much less for successive ones. Attackers, on the other hand, are trying to create exploitable conditions; they will try all kinds of erroneous entries and then pile more errors on top of those. Although this kind of attack may not do any damage at all, it can sometimes cause an error and occasionally cause an exploitable condition. As above, attackers may value their own time cheaply, may automate their attacks, and may be very patient.

112.5 Time of Check to Time of Use (TOCTU)

Recently, a user of a Web mail service application noticed that he could “bookmark” his Inbox and return to it directly in the future, even after shutting down and restarting his system, without going through log-on again.

On a Friday afternoon, the user pointed this out to some friends. By Saturday, another user had recognized that one of the things that made this work was that his user identifier (UID), encoded in hexadecimal, was included in the universal record locator (URL) for his Inbox page. That user wondered what would happen if someone else’s UID was encoded in the same way and put into the URL. The reader should not be surprised to learn that it worked. By Sunday, someone had written a page to take an arbitrary UID encoded in ASCII, convert it to hexadecimal, and go directly to the Inbox of any user. Monday morning, the application was taken down.

The programmer had relied on the fact that the user was invited to logon before being told the URL of the Inbox. That is, the programmer relied on the relationship between the time of the check and the time of use. The programmer assumes that a condition that is checked continues to be true. In this particular case, the result of the decision was stored in the URL, where it was vulnerable to both replay and interference. Like many of the problems discussed here, this one was first documented almost 30 years ago.

Now the story begins to illustrate another old problem.

112.6 Ineffective Binding

Here, the problem can be described as ineffective binding. The programmer, having authenticated the user on the server, stores the result on the client. Said another way, the programmer stores privileged state in a place where he cannot rely on it and where he is vulnerable to replay.

Client/server systems seem to invite this error. In the formal client/server paradigm, servers are stateless. That is to say, a request from a client to a server is atomic; the client makes a request, the server answers and then forgets that it has done so.

To the extent that servers remember state, they become vulnerable to denial-of-service attacks. One such attack is called the Syn Flood Attack. The attacker requests a TCP session. The victim acknowledges the request and waits for the attacker to complete and use the session. Instead, the attacker requests yet another session. The victim system keeps allocating resources to the new sessions until it runs out.

Because the server cannot anticipate the number of clients, it cannot safely allocate resource to more than one client at a time. Therefore, all application states must be stored on the clients. The difficulty with this is that it is then vulnerable to interference or contamination on the part of the user or other applications on the same system. The server becomes vulnerable to the saving, replicating, and replay of that state.

Therefore, at least to the extent that the state is privileged, it is essential that it be saved in such way as to protect the privilege and the server. Because the client cannot be relied on to preserve the state, the protection must rely on secret codes.

112.7 Inadequate Granularity of Controls

Managers often find that they must give a user more authority than they wish or than the user needs because the controls or objects provided by the system or application are insufficiently granular. Stated another way, they are unable to enforce usual and normal separation of duties. For example, they might wish to assign duties in such a way that those who can set up accounts cannot process activity against those accounts, and vice versa. However, if the application design puts both capabilities into the same object (and provides no alternative control), then both individuals will have more discretion than management intends. It is not unusual to see applications in which all capabilities are bundled into a single object.

112.8 Gratuitous Functionality

A related but even worse design or implementation error is the inclusion in the application of functionality that is not native or necessary to the intended use or application. Because security may depend on the system doing only what is intended, this is a major error and source of problems. In the presence of such functionality, not only will it be difficult to ensure that the user has only the appropriate application privileges but also that the user does not get something totally unrelated.

Recently, the implementer of an E-commerce Web server application did the unthinkable; he read the documentation. He found that the software included a script that could be used to display, copy, or edit any data object that was visible to the server. The script could be initiated from any browser connected to the server. He recognized that this script was not necessary for his use. Worse, its presence on his system put it at risk; anyone who knew the name of the script could exploit his system. He realized that all other users of the application knew the name of that script. It was decided to search servers already on the Net to see how many copies of this script could be found. It was reported that he stopped counting when he got to 100.

One form of this is to leave in the program hooks, scaffolding, or tools that were originally intended for testing purposes. Another is the inclusion of backdoors that enable the author of the program to bypass the controls. Yet another is the inclusion of utilities not related to the application. The more successful and sensitive the application, the greater the potential for these to be discovered and exploited by others. The more copies of the program in use, the bigger the problem and the more difficult the remedy.

One very serious form of gratuitous functionality is an escape mechanism.

112.9 Escape Mechanisms

One of the things that Ken Thompson pointed out is the difficulty maintaining the separation between data and procedure. One man's data is another man's program. For example, if one receives a file with a file name extension of.doc, one will understand that it is a document, that is, data to be operated on by a word processing program. Similarly, if one receives a file with.xls, one is expected to conclude that this is a spreadsheet, data to be operated on by a spreadsheet program. However, many of these word processing and spreadsheet application programs have mechanisms built into them that permit their data to escape the environment in which the application runs. These programs facilitate the embedding of instructions, operating system commands, or even programs, in their data and provide a mechanism by which such instructions or commands can escape from the application and get themselves executed on behalf of the attacker but with the identity and privileges of the user.

One afternoon, the manager of product security for several divisions of a large computer company received a call from a colleague at a famous security consulting company. The colleague said that a design flaw had been discovered in one of the manager's products and that it was going to bring about the end of the world. It seems that many terminals had built into them an escape mechanism that would permit user A to send a message to user B that would not display but would rather be returned to the shared system looking as if it had originated with user B. The message might be a command, program, or script that would then be interpreted as if it had originated with user B and had all of user B's privileges.

The manager pointed out to his colleague that most buyers looked at this "flaw" as a feature, were ready to pay extra for it, and might not consider a terminal that did not have it. The manager also pointed out that his product was only one of many on the market with the same feature and that his product enjoyed only a small share of the market. And, furthermore, there were already a million of these terminals in the market and that, no matter what was offered or done, they would likely be there five years hence. Needless to say, the sky did not fall and there are almost none of those terminals left in use today.

On another occasion, the manager received a call from another colleague in Austin, Texas. It seems that this colleague was working on a mainframe e-mail product. The e-mail product used a formatter produced by another of the manager's divisions. It seems that the formatter also contained an escape mechanism. When the exposure was described, the manager realized that the work required to write an exploit for this vulnerability was measured in minutes for some people and was only low tens of minutes for the manager.

The behavior of the formatter was changed so that the ability to use the escape mechanism could be controlled at program start time. This left the question of whether the control would default to "yes" so that all existing uses would continue to work, or to "no" so as to protect unsuspecting users. In fact, the default was set to the safe default. The result was that tens of thousands of uses of the formatter no longer worked, but the formatter itself was safe for the naïve user.

Often these mechanisms are legitimate, indeed even necessary. For example, MS Word for DOS, a single-user single-tasking system, required this mechanism to obtain information from the file system or to allow the user access to other facilities while retaining its own state. In modern systems, these mechanisms are less necessary. In a multi-application system, the user may simply "open a new window;" that is, start a new process.

Nonetheless, although less necessary, these features continue to proliferate. Recent instances appear in MS Outlook. The intent of the mechanisms is to permit compound documents to display with fidelity even in the preview window. However, they are being used to get malicious programs executed. All such mechanisms can be used to dupe a user into executing code on behalf of an attacker. However, the automation of these features makes it difficult for the user to resist, or even to recognize, the execution of such malicious programs.

They may be aggravated when the data is processed in an exceptional manner. Take, for example, so-called "Web mail." This application turns two-tier client/server e-mail into three-tier. The mail agent, instead of running as a client on the recipient's system, runs as a server between the mail server and the user. Instead of accessing his mail server using an application on his system, the user accesses it via this middleware server using his (thin client) browser. If HTML tags are embedded in a message, the mail agent operating on the server, like any mail agent, will treat them as text. However, the browser, like any browser, will treat these tags as tags to be interpreted.

In a recent attack, HTML tags were included in a text message and passed through the mail agent to the browser. The attacker used the HTML to "pop a window" labeled "…Mail Logon." If the user were duped into responding to this window, his identifier and password would then be broadcast into the network for the benefit of the attacker.

Although experienced users would not be likely to respond to such an unexpected log on window, many other users would. Some of these attacks are so subtle that users cannot reasonably be expected to know about them or to resist their exploitation.

112.10 Excessive Privilege

Many multi-user, multi-application systems such as the IBM AS/400 and most implementations of UNIX contain a mechanism to permit a program to run with privileges and capabilities other than those assigned to the user. The concept seems to be that such a capability would be used to provide access control more granular and more restrictive than would be provided by full access to the data object. Although unable to access object A, the user would be able to access a program that was privileged to access object A but which would show the user a only a specified subset of object A.

However, in practice, it is often used to permit the application to operate with the privileges of the programmer or even those of the system manager. One difficulty of such use is manifest when the user manages to escape the application to the operating system, but retain the more privileged state. Another manifests itself when a started process, subsystem, or daemon runs with excessive privilege. For example, the mail service may be set up to run with the privileges of the system manager rather than with a profile created for the purpose. An attacker who gains control of this application, for example by a buffer overflow or escape mechanism, now controls the system, not simply with the privileges required by the application or those of the user, but with those of the system manager.

One might well argue that such a coincidence of a flawed program with excessive privilege is highly unlikely to occur. However, experience suggests that it is not only likely, but also common. One might further argue that the application programmer causes only part of this problem; the rest of it is the responsibility of the system programmer or system manager. However, in practice, it is common for the person installing the program to be fully privileged and to grant to the application program whatever privileges are requested.

112.11 Failure to a Privileged State

Application programs will fail, often for reasons completely outside of their control, that of their programmers, or of their users. As a rule, such failures are relatively benign. Occasionally, the failure exposes their data or their environment.

It is easiest to understand this by comparing the possible failure modes. From a security point of view, the safest state for an application to fail to is a system halt. Of course, this is also the state that leaves the fewest options for the user and for system and application management. They will have to reinitialize the system, reload and restart the application. While this may be the safest state, it may not be the state with the lowest time to recovery. System operators often value short time to recovery more than long time to failure.

Alternatively, the application could fail to log on. For years, this was the failure mode of choice for the multi-user, multi-application systems of the time. The remedy for the user was to log on and start the application again. This was safe and fairly orderly.

In more modern systems like Windows and UNIX, the failure mode of choice is for the application to fail to the operating system. In single-user, multi-application systems, this is fairly safe and orderly. It permits the user to use the operating system to recover the application and data. However, although still common in multi-user, multi-application systems, this failure mode is more dangerous. Indeed, it is so unsafe that crashing applications has become a favored manner of attacking systems that are intended to be application-only systems. Crash the application and the attacker may find himself looking at the operating system (command processor or graphical user interface [GUI]) with the identity and privileges of the person who started the application. In the worst case, this person is the system manager.

112.12 Unsafe Defaults

Even applications with appropriate controls often default to the unsafe setting of those controls. That is to say, when the application is first installed and until the installing user changes things, the system may be unsafely configured. A widespread example is audit trails. Management may be given control over whether the application records what it has done and seen. However, out of the box, and before management intervenes, the journals default to “off.” Similarly, management may be given control of the length of passwords. Again, out of the box, password length may default to zero.

There are all kinds of good excuses as to why a system should default to unsafe conditions. These often relate to ease of installation. The rationale is that if the system initializes to safe settings, any error in the procedure may result in a deadlock situation in which the only remedy is to abort the installation and start over. The difficulty is that once the system is installed and running, the installer is often reluctant to make any changes that might interfere with it.

In some instances, it is not possible for designers or programmers to know what the safe defaults are because they do not know the environment or application. On the other hand, users may not understand the controls. This can be aggravated if the controls are complex and interact in subtle ways. One system had a control to ensure that users changed their passwords at maximum life. It had a separate control to ensure that it could not be changed to itself. To make this control work, it had a third control to set the minimum life of the password. A great deal of special knowledge was required to understand the interaction of these controls and their effective use.

112.13 Exclusive Reliance on Application Controls

The application designer frequently has a choice of whether to rely on application program controls, file system controls, database manager controls, or some combination of these. Application programmers sometimes rely exclusively on controls in the application program. One advantage of this is that one may not need to enroll the user to the file system or database manager or to define the user’s privileges and limitations to those systems. However, unless the application is tightly bound to these systems, either by a common operating system or by encryption, a vulnerability arises. It will be possible for the user or an attacker to access the file system or database manager directly. That is, it is possible to bypass the application controls. This problem often occurs when the application is developed in a single-system environment, where the application and file service or database manager run under a single operating system and are later distributed.

Note that the controls of the database manager are more reliable than those in the application. The control is more localized and it is protected from interference or bypass on the part of the user. On the other hand, it requires that the user is enrolled to the database manager and that the access control rules are administered.

This vulnerability to control bypass also arises in other contexts. For example, controls can be bypassed in single-user, multi-application systems with access control in the operating system rather than the file system. An attacker simply brings his own operating system in which he is fully privileged and uses that in lieu of the operating system in which he has no privileges.

112.14 Recommendations

The following recommendation should be considered when crafting and staging applications. By adhering to these recommendations, the programmer and the application manager can avoid many of the errors outlined in this chapter.

1. Enforce all restrictions that are relied on.
2. Check and restrict all parameters to the intended length and code type.
3. Prefer short and simple programs and program modules. Prefer programs with only one entry point at the top or beginning, and only one exit at the bottom or end.
4. Prefer reliance on well-tested common routines for both parameter checking and error correction. Consider the use of routines supplied with the database client. Parameter checking and error correcting code is difficult to design, write, and test. It is best assigned to master programmers.
5. Fail applications to the safest possible state. Prefer failing multi-user applications to a halt or to log-on to a new instance of the application. Prefer failing single-user applications to a single-user operating system.
6. Limit applications to the least possible privileges. Prefer the privileges of the user. Otherwise, use a limited profile created and used only for the purpose. Never grant an application systemwide privileges. (Because the programmer cannot anticipate the environment in which the application may run and the system manager may not understand the risks, exceptions to this rule are extremely dangerous.)
7. Bind applications end-to-end to resist control bypass. Prefer a trusted single-system environment. Otherwise, use a trusted path (e.g., dedicated local connection, end-to-end encryption, or a carefully crafted combination of the two).
8. Include in an application user’s privileges only that functionality essential to the use of the application. Consider dividing the application into multiple objects requiring separate authorization so as to facilitate involving multiple users in sensitive duties.
9. Controls should default to safe settings. Where the controls are complex or interact in subtle ways, provide scripts (“wizards”), or profiles.
10. Prefer localized controls close to the data (e.g., file system to application, database manager to file system).
11. Use cryptographic techniques to verify the integrity of the code and to resist bypass of the controls.
12. Prefer applications and other programs from known and trusted sources in tamper-evident packaging.

Developing Realistic Continuity Planning Process Metrics

Carl B. Jackson

Gaining a positive commitment from executive management for continuity planning has been a persistent issue in our industry since its inception. Without that commitment, it is probable that management expectations will not be met. To those of us who have been in the business continuity profession for any time at all, it is clear that we have a long history of bad practice in compelling executive management to take the steps necessary to ensure an effective enterprise-wide continuity planning strategy and infrastructure. To rectify this bad practice, I undertook what turned out to be an 18-month experiment: an attempt to define business continuity planning process metrics; if not precise metrics, then at least a process by which effective metrics can be developed within organizations.

The purpose of this chapter is to present a metrics development process. The concepts are presented utilizing a structured-project-plan approach and format. This should best prepare the reader to replicate the method for any business or organization.

113.1 Introduction

Ask yourself how your organization measures the effectiveness of their continuity planning business process.

- What metrics does the organization use to determine your compensation at the end of the year?
- Is your annual salary performance review criteria truly representative of the work that you perform?
- How do you, as a planner, obtain management awareness, buy-in, and funding?
- How do you demonstrate that the contributions of the enterprise continuity planning business process add value to your organization?
- What are the specific quantitative and qualitative metrics that demonstrate and validate that your program is doing what you assert it is doing?

If you cannot point fairly quickly to these metrics, then you are in good company. I estimate that 90% of all the continuity planning professionals in the world have no formal metrics in place.

The lack of appropriate metrics has often undermined the effectiveness of the continuity planning program. In my years in public accounting, auditing, and consulting, I have observed and learned that many, if not most, organizations have an on-again, off-again, rollercoaster continuity planning process. That process is sometimes effective, but more often entirely ineffective. Third-party reviews repeatedly demonstrate that this lack of useful metrics is the most significant cause of program failure. A false sense of security that stems from the assumption that you have a vital continuity planning process (without the benefit of effective metrics) can be more dangerous than allowing the organization to simply ignore continuity planning altogether.

Other than the most rudimentary financial measures, a formal metrics process that considers both qualitative and quantitative metrics is nonexistent in the traditional business continuity planning function. One conclusion from the metrics development project was the strong recommendation that every continuity planner's job description, mission charter, or supporting policy should specify that development and implementation of appropriate metrics is, in itself, a performance metric.

113.2 Metrics Definition

In context, the term *metrics* refers to any numerical measure of a company's or manager's performance in meeting their responsibilities. In relation to the continuity planning business process, *metrics* means the development of an appropriate set of qualitative and quantitative measures to which program effectiveness can be compared. Metrics are simply a predefined set of measurements that quantify results. Metrics come in many different packages. For instance, a performance metric quantifies a unit's performance, project metrics measure project status against predetermined goals, and business metrics define the progress of the enterprise in measurable terms against a set of predefined goals.

113.3 CPM Metrics Workshops

To get to the bottom of the metrics issue, I designed and facilitated a series of workshops with the intention of developing a method for gathering metrics from BCP practitioners. From 2002 to 2004, in conjunction with four *Continuity Management Planning Magazine* (CPM) (http://www.contingency-planning.com) annual conferences, I conducted several of these metrics development workshops with volunteer conference participants.

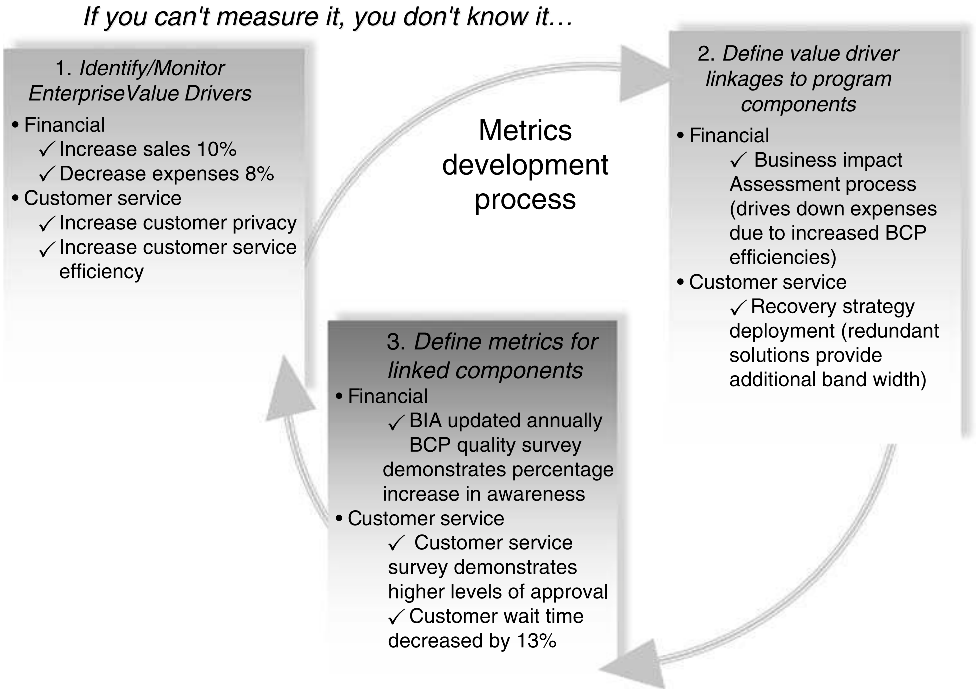
The following paragraphs outline the methods used during the research workshops at the CPM conferences. It is important to note that I merely facilitated these discussions; the workshop attendees did the heavy lifting. The metrics development process laid out in this chapter is, for all intents and purposes, the essential take-away from those workshop sessions.

113.3.1 Workshop Proceedings

113.3.1.1 Workshop Organization and Logistics

At the kickoff of each of the workshops, attendees were assigned to small, industry-specific groups (financial services, government, retail, healthcare, manufacturing, etc.). Each of the groups was directed to appoint a spokesperson (the group executive) and a scribe to document the steps and outcomes of each of the three exercises. The following three exercises were used when conducting the several actual workshops at the CPM conferences.

Prior to the beginning of the group exercises, Exhibit 113.1 was presented and discussed with the participants. The figure pictorially represents the three phases of the metrics development process.



If you can't measure it, you don't know it…
1. *Identify/Monitor EnterpriseValue Drivers*
• Financial
✓Increase sales 10%
✓Decrease expenses 8%
• Customer service
✓Increase customer privacy
✓Increase customer service efficiency
Metrics development process
2. *Define value driver linkages to program components*
• Financial
✓ Business impact Assessment process (drives down expenses due to increased BCP efficiencies)
• Customer service
✓Recovery strategy deployment (redundant solutions provide additional band width)
3. *Define metrics for linked components*
• Financial
✓BIA updated annually BCP quality survey demonstrates percentage increase in awareness
• Customer service
✓ Customer service survey demonstrates higher levels of approval
✓Customer wait time decreased by 13%

EXHIBIT 113.1 Metrics development process.

113.3.1.2 Exercise 1: Identify Value Drivers

Following the workshop attendee introductions and background conversation, the participants discussed the significance of understanding the precise marching orders for the organization's primary stakeholders. What and how does one determine the organization's value drivers? Each of the participants was asked to mull this over: "What does the stakeholder value from this organization?"
Value driver examples provided to the participants included:

1. Customer-satisfaction-related value drivers
   - Provide world-class customer service
   - Limit number of customers adversely impacted
   - Avoid enterprise embarrassment
2. People-related value drivers
   - Avoid loss/access to private employee information
   - Ensure workforce safety or productivity
   - Enable access to executive information, systems, etc.
3. Financial-related value drivers
   - Control expenses
   - Prevent revenue loss
   - Minimize capital market impact
4. Intangible value drivers
   - Protection of proprietary information
   - Protect brand image
   - Maintain regulatory confidence
   - Enhance operational productivity
   - Reduce waste

5. Other potential value drivers

What is the source of the value-driver information? This question was uppermost in the minds of the workshop participants. Subsequent discussion revealed likely sources of value drivers, including:

- Annual reports
- SEC filings
- Strategic planning documents
- Executive interviews
- Published core value statements
- Public notices, news releases, etc.
- Annual investor conference call

The groups then began the first step in the metric development process—that of identifying and documenting executive management value drivers. At first blush, it might seem surprising that value drivers are remarkably similar[1] among companies in the same industry, and even in different industry groups.

Many of the groups recorded an inventory and assigned a unique identifier to each of the value drivers to facilitate mapping activities later in the process. Exhibit 113.2 illustrates an example value driver inventory and the assigned identifier that resulted from the workshop.

Following the value-driver identification exercise, each of the several group executives made a short presentation to the entire group amplifying the thinking and dialogue that went on during the exercise. Open discussion frequently ensued with a comparison of value-driver similarities industry to industry, and significant differences among industries.

113.3.1.3 Exercise 2: Map Value Drivers to Continuity Planning Process Components

Each of the groups was then asked to map or otherwise link these defined value drivers to the individual components of the continuity program process.

What do we mean when we talk about continuity planning process components? Each of these individual components represents a major process or sub-process. The totality of each of these individual components represents the continuity planning business process. Following are examples of individual continuity planning process components:

- Business impact assessment/risk analysis: these activities are focused on identification of enterprise business processes, determination and prioritization of those business processes that are time-critical, and assigning each one an appropriate recovery time objective.

EXHIBIT 113.2 Sample Value Driver Inventory

Value Driver Identifier	Generic Value Driver Inventory
1.	Customer Satisfaction
1a.	Increase customer service efficiency
1b.	Increase number of customers served per day
1c.	Reduce duration of downtime events
2.	People
2a.	Loss/access to private employee information
2b.	Workforce endangerment
2c.	Access to executive information, systems, etc.
3.	Financial
3a.	Reduce overhead costs by 8%
3b.	Increase revenues 10%
4.	Intangible
4a.	Proprietary information
4b.	Damage to brand

- Recovery strategy choices: these processes identify and codify appropriate recovery strategies for business process, technology, facilities, and third-party related plans based upon the priorities for recovery identified during the business impact assessment.
- Plan documentation: more than simply documenting continuity plans, this activity includes understanding the tools or other mechanisms used by the organization to coordinate analysis, development, implementation, testing and maintenance of the plan infrastructure.
- Awareness and training: a key component, awareness and training issues are paramount to the success of any continuity planning program. Because it is the organization's people who will have to recover the enterprise following a disaster or disruption, it only makes sense that those same people are intimately involved in the development, implementation, testing and maintenance of the process. Once accomplished, however, it does not release those people from further responsibilities. It is, therefore, critically important that a regular and ongoing program of continuity planning awareness and training be put into place.
- Testing/maintenance: there are a multitude of program components related to continuity plan testing and maintenance that can be utilized in identifying program metrics. Examples include: test planning goals, timing, execution, and follow-up processes, all of which provide opportunities for the development of sound measurements. There are many opportunities to track maintenance activities. Utilization of change control, human resource evaluations, internal audits, and BCP management reviews can provide ample prospects for development of meaningful metrics.
- Continuity planning executive management organization and structure: examples include: Executive management support and funding, continuity program staffing commitment, enterprise continuity planning infrastructure, team structures, crisis/incident management process, and overall level of continuity planning awareness.
- Existing metrics: the review and analysis of any existing measurements which gauge the adequacy of continuity planning business processes, formal or informal. Analysis of these metrics, or lack thereof, will provide a solid foundation for the new metrics developed, and is a great opportunity to leverage work that has been done before.

Each business organizes and manages continuity planning a little differently, and structures their unique continuity planning components accordingly. There will always be, however, similarities of the continuity planning process components across organizations. With this in mind, the workshop groups utilized the generic inventory of operational continuity planning program components given in Exhibit 113.3 to link back to the value drivers.

The workshop attendees were asked to remember that when considering phase-2 tasks, they should consider each of these components in terms of their impacts upon the organization's people, process, technology, and mission (profits, service, etc.).

Once linked, the workshop group executive for each of the several represented industry groups presented the outcome as their group saw it. A map of value drivers to continuity planning process components was the deliverable from this phase of the workshop.

113.3.1.4 Exercise 3: Devise Metrics (Both Qualitative and Quantitative) for Each of the Mapped Continuity Program Components

Finally, the groups were asked to brainstorm the possible metrics for the linked components. Best accomplished in a workshop setting, brainstorming and documenting qualitative and quantitative metrics is a valuable process. The groups developed a draft set of likely metrics, both quantitative and qualitative. In actual practice, this working model should be drafted by the metrics project team. Several of the workshop groups set up matrices similar to Exhibit 113.4 that illustrated the connection between components of the program that support value drivers and an associated metric.

EXHIBIT 113.3 Mapping Value Drivers to Continuity Program Components

Continuity Program Components	Value Driver Mapping
Continuity program component: Assess	
Current state assessment	Value driver 3a, 3b (as an example only)
Business impact assessment (BIA report)	Etc.
Business driver(s) analysis	Etc.
Risk appetite analysis	Etc.
Risk assessment/risk management review (emergency response procedures, mitigating control implementation)	Etc.
Benchmarking/peer review	Etc.
Recovery alternative rough order of magnitude overview	Etc.
Continuity planning process assessment	Etc.
Continuity planning business capability analysis	Etc.
Continuity program component: Design/Develop	Etc.
Continuity strategy development	Etc.
Facilitated continuity strategy process	Etc.
Cost-benefit analysis	Etc.
Strategy development (crisis management approach vs. plan-centric approach)	Etc.
Action plan and schedule	Etc.
Business management review and approval	Etc.
Design testing, maintenance, awareness, education, measurement strategies	Etc.
Design continuity planning management process	Etc.
Continuity program component: Implement	Etc.
Contingency and crisis planning	Etc.
Acquire and implement continuity resources	Etc.
Determine scenarios/triggers	Etc.
Build teams (as needed)	Etc.
Construct plans (as needed)	Etc.
Validate interdependencies	Etc.
Program implementation	Etc.
Implement testing, maintenance, awareness, education, measurement strategies	Etc.
Implement continuity planning management process	Etc.
Continuity program component: Manage/Measure	Etc.
Continuity plan infrastructure management	Etc.
Rehearsal/Exercising/Maintenance	Etc.
Continuity program management	Etc.
Education/Awareness/Training	Etc.
Change management	Etc.
Measurement and reporting	Etc.
Continuous improvement	Etc.

At the conclusion of the exercise, each workshop group executive presented examples of qualitative and quantitative metrics for as many of the individual continuity planning program components as possible, time permitting.

113.3.1.5 Workshop Wrap-Up

Following the conclusion of the discussion, but in most cases because we simply ran out of time, the results of each group's work were collected and consolidated. Exhibit 113.5 presents a high-level consolidation of the most significant output of the group sessions.

113.3.1.6 Workshop Conclusions

The bottom line regarding metrics for continuity program performance was that, unfortunately, there are no predefined lists or readily accessible menus of metrics available on the Internet or elsewhere. Using another organization's metrics will help to ensure that your program meets the needs of their stakeholders, not yours. Metrics must be customized and focused on the particular organizational entity. They must also be facilitated in-house, and use of the metrics development process recommended

EXHIBIT 113.4 Matrix Illustrating the Connection Between Components of the Program that Support Value Drivers and an Associated Metric

	Potential Qualitative Metric	Potential Quantitative Metric
Continuity Program Components	Value Driver ID	Value Driver ID
Continuity program component: Assess		
Current state assessment	3a	3a
Business impact assessment (BIA report)		
Business driver(s) analysis		
Risk appetite analysis		
Risk assessment/risk management review (emergency response procedures, mitigating control implementation)		
Benchmarking/Peer review		
Recovery alternative rough order of magnitude overview		
Continuity planning process assessment		
Continuity planning business capability analysis		
Continuity program component: Design/Develop		
Continuity strategy development		
Facilitated continuity strategy process		
Cost-benefit analysis		
Strategy development (crisis management approach vs. plan-centric approach)		
Action plan and schedule		
Business management review and approval		
Design testing, maintenance, awareness, education, measurement strategies		
Design continuity planning management process		
Continuity program component- Implement		
Contingency and crisis planning		
Acquire and implement continuity resources		
Determine scenarios/triggers		
Build teams (as needed)		
Construct plans (as needed)		
Validate interdependencies		
Program implementation		
Implement testing, maintenance, awareness, education, measurement strategies		
Implement continuity planning management process		
Continuity program component: Manage/Measure		
Continuity plan infrastructure management		
Rehearsal/Exercising/Maintenance		
Continuity program management		
Education/Awareness/Training		
Change management		
Measurement and reporting		
Continuous improvement		

in this chapter ensures that the correct mix of stakeholders, practitioners, business owners, and other interested parties have a role to play and a contribution to make.

113.3.2 Metrics Development Approach

The results of these several CPM metrics development workshops suggest the following general approach to metrics development within an enterprise.

EXHIBIT 113.5 High-Level Consolidation of the Most Significant Output of the Group Sessions

	Workshop Output	
Value Drivers Identified	Continuity Process Component	Example Metric (Qualitative & Quantitative)
Financial related value drivers (financial services organization)		
Increase return on investment	Business impact assessment and risk assessment processes	BIA conducted
		BIA periodically updated
		Risk assessment conducted
Control costs	Business impact Assessment and risk Assessment processes	BIA conducted BIA periodically updated Risk assessment conducted
Regulatory compliance (oversight capabilities) (financial services organization)	Continuity plan infrastructure implementation, testing and maintenance	Number adverse regulatory comments
Enterprise reputation (financial services organization)	Crisis management (emergency response) and business impact assessment processes	Number of business units
		Number of business unit plans
		Number of tests performed per year
		Number of adverse audit findings
		Number of fire and other practice drills per year
		Employee survey's
Customer-service-related value drivers (financial services organization)	Documented continuity plans	Number of business units
		Number of business unit plans
		Number of tests performed per year
		Number of adverse audit findings
		Customer service related survey's
		Line item on change management request form relating to updating Plans
		Number of continuity plan changes per year
		Number third party contracts that reference continuity planning requirements
Gaining competitive advantage (financial services organization)	Continuity planning process	Number of situations where a continuity planning process was a determining factor
Maintenance of value brands (retail organization)	Crisis management process	Number crisis management team training sessions/drills
		Customer survey's
Quality management (healthcare organization)	Business impact assessment testing	Number of litigations per year (litigation avoidance)
Communications (government organization)	Crisis management process testing	Number of litigations per year (litigation avoidance)
		Demonstrated ability to recover time-critical business processes

113.3.2.1 Project Initiation: Forming the Metrics Development Project Team

- Name project team members: A useful step in undertaking the formal development of continuity planning process metrics is the formation of a metrics project team. This team should be composed of representatives from those business units that are considered stakeholders in the process. Ideally, one would expect to see the continuity planning, internal auditor, executive management representative, IT representative, and one or more representatives from key business units. The charter of this team would be to oversee the metrics development process from project initiation through phase 3 and implementation of the metrics. The team may use workshops or one-on-one/small group meetings to facilitate each of the phases.

- Identify stakeholders: The project team should identify and document all those personnel who would have a stake in the outcome of the metrics development process. These stakeholders will be asked to actively participate in the metric development effort and to attend a metrics workshop for brainstorming potential metrics.
- Obtain executive management sponsorship: In identifying stakeholders, it is obvious that one or more of the executive management group be called upon to participate. The executive management group defines the organization value drivers and are the same people who will be using the agreed-upon metrics to measure the effectiveness of the continuity planning program.
- Develop project plan and charter: As with any other significant project (and for the same reasons) it is useful to formalize a project plan and charter that clearly define the objectives, scope, timing, costs, participants, and expected results of the project.
- Prepare and present project kickoff meeting: To build awareness and to signify the initiation of the project, the project team should prepare for and conduct a metrics project kickoff meeting that includes all the identified stakeholders as well as others who will have an interest in the results of the process, or who will be needed to facilitate development of the metrics themselves.

113.3.2.2 Phase 1: Identify Value Drivers

1. Project team documents the value drivers: The first step in the metrics development process is to identify and document enterprise value drivers. After all, successfully mapping the value drivers to the supporting components of the continuity planning process, and defining appropriate qualitative and quantitative metrics is the overall goal of the project.
2. Project team obtains value-driver information: The project team can use various methods to identify enterprise value drivers. In some organizations, understanding what drives the executive management group is already clearly defined and easily recognized. In many other organizations, however, the value drivers are not readily apparent and difficult to pin down. There are various reasons why value drivers may be elusive, like undisclosed management direction, transition or upheaval in the organization or marketplace, or even management's lack of clarity in terms of the path forward. There are various methods for divining this information, including the review of:
   - Annual reports
   - Enterprise mission statements
   - Public financial disclosures
   - Conduct management interviews, etc.
3. Conduct stakeholder interviews, etc.: Schedule and conduct brief stakeholder meetings to introduce the scope, purpose and approach of the project, and obtain support for further meetings and eventual participation in the metrics development workshop.
4. Document/inventory value drivers: Using Exhibit 113.2 (above) as a guide, the project team should formally document the value-driver inventory. This inventory will feed into the next step.
5. Document and summarize data collection: At this point it is necessary to compile and document the results of the data gathering and stakeholder interviews. This documentation will eventually become a significant part of the metric development workshop brief and a transition into the final metrics development report deliverable.
6. Prepare management presentation: At this point, the project team should have successfully documented their understanding of the enterprise value drivers.

7. Obtain management approval/buy-in: To ensure executive management concurrence, the Value Drivers must be reviewed and approved by the management group.
8. Update project plan: Given management feedback, the project plan should be reviewed and changed accordingly.

113.3.2.3 Phase 2: Map Value Drivers to Continuity Planning Process Components

- Project Team documents BCP program components: If not already accomplished, the Project Team should document each of the individual components of the organization's existing continuity planning process (i.e., business impact assessment; risk analysis; program management and oversight; recovery strategy development and implementation; recovery plan development and infrastructure; continuity plan testing, maintenance and training, etc.).
- Project team maps value drivers to program components: During this activity, the project team, along with selected stakeholders, endeavors to map identified value drivers to individual or group components of the continuity planning process. Every effort should be made to ensure that each component is related to a specific value driver. If a component cannot be linked to a value driver, then a question may arise as to why the continuity planner implemented it, and retains it going forward.
- Project Team drafts value driver/component mapping report: This formal documentation of the value driver/component linkages forms the basis for the metrics development workshop brief that will eventually be reviewed and approved by the stakeholders, and will evolve into the final deployment plan.
- Prepare management presentation: Prepare and present value driver/component mapping report to management. This presentation ensures that the management group is kept informed at every milestone, and is necessary to level-set expectations and obtain approvals for next step activities.
- Obtain management approval/buy-in: See above.
- Update project plan: Management feedback should be reviewed and incorporated into the project plan accordingly.

113.3.2.4 Phase 3: Devise Metrics (Both Qualitative and Quantitative) for Each of the Mapped Continuity Program Components

- Project team documents the discussions in the metrics development workshop brief: The project team is prepared at this juncture to formalize the first draft of the brief. The input for this scoping and decision document is taken from the outputs of phases 1 and 2. The brief should include a statement for each of the following: Project scope, approach, objective, participants, timing, expected deliverables, etc. It should also contain the value driver/component mapping report, as well as the draft metrics that have been developed by the project team (working metrics only).
- Identify metrics workshop attendees: While project stakeholders have already been identified, and in all likelihood are the same folks who would participate in the workshop, all those who with input and buy-in into the process should be included.
- Project team maps program components to existing metrics: Should the organization utilize metrics of some type to measure the continuity planning process currently, they should be considered and included in the analysis and in future metric development.
- Project team develops draft metrics for input and review: At this point, the project team should be able to begin drafting a preliminary set of qualitative and quantitative metrics that align with the value driver/component mapping. The draft metrics are just that—draft. They will be used as a discussion starter and be subject to modification, enhancement or elimination by the participants at the workshop session.

- Distribute brief to workshop attendees for review and input: Once completed, this brief should be shared with all stakeholders and workshop attendees with a request to review and provide feedback.
- Interview workshop attendees for feedback on brief: Conducting one-on-one interviews with each of the workshop attendees will enable buy-in and identification of issues that should be reviewed and decided upon.
- Update brief including stakeholder input: Given the reviews and input asked previously, the brief should undergo one additional update in preparation for the workshop.
- Prepare and conduct workshop: These workshops are just that, not a lecture, but a true working session where the participants are facilitated in open discussion and consensus of the issues at hand. The goal of the workshop is to agree upon the metric components laid out in the brief and to provide justification for their implementation.
- Document workshop results: Ask a scribe to take notes and keep track of the workshop proceedings. This will allow the project team to rapidly pull together the outcome of the workshop in preparation of the metrics report, which will eventually become the final deliverable as well as the basis for the deployment plan.
- Obtain management approval/buy-in: As with prior references to management approval and buy-in, ensure that the management group is kept informed. An executive level presentation and approval milestone should be accomplished here.
- Finalize metrics report: Revise the metrics report, incorporating the contributions from the management team.

113.3.2.5 Phase 4: Develop the Metric Implementation Plan; Maintenance

- Project team develops the metric implementation plan: Taking the completed and approved output from the work of the first three phases, the project team focuses efforts on developing a suitable implementation plan. It is difficult to give generalizations here about what the implementation plan should look like or how it should be deployed. Suffice to say that it must fit the culture of the enterprise, and involve all those business units needed to guarantee its success.
- Project team develops the metric maintenance plan: As above, the metrics maintenance plan will be adapted to fit the business. The maintenance plan should, on the other hand, include a mechanism for the periodic review and process improvement of the metrics that have been developed. Good metrics evolve over time to keep pace with changing environments.
- Deploy the metrics in appropriate manner for the enterprise: At this point, the metrics are deployed per the approved implementation plan.
- Close project: Project wrap-up requires closing all the loopholes that may still exist and disbanding the project team.

  The summary of the deliverables are:
- The value driver/component mapping report
- The metric development workshop brief
- The metrics report
- The final metrics development report
- The metric implementation plan
- The metric maintenance plan

Exhibit 113.6 suggests a possible timeline for the development of continuity planning metrics.

Exhibit 113.7 represents a sample project plan for enterprise metric development as reflected above.

113.4 Conclusion

Continuity planning is rarely the core competency of an organization unless they are a hotsite vendor or consulting firm. Because of this, many companies have trouble understanding the appropriate role of the business continuity planning function. The purpose of this chapter is to attempt to describe at least one manner in which good metrics can be developed.

A well developed set of metrics should greatly enhance the business continuity planning program of any organization. This process for developing metrics should assist the planner when justifying the project to executive management. Whatever the metric, it must be broken down so it is operational, manageable, and one from which the impacts of management decisions can be measured.

As a reminder, no set of metrics should ever be considered final, but temporary, pending identification and implementation of a better, more mature and descriptive measurement.

At the end of the day, presenting a clearly articulated, solid set of continuity planning metrics should resonate with your executive management group, and demonstrate the value added to the enterprise by a well informed, professional continuity planning program.

Acknowledgments

I acknowledge from the outset that the approach for metric development described here is only one of a myriad of methods that can be used for this purpose, and that no exclusivity is implied. I also want to humbly thank the dozens of continuity planning professionals who participated in the workshops. The development of this chapter is due to their collective knowledge and assistance.

114

Building Maintenance Processes for Business Continuity Plans

Ken Doughty

114.1 Introduction

Management has a fiduciary duty to maintain and continue to support and fund the organization's risk management program—including business continuity. In the event of a disaster, the likelihood of a cost-effective recovery in a timely manner is compromised unless there has been continual executive management support for maintaining the plan in a state of readiness.

Business continuity/disaster recovery surveys in the United States have revealed that:

- 92 percent of Internet businesses are not prepared for a computer system disaster (*IBM Survey of 226 Business Recovery Corporate Managers*).
- 82 percent of companies are not prepared to handle a computer system disaster (*Comdisco 1997 Vulnerability Index Research Report*).

These survey results indicate that a large number of executive management have failed to recognize that they had not adequately prepared their organizations for a disaster event.

Too often, maintenance of the business continuity plan (BCP) is an afterthought rather than an integral part of the risk management program. Management fails to recognize the need to build and fund the processes that will ensure that the BCP remains in a state of readiness.

The two issues that need to be addressed by management are:

- Processes for maintaining business continuity plans
- Resource funding/expenditures for business continuity

114.2 Processes for Maintaining the BCP

Business continuity plans are often reviewed only on an annual basis. This cyclical basis, while having merit, may place the organization in a position where its plan may be out-of-date because it has not been updated in response to changes in critical business processes. This will require the business continuity recovery team to make decisions on-the-fly, which increases the level of risk and hence jeopardizes recovery. The *Disaster Recovery Journal*regularly conducts "straw" surveys of visitors to its Web site (www.drj.com), asking them to vote on various questions. While the results of the survey are somewhat subjective, they do have some value as indicators of trends.

A survey conducted between June 14 and 20, 1999, asked the question: how often are your business continuity plans reviewed? The total number of respondents to the question was 1728. The results of the survey are shown in Exhibit 114.1. This is a good indication that organizations still have a strong tendency to use static processes (i.e., cyclical) to review their business continuity plans rather than build processes to ensure maintenance of up-to-date plans as changes occur.

114.2.1 Static and Dynamic Maintenance Reviews

114.2.1.1 Static Reviews

A static review is a cyclical maintenance process whereby the business continuity plan at a predetermined point in time is reviewed. An annual review is a typical example of a static review regime.

114.2.1.2 Dynamic Reviews

Dynamic maintenance review occurs when a strategic change occurs—for example, organizational restructure or integration of a new business. Exhibit 114.2 compares the frequency of the static and dynamic review processes for a BCP. It is critical that review processes be established and continually maintained to ensure that the BCP is in a state of readiness, rather than rely on static reviews to identify that the plan is not up to date. Ideally, a combination of three processes will ensure that the plan remains up to date:

- Maintenance
- Static reviews
- Dynamic reviews

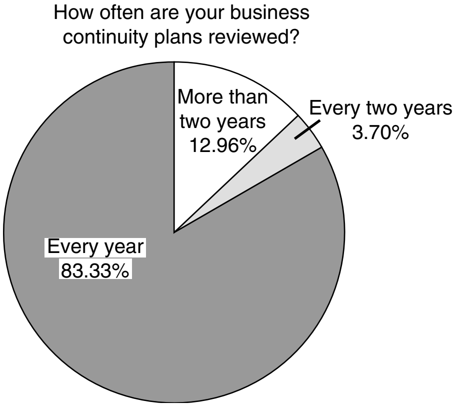

EXHIBIT 114.1 Frequency of the review of business continuity plans.

EXHIBIT 114.2 Business Continuity Plan Review Schedule

Business Continuity Plan Component	Static Review Cycle (Months)			Dynamic Review Events
	3	6	12	
Chapter 1. Introduction/Overview			X	Strategic changes
Chapter 2. Maintenance and Testing			X	Strategic and/or organizational changes, business process changes, information technology, service level agreements
Chapter 3. Plan Activation Procedures			X	Strategic and organizational changes, information technology
Chapter 4. Escalation Procedures			X	Strategic changes and business process changes
Chapter 5. Emergency Evacuation Procedures			X	Organizational and structural changes (e.g., buildings)
Chapter 6. Recovery Team Procedures		X		Strategic and organizational changes, business process changes
Contact Listing			X	Changes in personnel, emergency services, third-party service providers
Resource Listings				
Building Facilities		X		Organizational and structural changes; contractors, etc.
Information Technology		X		Software modifications and implementation; hardware changes, network changes; service level agreements
Personnel	X			Personnel changes or organizational changes
Third-Party Service Providers		X		Renewal of contracts, service level agreements

An understanding of the dynamics of the organization's operational processes is required to be able to identify the potential points of change. There are a number of key areas in which a change can occur. A maintenance process must be implemented to ensure detection of changes in any of the key areas.

114.2.2 Communications

The objective of maintaining the plan in a state of readiness is to provide assurance to the organization that, in the event of a disaster, critical business processes can be recovered in a timely manner. Without effective lines of communication between executive management and the business continuity manager, there is every likelihood that the plan will fail in the event of an actual disaster. The business continuity manager should have sufficient authority to ensure that he or she is informed of any changes arising from the implementation of management decisions (e.g., reorganization of management structure). This authority should be included in the organizational business continuity policy and regularly communicated throughout the organization. The corporate executive charged with the overall responsibility for business continuity (e.g., corporate governance, risk management) needs to be part of executive management and therefore part of the decision-making team. This ensures that organizational plans and decisions that may have a business continuity impact are communicated (the timing depends on the sensitivity of the information) to the business continuity manager. It also provides a safety net if the regular line of communication fails to inform the business continuity manager of proposed changes in operations that may have an impact on BCPs. Therefore, it is important that the line of communication is formalized and maintained to ensure that the flow of information that may have an impact on the organization's BCPs is received on a timely basis.

114.2.3 Corporate Planning

Many organizations today undertake the development of a corporate plan that provides a roadmap for the organization in the achievement of its strategic objectives. The corporate plan broadly details the organization's mission statement, strategic objectives, and strategies for a defined period (generally two to five years) with key performance indicators (KPIs) to measure their success or failure. As part of this planning process, the organization's business units develop business plans to support the organization in the achievement of its goals and objectives.

It is essential that processes be built and implemented that identify changes that may occur from the implementation of a new corporate plan, such as change in strategic direction by the organization may have an impact on the existing strategies of the BCPs (see Exhibit 114.3). Any change detailed in the new corporate plan needs to be analyzed to determine if these changes will have an impact on the existing plans or increase the level of risks associated with these plans.

114.2.3.1 Impact Analysis

An impact analysis is to be performed to identify and quantify the impact of the implementation of corporate strategies detailed in the corporate plan on the existing business continuity strategies. This is essential because the business continuity strategies are the bases upon which the business continuity plan was built. The analysis should include an examination of the planned implementation and timing of the new corporate plan. A risk analysis methodology (e.g., Australian Standard AS4360: Risk Management) should to be utilized to ensure a consistent approach in performing the impact analysis. The organization's risk management department or insurers should be able to provide a methodology to assist in performing the impact analysis. Strategic changes emanating from the corporate plan that can be identified by performing an impact analysis include:

- Development of new products or offering of new services to customers
- Expansion of products or services delivery channels
- Relocation of the organization or business units to another city or state
- Vertical or horizontal (or a combination) integration through strategic acquisitions
- Changes in the IT environment (i.e., hardware/software platforms, outsourcing of part or whole of its IT operations, changing the data/invoice communications network topology)

The organizational unit responsible for maintaining the BCPs is to perform an impact analysis by reviewing the corporate plan and business unit plans on a regular basis. The analysis must identify and

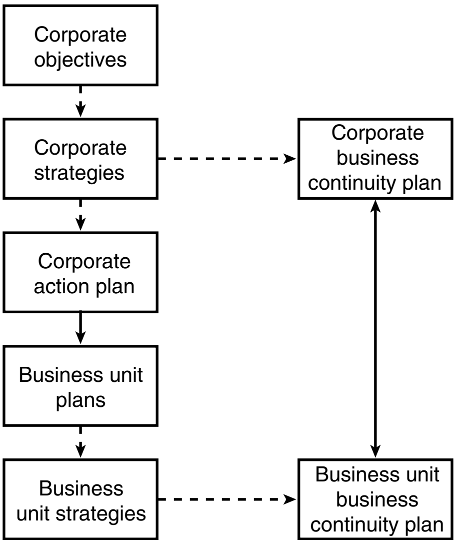

EXHIBIT 114.3 Corporate planning and business continuity planning.

assess the business continuity risks associated with the implementation of these strategic objectives—in particular, identification of any new risks that may not have been previously identified or previously considered in the development of the existing BCP. It may also require a re-rating of the existing risks applicable to the existing BCPs. The outcome of this impact analysis is a report to; the organization's executive management that provides an assessment of the impact the new corporate plan will have on the organization's business continuity plans. The report is to include an overall assessment of the risk and exposure with recommendations of how to mitigate these risks by changes to the BCPs to ensure that they will support the organization's strategic objectives.

114.2.4 Operational Impacts

One of the major threats to maintaining the organization's state of readiness is operational changes. Operational changes are those changes that occur outside the corporate planning process (referred to above). These changes can be structural in nature—that is, organizational, vertical, or horizontal. Such changes may occur due to:

- Reaction to changes in market dynamics (e.g., cost cutting, business process reengineering)
- Development or implementation of new lines of business
- Competitive acquisition
- Disposal of non-core business
- Recent developments in information technology (e.g., E-commerce)
- Outsourcing of services (e.g, information technology)

It is essential that an organization's ability to recover from a disaster not be compromised by the failure of business units to communicate operational changes. To ensure that this does not occur, the organizational policy for BCP must state the requirement that all changes that have a potential impact on the organization's BCPs must be communicated to the organizational unit that has responsibility for business continuity.

To support the policy, there must be processes that trigger the strategic maintenance review of business continuity as a result of changes. An example of such a process is the requirement that every project have business continuity as a project task item regardless of the type of project (e.g., construction, engineering, logistics, information technology restacking of buildings). This ensures that each project addresses business continuity during the planning process rather than as an afterthought.

From the planning process, the business unit that has responsibility for business continuity should:

- Analyze the project deliverables in terms of the planned changes (e.g., relocation of NT servers and supporting infrastructure).
- Evaluate the impact on the current BCPs, where applicable (e.g., the criticality of the applications installed on the servers).
- Determine the low-risk and low-cost business continuity strategies (where appropriate) and procedures to be included as a project deliverable. (As an example, there may have been no previous requirement for business continuity because the applications were considered not to be critical to the day-to-day operations of the organization; however, due to a relocation of servers to a centralized data center, an analysis of the applications may have indicated that applications had critically changed due to changes in business operations. Therefore, a hot-site business continuity strategy has been determined in consultation with the applications owners).
- Obtain management approval and funding for the implementation of the amended or new business continuity strategies and procedures.
- Develop an implementation plan (including training and testing) for the amended or new strategies and procedures.

- Implement the new strategies, and document the business continuity plan based on the strategy implemented.
- Identify and implement any applicable dynamic review points for the BCP to ensure that it remains in a state of readiness.

114.2.5 Physical Infrastructure

Changes to the organization's physical infrastructure, such as buildings and information technology, are often not considered as part of the maintenance process for business continuity plans. It is considered that changes or maintenance to the physical infrastructure do in fact have a major impact on the level of risk that had previously been assessed in the development of the organization's business continuity plans. Therefore, to minimize the likelihood of a disaster occurring, maintenance processes to identify potential risks are essential.

114.2.5.1 Internal Environment

Any proposed physical infrastructure changes must be communicated to ensure that potential risks to the existing BCPs can be assessed. For example, proposed changes to the layout of a floor (e.g., cabling, workstation setup, voice communications) due to restacking of the building to increase the floor occupancy density rate may have an impact on the strategy of an existing BCP. The floor in question may have been designated as the area for another business unit to occupy during a disaster event. The necessary infrastructure for successful execution of the BCP had been previously established. By implementing the restacking requirements, however, the business unit's business continuity strategy has now been compromised. The risk is that, in the event of a disaster, the business unit may not be able to gain access to its critical applications, access its voice communication, or call diversion setup arrangements—thereby either delaying or failing to recover in the event of a disaster.

Any proposed physical infrastructure changes must be communicated via processes previously detailed in the section entitled "Operational Impacts."

Maintenance of the physical infrastructure environment is critical to minimize the likelihood of a disaster. Maintenance should include:

- Air-conditioning systems
- Fire detection and prevention systems
- Security systems
- Electrical systems (including lightning rods)
- Water systems
- Information technology (including voice and data communications)

Although considered by many to be outside the control of the business unit responsible for the organization's BCPs, a strong maintenance regime is essential to minimize the likelihood and recovery of a disaster event.

114.2.5.2 External Environment

Changes to the external physical environment may introduce a risk that was not previously applicable. For example, the flood rating of a region where an organization has a manufacturing plant had been assessed by the local authorities as 1:200 years; however, an upgrade of major highway near the manufacturing plant had caused the diversion of water to be channeled into local creeks. As a direct result, the flood rating was reassessed by local authorities and upgraded to 1:50 years. Without having maintenance processes in place (i.e., the local authorities advising of the change in flood rating), this would not have been detected by the business continuity manager. To minimize the impact of possible flooding, the organization constructed a levy with local flora (the local authorities called it a gardening mound) surrounding the manufacturing plant to a height of 1 meter. Approximately 18 months later, a flood occurred. Without construction of the levy, the manufacturing plant would have been severely flooded, causing over $10M in damage.

114.2.6 Information Technology

For many organizations, information technology is the primary driver of their business. Therefore, a BCP for information technology—often referred to as a disaster recovery plan—is critical to ensure that the business can survive in the event of a disaster and continue to deliver products and services. Information technology BCPs are dependent on maintenance processes being developed and implemented as part of the system development life cycle (SDLC). Modern SDLC methodologies, and best practices for information technology (e.g., IT Infrastructure Library) include business continuity or disaster recovery as a task item to be addressed as part of the development, enhancement, maintenance, and acquisition phases of a system. To provide assurance that business continuity has been addressed as part of the SDLC processes, the business unit responsible for business continuity must sign-off all SDLC projects. This means that the project or task scoping document and engagement plan must be forwarded to the business continuity manager. The business continuity manager needs to determine if there is a business continuity issue for the project or task being planned.

114.2.6.1 Example

- *Business continuity deliverable*—An NT server with an HP Optical Storage Unit (often referred to as a Jukebox) with 64 CD platters within 24 hours of a disaster declaration with full connectivity to the organization's WAN–ATM network.
- *Change requirement*—Due to continued growth in the business, the imaging capacity of the Jukebox has increased to a level where within six months there is insufficient capacity to meet production requirements.
- *Solution*—Upgrade the Jukebox from 2.6-Gbyte drives to 5.2-Gbyte drives and increase the number of CD platters from 64 to 128.
- *Risk*—In the event of a disaster, there will be insufficient capacity to meet production requirements. The current business continuity capability meets only the current production requirements.

Without having the business continuity maintenance processes included in the SDLC, recovery and delivery of mission-critical information technology services and products may be in doubt.

114.2.7 Third-Party Service Providers

Today, outsourcing is popular because organizations recognize that information technology is not one of their core competencies. One reason for outsourcing is that organization's think they lack adequate infrastructure or resources and skills to develop BCPs for the delivery of information technology services and products. The belief that an organization can transfer the risk for business continuity as part of the outsourcing arrangement is wrong. The organization still owns the risk! In the event of a disaster, if the outsourcer fails to provide adequate business continuity, the contractual dispute will not help the organization recover; in fact, the organization may go out of business while waiting to resolve the contractual dispute through litigation. Business continuity requirements, including maintenance processes, must be included as part of the outsourcing contract. Periodically, the (information technology) outsourcer's business continuity maintenance processes must be audited to provide assurance that the organization's recovery from a disaster is not compromised.

114.3 Resource Funding/Expenditure for Business Continuity

Executive management's commitment and support for BCP extends beyond issuing a policy on BCP and funding its initial development. Management commitment and support must encompass development of the infrastructure for the implementation of the policy and ongoing maintenance of the plan, as well as the ongoing provision of critical resources (financial and human). Investing in BCP is a difficult decision for any organization. The questions to be answered are:

- Who should fund BCP?
- How much should be invested?

The three major ways to fund BCP for an organization are:

- Corporate funding
- Business unit funding
- Information technology funding

114.3.1 Corporate Funding

For many organizations, the funding decision is very simple. Because business continuity is viewed as an organizational responsibility and is part of the cost of being in business, funding is provided at the corporate level. The benefit of this strategy is that business continuity will have a strong and continuous commitment from executive management. Further, the organization's executive management has carried out its fiduciary duties and in the event of a disaster would be protected from any legal action.

114.3.2 Business Unit Funding

Many organizations view business continuity funding as a business unit expense and therefore each business unit must fund the cost of its business continuity. The disadvantage of this strategy is that the business unit managers, who are often under pressure to control costs, will often target business continuity as a candidate for cost-cutting. In particular, business continuity is often eliminated because it is seen as an easy target. Such a decision, which in the short term may be cost effective, can expose the organization's management to criticism from third parties (e.g., shareholders, external auditor) and, in the event of a disaster, may expose executive management to legal action for failing to perform its fiduciary duties.

114.3.3 Information Technology Funding

A number of organizations view business continuity as an information technology (IT) issue, rather than a corporate or business unit issue; therefore, funding is provided through the IT department budget. The advantage of this approach is that IT departments historically have a good understanding of the need to have a BCP. The disadvantage of this approach is that it focuses only on the IT dependency of the organization and not other critical business processes and dependencies other than IT. The *Disaster Recovery Journal*survey conducted between October 11 and 17, 1999, posed the question: "How are contingency costs funded?" The total number of respondents to the question was 1547, and the results of the survey are shown in Exhibit 114.4. Survey results indicate that the major source of funding is still with the IT department. Organizations have realized that it is no longer an IT issue; therefore, one is starting to see funding being evenly distributed between both the corporate and business units.

114.3.4 BCP Investment

Determining how much the organization should invest in business continuity is difficult; however, one of the outcomes of a business impact assessment (see Exhibit 114.5) provides the organization with an

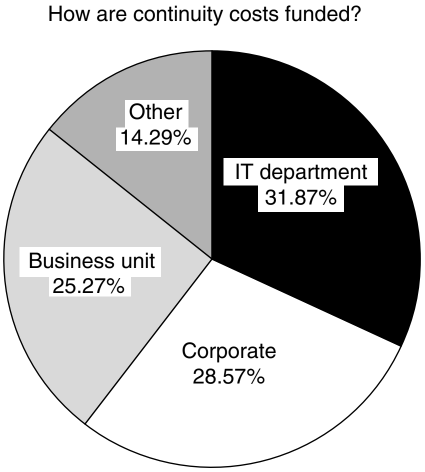

EXHIBIT 114.4 Continuity cost funding.

indication of the financial impact if a disaster did strike the organization. Therefore, the organization needs to determine how much it is prepared to spend to minimize this financial impact. In other words, how much insurance will it take out? Management has asked the question, "How much are other organizations spending on business continuity?" To answer this question, one needs to benchmark how much other organizations are spending; however, there are many variables in measuring the expenditure, for example:

- Industry
- Size of organization
- Total revenue
- Number of employees
- Number of organizational divisions, business units, departments, sections
- Location
- Range and distribution of products and services

EXHIBIT 114.5 Business Impact Assessment

Identify the impacts resulting from disruptions and disaster scenarios that can affect the organization and techniques that can be used to quantify and qualify such impacts. Establish critical functions, their recovery priorities, and interdependencies so that recovery time objectives can be set

The professional's role is to:

1. Identify organization functions
2. Identify knowledgeable and credible functional area representatives
3. Identify and define criticality criteria
4. Present criteria to management for approval
5. Coordinate analysis
6. Identify interdependencies
7. Define recovery objectives and time frames, including recovery times, expected losses, and priorities
8. Identify information requirements
9. Identify resource requirements
10. Define report format
11. Prepare and present

Source: From Disaster Recovery Institute International's Professional Practices, www.dr.org.

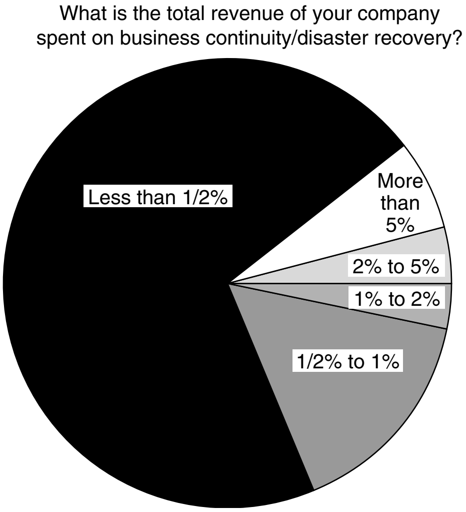

EXHIBIT 114.6 Total revenue spent on business continuity/disaster recovery.

Research conducted by the Gartner Group (Determinants of Business Continuity Expenditure—Research Note March 21, 1996) found that, "On average, data centers spend around 2 percent of their budget on disaster recovery." Gartner further stated that the move away from centralized processing has meant "that the proportion of total IT expenditure dedicated to recovery-related matters is already below the reported average." This suggests that organizations have not recognized that there are still risks in a decentralized (client-server) versus centralized processing (i.e., mainframe) environment. This is of particular relevance because many organizations today conduct a large portion of their business through E-commerce.

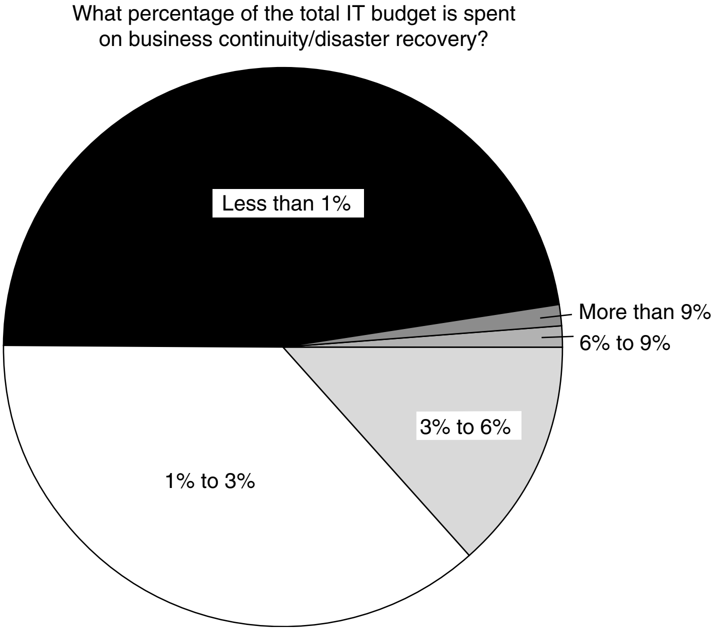

EXHIBIT 114.7 IT budget spent on business continuity/disaster recovery.

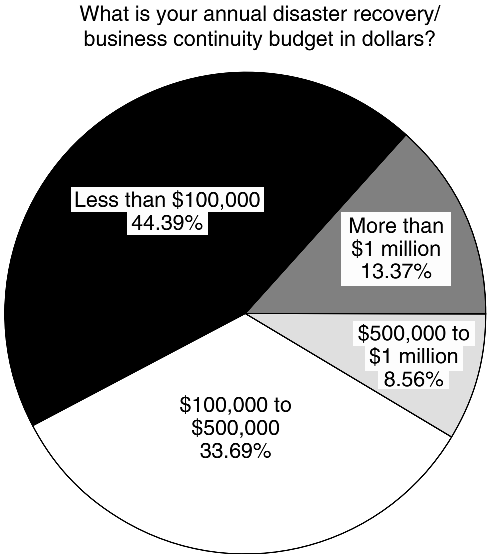

EXHIBIT 114.8 Annual disaster recovery/business continuity budget.

More recently, the *Disaster Recovery Journal*conducted a number of surveys regarding the expenditure of business continuity/disaster recovery:

What percent of your company's total revenue is spent on BC/DR?
This survey was conducted between June 28 and July 4, 1999. The total number of respondents to this question was 2091. The results of that survey are displayed in Exhibit 114.6.

What percent of your company's total IT budget is spent on BC/DR?
This survey was conducted between July 5 and July 11, 1999. The total number of respondents to this question was 1501. The results of that survey are shown in Exhibit 114.7.

What is your annual BC/DR budget in dollars?
This survey was conducted between September 6 and September 19, 1999. The total number of respondents to this question was 3179. The results of that survey are displayed in Exhibit 114.8.

The results of the surveys indicate that there has been no *major* increase in expenditures by organizations on business continuity. This result is surprising when one considers that in the last few years organizations have dramatically changed the way they conduct business, in particular EDI and E-commerce. The surveys also indicate that funding for business continuity is slowly moving away from the historical champion of business continuity, the IT department. Responsibility is now being shared equally among the corporate and business process owners.

114.4 Conclusion

Executive management must recognize that the maintenance of business continuity plans is an integral part of the organization's risk management program. Further, they should ensure that the business continuity maintenance processes are built into the change management process of the organization (e.g., system development, building maintenance programs, corporate planning). This will ensure that appropriate action is taken in a timely manner to maintain the plan in a state of readiness. Management will only recognize its investment in business continuity in the event of a disaster.

115

Identifying Critical Business Functions

Bonnie A. Goins

115.1 Introduction

Important to the proper implementation of a security strategy within an organization is its alignment to that organization's business objectives. Performing security activities for technology's sake does nothing to protect, or assure, those components that fall outside the purview of technical security. At a high level, people, processes, facilities, and, arguably, data typically fall outside of technical security inspection. It is clear that security, as a process itself, must consider these inputs in order to provide a comprehensive view of protection for the organization. Equally important to achieving a balanced security program is the understanding that an organization will not protect all of its assets equally; that is, aspects of the organization necessary to the continued fulfillment of the organization's business goals must take precedence over those activities or inputs that are not essential to the organization's survival. This notion is crucial to the concept of controls within the organization; resources used to protect the environment should first be allocated to those aspects of the organization that are essential for the continued operation of the business. The organization may also decide to protect aspects of its organization that are not critical to continued operation; however, it is customary for organizations to allocate fewer resources to accomplish this objective. This scenario concurs with the industry view that critical assets and functions require greater protection than noncritical assets and functions.

115.2 What Is a Critical Function?

The *Disaster Recovery Journal* formally identifies critical functions as "business activities or information that could not be interrupted or unavailable for several business days without significantly jeopardizing operation of the organization." Before an organization can begin to identify business functions that are essential to its survival, it must understand the difference between *criticality* and *sensitivity.* Criticality relates to the importance of the asset or function in enabling the organization to operate and protect itself, and sensitivity relates to the classification of the data and systems existing within the organization.

Let's look at an example of each of these definitions. The National Security Agency's INFOSEC Assessment Methodology (NSA IAM) takes as one of its principle tenets the concept of criticality; it does so for the very reason mentioned above. Assessment of the organization's security state revolves around its definition of criticality. Senior executives are asked to identify one to ten activities that, if not performed, would cause the organization to cease to operate its core business. Many senior executives struggle with this preassessment identification because they often cannot immediately separate essential from nonessential business functions.

The concept of sensitivity is central to many regulated environments. Organizations bound by legislation, such as the Health Insurance Portability and Accountability Act of 1996 (HIPAA), are guided to review their electronic data assets to determine whether those data are identified by the legislation as being central to meeting compliance objectives. In the case of HIPAA, electronic protected health information (ePHI) is identified as a sensitive data element that requires the highest level of protection. Organizations covered by this legislation (covered entities, or CEs) face stiff fines, sanctions, potential lawsuits, and even jail time for maliciously divulging this information or for failing to promote duly diligent (reasonable and appropriate) security measures within the organization.

A reader who has considered these examples carefully might be asking whether it is possible to have a business function that could be considered both critical and sensitive. If so, congratulations! Business functions that are essential to the organization's continued operations and those that process, transmit, or store sensitive data are considered to be critical *and* sensitive business functions. An example of a critical and sensitive business function is a healthcare insurer's claim processing function. Processing claims is central to a healthcare insurer's business function; as such, the claims function is critical to the organization's continued operation. Further, because a healthcare insurer is a payer, it is obliged to meet the compliance objectives contained in the HIPAA legislation; hence, the data it processes, stores, and transmits during the claims function is considered sensitive, making the function itself sensitive.

115.3 Where Do I Begin To Identify Critical Business Functions?

A good place to begin identification of critical business functions is within the organization's business units. One caveat is that each business unit is likely to view its business functions as being most critical to the organization. This is contrary to the fact that senior executives determine the criticality of business functions within their organizations. As such, it is important for senior executives to review and "rightsize" business unit expectations regarding the priority of their critical functions so they fit properly within the context of the entire organization. Working with business units can sometimes be a challenge for the security professional. Business units may be unfamiliar with the task at hand and, as such, require some coaching in order to complete the effort. Also difficult for most organizations is determination of the appropriate level of detail for describing each critical business function. Many times it is easier for the business units to identify each of their business functions, regardless of criticality, and then to prioritize the functions based on criteria that align them with their importance to the organization.

In choosing this approach, the organization has produced a complete picture of its function that can be visually depicted through data flows and other graphical methods to produce a roadmap that shows the organization its workflow. This roadmap can also help to identify functions that are missing procedures, as well as procedures that are missing functions. In each case, the organization should then determine whether these functions or procedures are extraneous to the organization's operation. If so, they can be removed; if not, then an issue with the process exists, and the organization can now evaluate that issue. This identification and activity are at the center of the business process reengineering effort for organizations.

If interviewing the business units is the approach chosen to begin the critical function identification, the security professional can ask the business units particular questions that will help them to reach the appropriate determination of criticality to the organization. Examples of these questions are listed in Exhibit 115.1. Following is a discussion of the role of each question within the identification process.

EXHIBIT 115.1 Questions to Assist in Determining the Criticality of Business Functions

What business objective does this function support for your organization?

How often is this function performed?

Is this function performed only by your business unit, or is it also performed by other business units within your organization?

Does the successful completion of this function depend on interaction with other business units, vendors, business partners, or external organizations? Does another business unit, vendor, business partner, or external organization depend on this function for successful completion of its functions?

Is there a potential for loss of life or injury to personnel, business associates, or externals if this function is not carried out?

Is there a potential for significant dollar loss to the organization if this function is not carried out?

Is there a potential for significant fines, litigation, jail terms, or other punishment for noncompliance to a required regulatory requirement?

Is noncompliance tied to a specific threshold for downtime for this function?

Is noncompliance tied to a specific threshold for data loss or disclosure of sensitive information for this function?

Is this function carried out by key personnel within the business unit?

Are other personnel within the business unit or organization available and capable of performing the function in the absence of key personnel?

What priority would your organization give this function within the entire organization?

How can these questions assist with identifying critical functions within the organization? By asking the business units how their functions align to the organization's business goals, it is possible to classify any outliers (i.e., those functions that are performed in support of a function that is not critical to the organization's continued operations or are not critical to the continuing operation of the organization themselves) as noncritical business functions. These functions can still be prioritized but will not fall into the critical category.

Periodicity, or the frequency at which the function is performed, can also assist in determining whether a business function plays a role in continuing an organization's business operations. It is important to note, however, that periodicity by itself does not determine criticality of a business function. As an example, a staff member of a large financial services firm has many job functions that he performs daily. One of these job functions is to remind business unit managers to review the organization's proposed training classes and to weigh in on the selection. Although it is important to provide training to employees, training is often curtailed as a result of reallocation of resources in the event of a disaster. Doing so does not bring operations to an end but rather frees resources to accomplish other more critical tasks. The function the staff member plays (i.e., notification of the business unit managers) can be discontinued in the event of disaster with no ill effects; therefore, the function may be viewed as being low priority for continued operation of the organization.

The notion of interdependence is of extreme importance to an organization and its operational continuity. Business functions that appear to be noncritical may be identified by a business unit as critical; upon further examination, it may become apparent that critical business functions from other business units rely on input from this "noncritical" business function to perform satisfactorily! Taking a look at our previous example again, a staff member identified a business function as notification of business unit managers regarding training. We determined initially that the notification was low priority and related that assessment to the business goal of continuing operations for the organization. Let's take a deeper look, though. What if the notification involved relaying to the managers information on mandatory training for business continuity? If the business unit managers could not get that information from any other source in the organization, such notification from the staff member is now critical for ensuring that all personnel are trained in business continuity efforts. For most organizations, business continuity training is highly critical, especially in light of the lessons taught to us by September 11; therefore, any function that is key to promoting the business continuity effort may be considered to be critical.

Loss potential is another way to uncover criticality in an organization. Losses can typically be categorized as human, financial, informational, technological, or facility oriented. Any business function where the loss of life or an injury to an individual figures prominently if the function cannot be successfully completed must be considered to be critical. An example of such a function is the coordination of logistics in an army on the move. If logistics cannot be properly coordinated, troops can be placed in jeopardy.

Financial losses are frequently evaluated when determining criticality. The organization must determine for itself what the definition of "significant financial losses" really is. It is important to note that, many times, financial losses come as a result of an interaction of issues. In this case, this translates to the fact that the business functions involved must be evaluated very carefully to identify which are truly critical, if any, to the organization's operations.

Compliance to a regulated state can also pose challenges for identification of critical business functions. Most often, the challenge arises from the fact that legislation is not always prescriptive; that is, legislation is not always specific in detailing what is expected from the covered organization. HIPAA regulations are a good example of this. Implementation specifics are listed, but in an extremely broad context. The reasons cited for these broad strokes include consideration for the uniqueness of each organization and a desire to take into account the availability of resources at each organization. As such, organizations must fend for themselves, often by working together as a group or collaborative to interpret the law; the HIPAA Collaborative of Wisconsin is an example of this type of group. From their interpretation comes a recommendation for the work that is required to meet the legislation. Organizations can choose to follow the recommendations or to implement their own interpretations.

Most organizations bound by regulations come to view the regulations themselves as the critical business function and apply the policies and procedures that are derived from the regulation as satisfaction of the legislative requirement. Organizations must also take into account whether a violation of appropriate downtime, data loss, or disclosure of information will trigger a shift into noncompliance. Data gathered during the business impact assessment process can assist with providing a stated threshold within the organization that can then be compared to the stated goals of the legislation. Gaps between the organization's stated threshold and the stated goals of the legislation point to an area for remediation (i.e., correction) for the organization, if it is to maintain a state of compliance.

What is the possibility for an organization to continue operations if its key (read critical) personnel are no longer available to perform their job functions? If no surrogate, or back-up, resources are available who can perform these critical functions in the absence of primary or key personnel, then it is likely that continued operations will be extremely difficult and haphazard, at best. It is extremely important for an organization to identify individuals key to its function. When a business unit manager is asked for his or her key personnel, typically the answer that is given corresponds to the set of activities (or business functions) he or she performs. This assists the security professional in identifying two critical elements in one round of questioning; the business unit's critical functions and the personnel responsible for carrying them out.

Although it is often the case that the business units within an organization view their functions as being of the highest priority to the organization, it is still worth the time to ask the business units where they think their business functions fall with regard to priority within the organization as a whole. In some cases, the request for the business units to look at the bigger picture may yield unexpected results. In the case where an organization's personnel has longevity and the organization is supportive of promotions, lateral moves to different business units, and job sharing, personnel may indeed have a deeper perspective of how the organization functions as a whole. Because experience brings so much to the table in this endeavor, it is advisable to at least make the effort to inquire.

115.4 Functions *versus* Procedures

As we stated above, ultimately senior executives are responsible for identifying their organization's critical business functions. Often, these functions are further elaborated in an organization's business plan and reports to the organization's board of directors, stockholders, and employees. Some organizations do not document their critical functions as such, but rather identify core competencies. This can be workable if senior executives can identify how those core competencies are broken into functions and are represented by workflow in the organization. If the senior executives are not successful at doing this, then the core competency identification is at too high a level to be productive for this identification of critical business functions within the organization.

Many organizations also confuse business functions with functional procedures. It is often useful to view the business functions as the "what," or a set of procedures which themselves are the "how" with respect to implementing the business function. The combination of these interact to complete a business objective, when combined with appropriate policies. Sometimes, we see that the relationship of a critical function to a procedure is one to one; that is, one procedure can elaborate an entire business function.

Many times, however, we see that the correspondence between a business function and its corresponding procedures is one to many; that is, more than one procedure elaborates a business function. Consider the example of an information technology department. One of its stated critical business functions is to build appropriate architecture to support the business processes that drive the organization. An organization's technology architecture consists of several layers: network devices, such as routers, switches, and firewalls; network servers (perhaps with different operating system needs); application systems; and end-user systems. This is a very simplistic view of architectural needs, but it demonstrates the notion of multiple procedures for one business function. Clearly, the procedure for building a firewall, with its complex set of rules, is not the same procedure an organization would use for building an application server of any kind. Exhibit 115.2 depicts the hierarchy of business functions, procedures, and individual responsibilities, or accountability, for completion of the procedures.

It is important to note that the detail to which unique organizations define and elaborate business functions may vary; that is, some organizations are much more specific in defining their business functions. A good example of this difference can often be seen at organizations that are being held to compliance, or regulatory, requirements. For example, senior executives at publicly held companies are now obligated to attest to the accuracy of their financial reporting. Along with this requirement comes the requirement to fully document the financial reporting environment. For this reason, many

organizations choose to upgrade their businesses' functional definitions to more easily comply with the legislation. For more information on elaboration of business functions with regard to such legislation, see discussions regarding the Sarbanes–Oxley Act elsewhere in this book.

115.5 Conclusion

Although identification of critical business functions may be, at times, difficult, certain practices can assist the security professional with completion of this important activity. Constructing an appropriate data gathering instrument, such as a business impact assessment questionnaire, is a first step (see Exhibit 115.3). When this data has been gathered, analysis of the important elements—maximum downtime; maximum allowable data loss; cost to the organization; resumption and recovery time objectives; key infrastructure, applications, and personnel; and others—will provide the information necessary to identify activities that can keep an organization operational, even into times of need.

Selecting the Right Business Continuity Strategy

Ken Doughty

116.1 Introduction

The first step in developing a customized business continuity plan (BCP) is to conduct a business impact assessment. This comprehensive risk evaluation and business impact assessment (BIA) will identify the organization's core business processes and their critical dependencies. Because the organization's recovery strategy must be based on the recovery of the core business processes and their critical dependencies, the strategy ultimately selected may be two-tiered:

- *Technical*—desktop, client/server, midrange, mainframes, data and voice networks, third-party providers
- *Business*—logistics, accounting, human resources, etc.

When the organization's executive management has signed off on the BIA report and endorsed the recovery of the recommended core business processes and the priority of recovery, BCP recovery strategies must be developed for each business process. Ideally, all business units should participate in the development of these BCP recovery strategies. As experienced staff in the business unit's understands their business processes, they should be approached to suggest recovery strategies. A recovery strategy work-shop is an ideal forum to develop the BCP recovery strategy with input from the business units. This will ensure that there is ownership of the BCP strategy and the "plan" by the business units.

116.2 Recovery Strategy Workshop

The purpose of the recovery strategy workshop is to identify appropriate recovery strategies for each core business process and the risks associated with each strategy. Of particular interest are recovery strategies that are low risk and cost effective. Too often, there is a greater emphasis on cost and benefits without consideration given to the risks associated with the recovery strategy. The BCP coordinator (i.e., the person responsible for developing, implementing, and maintaining the organization's BCP) must select the right recovery strategy and must also minimize the risks associated with that strategy. The BCP coordinator should be the workshop facilitator because he or she has a deep knowledge of business continuity planning and risk management training, as well as a good understanding of the organization's strategic objectives and processes. Business unit attendees should have a good working knowledge of their business processes.

116.2.1 Recovery Strategies

During the workshop, the BCP coordinator will assist the business unit staff in identifying BCP recovery strategies for each core business process. It is not unusual to find that the initial recovery strategy suggested by the workshop attendees is high risk and not cost effective. As a case study, take a look at the banking sector and one of its core business processes, that of processing customer checks and exchanging checks with other banking institutions. At the workshop, attendees would identify a number of BCP recovery strategies for processing checks; for example:

- Have a service level agreement with another bank to process all work.
- Branch network processes all credits and service level agreements with another bank to complete check processing and exchange checks.
- Branch network to processes all credits and forwards all checks to an intrastate/interstate center for final processing and check exchange.
- Forward all work to an intrastate/interstate center for processing.
- Do nothing.

116.2.2 Strategy Risks

To continue this case study for the core business process of processing checks, the workshop attendees (with the assistance of the BCP coordinator) would identify a range of recovery risks that may be applicable (see Exhibit 116.1).

EXHIBIT 116.1 Recovery Risks

No.	Risk Description
1	Damage to the bank's brand (i.e., reputation)
2	Customer impact—financial and service
3	External service level agreement (SLA) partner not compliant with agreement
4	Holdover (delayed processing)
5	Timeframe lag
6	Funding of recovery
7	Resource shortage—staff
8	Resource shortage—skills
9	Resource shortage—equipment
10	Resource shortage—stationery/stores
11	Internal coordination
12	External coordination
13	Logistics (e.g., transportation of staff, work)
14	Employee's union
15	Legislative requirements
16	Third-party suppliers (non-provision of services)
17	Denial of access to alternative processing sites
18	Internal/external communications
19	Incompatible information technology
20	Internal SLA partner not compliant with agreement
21	Physical security over source documents

116.2.3 Assessing Risks

The BCP coordinator, with assistance from the workshop attendees and utilizing the BCP recovery strategy risks (as per Exhibit 116.1) and a risk assessment methodology (e.g., AS4360 Risk Management; refer to Exhibit 116.2), assesses each recovery strategy and the associated risks. A risk assessment matrix is then applied for likelihood and consequences to derive a risk score.

Each recovery strategy score is then risk ranked to provide an indication of the level of risk associated with each recovery strategy (refer to Exhibit 116.3). The BCP recovery strategy that offers the lowest levels of risk in execution and the greatest opportunity of success will be costed.

116.3 Recovery Strategy Costs

The two levels of costs are pre-event and event costs. Pre-event costs are incurred in either implementing risk mitigation strategies or allocating of resources (including human and financial) and capital expenditure to developing the necessary infrastructure for the BCP recovery strategy. These costs may include, for example:

- *Information technology*
- Hot site—Fully operational computer center, including data and voice communications
- Alternate LAN server—LAN server fully configured, ready to be shipped and installed at the same site or alternate site

EXHIBIT 116.2 Risk Management Methodology

Descriptor	Meaning
Likelihood of Event Table	
Almost	Certain the event is expected to occur in most circumstances
Likely	The event will probably occur in most circumstances
Moderate	The event should occur at some time
Unlikely	The event could occur at some time
Rare	The event may occur only in exceptional circumstances
Consequences of Event Table	
Catastrophic	Complete disaster with potential to collapse activity
Major	Event that, with substantial management, will be endured
Moderate	Event that, with appropriate process, can be managed
Minor	Consequences can be readily absorbed; however, management effort is required to minimize impact

Risk Assessment Matrix

	Likelihood					
Consequences	Almost Certain	Likely	Moderate	Unlikely	Rare	Irrelevant
Catastrophic	High	High	High	High	Significant	N/A
Major	High	High	High	Significant	Significant	N/A
Moderate	High	Significant	Significant	Moderate	Moderate	N/A
Minor	Significant	Significant	Moderate	Low	Low	N/A

What the risk value meanings are:

High	High risk—detailed research and management planning required at high levels
Significant	Significant risk—senior management attention needed
Moderate	Moderate risk—specific risk management processes must be developed
Low	Low risk—can be managed by routine procedures

	11. Stationery/stores	Significant
	12, AOCA requirements	Moderate
	13. Denial of access to alternative premises	Moderate
	14. Internal/external communications	
BCP Strategy 5		
Do nothing	Not considered, as it is unrealistic	N/A

- Physical separation of telecommunications network devices (previously centralized) to reduce the likelihood of a single point of failure
- Establishment of service level agreements with BCP recovery company (i.e., hot, warm, or cold sites and mobile).
- Duplication of telecommunications network (e.g., another telecommunication carrier, switching capability)
- Creation of a full-time BCP team that is responsible for maintaining and testing the organization's technical BCP
- *Equipment*. The purchase and maintenance of redundant equipment at an alternative site (e.g., microfilm readers, proof machines, image processors), particularly if there is a long lead time to source and procure equipment.
- *Third-party service providers*. Third-party service providers are requested to develop a BCP requirement to meet organizational (customer) requirements. Some proportion of this cost may be borne by the organization requesting that this functionality or facility be provided.
- *Dependency on third-party service providers for business continuity purposes*. This is a major concern to BCP coordinators. When third-party service providers have been identified as critical to the day-to-day operations of the business, BCP coordinators are to seek assurance that these service providers have a demonstrable BCP in the event of disaster striking their organization.
- *Service level agreements (SLAs)*. The costs associated with external suppliers readily providing services or products (non-IT) in the event of a disaster.
- *Vital records*. A vital record program that identifies all critical records required for post-recovery core business processes. Costs may be incurred in the protection of these records (e.g., imaging, offsite storage) to ensure that they will be available in the event of a disaster.

Event costs are incurred in implementing the BCP strategies in the event of a disaster. The costs are an estimation of the likely costs that would be incurred if the BCP were activated for a defined period (e.g., 1 day, 7 days, 14 days, 21 days, 30 days). These costs would include, but are not limited to:

- Activation of SLA—Often a once up cost plus ongoing costs until services or products are no longer required (cessation of disaster)
- Staffing (e.g., overtime, temporary, contractors)
- Logistics (e.g., transportation of staff and resources, couriers)
- Accommodation costs (e.g., hire/lease of temporary offices, accommodations for staff and other personnel)
- Hire/lease or procurement of non-IT resources (e.g., desks, chairs, tables, safes, cabinets, photocopiers, stationery)
- Hire/lease or procurement of IT resources (e.g., faxes, handsets, printers, desktop PCs, notebook computers, terminals, scanners)
- Miscellaneous costs (e.g., insurance deductible, security and salvage of assets at disaster site, cleanup of disaster site, emergency services costs)

The BCP coordinator is to determine that all pre-event and event costs have been included and are reasonably accurate. Ideally, the BCP coordinator should request an independent party (for example, the organizations' audit department) to review the cost components and value to ensure they are all complete and accurate.

116.4 Recovery Strategy Risks *versus* Costs

Once the costs (pre-event and event) have been determined, an analysis of the recovery strategy risks *versus* costs is to be performed. The objective of this analysis is to select the appropriate recovery strategy, which is balanced against risk and cost. For example, using the case study above, the recovery strategies that offer the lowest risks for implementation are:

- *Strategy 2*. Branch network processes all credits and SLAs with another bank to complete check processing and exchange checks.
- *Strategy 3*. Branch network processes all credits and forwards all checks to an intrastate/interstate center for final processing and check exchange.

An analysis of Exhibit 116.4 indicates the following:

- Strategy 2
  - Highest risk of the two strategies being considered for implementation
  - Pre-event cost of $150,000 per annum for the service level agreement
  - Lowest event cost of the two strategies of $730,000

EXHIBIT 116.4 Costs of Two Strategies

		Accumulative Event Costs					
BCP Strategy	Pre-Event Costs	1 Day	1 Week	2 Weeks	3 Weeks	4 Weeks	Total Costs
Strategy 2	$150K per annum	$75K	$255K	$375K	$515K	$730K	$880K
Strategy 3	Nil	$150K	$415K	$875K	$1.2M	$3.2M	$3.2M

- Strategy 3
  - Lowest risk of the two strategies being considered for implementation
  - No pre-event costs
  - Highest event cost of the two strategies by $3.2 million
  - The longer the outage lasts, the greater the increase in event costs

The decision to be made is whether the organization is prepared to accept higher risks with lower event costs or a lower risk strategy with higher event costs. In other words, it is a trade-off between risks the organization is prepared to accept and the costs the organization is prepared to spend. However, where two strategies are of equal risk and similar cost value, then a third element is brought into the evaluation process—benefits. The benefits, including tangible and intangible, for each strategy are to be evaluated against the risks associated with the recovery strategy. Further, the benefits are to be considered in the short and long term with regard to the added value to the organization operating in a dynamic and competitive market.

116.5 Summary

Organizations who undertake business continuity planning often do not take the time to analyze the risks associated with a selected BCP recovery strategy, to determine if it is low risk and the cost of implementation is acceptable. The BCP coordinator's role is enhanced by ensuring that the right BCP recovery strategies are selected for the organization. The reality is that in the event of a disaster, selecting the wrong strategy may actually exacerbate the disaster. This potentially may lead to the organization going out of business. However, by performing a risk *versus* cost analysis of the BCP strategies, the BCP coordinator will reduce the potential exposures the organization will face in the execution of the business continuity plan (i.e., implementation of the recovery strategy) and strengthening the recovery process.

117

Contingency Planning Best Practices and Program Maturity

Timothy R. Stacey

117.1 Introduction

117.1.1 Disaster Recovery Planning

Disaster recovery planning is the process that identifies all activities that will be performed by all participating personnel to respond to a disaster and recover an organization’s IT infrastructure to normal support levels. The recovery process is typically addressed as a series of phases that include the *response phase* (including emergency response, damage assessment, and damage mitigation); the *recovery phase* (instructions on migration to a temporary alternate site); the *resumption phase* (instructions on transitioning to “normal” IT service levels from the temporary alternate site[s]); and the *restoration phase* (instructions on migration back to the original site or to a new, permanent location).

The Disaster Recovery Plan (DRP) identifies all corporate personnel responsible for participating in the recovery. The plan typically groups these individuals into recovery teams such as: Initial Response Team, Communications Support Team, Operating Systems Support Team, Applications Support Team, Administrative Support Team, etc. Team roles and responsibilities are detailed, inter-team dependencies are identified, and the team steps are coordinated and synchronized. The DRP is a stand-alone document. Hence, the document fully identifies all equipment, personnel, vendors, external support organizations, utilities, service providers, etc. that may be involved in the recovery. The plan will define the organization's recovery policy and contain all procedures and detailed equipment recovery scripts, written to a level sufficient to achieve a successful recovery by technically competent IT personnel and outside contractors. The plan will also define its test and maintenance process. In short, the DRP is a stand-alone collection of documents that define the entire recovery process for the organization's IT infrastructure.

117.1.2 Disaster Recovery Solutions

Some sample recovery solutions that might be explored during a disaster recovery planning requirements definition phase are listed below. Estimated recovery timeframes are given but may vary due to a number of factors (e.g., system and resource requirements, type of disaster, accessibility of the recovery site, etc.). Additionally, a potential recovery solution can be derived from a hybrid of any of the following solutions.

117.1.2.1 Time-of-Disaster

The time-of-disaster recovery solution involves creating a detailed system "blueprint" and the recovery procedures necessary to enable the acquiring and replacement of the computing systems. Neither communications nor computing equipment or resources are acquired or reserved before an emergency occurs. Rather, all resources are procured at time of disaster. The recovery procedures address procurement of facilities, equipment, and supplies, and the rebuilding of the information technology infrastructure. This is typically the least expensive recovery solution to implement and maintain; however, recovery can require up to 30 to 45 days.

117.1.2.2 Reservation of Vendor Equipment for Shipment at Time of Disaster

This recovery solution involves the reservation of equipment from third-party vendors and the prearranged shipment of these systems to a company's "cold site" following a disaster. The recovery time period may vary anywhere from 48 hours to a few weeks (typically several days).

117.1.2.3 Disaster Recovery Vendor Facilities

This recovery solution takes advantage of third-party recovery facilities, providing additional assurance for rapid, successful recovery. Through the coupling of subscriptions with disaster declaration fees, this method offers a way of sharing the costs of disaster recovery preparation among many users. This type of assurance typically provides a greater statistical probability of successful recovery within the targeted 48-hour recovery period. However, it suffers from the potential that several subscribers may declare a disaster at the same time and contend for resources.

117.1.2.4 Online Redundant Systems

This recovery solution entails the provisioning of remote redundant computing systems that are continuously updated to ensure that they stay synchronized with their production counterparts. High-speed lines to connect the production and remote recovery sites are necessary to ensure near-mirror-image copies of the data. Recovery can be accomplished within minutes or hours utilizing the online redundant systems solution. Obviously, due to the possibly exorbitant cost of these types of recovery solutions, a thorough analysis of the recovery time requirements must be performed to justify the expenditure.

117.1.3 Business Continuity Planning

Business continuity planning identifies all activities that must be accomplished to enable an organization or business functional area to continue business and business support functions during a time of disaster. While a DRP identifies the IT assets and concentrates on recovery of the IT infrastructure, the Business Continuity Plan (BCP) concentrates on maintaining or performing business when the IT assets are unavailable or the physical plant is inaccessible. The BCP recovery process will be synchronized to the recovery process identified in the DRP. Thus, the BCP is an extension of the DRP process. The BCP will identify all equipment, processes, personnel, and services required to keep essential business functions operating, and it will describe the process required to transition business back on to the recovered IT infrastructure and systems.

117.1.4 Contingency Planning Process

The Disaster Recovery Institute International (DRII),[1] associates eight tasks to the contingency planning process:

1. *Business impact analysis*: the analysis of the critical business function operations, identifying the impact of an outage with the development of time-to-recover requirements. This process identifies all dependencies, including IT infrastructure, software applications, equipment, and other business functions.
2. *Risk assessment*: the assessment of the current threat population, the identification of risks to the current IT infrastructure, and the incorporation of safeguards to reduce the likelihood and impact of potential incidents.
3. *Recovery strategy identification*: the development of disaster scenarios and identification of the spectrum of recovery strategies suitable for restoration to normal operations.
4. *Recovery strategy selection*: the selection of an appropriate recovery strategy(ies) based on the perceived threats and the time-to-recover requirements and impact/loss expectancies previously identified.
5. *Contingency plan development*: the documentation of the processes, equipment, and facilities required to restore the IT assets (DRP) and maintain and recover the business (BCP).
6. *User training*: the training program developed to enable all affected users to perform their tasks identified in the contingency plan.
7. *Plan verification*: the testing and exercising of the plan to verify its correctness and adequacy.
8. *Plan maintenance*: the continued modification of the plan coupled with plan verification and training performed either periodically or based on changes to the IT infrastructure or business needs.

The DRII describes the contingency planning project as a process similar to the classical “Waterfall” model of software/system development, namely Requirements Analysis, Design, Implementation, Testing and Maintenance. Exhibit 117.1, the contingency plan development project plan, illustrates the allocation of the detailed contingency planning-related tasks to the typical project phases.

The DRII goes on to describe the contingency planning life cycle as a continuous process. For example, once an initial disaster recovery plan has been developed, the plan should be made to remain “evergreen” through a periodic review process. The DRII recommends review and maintenance on an annual basis (or upon significant change to the system architecture or organization). Exhibit 117.2, the contingency plan maintenance life cycle, illustrates the tasks that should be addressed in the verification and continued improvement of the contingency plans over time.

117.1.5 Industry Best Practices

117.1.5.1 Requirements Analysis

The discussion of “best practice” as it relates to continuity planning is similar to that of determining the “best quality” of an item. Just as the true quality of an item can only be evaluated based on the item’s intended use rather than on its “luxuriousness,” the best practice in contingency planning is determined in the context of the business’ recovery needs. The recovery strategy and the level of planning and documentation should be designed to meet (rather than exceed) those needs. An adequate recovery

[1] The Disaster Recovery Institute International is the industry-recognized international certifying body and it sponsors the Certified Business Continuity Professional (CBCP) certification. They can be found at http://www.DRII.org.

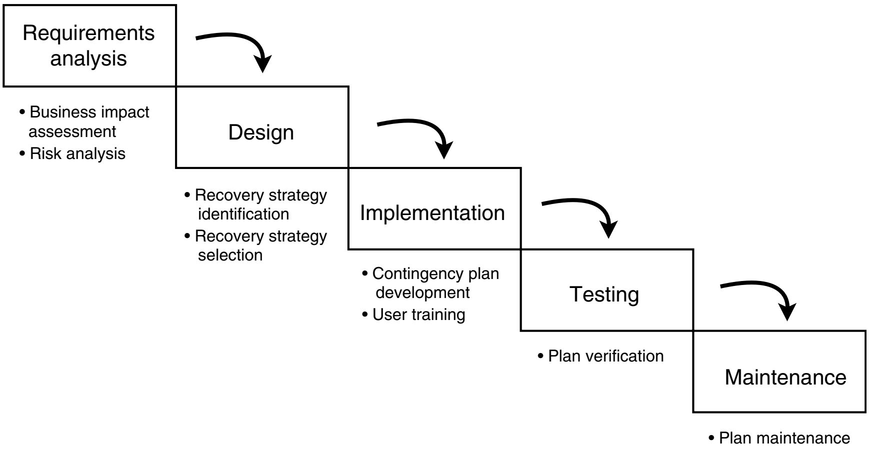

EXHIBIT 117.1 Contingency plan development project plan.

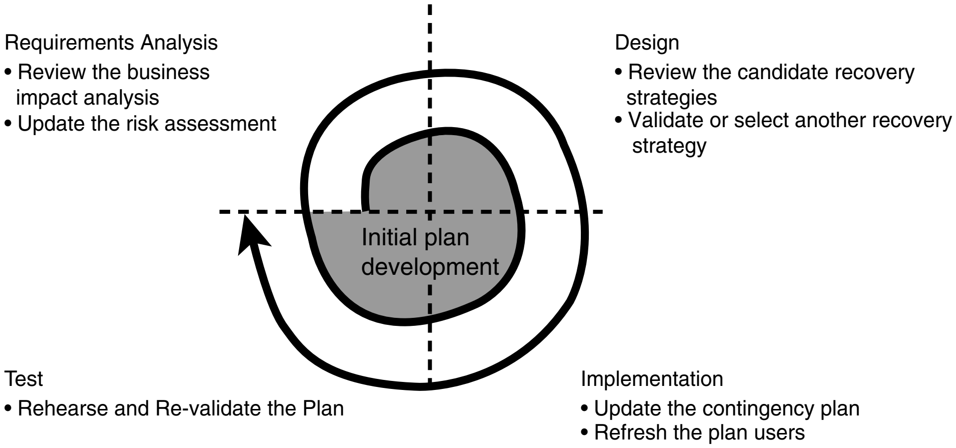
strategy for one enterprise may simply consist of time-of-disaster crisis management, while other enterprises will demand IT disaster recovery planning or perhaps even a guaranteed continual, uninterrupted business operation through the adoption of elaborate contingency plans coupled with redundant systems.

117.1.5.2 Test

Verification can take many forms, including inspection, analysis, demonstration, and test. The chosen recovery strategies to a great extent limit the verification methods to be employed. For example, for a true time-of-disaster recovery approach (which may be entirely valid for a given business), actual testing of the recovery of the systems would be prohibitively expensive. Testing would require the actual procurement of hardware and configuring a new system in real-time. However, inspection of the plan coupled with analysis of the defined process may provide adequate assurance that the plan is sound and well-constructed. Conversely, verification of a disaster recovery plan predicated on the recovery at a vendor cold site may involve the testing of the plan, to include shipping of tapes, restoration of the system, and restoration of the communications systems.



Requirements Analysis
• Review the business impact analysis
• Update the risk assessment
Design
• Review the candidate recovery strategies
• Validate or select another recovery strategy
Initial plan development
Test
• Rehearse and Re-validate the Plan
Implementation
• Update the contingency plan
• Refresh the plan users

EXHIBIT 117.2 Contingency plan maintenance life cycle.

Plan verification should occur on a periodic basis (perhaps annually) and whenever changes are made to the plan. Call lists and other dynamic sections of the plan should be verified on a more frequent basis.

117.1.5.3 Maintenance

Today more than ever before, we are faced with the furious pace of both IT and business evolution. Concepts such as office automation, e-mail, E-commerce, decentralization, centralization, downsizing, right-sizing, etc. have all impacted our business lives. Certainly, the best contingency planning maintenance practice is to continually revisit the plans. Revalidate the requirements, review the design and implementation strategies, exercise the plans, perform continual training, and update the plans. Best practice dictates that these tasks occur annually or when any major change to the system or to the business processes occurs.

117.1.5.4 Project Approach

The goal of contingency planning is to protect the enterprise (the business). If best practice involves the analysis and development of recovery requirements, the determination of these requirements should arise from a continuous refinement process rather than from a massive, single, protracted recovery requirement analysis project. As with other projects, exhaustive requirements analysis can lead to "paralysis through analysis," leading to the failure to get protective measures in place.

It is the prime responsibility of the enterprise to immediately implement measures to protect the workforce (i.e., evacuation plans, etc.). However, the responsibility to immediately implement the intuitive measures to protect the enterprise's other assets closely follows the requirement to protect the workforce. These immediate measures can be identified from the most cursory examination (i.e., securing corporate intellectual assets, data archival, backup and recovery, implementation of basic information security measures, protection of essential equipment, etc.). A "spiral-based," continuous process of contingency planning as advocated in Exhibit 117.2 (above) clearly represents the industry best practice of process improvement. This approach enables the rapid implementation of immediate safeguards with the guarantee of future enhancements to more fully meet the enterprise's needs.

117.2 Contingency Planning Maturity

In the landmark book entitled *Quality is Free*,[2] Philip Crosby outlines a simple tool, the Quality Management Maturity Grid, with which " … even the manager who isn't professionally trained in the quality business can determine where the operation in question stands from a quality standpoint." Based on the interrelationships of quality assurance, configuration management, and the security field, and upon the relationship between process maturity and risk reduction, it appears natural that the above-mentioned maturity grid could be tailored for use by the manager in assessing an enterprise's contingency planning program maturity.

117.2.1 Stages

Exhibit 117.3, the contingency planning maturity grid, contains five stages of maturity. They include uncertainty, awakening, enlightenment, wisdom, and certainty.

117.2.1.1 Stage I: Uncertainty

The lowest stage of contingency planning maturity, "Uncertainty," is characterized by a total lack of understanding of the importance of contingency planning. Contingency planning is viewed as a "paper exercise." While IT availability requirements may be understood, failures to live up to these reliability requirements are viewed as design or product failure, user error, or "acts of God," rather than as security incidents. Threats are not analyzed or understood. The information security protection strategies of

[2] Crosby, Philip B. 1979. *Quality is Free*, McGraw-Hill, New York.

EXHIBIT 117.3 The Contingency Planning Maturity Grid

	Management Understanding and Attitude	Contingency Planning Organization Status	Incident Handling	Contingency Planning Economics	Contingency Planning Improvement Actions
Stage V: Certainty	Management considers contingency planning an essential part of the enterprise's internal controls and provides adequate resources to fully support contingency planning.	Information security officer regularly meets with top management. Process and technology improvement is the main concern.	Business interruption causes are determined and corrective actions are prescribed and monitored. Incident data feeds back into risk management and contingency planning.	Prevention: justified and reduced. This ultimate level of business operations stability becomes recognized within the industry. Loss: minimized.	Business continuity activities are normal and continual activities. Process improvement suggestions readily come from end users and from the public forum.
Stage IV: Wisdom	Management participates. Management understands contingency planning. Management makes informed policy decisions. Management empowers business units to identify their critical needs and identify their critical business functions.	Contingency planning transitions into information security organization. Alliances are formed with other organizations (e.g., line management, product assurance, purchasing, etc.).	Threats are continually reevaluated based on the continually changing threat population and on the security incidents. Legal actions are prescribed for each type of incident.	Prevention: managed and continually justified. Reduced losses due to periodic risk analyses, more effective safeguards.Reduced losses due to periodic risk analyses, more effective safeguards. Loss: managed through continual cost/benefit trade-offs.	Risks are accurately evaluated and managed. Contingency planning activity emphasizes business continuity. Business impact analyses are performed and critical.
Stage III: Enlighenment	Management realization that a robust disaster recovery plan is necessary to ensure adequate service levels. Management becomes supportive but focuses on critical IT assets and infrastructure.	The contingency planning function reports to IT operations with a "dotted-line" to information security. The recovery planner develops corporate recovery policy and implements disaster recovery training.	Better statistics gathered from the incident reports provide a clearer view of the threats. Initial metrics indicate a reduction of the amount of data restores and an increase in the ability to restore in a timely manner.	Prevention: DR planning strategy aimed at assurance of IT service levels. DR activities initially funded, but complacency may set in. Loss: managed through a cost/benefit trade-off study.	End users become more confident in operations' ability to restore critical information from backups. End users become more reliant on higher service-level expectations. Business unit productivity increases.
Stage II:Awakening	Rely on vendor solutions (i.e., tape management systems, off-site storage, hardware replacement "on-the-fly").	A contingency planning function may be appointed. Main emphasis is on backup and file restores.	Incidents handled after the fact. Rudimentary statistics are gathered regarding major service interruptions.	Prevention: minimal. Loss: mismanaged and unpredictable. Impacts of disasters higher.	Some enterprisewide policies and procedures are developed to address the most visible threats.

Stage I:Uncertainty	No use of risk assessment to reduce incidents. Tend to blame other factors (e.g., system design, unreliable equipment, weather, utilities, etc.) for outages.	Contingency planning has no organizational recognition. Operations personnel protect their own interests (i.e., creation of backups).	Incidents are addressed after they occur; recovery rather than a prevention strategy. Crisis management. Impacts of even minor incidents may be disastrous.	Prevention: minimal to no funds spent for prevention. Loss: unmanaged, unpredictable, and exacerbated.	No organized contingency planning improvement activities. The enterprise has no understanding of risk reduction activities.

The Enterprise's View of its Contingency Planning Posture

"We are known in the industry by the stability and reliability of our business." … or … "We continually review our business processes and ensure the protection of their critical needs."
"We have identified our critical business functions and know what we need to continue business." … or … "We have a business continuity plan in place."
"Through management commitment and investment, we are protecting our information assets." … or … "We have an active disaster recovery planning program in place."
"Is it absolutely necessary to always have problems with IT uptime (i.e., e-mail, critical applications, etc.)?"
"We can't conduct business when our computers are so 'flaky', misconfigured and mismanaged."

prevention, detection, and recovery are not formally addressed. Contingency planning, if undertaken at all, usually consists of emergency evacuation plans and documented operations procedures such as backup and recovery procedures. While the people and data may be protected, the information assets and the business may be destroyed.

If in place at all, contingency planning will be implemented from the "time-of-disaster" point-of-view. However, in this stage, time-of-disaster strategy actually implies that no preparation or actual plan is in place for rebuilding or reconfiguring. Rather, the organization will "take its chances" and "recover on-the-fly." Ad hoc recovery may be attempted by the IT operations group. The end users are usually "in the dark" while the IT operations group is busy recovering.

When minor information security incidents occur, if recognized as incidents, they may be reported to a general help desk, to industrial security, or to a system administrator. However, a mechanism is usually not in place to investigate or track the reports. Due to the lack of contingency plans and documented procedures, the impacts of these minor incidents are higher and may actually lead to disaster declaration.

When security incidents occur, blame is placed on external forces rather than on the lack of protections. The threat population and their anticipated frequencies are unknown. Crisis management is the norm. When incidents occur, the question becomes: How can we recover? Due to this mentality, many organizations in this state may find that they cannot recover and they perish.

Spending is rarely targeted for incident frequency reduction or impact reduction initiatives such as formal risk analyses or recovery planning. Spending, when allocated, is channeled toward purchasing assets with higher mean-time-between-failure ratings. The frequency and cost impacts of the incidents that occur are unpredictable. Thus, business planning and strategies depend on the crisis management environment. When incidents occur, the entire enterprise can be thrown into turmoil. Business units must suspend operations and must re-plan when incidents occur.

The enterprise does not learn. The enterprise does not have time to learn. The more dependent the enterprise is on its data processing capabilities, the more crisis driven the enterprise becomes. Re-planning is commonplace. The enterprise does not take time for contingency planning.

In summary, in this state, the enterprise does not understand why it continually has problems with its IT systems. The enterprise experiences IT and business interruptions frequently, its information assets appear "brittle" and unstable, and the business productivity seems continually impacted.

117.2.1.2 Stage II: Awakening

The second stage of contingency planning maturity, "Awakening," is characterized by both the realization that IT disaster recovery planning may be of some value, and by the inability to provide money or time to support planning activities. Systems reliability is viewed as a commodity that can be bought on the open market. Management spends to procure systems or hardware components with high-reliability components, rather than determine their actual reliability needs. Tape management systems may be bought to manage the burgeoning number of tapes produced as a response to the identified data recovery needs. In reality, management often overspends, buying equipment far above the requirements.

With the realization that disaster recovery planning may be of value, management may appoint a contingency planner (often selected from the IT operations staff). However, once the planner has been appointed, he or she will most likely report to IT operations or some other functional area. The function of the contingency planner will be to collect and document operational procedures and to develop a disaster recovery plan document. However, creation of the DRP is typically viewed as a static endpoint in the contingency planning process rather than the beginning of a continual process aimed at maintaining an "evergreen" recovery solution.

The planner's approach may be to focus on a high-visibility, dramatic threat (e.g., hurricane) and develop a recovery strategy in response to that most dramatic crisis while ignoring the more frequent, significant threats that can readily compromise the business (e.g., routine hardware failure, malicious program attacks, key personnel loss). Because most day-to-day incidents involve restoring data files, the disaster recovery plan will typically focus on restoring all data files as soon as possible. The long lead-time process of restoring communications to these restored systems and the restoration of corporate communications (i.e., e-mail and voice services) will most likely be ignored.

Little funding will be allocated to the study or development of optimum recovery strategies. The funding will primarily be spent on procuring expensive, higher reliability components. Money will be wasted on the wrong or inadequate recovery strategy (perhaps supplied by service providers touting their technical expertise or redundant infrastructure). Recovery will focus on restoring IT operations rather than on continuing business operations. Because the recovery plan is designed based on past "major threats" and because the relative costs of differing recovery strategies are not explored, money spent in service subscriptions or at the time of crisis appears high.

During this phase, data management issues continue to surface. Data storage issues, either associated with e-mail systems or core application data, represent the bulk of the calls to the support desk. As a result, the data management process is documented in the disaster recovery plan and there is a continual procurement of assets to manage the increasing storage requirements.

In summary, while the enterprise believes that its underlying IT infrastructure is protected from a major calamity, the business operations do not understand why they continually have problems with the reliability or stability of the IT systems. Downtime is high and the business' productivity is routinely affected by low-level crises.

117.2.1.3 Stage III: Enlightenment

The third stage of contingency planning maturity, "Enlightenment," is characterized by the realization that disaster recovery planning is necessary and that resources had better be allocated to support recovery planning activities in support of the IT systems. Reliability is no longer viewed solely as a commodity that can be purchased. Rather, recovery plans must be designed to ensure adequate IT service levels through the ready recovery of compromised systems.

Management reaches the realization that due to the importance of IT on the entire enterprise, recovery planning must be formally endorsed. This endorsement enables the contingency planner to be more effective. Corporate contingency planning policy and a corporate emergency response and disaster recovery training program is developed. With the realization that contingency planning as an activity is closely related with information security, the contingency planning function managed from within the IT operations group forms a "dotted-line" relationship with the information security group.

Management may authorize the planner to conduct an initial business impact assessment in an attempt to identify the business-critical IT systems/applications and attempt to identify time-to-recover (TTR) requirements for these IT assets.

Due to the implementation of a formal incident reporting and tracking system and the ability of information security to prepare higher fidelity risk assessments based on the actual threat population, the contingency planner is better able to develop disaster scenarios relevant to the business' threats. These risk analyses convince management to allocate resources toward the prevention of and recovery from security incidents. However, once the initial studies have been conducted, the recovery strategies developed, and the safeguards installed, the fervor for disaster prevention and readiness diminishes. The information assets are believed to be safe.

At first, losses appear to be both expected (predicted through risk analyses) and manageable (planned, anticipated, and consciously accepted as security cost/benefit trade-offs). However, as time progresses, losses increase. This is due to the complacency of the enterprise; the changing threat population; and the evolving, rapidly changing nature of information technology. Previously prepared risk analyses and business impact assessments become stale and lose applicability in the evolving IT and business environment.

Due to the thorough disaster recovery training program, recovery personnel are cross-trained and the likelihood of a successful IT recovery is increased. Cost/benefit studies convince management personnel and they understand the "business case" for contingency planning. The information security engineering activities of awareness training, risk analysis, and risk reduction initiatives reduce the likelihood of an IT disaster declaration.

In summary, in this stage, through management commitment and disaster recovery planning improvement, the enterprise is protecting its IT assets and corporate infrastructure. And, the enterprise is seeking solutions to prevent IT outages rather than simply recovering from incidents as they occur.

117.2.1.4 Stage IV: Wisdom

The fourth stage of contingency planning maturity, "Wisdom," is characterized by a contingency planning program that more closely reflects the business's needs rather than only the IT operations group's needs.

If Stage III is characterized by a focused approach toward protecting the IT assets and IT infrastructure, Stage IV represents a business-centric focus. In this approach, the business units are empowered and encouraged to evaluate and develop their own recovery strategies and business continuity plans to respond to their own unique needs.

Due to an increased understanding of contingency planning principles, management visibly participates in the contingency planning program. Management actively encourages all business units and employees to participate as well. Management is able to make policy decisions and to support its decisions with conviction. With the realization that contingency planning is an internal control function rather than an IT operations function, contingency planning is formally under the auspices of the information security officer. While the contingency planning function may not necessarily be represented on the enterprise's senior staff, contingency planning principles are accurately represented there by the information security officer.

Based on the increased responsibilities and workload, the contingency planning function may have established an infrastructure. Responsibilities have increased to include periodic business impact assessments and auditing. The contingency planning function has developed positive, mutually beneficial relationships with all support organizations. These interfaces to other organizations (e.g., line management, product assurance, purchasing, etc.) promote buy-in and enhance an effective enterprisewide implementation of the contingency planning program.

Threats are continually reevaluated based on the continually changing threat population and on the security incidents. All security safeguards are open to suggestion and improvement. Legal actions are prescribed for each type of incident.

Risk analyses are now developed that contain greater detail and accuracy. They are more accurate due to a greater understanding of the threat population, and due to a greater understanding of the enterprise's vulnerabilities. Resources are continually allocated toward the optimization of the information security program. Additional or more cost-effective safeguards are continually identified.

Studies are now continually conducted due to the realization that the threat evolves and that the enterprise's information systems and the technologies continually grow. Losses that occur have been managed, anticipated through continual cost/benefit trade-offs (e.g., risk analyses). The likelihood of incidents has been significantly reduced, and minor incidents rarely impact business operations.

Business impact assessments are performed across the enterprise to identify all critical business functions to understand their time-to-recover needs, and to understand their IT dependencies and their dependencies with other business units. Recovery strategies are adjusted and tuned based on the findings of the risk analyses and business impact assessments.

With the empowerment of the business units to augment the enterprise's contingency planning program with the development of their own business continuity plans, contingency planning occurs at all levels of the enterprise. Research activities are initiated to keep up with the rapidly changing environment. The contingency planners now undergo periodic training and refresher courses. A complete contingency planning program has been developed, expanded from attention solely to the IT assets to a complete, customized business continuity solution. The contingency planning training is tailored to the needs of the differing audiences (i.e., awareness, policy-level, and performance-level training).

In summary, in this stage, contingency planning activities are budgeted and routine. Through the use of enterprise-specific threat models, and through the preparation of detailed risk analyses, the enterprise understands its vulnerabilities and protects its information assets. Through the preparation of detailed business impact assessments, the enterprise understands its critical functions and needs. Through the study of disaster scenarios and recovery strategies, the enterprise has implemented a risk-based, cost-effective approach toward business continuity. Thus, the organization has identified the critical business functions and knows what it needs to continue business and has responded through the implementation of business continuity plans.

117.2.1.5 Stage V: Certainty

The fifth stage of contingency planning maturity, "Certainty," is characterized by continual contingency planning process improvement through research and through participation and sharing of knowledge in the public and professional forums.

In this stage, contingency planning as a component of information security engineering is considered an essential part of the enterprise's internal controls. Adequate resources are provided and management fully supports the contingency planning program. Management support extends to the funding of internal research and development to augment the existing plans and strategies.

The information security officer regularly meets with top management to represent contingency planning interests. Process and technology improvement is the main concern. Business continuity is a thought leader. The enterprise's contingency planning professionals are recognized within the enterprise, within the security industry, and even by the enterprise's competitors. These professionals reach notoriety through their presentations at information technology conferences, through their publishing in trade journals, and through their participation on government task forces. The involvement and visibility of the enterprise's contingency planning professional contributes toward enhancing the enterprise's image in the marketplace.

The causes of incidents are determined and corrective actions are prescribed and monitored. Incident data feeds back into risk management to improve the information security posture.

Prevention strategies are implemented to their fullest allowed from detailed and accurate cost/benefit analyses, and losses are minimized and anticipated. Information security and continuity of operations costs are justified and promoted through its recognized contribution in reducing the enterprise's indirect costs of doing business (i.e., from the realization that incidents and their associated costs of recovery, which drain the enterprise's overhead, have diminished). The enterprise recovers information security and contingency planning costs through the positive impact of a stable environment within the enterprise (i.e., enabling productivity increase). The contingency planning program may be partially funded through its contribution to marketing. This ultimate level of documented systems availability may become a marketing tool and encourage business expansion by consumer recognition of a quality boost to the enterprise's ability to deliver on time without interruption. Additionally, the information security program may be partially funded through the external marketing of its own information security services.

In this stage, information security protections are optimized across the enterprise. Enterprisewide protection strategies are continually reevaluated based on the needs and customized protection strategies identified by the enterprise's functional elements. Contingency planning activities (e.g., risk analyses, risk reduction initiatives, business impact assessments, audits, research, etc.) are normal and continual activities. Desirable contingency planning improvement suggestions come from end users and system owners.

In summary, in this stage, the enterprise knows that its assets are protected now and the enterprise is assured that they will continue to be adequately protected in the future. The enterprise is protected because its planned, proactive information security activities are continually adjusting and their protection strategies are optimized.

117.3 Instructions for Preparing a Maturity Profile

The assessor simply reviews each cell on the Contingency Planning Maturity Grid (Exhibit 117.3, above) to determine whether that cell best describes the enterprise's level of maturity. For each column, if only

EXHIBIT 117.4 Summation of Contingency Planning Posture

Uncertainty:

- They rely on hardware reliability ratings and commercial-off-the-shelf (COTS) software solutions.
- There is no contingency planning function.
- They have no incident-handling infrastructure.
- Minimal funds are spent on prevention; funds are spent for recovery.

	Management	Organization	Incidents	Economics	Improvement

II	░				
I	░	▓	▓	▓	▓

Awakening:

- They rely on hardware reliability ratings and commercial-off-the-shelf (COTS) software solutions.
- The contingency planner has policies in place.
- Incidents are collected.
- Funds are spent only on COTS safeguards and on IT recovery.
- Some enterprisewide preventative measures are in place.

	Management	Organization	Incidents	Economics	Improvement
V					
IV					
III		░			
II	░	░	░	░	░
I	░	░	░	░	░

Enlightenment:

- Management is supportive, providing resources.
- The contingency planner has developed a program and has obtained “buy-in” (i.e., support) from other organizations.
- Incidents are collected and analyzed.
- Funds are allocated based on an analysis of the risks.
- Disaster recovery is viewed as necessary by the end users.

the bottom row applies, that category should be considered immature. If the second and (or) third rows apply, that category should be considered moderately mature. If the fourth and (or) fifth rows apply, that category should be considered mature.

117.3.1 Example Profiles

Exhibit 117.4 provides an enterprise's summation of its contingency planning posture, as well as a sample contingency planning maturity grid for that posture.

117.4 Contingency Planning Process Improvement

The five measurement categories are management understanding and attitude, contingency planning organization status, incident handling, contingency planning economics, and contingency planning improvement actions. The following paragraphs outline the steps necessary to improve one's ratings within these measurement categories.

117.4.1 Management Understanding and Attitude

To attain Stage II:

- Management will approve the procurement of vendor-supplied, "built-in" software solutions to increase system reliability (i.e., backup software, configuration management tools, tape archiving tools, etc.).
- Management will approve the procurement of vendor-supplied, "built-in" hardware solutions to increase system reliability (i.e., equipment with high mean-time-between-failure ratings, inventorying spare line-replaceable-units, etc.).

To attain Stage III:

- Management will endorse IT disaster recovery policies.
- Management will support development of robust IT disaster recovery plans.
- Management will support disaster recovery training for operations personnel.

To attain Stage IV:

- Management will shift its focus from IT disaster recovery to the identification of and recovery of critical business functions.
- Management will commission a detailed business impact assessment(s) and gain a clear understanding of the critical business functions and IT infrastructure.

- Management will obtain an understanding of the absolutes of business continuity planning and become able to make informed policy decisions.
- Management will promote business continuity.
- Management will empower organizational elements to augment the enterprise's contingency planning program consistent with the business unit's needs.

To attain Stage V:

- Management will understand that business continuity planning is an essential part of the enterprise's internal controls.
- Management will provide adequate resources and fully support continual improvement of the business continuity planning program, to include internal research and development.

117.4.2 Contingency Planning Organization Status

To attain Stage II:

- Management will appoint a contingency planner.
- Emphasis will be placed on the recovery of IT operations from a worst-case disaster.

To attain Stage III:

- The contingency planning function will be matrixed to the corporate information security function.
- The Disaster Recovery Plan will be based on recovery from more realistic disasters as well.
- Disaster recovery will include the ability to recover corporate communications.

To attain Stage IV:

- The contingency planning function will be transitioned into the corporate information security function.
- Focus will change from IT disaster recovery toward business continuity.
- Risk analyses and business impact assessments will be updated periodically, and penetration and audit capabilities will be supported.
- The contingency planning function will develop strategic alliances with other organizations (i.e., configuration management, product assurance, procurement, etc.).

To attain Stage V:

- Top management will regularly meet with the information security officer regarding business continuity issues.
- Through internal research and development, contingency planning will be able to address technical problems with leading-edge solutions.
- Contingency planning's role will expand into the community to augment the enterprise's image.
- The enterprise will be noted for its ability to consistently deliver on time.

117.4.3 Incident Handling

To attain Stage II:

- Data management issues (file recovery) gain visibility.
- Rudimentary statistics will be collected to identify major trends.
- Contingency planning will focus on response to a high-visibility dramatic incident.

To attain Stage III:

- An initial business impact assessment will have been performed to determine the relative criticality of IT assets and services, and to reveal the business's time-to-recover requirements.
- Based on detailed statistics available due to implementation of a formal incident reporting process, the information security threat can be better identified, thus enabling the development of more realistic disaster scenarios.

To attain Stage IV:

- Threats will continually be reevaluated based on the continually changing threat population and on the security incidents enhancing the accuracy of the risk analyses.
- Thorough business impact assessments will be conducted across the entire enterprise.

To attain Stage V:

- Incident data will be continually analyzed and fed back to continually improve the information security process.

117.4.4 Contingency Planning Economics

To attain Stage II:

- Management will provide contingency planning only limited funding, allocated primarily for the procurement of higher reliability equipment supplied by vendors touting their "built-in" reliability

To attain Stage III:

- Expenditures will be managed and justified, funding IT disaster recovery activities selected as a result of a risk analysis.

To attain Stage IV:

- Expenditures will be managed and continually justified through periodic risk analyses and business impact assessments of greater accuracy, identifying additional or more cost-effective recovery strategies in response to the continually changing threat environment.
- Losses will be anticipated through cost/benefit trade-offs.

To attain Stage V:

- The cost-savings aspect of a completely implemented contingency planning program will be thoroughly understood and realized.
- Contingency planning expenditures will be justified and reduced, being partially funded through its contribution to marketing.

117.4.5 Contingency Planning Improvement Actions

To attain Stage II:

- The contingency planner will begin to implement and document IT operations procedures and develop an initial IT disaster recovery plan.

To attain Stage III:

- The contingency planner will develop a robust IT disaster recovery plan.
- A training program will be offered for recovery personnel to increase the likelihood of a successful recovery of the IT assets.

- Management will understand the "business case" for contingency planning.
- Management will fund the contingency planning activities of risk analysis, risk reduction initiatives; business impact assessment, and audits.

To attain Stage IV:

- Risks will be accurately evaluated and managed.
- Contingency planning/recovery research activities will be initiated to keep up with the rapidly changing environment.
- A continual, detailed business continuity training program will be developed.

To attain Stage V:

- The contingency planning activities (e.g., risk analyses, risk reduction initiatives, business impact assessment, audits, training, research, etc.) will become normal, continual activities.
- The contingency planning function will obtain desirable contingency planning improvement suggestions from end users and system owners.

117.5 Conclusion

A tool, the Contingency Planning Maturity Grid, was introduced to aid the manager in the appraisal of an enterprise's contingency planning program. Additionally, contingency planning improvement initiatives were proposed for each of the measurement categories.

118

Reengineering the Business Continuity Planning Process

Carl B. Jackson

The initial version of this chapter was written for the 1999 edition of the *Information Security Management Handbook*. Since then, E-commerce has seized the spotlight and Web-based technologies are the emerging solution for almost everything. The constant throughout these occurrences is that no matter what the climate, fundamental business processes have changed little. And, as always, the focus of any business impact assessment is to assess the time-critical priority of these business processes. With these more recent realities in mind, this chapter has been updated and is now offered for the reader's consideration.

118.1 Continuity Planning: Management Awareness High—Execution Effectiveness Low

The failure of organizations to accurately measure the contributions of the continuity planning (CP) process to their overall success has led to a downward spiraling cycle of the total business continuity program. The recurring downward spin or decomposition includes planning, testing, maintenance, decline → replanning, testing, maintenance, decline → eplanning, testing, maintenance, decline, etc.

In the past, *Contingency Planning & Management (CPM)/Ernst & Young Continuity Planning Benchmark* surveys have repeatedly confirmed that continuity planning (CP) is ranked as being either "extremely important" or "very important" to executive management. The most recent *2000–2001 CPM/KPMG Continuity Planning Survey*[1] clearly supports this observation. This study indicates that a growing number of CP professional positions are migrating from the IT infrastructure to corporate or general management positions; however, CP reporting within the IT organization is still the norm. Approximately 40 percent of CP professionals currently report to IT, while around 30 percent report to corporate positions.

118.1.1 Continuity Planning Measurements

While the trends of this survey are encouraging, there is a continuing indication of a disconnect between executive management's perceptions of CP objectives and the manner in which they measure its value. Traditionally, CP effectiveness was measured in terms of a pass/fail grade on a mainframe recovery test, or on the perceived benefits of backup/recovery sites and redundant telecommunications weighed against the expense for these capabilities. The trouble with these types of metrics is that they only measure CP direct costs, or indirect perceptions as to whether a test was effectively executed. These metrics do not indicate whether a test validates the appropriate infrastructure elements or even whether it is thorough enough to test a component until it fails, thereby extending the reach and usefulness of the test scenario.

Thus, one might inquire as to the correct measures to use. Although financial measurements do constitute one measure of the CP process, others measure the CPs contribution to the organization in terms of quality and effectiveness, which are not strictly weighed in monetary terms. The contributions that a well-run CP process can make to an organization include:

- Sustaining growth and innovation
- Enhancing customer satisfaction
- Providing people needs
- Improving overall mission-critical process quality
- Providing for practical financial metrics

118.2 A Receipt for Radical Change: CP Process Improvement

Just prior to the millennium, experts in organizational management efficiency began introducing performance process improvement disciplines. These process improvement disciplines have been slowly adopted across many industries and companies for improvement of general manufacturing and administrative business processes. The basis of these and other improvement efforts was the concept that an organization's processes (Process; see Exhibit 118.1) constituted the organization's fundamental lifeblood and, if made more effective and more efficient, could dramatically decrease errors and increase organizational productivity.

An organization's processes are a series of successive activities; and when they are executed in the aggregate, they constitute the foundation of the organization's mission. These processes are intertwined throughout the organization's infrastructure (individual business units, divisions, plants, etc.) and are

EXHIBIT 118.1 Definitions

Activities: Activities are things that go on within a process or sub-process. They are usually performed by units of one (one person or one department). An activity is usually documented in an instruction. The instruction should document the tasks that make up the activity.

Benchmarking: Benchmarking is a systematic way to identity, understand, and creatively evolve superior products, services, designs, equipment, processes, and practices to improve the organization's real performance by studying how other organizations are performing the same or similar operations.

Business process improvement: Business process improvement (BPI) is a methodology that is designed to bring about self-function improvements in administrative and support processes using approaches such as FAST, process benchmarking, process redesign, and process reengineering.

Comparative analysis: Comparative analysis (CA) is the act of comparing a set of measurements to another set of measurements for similar items.

Enabler: An enabler is a technical or organizational facility/resource that make it possible to perform a task, activity, or process. Examples of technical enablers are personal computers, copying equipment, decentralized data processing, voice response, etc. Examples of organizational enablers are enhancement, self-management, communications, education, etc.

Fast analysis solution technique: *FAST* is a breakthrough approach that focuses a group's attention on a single process for a one- or two-day meeting to define how the group can improve the process over the next 90 days. Before the end of the meeting, management approves or rejects the proposed improvements.

Future state solution: A combination of corrective actions and changes that can be applied to the item (process) under study to increase its value to its stakeholders.

Information: Information is data that has been analyzed, shared, and understood.

Major processes: A major process is a process that usually involves more than one function within the organization structure, and its operation has a significant impact on the way the organization functions. When a major process is too complex to be flowcharted at the activity level, it is often divided into sub-processes.

Organization: An organization is any group, company, corporation, division, department, plant, or sales office.

Process: A process is a logical, related, sequential (connected) set of activities that takes an input from a supplier, adds value to it, and produces an output to a customer.

Sub-process: A sub-process is a portion of a major process that accomplishes a specific objective in support of the major process.

System: A system is an assembly of components (hardware, software, procedures, human functions, and other resources) united by some form of regulated interaction to form an organized whole. It is a group of related processes that may or may not be connected.

Tasks: Tasks are individual elements or subsets of an activity. Normally, tasks relate to how an item performs a specific assignment.

Source: From Harrington, H. J., Esseling, E. K. C., and Van Nimwegen, H. 1997. *Business Process Improvement Workbook*, pp. 1–20. McGraw-Hill.

tied to the organization's supporting structures (data processing, communications networks, physical facilities, people, etc.).

A key concept of the process improvement and reengineering movement revolves around identification of process enablers and barriers (see Exhibit 118.1). These enablers and barriers take many forms (people, technology, facilities, etc.) and must be understood and taken into consideration when introducing radical change into the organization.

The preceding narration provides the backdrop for the idea of focusing on continuity planning not as a project, but as a continuous process, that must be designed to support the other mission-critical processes of the organization. Therefore, the idea was born of adopting a continuous process approach to CP, along with understanding and addressing the people, technology, facility, etc., enablers and barriers. This constitutes a significant or even radical change in thinking from the manner in which recovery planning has been traditionally viewed and executed.

118.2.1 Radical Changes Mandated

High awareness of management and low CP execution effectiveness, coupled with the lack of consistent and meaningful CP measurements, call for radical changes in the manner in which one executes recovery planning responsibilities. The techniques used to develop mainframe-oriented disaster recovery (DR) plans of the 1980s and 1990s consisted of five to seven distinct stages, depending on whose methodology was being used, that required the recovery planner to:

1. Establish a project team and a supporting infrastructure to develop the plans.
2. Conduct a threat or risk management review to identify likely threat scenarios to be addressed in the recovery plans.
3. Conduct a business impact analysis (BIA) to identify and prioritize time-critical business applications and networks and determine maximum tolerable downtimes.
4. Select an appropriate recovery alternative that effectively addressed the recovery priorities and timeframes mandated by the BIA.
5. Document and implement the recovery plans.
6. Establish and adopt an ongoing testing and maintenance strategy.

118.2.2 Shortcomings of the Traditional Disaster Recovery Planning Approach

The old approach worked well when disaster recovery of "glass-house" mainframe infrastructures was the norm. It even worked fairly well when it came to integrating the evolving distributed client/server systems into the overall recovery planning infrastructure. However, when organizations became concerned with business unit recovery planning, the traditional DR methodology was ineffective in designing and implementing business unit/function recovery plans. Of primary concern when attempting to implement enterprisewide recovery plans was the issue of functional interdependencies. Recovery planners became obsessed with identification of interdependencies between business units and functions, as well as the interdependencies between business units and the technological services supporting time-critical functions within these business units.

118.2.3 Losing Track of the Interdependencies

The ability to keep track of departmental interdependencies for CP purposes was extremely difficult and most methods for accomplishing this were ineffective. Numerous circumstances made consistent tracking of interdependencies difficult to achieve. Circumstances affecting interdependencies revolve around the rapid rates of change that most modern organizations are undergoing. These include reorganization/restructuring, personnel relocation, changes in the competitive environment, and outsourcing. Every time an organizational structure changes, the CPs must change and the interdependencies must be reassessed; and the more rapid the change, the more daunting the CP reshuffling. Because many functional interdependencies could not be tracked, CP integrity was lost and the overall functionality of the CP was impaired. There seemed to be no easy answers to this dilemma.

118.2.4 Interdependencies Are Business Processes

Why are interdependencies of concern? And what, typically, are the interdependencies? The answer is that, to a large degree, these interdependencies are the business processes of the organization and they are of concern because they must function in order to fulfill the organization's mission. Approaching recovery planning challenges with a business process viewpoint can, to a large extent, mitigate the problems associated with losing interdependencies, and also ensure that the focus of recovery planning efforts is on the most crucial components of the organization. Understanding how the organization's time-critical business processes are structured will assist the recovery planner in mapping the processes back to the business units/departments; supporting technological systems, networks, facilities, vital records, people, etc.; and keeping track of the processes during reorganizations or during times of change.

118.3 The Process Approach to Continuity Planning

Traditional approaches to mainframe-focused disaster recovery planning emphasized the need to recover the organization's technological and communications platforms. Today, many companies have shifted away from technology recovery and toward continuity of prioritized business processes and the development of specific business process recovery plans. Many large corporations use the process reengineering/improvement disciplines to increase overall organizational productivity. CP itself should also be viewed as such a process. Exhibit 118.2 provides a graphical representation of how the enterprisewide CP process framework should look.

This approach to continuity planning consolidates three traditional continuity planning disciplines, as follows:

1. *IT disaster recovery planning (DRP)*. Traditional IT DRP addresses the continuity planning needs of the organizations' IT infrastructures, including centralized and decentralized IT capabilities and includes both voice and data communications network support services.
2. *Business operations resumption planning (BRP)*. Traditional BRP addresses the continuity of an organization's business operations (e.g., accounting, purchasing, etc.) should they lose access to their supporting resources (e.g., IT, communications network, facilities, external agent relationships, etc.).
3. *Crisis management planning (CMP)*. CMP focuses on assisting the client organization develop an effective and efficient enterprisewide emergency/disaster response capability. This response capability includes forming appropriate management teams and training their members in reacting to serious company emergency situations (e.g., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.). CMP also encompasses response to life-safety issues for personnel during a crisis or response to disaster.

EXHIBIT 118.2 The enterprisewide CP process framework.

4. *Continuous availability (CA)*. In contrast to the other CP components as explained above, the recovery time objective (RTO) for recovery of infrastructure support resources in a 24×7 environment has diminished to *zero* time. That is, the client organization cannot afford to lose operational capabilities for even a very short period of time without significant financial (revenue loss, extra expense) or operational (customer service, loss of confidence) impact. The CA service focuses on maintaining the highest uptime of support infrastructures to 99 percent and higher.

118.4 Moving to a CP Process Improvement Environment

118.4.1 Route Map Profile and High-Level CP Process Approach

A practical, high-level approach to CP process improvement is demonstrated by breaking down the CP process into individual sub-process components as shown in Exhibit 118.3.

The six major components of the continuity planning business process are described below.

1. *Current State Assessment/Ongoing Assessment*. Understanding the approach to enterprisewide continuity planning as illustrated in Exhibit 118.3, one can measure the "health" of the continuity planning process. During this process, existing continuity planning business sub-processes are assessed to gauge their overall effectiveness. It is sometimes useful to employ gap analysis techniques to understand current state, desired future state, and then understand the people, process, and technology barriers and enablers that stand between the current state and the future state. An approach to co-development of current state/future state visioning sessions is illustrated in Exhibit 118.4.

EXHIBIT 118.4 Current state/future state visioning overview.

The current state assessment process also involves identifying and determining how the organization "values" the CP process and measures its success (often overlooked and often leading to the failure of the CP process). Also during this process, an organization's business processes are examined to determine the impact of loss or interruption of service on the overall business through performance of a business impact assessment (BIA). The goal of the BIA is to prioritize business processes and assign the recovery time objective (RTO) for their recovery, as well as for the recovery of their support resources. An important outcome of this activity is the mapping of time-critical processes to their support resources (e.g., IT applications, networks, facilities, communities of interest, etc.).

2. *Process Risk and Impact Baseline*. During this process, potential risks and vulnerabilities are assessed, and strategies and programs are developed to mitigate or eliminate those risks. The stand-alone risk management review (RMR) commonly looks at the security of physical, environmental, and information capabilities of the organization. In general, the RMR should identify or discuss the following areas:

   - Potential threats
   - Physical and environmental security
   - Information security
   - Recoverability of time-critical support functions
   - Single-points-of-failure
   - Problem and change management
   - Business interruption and extra expense insurance
   - An offsite storage program, etc.

3. *Strategy Development*. This process involves facilitating a workshop or series of workshops designed to identify and document the most appropriate recovery alternative to CP challenges (e.g., determining if a hotsite is needed for IT continuity purposes, determining if additional communications circuits should be installed in a networking environment, determining if additional workspace is needed in a business operations environment, etc.). Using the information derived from the risk assessments above, design long-term testing, maintenance, awareness, training, and measurement strategies.
4. *Continuity Plan Infrastructure*. During plan development, all policies, guidelines, continuity measures, and continuity plans are formally documented. Structure the CP environment to identify plan owners and project management teams, and to ensure the successful development

of the plan. In addition, tie the continuity plans to the overall IT continuity plan and crisis management infrastructure.

5. *Implementation*. During this phase, the initial versions of the continuity or crisis management plans are implemented across the enterprise environment. Also during this phase, long-term testing, maintenance, awareness, training, and measurement strategies are implemented.
6. *Operate Environment*. This phase involves the constant review and maintenance of the continuity and crisis management plans. In addition, this phase may entail maintenance of the ongoing viability of the overall continuity and crisis management business processes.

118.5 How Does One Get There? The Concept of the CP Value Journey

The CP value journey is a helpful mechanism for co-development of CP expectations by the organization's top management group and those responsible for recovery planning. To achieve a successful and measurable recovery planning process, the following checkpoints along the CP value journey should be considered and agreed upon. The checkpoints include:

- *Defining success*. Define what a successful CP implementation will look like. What is the future state?
- *Aligning the CP with business strategy*. Challenge objectives to ensure that the CP effort has a business-centric focus.
- *Charting an improvement strategy*. Benchmark where the organization and the organization's peers are, the organization's goals based on their present position as compared to their peers, and which critical initiatives will help the organization achieve its goals.
- *Becoming an accelerator*. Accelerate the implementation of the organization's CP strategies and processes. In today's environment, speed is a critical success factor for most companies.
- *Creating a winning team*. Build an internal/external team that can help lead the company through CP assessment, development, and implementation.
- *Assessing business needs*. Assess time-critical business process dependence on the supporting infrastructure.
- *Documenting the plans*. Develop continuity plans that focus on ensuring that time-critical business processes will be available.
- *Enabling the people*. Implement mechanisms that help enable rapid reaction and recovery in times of emergency, such as training programs, a clear organizational structure, and a detailed leadership and management plan.
- *Completing the organization's CP strategy*. Position the organization to complete the operational and personnel related milestones necessary to ensure success.
- *Delivering value*. Focus on achieving the organization's goals while simultaneously envisioning the future and considering organizational change.
- *Renewing/recreating*. Challenge the new CP process structure and organizational management to continue to adapt and meet the challenges of demonstrate availability and recoverability.

118.5.1 The Value Journey Facilitates Meaningful Dialogue

This value journey technique for raising the awareness level of management helps to both facilitate meaningful discussions about the CP process and ensure that the resulting CP strategies truly add value. As discussed later, this value-added concept will also provide additional metrics by which the success of the overall CP process can be measured.

118.6 The Need for Organizational Change Management

In addition to the approaches of CP process improvement and the CP value journey mentioned above, the need to introduce people-oriented organizational change management (OCM) concepts is an important component in implementing a successful CP process.

H. James Harrington et al. in their book *Business Process Improvement Workbook*,[2] point out that applying process improvement approaches can often cause trouble unless the organization manages the change process. They state that, "Approaches like reengineering only succeed if we challenge and change our paradigms and our organization's culture. It is a fallacy to think that you can change the processes without changing the behavior patterns or the people who are responsible for operating these processes."[3]

Organizational change management concepts, including the identification of people enablers and barriers and the design of appropriate implementation plans that change behavior patterns, play an important role in shifting the CP project approach to one of CP process improvement. The authors also point out that, "There are a number of tools and techniques that are effective in managing the change process, such as pain management, change mapping, and synergy. The important thing is that every BPI (Business Process Improvement) program must have a very comprehensive change management plan built into it, and this plan must be effectively implemented."[4]

Therefore, it is incumbent on the recovery planner to ensure that, as the concept of the CP process evolves within the organization, appropriate OCM techniques are considered and included as an integral component of the overall deployment effort.

118.7 How Is Success Measured? Balanced Scorecard Concept[5]

A complement to the CP process improvement approach is the establishment of meaningful measures or metrics that the organization can use to weigh the success of the overall CP process. Traditional measures include:

- How much money is spent on hotsites?
- How many people are devoted to CP activities?
- Was the hotsite test a success?

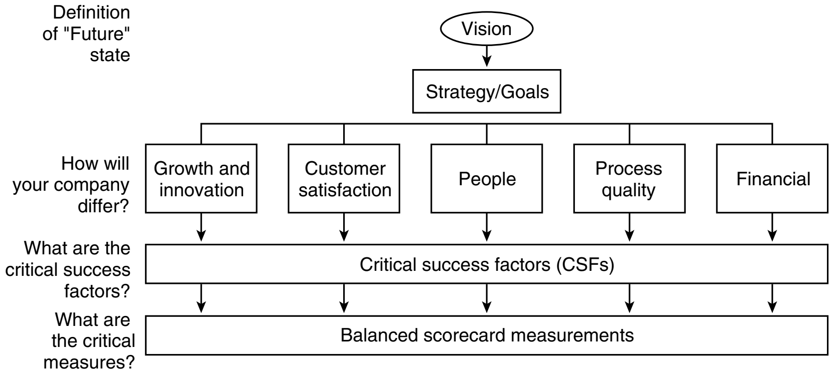
Instead, the focus should be on measuring the CP process contribution to achieving the overall goals of the organization. This focus helps to:

- Identify agreed-upon CP development milestones.
- Establish a baseline for execution.
- Validate CP process delivery.
- Establish a foundation for management satisfaction to successfully manage expectations.

The CP balanced scorecard includes a definition of the:

- Value statement
- Value proposition
- Metrics/assumptions on reduction of CP risk
- Implementation protocols
- Validation methods

Exhibit 118.5 and Exhibit 118.6 illustrate the balanced scorecard concept and show examples of the types of metrics that can be developed to measure the success of the implemented CP process. Included in this balanced scorecard approach are the new metrics upon which the CP process will be measured.



Definition of "Future" state
Vision
Strategy/Goals
How will your company differ?
Growth and innovation
Customer satisfaction
People
Process quality
Financial
What are the critical success factors?
Critical success factors (CSFs)
What are the critical measures?
Balanced scorecard measurements

EXHIBIT 118.5 Balanced scorecard concept.

Following this balanced scorecard approach, the organization should define what the future state of the CP process should look like (see the preceding CP value journey discussion). This future state definition should be co-developed by the organization's top management and those responsible for development of the CP process infrastructure. Exhibit 118.4 illustrates the current state/future state visioning overview, a technique that can also be used for developing expectations for the balanced scorecard. Once the future state is defined, the CP process development group can outline the CP process implementation critical success factors in the areas of:

- Growth and innovation
- Customer satisfaction
- People
- Process quality
- Financial state

These measures must be uniquely developed based on the specific organization's culture and environment.

EXHIBIT 118.6 Continuity Process Scorecard

Question: How should the organization benefit from implementation of the following continuity process components in terms of people, processes, technologies, and mission/profits?

Continuity Planning Process Components	People	Processes	Technologies	Mission/Profits
Process methodology				
Documented DRPs				
Documented BRPs				
Documented crisis management plans				
Documented emergency response procedures				
Documented network recovery plan				
Contingency organization walk-throughs				
Employee awareness program				
Recovery alternative costs				
Continuous availability infrastructure				
Ongoing testing programs				
etc.				

118.8 What about Continuity Planning for Web-Based Applications?

Evolving with the birth of the Web and Web-based businesses is the requirement for 24×7 uptime. Traditional recovery time objectives have disappeared for certain business processes and support resources that support the organizations' Web-based infrastructure. Unfortunately, simply preparing Web-based applications for sustained 24×7 uptime is not the only answer. There is no question that application availability issues must be addressed, but it is also important that the reliability and availability of other Web-based infrastructure components (such as computer hardware, Web-based networks, database file systems, Web servers, file and print servers, as well as preparing for the physical, environmental, and information security concerns relative to each of these [see RMR above]) also be undertaken. The terminology for preparing the entirety of this infrastructure to remain available through major and minor disruptions is usually referred to as continuous or high availability.

Continuous availability (CA) is not simply bought; it is planned for and implemented in phases. The key to a reliable and available Web-based infrastructure is to ensure that each of the components of the infrastructure have a high-degree of resiliency and robustness. To substantiate this statement, *Gartner Research* reports "Replication of databases, hardware servers, Web servers, application servers, and integration brokers/suites helps increase availability of the application services. The best results, however, are achieved when, in addition to the reliance on the system's infrastructure, the design of the application itself incorporates considerations for continuous availability. Users looking to achieve continuous availability for their Web applications should not rely on any one tool but should include the availability considerations systematically at every step of their application projects."[7]

Implementing a continuous availability methodological approach is the key to an organized and methodical way to achieve 24×7 or near 24×7 availability. Begin this process by understanding business process needs and expectations, and the vulnerabilities and risks of the network infrastructure (e.g., Internet, intranet, extranet, etc.), including undertaking single-points-of-failure analysis. As part of considering implementation of continuous availability, the organization should examine the resiliency of its network infrastructure and the components thereof, including the capability of its infrastructure management systems to handle network faults, network configuration and change, the ability to monitor network availability, and the ability of individual network components to handle capacity requirements. See Exhibit 118.7 for an example pictorial representation of this methodology.

The CA methodological approach is a systematic way to consider and move forward in achieving a Web-based environment. A very high-level overview of this methodology is as follows.

- *Assessment/planning*. During this phase, the enterprise should endeavor to understand the current state of business process owner expectations/requirements and the components of the technological infrastructure that support Web-based business *processes*. Utilizing both interview techniques (people to people) and existing system and network automated diagnoses tools will assist in understanding availability status and concerns.
- *Design*. Given the results of the current state assessment, design the continuous availability strategy and implementation/migration plans. This will include developing a Web-based infrastructure classification system to be used to classify the governance processes used for granting access to and use of support for Web-based resources.
- *Implementation*. Migrate existing infrastructures to the Web-based environment according to design specifications as determined during the design phase.
- *Operations/monitoring*. Establish operational monitoring techniques and processes for the ongoing administration of the Web-based infrastructure.

EXHIBIT 118.7 Continuous availability methodological approach.

Along these lines, in their book *Blueprints for High Availability: Designing Resilient Distributed Systems*,[8] Marcus and Stern recommend several fundamental rules for maximizing system availability (paraphrased):

- *Spend money…but not blindly.* Because quality costs money, investing in an appropriate degree of resiliency is necessary.
- *Assume nothing.* Nothing comes bundled when it comes to continuous availability. End-to-end system availability requires up-front planning and cannot simply be bought and dropped in place.
- *Remove single-points-of-failure.* If a single link in the chain breaks, regardless of how strong the other links are, the system is down. Identify and mitigate single-points-of-failure.
- *Maintain tight security.* Provide for the physical, environmental, and information security of Web-based infrastructure components.
- *Consolidate servers.* Consolidate many small servers' functionality onto larger servers and less numerous servers to facilitate operations and reduce complexity.
- *Automate common tasks.* Automate the commonly performed systems tasks. Anything that can be done to reduce operational complexity will assist in maintaining high availability.
- *Document everything.* Do not discount the importance of system documentation. Documentation provides audit trails and instructions to present and future systems operators on the fundamental operational intricacies of the systems in question.
- *Establish service level agreements (SLAs).* It is most appropriate to define enterprise and service provider expectations ahead of time. SLAs should address system availability levels, hours of service, locations, priorities, and escalation policies.
- *Plan ahead.* Plan for emergencies and crises, including multiple failures in advance of actual events.
- *Test everything.* Test all new applications, system software, and hardware modifications in a production-like environment prior to going live.
- *Maintain separate environments.* Provide for separation of systems, when possible. This separation might include separate environments for the following functions: production, production mirror, quality assurance, development, laboratory, and disaster recovery/business continuity site.

- *Invest in failure isolation*. Plan—to the degree possible—to isolate problems so that if or when they occur, they cannot boil over and affect other infrastructure components.
- *Examine the history of the system*. Understanding system history will assist in understanding what actions are necessary to move the system to a higher level of resiliency in the future.
- *Build for growth*. A given in the modern computer era is that system resource reliability increases over time. As enterprise reliance on system resources grow, the systems must grow. Therefore, adding systems resources to existing reliable system architectures requires preplanning and concern for workload distribution and application leveling.
- *Choose mature software*. It should go without saying that mature software that supports a Web-based environment is preferred over untested solutions.
- *Select reliable and serviceable hardware*. As with software, selecting hardware components that have demonstrated high mean times between failures is preferable in a Web-based environment.
- *Reuse configurations*. If the enterprise has stable system configurations, reuse or replicate them as much as possible throughout the environment. The advantages of this approach include ease of support, pretested configurations, a high degree of confidence for new rollouts, bulk purchasing possible, spare parts availability, and less to learn for those responsible for implementing and operating the Web-based infrastructure.
- *Exploit external resources*. Take advantage of other organizations that are implementing and operating Web-based environments. It is possible to learn from others' experiences.
- *One problem, one solution*. Understand, identify, and utilize the tools necessary to maintain the infrastructure. Tools should fit the job; so obtain them and use them as they were designed to be used.
- *KISS: keep it simple*…. Simplicity is the key to planning, developing, implementing, and operating a Web-based infrastructure. Endeavor to minimize Web-based infrastructure points of control and contention, as well as the introduction of variables.

Marcus and Stern's book[8] is an excellent reference for preparing for and implementing highly available systems.

Reengineering the continuity planning process involves not only reinvigorating continuity planning processes, but also ensuring that Web-based enterprise needs and expectations are identified and met through the implementation of continuous availability disciplines.

118.9 Summary

The failure of organizations to measure the success of their CP implementations has led to an endless cycle of plan development and decline. The primary reason for this is that a meaningful set of CP measurements has not been adopted to fit the organization's future-state goals. Because these measurements are lacking, expectations of both top management and those responsible for CP often go unfulfilled. Statistics gathered in the *Contingency Planning & Management/KPMG Continuity Planning Survey* support this assertion. Based on this, a radical change in the manner in which organizations undertake CP implementation is necessary. This change should include adopting and utilizing the business process improvement (BPI) approach for CP. This BPI approach has been implemented successfully at many Fortune 1000 companies over the past 20 years. Defining CP as a process, applying the concepts of the CP value journey, expanding CP measurements utilizing the CP balanced scorecard, and exercising the organizational change management (OCM) concepts will facilitate a radically different approach to CP. Finally, because Web-based business processes require 24×7 uptime, implementation of continuous availability disciplines are necessary to ensure that the CP process is as fully developed as it should be.

119

The Role of Continuity Planning in the Enterprise Risk Management Structure

Carl B. Jackson

119.1 Driving Continuity Planning to the Next Level

Traditional approaches to IT-centric disaster planning emphasized the need to recover the organization's technological and communications platforms. Today, many organizations have shifted away from focusing strictly on technology recovery and more toward continuity of prioritized business processes and the development of specific business process recovery plans. In addition, continuity planners are also beginning to articulate the value of a fully functioning and ongoing continuity planning (CP) business process to the enterprise, and not just settling for BCP as usual. In fact, many organizations are expanding the CP business process beyond traditional boundaries to combine and support a larger organizational component, i.e., enterprise risk management (ERM) functionality.

EXHIBIT 119.1 How Does an Organization Measure the Performance of Its BCP Program?

	Percent
Service-level monitoring	26
Results of BCP testing	54
Audit findings	40
Performance reviews	30
Benchmarking/comparison to industry norms	14

The purpose of this chapter is to discuss the role of continuity planning business processes in supporting an enterprise view of risk management and to highlight how the ERM and CP organizational components, working in harmony, can provide measurable value to the enterprise, people, technologies, processes, and mission. The chapter also focuses briefly on additional continuity process improvement techniques.

If not already considered a part of the organization's overall enterprise risk management program, why should business continuity planning professionals seriously pursue aligning their continuity planning programs with ERM initiatives? The answer follows.

119.2 The Lack of Meaningful Metrics

Lack of suitable business objectives-based metrics has forever plagued the CP profession. As CP professionals, we have for the most part failed to sufficiently define and articulate a high-quality set of metrics by which we would have management gauge the success of CP business processes. So often, we allow ourselves to be measured either by way of fiscal measurements (i.e., cost of hot-site contracts, cost of software, cost of head count, etc., all in comparison to some ill-defined percentage of the annual IT budget), or in terms of successful or nonsuccessful CP tests, or in the absence of unfavorable audit comments.

On the topic of measurement, the most recent Contingency Planning & Management/KPMG 2002 Business Continuity Planning Survey,[1] (http://www.contingencyplanning.com/) had some interesting insights. When asked how their organization measured the performance of their BCP program, survey respondents answered as shown in Exhibit 119.1.

This annual BCP survey makes it clear that rather than measure CP program effectiveness based on value-added contributions to enterprise value drivers, management continues to base CP performance on the results of tests or on adverse audit comments.

119.2.1 Shareholder Expectations

Should shareholders hold an executive manager responsible for overall enterprise performance? Or should management be held accountable for the success or failure of individual board of director votes, or one or two tactical decisions in support of strategic goals? Overall enterprise performance against revenue, profit, and marketplace goals is the usual answer given to these questions. Tactical decisions made to achieve those goals sometimes are successful and sometimes they are not, but it is the overall effect that is important.

Rather than being measured on quantitative financial measures only, why should the CP profession not consider developing both quantitative and qualitative metrics that are based on the value drivers and business objectives of the enterprise? We need to be phrasing CP business process requirements and value contributions in terms with which executive management can readily identify. Consider the issues

[1] Contingency Planning and Management/KPMG 2002 Business Continuity Planning Survey, *Contingency Planning and Management Magazine*, 2003.

from the executive management perspective. They are interested in ensuring that they can support shareholder value and clearly articulate this value in terms of business process contributions to organizational objectives. As we recognize this, we need to begin restructuring how the CP processes are measured. Many organizations have redefined or are in the process of redefining CP as part of an overarching ERM structure. The risks that CP processes are designed to address are just a few of the many risks that organizations must face. Consolidation of risk-focused programs or organizational components, like information security, risk management, legal, insurance, etc., makes sense; and in most cases capitalizes on economies of scale.

Given this trend, consider the contribution an enterprise risk management program should make to an organization.

119.3 The Role of Enterprise Risk Management

The Institute of Internal Auditors (IIA), in its publication, *Enterprise Risk Management: Trends and Emerging Practices*,[2] describes the important characteristics of a definition for ERM as:

- Inclusion of risks from all sources (financial, operational, strategic, etc.) and exploitation of the "natural hedges" and "portfolio effects" from treating these risks in the collective
- Coordination of risk management strategies that span:
  - — Risk assessment (including identification, analysis, measurement, and prioritization)
  - — Risk mitigation (including control processes)
  - — Risk financing (including internal funding and external transfer such as insurance and hedging)
  - — Risk monitoring (including internal and external reporting and feedback into risk assessment, continuing the loop)
- Focus on the impact to the organization's overall financial and strategic objectives

According to the IIA, the true definition of ERM is "dealing with uncertainty" and is defined by them as "a rigorous and coordinated approach to assessing and responding to all risks that affect the achievement of an organization's strategic and financial objectives. This includes both upside and downside risks."

It is the phrase "coordinated approach to assessing and responding to all risks" that is driving many continuity planning and risk management professionals to consider proactively bundling their efforts under the banner of ERM.

119.3.1 Trends

What are the trends that are driving the move to include traditional continuity planning disciplines within the ERM arena? Following are several examples of the trends that clearly illustrate that there are much broader risk issues to be considered, with CP being just another mitigating or controlling mechanism.

- *Technology risk:* To support mission-critical business processes, today's business systems are complex, tightly coupled, and heavily dependent on infrastructure. The infrastructure has a very high degree of interconnectivity in areas such as telecommunications, power generation and distribution, transportation, medical care, national defense, and other critical government services. Disruptions or disasters cause ripple effects within the infrastructure with failures inevitable.
- *Terrorism risk:* Terrorists have employed low-tech weapons to inflict massive physical or psychological damage (box cutters, anthrax-laden envelopes). Technologies and tools that have

[2] *Enterprise Risk Management: Trends and Emerging Practices*, The Institute of Internal Auditors Research Foundation, 2001.

the ability to inflict massive damage are getting cheaper and easier to obtain every day, and are being used by competitors, customers, employees, litigation teams, etc. Examples include:

- *Cyber-activism:* The Electronic Disturbance Theater and Floodnet, which conducts virtual protests by flooding a particular Web site in protest
- *Cyber-terrorism:* NATO computers hit with e-mail bombs and denial-of-service attacks during the 1999 Kosovo conflict.
- *Legal and regulatory risk:* There is a large and aggressive expansion of legal and regulatory initiatives, including the Sarbanes–Oxley Act (accounting, internal control review, executive verification, ethics and whistleblower protection), HIPAA (privacy, information security, physical security, business continuity), Customs-Trade Partnership Against Terrorism (process control, physical security, personnel security), and the Department of Homeland Security initiatives, including consolidation of agencies with various risk responsibilities.
- *Recent experience:* Recent events including those proclaimed in headlines and taking place in such luminary companies as Enron, Arthur Andersen, WorldCom, Adelphia, HealthSouth, and GE have shaken the grounds of corporate governance. These experiences reveal and amplify underlying trends impacting the need for an enterprise approach to risk management.

119.3.2 Response

Most importantly, the continuity planner should start by understanding the organization's value drivers, those that influence management goals and answer the questions as to how the organization actually works. Value drivers are the forces that influence organizational behavior, how the management team makes business decisions, and where it spends its time, budgets, and other resources. Value drivers are the particular parameters that management expects to impact its environment. Value drivers are highly interdependent. Understanding and communicating value drivers and the relationship between them are critical to the success of the business to enable management objectives and prioritize investments.

In organizations that have survived through events such as September 11, 2001, the War on Terrorism, Wall Street roller coasters, world economics, and the like, there is a realization that ERM is broader than just dealing with insurance coverage. The enterprise risk framework is similar to the route map pictured in Exhibit 119.2. Explanations of the key components of this framework are as follows:

119.3.2.1 Business Drivers

Business drivers are the key elements or levers that create value for stakeholders, and particularly shareholders. Particular emphasis should be made on an organization's ability to generate excess cash, and the effective use of that cash. Business drivers vary by industry; however, they will generally line up in four categories:

1. *Manage growth:* Increasing revenue or improving the top line is achieved in many ways, such as expanding into new markets, overseas expansion, extending existing product lines, developing new product areas, and customer segments.
2. *Drive innovation:* The ability to create new products and markets through product innovativeness, product development, etc. New products and markets often give the creator a competitive advantage, leading to pricing power in the market, which allows the company to generate financial returns in excess of its competition.
3. *Control costs:* Effectively managing cost increases the competitive positioning of the business and the amount of cash left over.
4. *Allocate capital:* Capital should be effectively allocated to those business units, initiatives, markets, and products that will have the highest return for the least risk. These are the primary business drivers; they are what the organization does and the standards by which it expects to be measured.

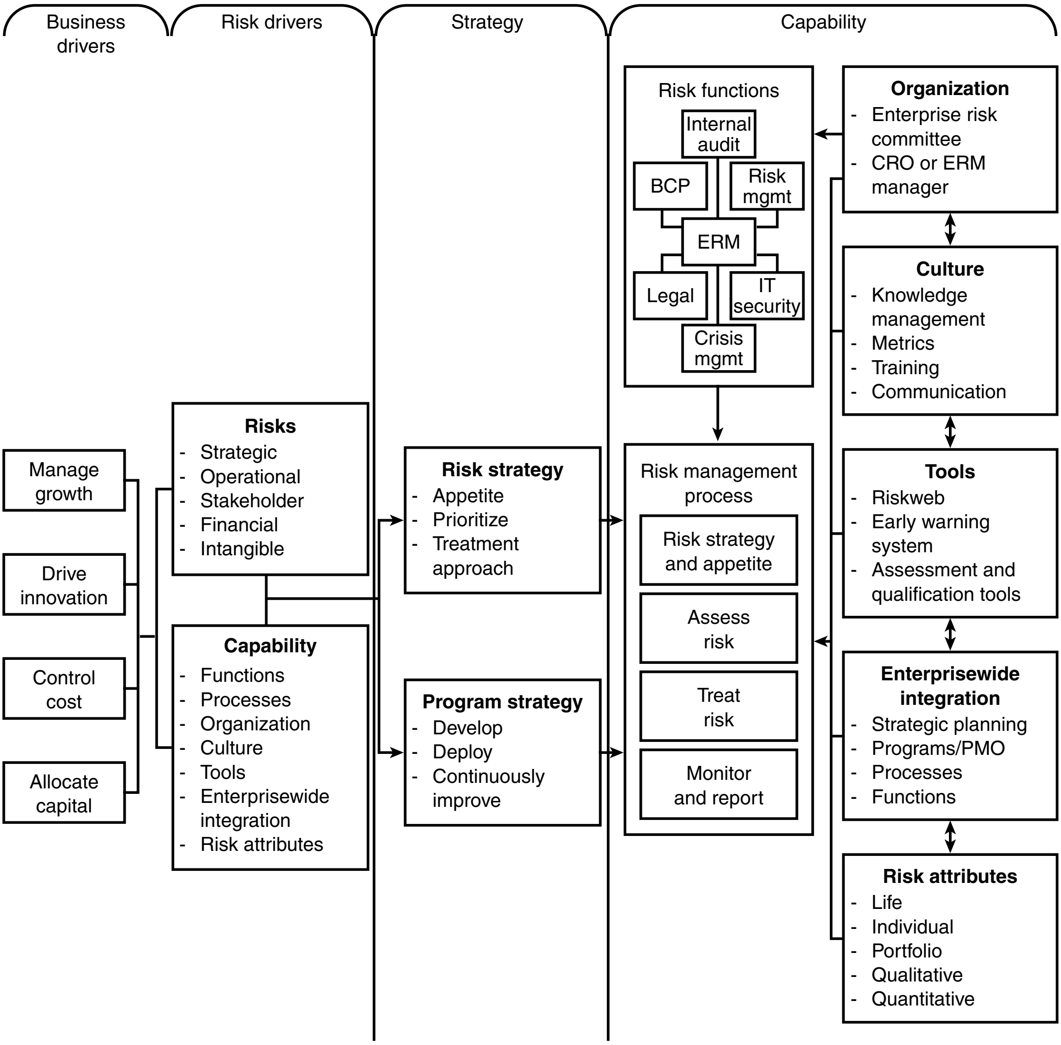

EXHIBIT 119.2 Enterprise risk management framework.

119.3.2.2 Risk Drivers

Both the types of risk and the capability of the organization to manage those risks should be considered.

- *Risk types:* The development of a risk classification or categorization system has many benefits for an organization. The classification system creates a common nomenclature that facilitates discussions about risk issues within the organization. The system also facilitates the development of information systems that gather, track, and analyze information about various risks, including the ability to correlate cause and effect, identify interdependencies, and track budgeting and loss experience information. Although many risk categorization methods exist, Exhibit 119.3 provides examples of risk types and categories.
- *Risk capability:* The ability of the organization to absorb and manage various risks, including how well the various risk management-related groups work together, what the risk process is within the enterprise, what organizational cultural elements should be considered, etc. The key areas of the risk capability will be discussed in greater detail later.

EXHIBIT 119.3 Risk Types and Categories

Strategic	Operational	Stakeholder	Financial	Intangible
Macro trends	Business interruption	Customers	Transaction fraud	Brand/reputation
Competitor	Privacy	Line employees	Credit	Knowledge
Economic	Marketing	Management	Cash management	Intellectual property
Resource allocations	Processes	Suppliers	Taxes	Information systems
Program/project	Physical assets	Government	Regulatory compliance	Information for decision making
Organization structure	Technology infrastructure	Partners	Insurance	
Strategic planning	Legal	Community	Accounting	
Governance	Human resources			
Brand/reputation				
Ethics				
Crisis				
Partnerships/JV				

119.3.2.3 Risk Strategy

The strategy development section focuses management attention on both risk strategy and program strategy.

- *Risk appetite:* Of importance in the risk strategy is the definition of appetite for risk. Risk appetite levels need to be set for various types of impacts. Each risk level should have a corresponding response that then is cascaded throughout the organization.
- *Prioritization:* Based on the risk level, the inventory of risks should be prioritized and considered for the treatment approach.
- *Treatment approach:* Although most continuity planners focus on reducing risk through contingency planning, many alternatives exist and should be thoroughly considered.
  - —*Accept risk:* Management decides to continue operations as-is with a consensus to accept the inherent risks.
  - —*Transfer risk:* Management decides to transfer the risk, for example, from one business unit to another or from one business area to a third party (i.e., insurer).
  - —*Eliminate risk:* Management decides to eliminate risk through the dissolution of a key business unit or operating area.
  - —*Acquire risk:* Management decides that the organization has a core competency managing this risk, and seeks to acquire additional risk of this type.
  - —*Reduce risk:* Management decides to reduce current risks through improvement in controls and processes.
  - —*Share risk:* Management attempts to share risk through partnerships, outsourcing, or other risk-sharing approaches.

119.3.2.4 Program Strategy

Business continuity planning programs, like all other risk management programs, require strategic planning and active management of the program. This includes developing a strategic plan and implementation work plans, as well as obtaining management support, including required resources (people, time, and funding) necessary to implement the plan.

119.3.3 Capabilities

The risk management capability speaks to the ability of the organization to effectively identify and manage risk. Following is a list of some of the key elements that make up the risk management capability:

- *Risk Functions:* Various risk management functions must participate, exchange information and processes, and cooperate on risk mitigation activities to fully implement an ERM capability. Some of these risk management functions might include:
  — Business continuity planning
  — Internal audit
  — Insurance
  — Crisis management
  — Privacy
  — Physical security
  — Legal
  — Information security
  — Credit risk management

119.4 Defining Risk Management Processes

Effective risk management processes can be used across a wide range of risk management activities, including:

- Risk strategy and appetite
  — Define risk strategy and program
  — Define risk appetite
  — Determine treatment approach
  — Establish risk policies, procedures, and standards
- Assess risk
  — Identify and understand value and risk drivers
  — Categorize risk within the business risk framework
  — Identify methods to measure risk
  — Measure risk
  — Assemble risk profile and compare to risk appetite and capability
- Treat risk
  — Identify appropriate risk treatment methods
  — Implement risk treatment methods
  — Measure and assess residual risk
- Monitor and report
  — Continuously monitor risks
  — Continuously monitor risk management program and capabilities
  — Report on risks and effectiveness of risk management program and capabilities

119.5 Organization

A Chief Risk Officer (CRO), an enterprise risk manager, or even an enterprise risk committee may manage the enterprise risk management activities. Their duties would typically include:

- Provide risk management program leadership, strategy, and implementation direction.
- Develop risk classification and measurement systems.
- Develop and implement escalation metrics and triggers (events, incidents, crisis, operations, etc.).

- Develop and monitor early warning systems based on escalation metrics and triggers.
- Develop and deliver organizationwide risk management training.
- Coordinate risk management activities; some functions may report to the CRO, others will be coordinated.

119.6 Culture

Creating and maintaining an effective risk management culture is very difficult. Special consideration should be given to the following areas:

- *Knowledge management:* Institutional knowledge about risks, how they are managed, and experiences by other business units should be effectively captured and shared with relevant peers and risk managers.
- *Metrics:* The accurate and timely collection of metrics is critical to the success of the risk management program. Effort should be made to connect the risk management programs to the Balanced Scorecard, EVA, or other business management and metrics systems.
  - — The Balanced Scorecard is a management system (not only a measurement system) that enables organizations to clarify their vision and strategy and translate them into action. It provides feedback around both the internal business processes and external outcomes to continuously improve strategic performance and results. When fully deployed, the Balanced Scorecard transforms strategic planning from an academic exercise into the reality of organizational measurement processes.[3]
  - — EVA (Economic Value Added) is net operating profit minus an appropriate charge for the opportunity cost of all capital invested in an enterprise. As such, EVA is an estimate of true “economic” profit, or the amount by which earnings exceed or fall short of the required minimum rate of return that shareholders and lenders could get by investing in other securities of comparable risk. Stern Stewart developed EVA to help managers incorporate two basic principles of finance into their decision making. The first is that the primary financial objective of any company should be to maximize the wealth of its shareholders. The second is that the value of a company depends on the extent to which investors expect future profits to exceed or fall short of the cost of capital.[4]
- *Training:* Effective training programs are necessary to ensure that risk management programs are effectively integrated into the regular business processes. For example, strategic planners will need constant reinforcement in risk assessment processes.
- *Communication:* Frequent and consistent communications around the purpose, success, and cost of the risk management program are a necessity to maintain management support and to continually garner necessary participation of managers and line personnel in the ongoing risk management program.
- *Tools:* Appropriate tools should be evaluated or developed to enhance the effectiveness of the risk management capability. Many commercial tools are available and their utility across a range of risk management activities should be considered. Quality information about risks is generally difficult to obtain and care should be exercised to ensure that information gathered by one risk function can be effectively shared with other programs. For example, tools used to conduct the business impact assessment should facilitate the sharing of risk data with the insurance program.
- *Enterprisewide Integration:* The ERM and BCP programs should effectively collaborate across the enterprise and should have a direct connection to the strategic planning process, as well as the critical

[3] “What Is the Balanced Scorecard,” www.balancedscorecard.org/basics/bsc1.html.

[4] Bennett Stewart, “About EVA,” www.sternstewart.com/evaabout/whatis.php.

projects, initiatives, business units, functions, etc. Broad, comprehensive integration of risk management programs across the organization generally lead to more effective and efficient programs.

119.7 Risk Attributes

Risk attributes relate to the ability or sophistication of the organization to understand the characteristics of specific risks, including their life cycle, how they act individually or in a portfolio, and other qualitative or quantitative characteristics.

- *Life Cycle:* Has the risk been understood throughout its life cycle and have risk management plans been implemented before the risk occurs, during the risk occurrence, and after the risk? This obviously requires close coordination between the risk manager and the continuity planner.
- *Individual and Portfolio:* The most sophisticated organizations will look at each risk individually, as well as in aggregate or in portfolio. Viewing risks in a portfolio can help identify risks that are natural hedges against themselves, and risks that amplify each other. Knowledge of how risks interact as a portfolio can increase the ability of the organization to effectively manage the risks at the most reasonable cost.
- *Qualitative and Quantitative:* Most organizations will progress from being able to qualitatively assess risks to being able to quantify risks. In general, the more quantifiable the information about the risk, the more treatment options available to the organization.

119.8 The Role of Continuity Planning

From the enterprise view, business continuity planning is an integral element of the risk functionality as mentioned earlier. The main message is that the control functions should be organized and exercised in a planned manner for the good of the enterprise.

A well-constructed and implemented enterprisewide approach to continuity planning enables an organization to deal effectively with a major business disruption. Continuity planning is a process that minimizes the impact on an organization's time-critical business processes given significant disruptive events such as power outages, natural disasters, accidents, acts of sabotage, or other such occurrences. The CP process is intended to help management develop cost-effective approaches to ensuring continuity during and after an interruption of time-critical processes, supporting systems, and resources. An effective planning structure will address the information required and steps involved in recovering and maintaining time-critical business processes — the lifeblood of an organization. Continuity planning services should be designed to assist in the development, implementation, and maintenance of effective continuity plans focused on the unique needs of the organization.

The CP process also includes assessing and improving the overall Crisis Management Planning (CMP) infrastructure of the organization. CMP focuses on assisting the organization to develop an effective and efficient enterprisewide emergency and disaster response capability. This response capability includes forming appropriate management teams and training team members in reacting to serious company emergency situations (i.e., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.).

The continuity planning approach consolidates three traditional continuity-planning disciplines as follows:

1. IT disaster recovery planning (DRP). Traditional disaster recovery planning addresses the restoration planning needs of the organization's IT infrastructures, including centralized and decentralized IT capabilities, and includes both voice and data communications network support services.
2. Business continuity planning (BCP). Traditional BCP addresses continuity of an organization's business operations (i.e., Accounting, Procurement, HR, etc.) should they lose access to their supporting resources (i.e., IT, communications network, facilities, external agent relationships, etc.).

3. Crisis management planning (CMP). CMP focuses on assisting the organization to develop an effective and efficient enterprisewide emergency and disaster response capability. This response capability includes forming appropriate management teams and training their members in reacting to serious company emergency situations (i.e., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.) to at least minimize but avoid (hopefully) a disaster. CMP also encompasses response to life-safety issues for personnel during a crisis or response to disaster. Nowhere is the need for effective risk management capabilities more evident than at a time of managing a crisis. In light of the recent headline incidents of corporate meltdowns, global terrorism, and a rapidly changing business environment, boards of directors and senior management must now take the time to reassess their organizations' crisis and enterprise risk management (ERM) capabilities.

The key components of the continuity planning development methodology are discussed next.

119.8.1 Assessment Phase

- *Business impact assessment (BIA):* During this process, an organization's business objectives and processes are examined to determine the impact of loss or interruption of service on the overall business. The goal of the BIA is to prioritize business processes and assign the recovery time objective (RTO) for their recovery and the recovery of their support resources. An important outcome of this activity is the mapping of time-critical processes to their support resources (i.e., IT applications, networks, facilities, third parties, etc.).
- *CP process current state assessment:* This process involves analyzing the organization's environment to gauge the health and vitality of the continuity planning process. This process also involves identifying or determining how the organization values the CP process and measures its success (an often-overlooked process and one that frequently leads to the failure of the CP process).
- *Risk management review (RMR):* During this process, potential risks and vulnerabilities are assessed and strategies and programs are developed to mitigate or eliminate those risks. Using traditional qualitative risk assessment approaches that focus on the security of physical, environmental, and information capabilities of the organization can support this process. In general, the RMR should identify or discuss seven basic areas:
  1. Potential threats
  2. Physical security
  3. Recoverability of time-critical processes and support resources
  4. Single points of failure
  5. Problem and change management
  6. Business interruption and extra-expense insurance
  7. A critical system off-site storage program

119.8.2 Design Phase

- *Leading practices/benchmarking services:* This optional component encompasses reviewing the performance of industry and peer benchmarking studies to determine leading practices, which can then be used to help establish the most appropriate Future State Vision for the organization's CP infrastructure.
- *Recovery strategy visioning:* This interactive, facilitated process includes developing an appropriate and measurable CP process. Major organization stakeholders can use this technique to develop the best possible overall CP process by encouraging input and buy-in.
- *Recovery strategy development:* This practice involves facilitating a workshop or series of workshops designed to determine and document the most appropriate recovery alternative to

CP challenges (i.e., determining whether a hot site is needed for IT continuity purposes; whether additional communications circuits should be installed in a networking environment; whether additional workspace is needed in a business operations environment, etc.) using the information derived from the business impact assessments. From these facilitated workshops, the CP development team works with the organization teams to create a business case documenting the optimal recovery alternative solutions.

- *Continuity plan development:* During plan development, the recovery team members are selected, assigned, and formally documented. The detailed activities and tasks associated with the recovery of time-critical processes (or IT infrastructure components, etc.) are detailed and assigned to recovery team members. All the inventory information needed by the recovery team members is also collected and documented, including data, software, telecommunications, people, space, documentation, offsite workspace, equipment, etc.
- *CP testing, maintenance, training, and measurement:* During this process, the CP development team works with the organization management to design appropriate CP testing, maintenance, training, and measurement strategies and guidelines.

119.8.3 Implement Phase

- *Plan testing:* During plan testing, the CP development team works with business unit leaders to simulate potential disasters and test continuity plans for effectiveness. Any necessary adjustments and modifications are incorporated into the plan.
- *CP process implementation:* During this phase, the development team will work with the organization to deploy the continuity plans that have been developed, and to implement long-term testing, maintenance, training, and measurement strategies, as determined in the Design Phase.
- *Continuity and crisis management plan implementation:* During this phase, the initial versions of the continuity and crisis management plans are implemented across the enterprise environment.

119.8.4 Measure Phase

The continuity plan and process review and maintenance phase involves the regular review and maintenance of the continuity and crisis management plans.

119.9 Other Techniques for Improving CP Efficiencies

In combination with the introduction of ERM disciplines in improving the CP function, traditional CP Process Improvement, Organizational Change Management, and Balanced Scorecard techniques can also be used to assist in improving the efficiencies of continuity planning business processes.

119.9.1 CP Process Improvement

Harrington et al., in *Business Process Improvement Workbook*,[5] point out that applying process improvement approaches can often cause trouble unless the organization manages the change process. They state that

> …approaches like reengineering only succeed if we challenge and change our paradigms and our organization's culture. It is a fallacy to think that we can change the processes without changing the behavior patterns or the people who are responsible for operating these processes.

[5] Harrington, H. James, Esseling, Erick K.C. and Van Nimwegen, H. 1997. *Business Process Improvement Workbook*, McGraw-Hill, New York.

119.9.2 The Need for Organizational Change Management

The plans may be ready for the company, but the company may not be ready for the plans. Organizational change management concepts, including the identification of people enablers and barriers, and the design of appropriate implementation plans that change behavior patterns, play an important role in shifting the CP project approach to one of CP process improvement.

> There are a number of tools and techniques that are effective in managing the change process, such as pain management, change mapping, and synergy. The important thing is that every BPI program must have a very comprehensive change management plan built into it, and this plan must be effectively implemented.[5]

119.9.3 How Can We Measure Success? The Balanced Scorecard Concept

A complement to the CP Process Improvement approach is the establishment of meaningful measures or metrics that the organization can use to weigh the success of the overall CP process. This concept was mentioned briefly when discussing development of metrics that fit the culture of the organization. Traditional CP measures have included:

- How much money is spent on hot sites?
- How many people are devoted to CP activities?
- How many adverse audit comments have been brought to management's attention?

Instead, the focus should be on measuring the CP process contribution to achieving the overall goals of the organization, as mentioned in the ERM discussion. This focus helps us to:

- Identify agreed-upon CP development milestones
- Establish a baseline for execution
- Validate CP process delivery
- Establish a foundation for management satisfaction to successfully manage expectations

The *CP Balanced Scorecard* includes a definition of the:

- Value Statement
- Value Proposition
- Metrics and assumptions on reduction of CP risk
- Implementation Protocols
- Validation Methods

Following this Balanced Scorecard[6] approach, and aligning development of the scorecard with the ERM business and risk drivers mentioned earlier, the organization could define what the future-state of the CP process should look like. This future-state definition should be co-developed by the organization's top management and those responsible for development of the CP process infrastructure. Current State/Future State Visioning is a technique that can also be used for developing expectations for the Balanced Scorecard. Once the future-state vision is defined, the CP process development group can outline the CP process implementation critical success factors in the areas of:

- Growth and innovation
- Customer satisfaction
- People

[6] Kaplan Robert S. and Norton, David P. 1996. *Translating Strategy Into Action: The Balanced Scorecard*, HBS Press.

- Process quality
- Financial state

These measures must be uniquely developed based on the specific organization's culture and environment.

119.10 Next Steps

What can the CP professional do within his organization to begin considering the feasibility of shifting the continuity planning processes under the ERM umbrella? One suggestion might be to identify the Enterprise Risk Committee or other suitable risk management organizational components within the company and initiate discussions relative to some of the issues raised in this chapter. In addition, depending on the industry group your organization is in, there may well be industry leading practices or examples of other organizations that have undertaken this course of action. You may well be able to profit from the experiences of others. There are professional societies such as the Risk and Insurance Managers Society, Inc. (http://www.rims.org/) and the Institute of Internal Auditors (http://www.theiia.org) where additional information can be obtained on this subject.

119.11 Summary

The failure of organizations to measure the success of their CP implementations has led to what seems like an endless cycle of plan development and decline. The chief reason for this cycle is that a meaningful set of CP measurements that complement the organization's business drivers have not been adopted. Because these measurements are lacking, expectations, reasonable or otherwise, of both executive management and those responsible for CP often go unfulfilled. Statistics gathered in the Contingency Planning and Management/KPMG Continuity Planning Survey support this assertion.

A true understanding of business objectives and their value-added contributions to overall business goals is a powerful motivator for achieving success on the part of the CP manager. There are many value drivers of strategic (competitive forces, value chains, key capabilities, dealing with future value, business objectives, strategies and processes, performance measures, etc.), financial (profits, revenue growth, capital management, sales growth, margin, cash tax rate, working capital, cost of capital, planning period and industry-specific subcomponents, etc.), and operational value (customer or client satisfaction, quality, cost of goods, etc.) that the CP professional should focus on, not only during the development of successful continuity planning strategies, but also when establishing performance measurements.

This chapter has introduced the role of continuity planning business processes in supporting an enterprise view of risk management, and to highlight how, working in harmony, the ERM and CP functions can provide measurable value to the enterprise, people, technologies, processes, and mission. It is incumbent upon continuity planning managers and enterprise risk managers to search for a way to merge efforts to create a more effective and efficient risk management structure within the enterprise.

Special thanks go to Mark Carey, President, DelCreo, Inc., for his valuable contributions to this chapter.

120 Contingency at a Glance

Ken M. Shaurette
Thomas J. Schleppenbach

120.1 Introduction

Beginning in the 1980s, information security attracted the attention of the boardrooms and information superhighways of corporate America but was not a major concern. Then came the disastrous events of September 11, 2001, which more than any other event in history assured security forever a place in the media and, at least for a few months, caused organizations around the world to evaluate their contingency plans. Executives could no longer overlook the importance of security; they finally recognized that information security was an issue that required proper diligence. It is no longer possible to plead ignorance, because nearly every trade magazine reports on incidents of security breaches on an almost daily basis. The catastrophe of 9/11 shed light on the scope and importance of information security. September 11 also made organizations wake up to the fact that people and business processes were also critical to an organization's survival. Just recovering the data center is not enough, as it is still necessary to have the people to run the computers, answer the telephones, and input the data.

Information security and contingency planning are quickly becoming routine requirements for day-to-day business operations. They are singled out as specific requirements in many of the regulations with which organizations must comply. Planning continuation of a business in the aftermath of a disaster is a complex task. An organization's preparation for, response to, and recovery from a disaster require the cooperative efforts of third-party organizations in partnership with the functional areas supporting the business. This chapter uses a simple real-life example to explore disaster recovery, followed by discussing the contingency plan that outlines and coordinates business survival efforts.

The terms *disaster recovery*, *business continuity*, and *IT contingency* are all used rather interchangeably and all relate to the business contingency process, but they are defined differently. For definitions of these terms, a very good reference is the National Institute of Standards and Technology (NIST) publication SP800-34 (*Contingency Planning Guide for Information Technology*, 2002). This chapter discusses disaster recovery or business continuity or, more generally, contingency planning. Several standards, guidelines, books, and articles have already been published on this subject, so we will try to keep this discussion concise and entertaining.

120.2 The Story

You are at work at about 1:30 in the afternoon when your wife pages you. Of course; this lets you know that something critical must be going on at home, because that pager the company gave you is for business use only. When you call her back, all you hear is a very frantic "…water everywhere…" and you realize that she is serious. She is excited about something very important, and it takes you a couple minutes just to calm her down. She tells you that she put your daughter down for a nap and when she stepped back into the hallway she found herself ankle deep in water. Water? Where did all the water come from? Did you get it cleaned up? She says, "Of course it's not cleaned up! It's still rising!" You calmly explain to her that she needs to get off the phone and turn off the main water valve. Then you helpfully tell her to put down as many towels as possible and use the wet–dry vacuum to suck up as much water as possible before it begins to leak down to the first floor. (To clarify things a bit, we need to tell you that this is a traditional two-story home with three bedrooms and two bathrooms, both upstairs.)

At about 3:30 your wife calls back to let you know that things are under control but there is a significant amount of damage. It appears that one of your four kids was in the bathroom on the second floor across the hall while your wife was putting the youngest down for a nap. As usual, the child used the traditional half roll of toilet paper and then flushed. Of course, this resulted in a plugged toilet. To compound the problem, though, when the toilet was flushed, the little chain on the inside of the toilet tank wrapped around the little bar connected to the flush lever, so the water continued to flow until the handle was jiggled to shut it off. This had been happening on occasion over the last few months any time the lever was flushed real hard but you hadn't gotten around to fixing it. This time, the water flowed and flowed some more, creating a rather impressive waterfall effect in the bathroom.

Timing is everything with these types of incidents. And timing was not on your side. It always takes 30–45 minutes to rock your daughter to sleep so there was plenty of time for the disaster to magnify. When your wife stepped into the hallway from the bedroom she stepped into about two inches of water.

After the first phone call, she began to take some recovery actions, such as placing several towels down and emptying the linen closet. She surveyed the extent of the damage when she went downstairs to get the vacuum. The kitchen had over an inch of water. She continued down to the basement and strategically placed buckets to begin collecting the dripping water. She spent the next two hours vacuuming. You were lucky because by the time you got home from work much of the cleanup was done; however, the significant amount of water damage still had to be dealt with. The upstairs carpet was ruined, and the kitchen ceiling was obviously sagging and still holding water. In fact, it was pretty much destroyed.

120.3 Incident Management

Reacting to an incident and preparing for one are two very different things. Risk can be handled one of three ways. It can be accepted, mitigated, or transferred. It would be quite difficult to put special controls in place to mitigate the risk of an incident such as we just described; however, you could have been a little less lazy and fixed the chain in the toilet when you noticed it was sticking. Many people experiencing a similar scenario are not able to simply accept the risk, because the mortgage company still owns most of the home and they still need to live there, so risk is transferred by purchasing homeowners' insurance, thus transferring the risk to an insurance policy to help recover from the damage.

Risk management must also identify residual risks for which a contingency plan must be put into place; thus, the contingency plan requires that a business impact assessment be done to determine the most critical assets—not necessarily the most valuable to the company but those that are critical to continuation of normal business and business survival. Preventing an incident can be best managed by periodic security risk assessments to identify measures and controls that can mitigate the risk. There are well-defined relationships between identifying and implementing security controls to prevent and minimize potential critical incidents and the process of developing and maintaining the contingency plan and implementing the contingency plan when the event has occurred. In our story, your homeowner's policy covered the costs to repair the damage.

120.4 Getting the Contingency Process Started

Contingency can be defined as a coordinated strategy involving plans, procedures, and technical measures that enable the recovery of information technology (IT) systems, operations, and data after a disruption. Contingency planning generally includes one or more approaches to restore disrupted services, and it is designed to mitigate the risk of system and service unavailability by focusing on effective and efficient prevention and recovery solutions. The contingency planning process can be described as these basic steps:

- Develop contingency planning policy.
- Conduct business impact assessment.
- Identify preventative controls.
- Develop recovery strategies.
- Develop contingency plan.
- Plan testing, training, and exercises.
- Plan maintenance activities.

A great place to begin is to have a methodology. NIST methodologies and special publications can be found on their Web site at http//csrc.nist.gov/publications/nistpubs/index.html. These resources are outstanding and are referenced in many federal regulations pertaining to information security, such as the Health Insurance Portability and Accountability Act (HIPAA) or the Gramm–Leach–Bliley Act (GLBA).

Various processes are involved in ensuring business continuity. Listed below are some to give you an idea of how many are involved (all of these are defined in various NIST publications):

- Business continuity plan (BCP)
- Business recovery (or resumption) plan (BRP)
- Continuity of operations plan (COOP)
- Continuity of support plan/IT contingency plan
- Crisis communications plan
- Cyber incident response plan
- Disaster recovery plan (DRP)
- Occupant emergency plan (OEP)

120.5 The Policy

So far this chapter has provided a high-level framework and methodology. An important next component is policy. The purpose of this section is to assist with assessing an organization's current contingency planning policy. If an organization does not have an existing contingency planning policy, this section will assist in creating one. Most organizational operations managers and security officers recognize that business continuity planning and disaster recovery planning are vital activities necessary to protect the well-being of the organization, In many cases, the regulations that organizations must comply with make this a requirement. Even so, many organizations are still operating with plans that are out of date or inadequate. The issue is not whether a disaster will happen or even reaching agreement on the need for a plan. Nonetheless, there remains a gap for many organizations between what should be in place and what is.

Among the numerous reasons for this large gap between adequate, necessary contingency plans and actual plans that organizations have in place is that developing a contingency policy can be a very complex and difficult task. When viewed as such a large project, often it is easier to let it slide because no one knows where or how to start. In addition, some of the commercially available planning products are extremely difficult to master, adding to the frustration of developing the policy. Finally, the time and effort necessary to develop and maintain a contingency policy are expensive. If the business continuity process is not seen as mission critical or having direct organizational benefit, it is often of a lower priority for staff. Contingency planning is like insurance, and unfortunately many of us despise the need to pay a premium just because something might happen.

The contingency planning policy statement should define the organization's overall contingency objectives and establish the organizational framework and responsibilities for IT contingency planning. When addressing regulatory risk issues, regulatory agencies will have alerted the organization to the importance of contingency planning. Disruption of organizational operations can result in exposing a company to various risks. These risks include compliance risk, transaction risk, reputation risk, and strategic risk. Organizational leadership and the board of directors are responsible for developing emergency and disaster recovery plans designed to keep disruption of operations at a minimum.

The contingency policy and procedures should contain the following key elements:

- Assigning authority for implementing the emergency disaster recovery plan and identifying who is responsible and their roles
- Identification of risk
- Description of data center emergency procedures established to protect personnel and property during emergencies
- Identification of resource and training requirements
- Description of backup considerations
- Standards for testing the disaster recovery plan
- Guidelines for disaster recovery planning

Other considerations are emergency procedures and plans for contingency initiatives in the event of a disaster affecting organizational operations, which are a critical part of any institution's overall corporate contingency plan. For additional references and insights, refer to the NIST contingency plan guide (SP800-34), also referred to as the *Disaster Recovery Planning Manual.*

To provide an easy-to-use, understandable, and effective tool to create a contingency policy, we will begin by discussing the basic process. The process of creating a sound business continuity and disaster recovery plan can be broken down into several easily understood and accomplished tasks. The policy development process is broken down into the following steps:

- Consider the potential impacts of disaster and understand the underlying risks.
- Construct the IT contingency policy.
- Implement steps to maintain, test, and audit the IT contingency policy.
- Identify senior management support and ownership.
- Identify and acquire resources.
- Define responsibilities.
- Define project deliverables and timeline and budget.

Policies and procedures will address each of the following areas:

- Statement of need and definitions (e.g., leadership, management, and directors recognize the need to establish comprehensive emergency and disaster recovery policies and plans to protect employees during emergencies and to provide for the continuity of data processing operations)

- Purpose (e.g., the purpose of the policy is to protect personnel and property during emergencies and to provide procedures to recover operations should an emergency render any part of the organization's IT operations or data access unusable or unavailable)
- Specific goals.

Samples of these goals would include:

- Establish authority and responsibility in the development, implementation, and maintenance of an emergency and disaster recovery policy and plan especially considering the IT department.
- Provide documentation of any emergency prevention measures that have been implemented.
- Document backup plans for hardware, programs, and documentation, as well as all data.
- Document criticality, priority, and dependency of one system on another or applications on specific systems.
- Establish recovery timeline.
- Outline strategies for disaster recovery.
- Establish requirements to periodically test the adequacy of the backups and ability to restore following the recovery plans.

The following are elements to include:

- Authority
- Risk management
- Compliance risk
- Transaction risk
- Strategic risk
- Reputation risk
- Definitions
- Emergency procedures
- Emergency phone numbers
- Disaster recovery planning
- User involvement in disaster recovery strategies
- Standards for testing disaster recovery plan
- Services
- Regulatory compliance checklist (if appropriate)

120.6 The Process and Plan

Step 1: Gather information about the environment.

The kind of information that would be included in the data gathering includes:

- IT systems (applications, databases, networks, systems)
- Business unit manual processes
- Key people involved in each business unit's critical processes
- Document storage locations
- Current work flow documentation
- Business strategy plans

- Service level agreements between IT and the business units
- IT strategy plans
- Resources
- Current and past availability processes
- How past availability problems were solved
- Current vendor list for IT and business equipment
- Insurance policy (does it cover business disruption?)
- Industry peers' approach to IT contingency planning

To formulate a plan it is helpful to find out what your industry peers are doing with their contingency planning. How similar are your efforts to those of your peers? Any information that is gathered or generated must be centralized. If gathered information is outdated, it should be updated to match the current environment. This may take a lot of resources from each of the business units, depending on how outdated the information has become. It is very important to locate these items prior to developing the plan and starting the contingency planning process because it will help make the contingency process more efficient and affordable. Other considerations are to know your resources (critical to project efforts), to have dedicated resources (or the plan will never get done), and to consider using interns for repetitive tasks to free up critical IT resources.

Step 2: Perform a business impact assessment.

The most time-consuming, but critical, part of any contingency planning process is the business impact assessment (BIA). The BIA is used to prioritize systems by determining how long a system or process can be unavailable before it severely impacts the organization and how new data, generated since an incident, should be defined when the systems or processes become available again. To conduct the business impact assessment, identify critical resources, identify outage impacts and allowable outage times, and develop recovery priorities. One of the more difficult activities will be to identify the important technology systems and components of the company network that are necessary to support business systems. Especially tough will be documenting dependencies between the systems and network to determine recovery order.

Step 3: Identify, implement, and maintain preventive controls.

Where feasible and cost effective, putting in place preventive methods to avoid system loss is preferable to the actions that will be necessary to recover a system after a disruption. A wide variety of basic preventive controls are available, depending on system type and configuration; however, some common measures are listed below:

- Uninterruptible power systems (UPSs) provide short-term backup power to all system components. This will include supporting environmental and safety controls systems.
- Putting in place gasoline or diesel-powered generators will provide longer term backup power to withstand outages of longer duration, especially to allow systems to be shut down properly to reduce data loss and corruption.
- An emergency "master system shutdown" switch will provide immediate shutdown of equipment to reduce even greater damage in case of an incident requiring immediate system shutdown.
- Air-conditioning systems should have excess capacity that does not allow the failure of one component, such as a compressor, to jeopardize its continued operation to provide an adequate climate-controlled environment.
- Fire and smoke detectors as well as water sensors properly placed in the computer room ceiling and floor are preventive measures that also reduce loss and damage. Valuable in the computer

room and near critical hardware are plastic tarps, which can be unrolled over equipment to protect it from water damage. This can reduce costs for replacement of equipment.

- Fire suppression systems are necessary controls that also prevent extensive damage to hardware and reduce loss in the case of fire.
- Heat-resistant and waterproof containers should be available for the storage of backup media and vital records that are not in electronic format. These can be used to store media before transporting them to an offsite storage facility as part of an emergency recovery procedure.
- Proper offsite storage locations should be identified for backup media and any critical records that are not electronic, including system documentation.
- Technical security controls should be in place, such as encryption (including key management and access controls systems with least-privilege access implementation based on corporate roles for access to data).
- Backups should be performed frequently and tested regularly.

Step 4: Develop recovery strategies.

Thorough recovery strategies ensure that any critical system can be recovered in an appropriate timeframe based on the requirements defined during the business impact assessment. Important considerations for the recovery strategies include:

- Backup methods
- Alternate sites
- Equipment replacement
- Roles and responsibilities
- Cost consideration

Recovery strategies provide a means to restore critical operations quickly and effectively following a service disruption. The strategies should address disruption impacts and allowable outage times identified in the BIA. Several alternatives should be considered when developing the strategy, including cost, allowable outage time, security, and integration with larger, organization-level security and safety plans.

Step 5: Develop the contingency plan.

Contingency plan development is a critical step in the process of implementing a comprehensive contingency planning program. The plan contains detailed roles, responsibilities, teams, and procedures associated with restoring an IT system following a disruption. The contingency plan should detail and document technical capabilities designed to support contingency operations. The contingency plan should be tailored to the organization and its requirements. Plans need to balance detail with flexibility; usually the more detailed the plan is, the less scalable and versatile the approach. The information presented here is meant to be a guide.

Step 6: Plan testing, training, and contingency plan exercises.

- Develop test objectives.
- Develop success criteria.
- Document lessons learned.
- Incorporate them into the plan.
- Train personnel.

Training prepares recovery personnel for plan activation and improves the plans effectiveness and preparedness. Plan testing is a critical element of successful contingency capabilities. Testing enables plan deficiencies to be identified and addressed. Testing also helps evaluate the ability of the recovery staff to implement the plan quickly and effectively. Each contingency plan element should be tested to confirm the accuracy of individual recovery procedures and the overall effectiveness of the plan.

In the contingency test) perform system recovery on an alternative hardware platform from backup media stored offsite. The recovery testing provides verification that the recovery media still function and it demonstrates the level of coordination among members of the recovery team and the effectiveness of documentation and communication. Also verified by testing the contingency plan are:

- Internal and external connectivity
- System performance using alternative equipment
- Restoration of normal operations
- Notification and communication procedures
- Coordination with internal and external organizations
- Thoroughness and accuracy of documentation

Step 7: Plan maintenance.

The contingency plan must be reviewed and updated as part of normal day-to-day operations. Any plan document changes are made as systems, networks, and applications are changed. A good way to keep documentation up to date is to make updating of contingency plan documentation a routine requirement of change management. Change management quality procedures should include this validation as part of change approval. To be effective, the plan must be maintained in a readiness state that accurately reflects system requirements, procedures, organizational structure, and policies. IT systems undergo frequent changes because of shifting business needs, technology upgrades, or new internal or external policies; therefore, it is essential to update the contingency plan as part of the change management procedures to ensure that any new information is documented and contingency measures are revised as appropriate. As a rule, the entire plan should be reviewed for accuracy and completeness using the testing procedures at least annually. Other major reviews of the plan documentation should be completed whenever significant changes occur to any element of the plan. Certain elements will require more frequent reviews, such as contact lists and roles and responsibilities. Based on the system type and criticality, it may be reasonable to evaluate plan contents and procedures more frequently. At minimum, plan reviews should focus on the following elements:

- Operational requirements
- Security requirements
- Technical procedures
- Software and hardware and other equipment (types, specifications, and amount)
- Names and contact information of team members
- Names and contact information of vendors, including alternate and off-site vendor points of contact (POCs)
- Alternative and off-site facility requirements
- Vital records (electronic and hardcopy).

120.7 Epilogue

Contingency planning represents a broad scope of activities designed to sustain and recover critical IT services after an emergency. Contingency planning fits into a much broader emergency preparedness environment that includes organizational and business process continuity and general business recovery planning. An organization can use a suite of plans to properly prepare response, recovery, and continuity activities for disruptions affecting the organization's IT systems, business processes, and facilities. Because of the inherent relationship between an IT system and the business process it supports, plans should be coordinated as they are developed and updated to ensure that recovery strategies and supporting resources neither negate each other nor duplicate efforts. So, remember, every time you flush consider the risks and whether or not you are prepared to deal with the consequences.

121

The Business Impact Assessment Process and the Importance of Using Business Process Mapping

Carl B. Jackson

121.1 Introduction

Without question, business continuity planning (BCP) is a business process issue, not a technical one. In fact, business continuity planning is a business process in itself. We understand that each time-critical business process and support component of the enterprise must play a part during the development, implementation, testing, and maintenance of the BCP process, and it is the results of the business impact assessment (BIA) that will be used to make a case for further action. With these thoughts in mind, the objective of this chapter is to discuss the BIA and the importance of identifying enterprise business processes and standardizing a business process naming convention to facilitate an efficient BIA process.

121.1.1 Not Just Information Technology Focused

In the past, business continuity planning has often been thought of as focusing simply on the recovery of computer systems, often referred to as disaster recovery planning. Evolving experience in the field of continuity planning has led us to understand that recovery of only information technology (IT) does not promise the survival of an organizational following a serious disruption or disaster. Indeed, speedy recovery of an IT function is useful only if the organizational business units themselves are able to continue to operate, even at reduced efficiencies. That is, they must be in a position to communicate with customers or clients, business partners, vendors, and the like; to receive and enter orders; to produce and deliver goods and services; and to collect and book revenue. The most efficient approach toward ensuring enterprise continuity is to anticipate and prepare continuity plans that not only include the IT infrastructure but also begin with and focus attention on the organization's time-critical business processes and the resources that support those processes.

121.1.2 The Importance of the Business Impact Assessment

While attempting to prepare to recover every enterprise mission-critical business process within the first few minutes or hours following a major disruption or disaster may appear to be a practical or reasonable approach to continuity planning, it quickly becomes apparent to those involved in the planning process that recovering everything quickly is simply impossible. Even if it were possible, the cost of acquiring hot backup resources to support every mission-critical process is simply an unacceptable one. This is where the BIA process plays a pivotal role. The purpose of the BIÁ has traditionally been twofold. This first is to provide a basis upon which to prioritize mission-critical processes, yes, but more importantly it is to prioritize a hierarchy of mission critical processes that are time critical. It can truly be said that, although all time-critical processes are mission critical, not all mission-critical processes are time critical.

121.2 Executive Management Support

Gaining executive management support is where to begin. This support must be clearly articulated to the organization and is critical to the success of the continuity planning infrastructure. The folks responsible for the project must have the authority and resources to undertake such a project. The ability to reach consensus with the varied organizational interests also hinges on the presence of a strong executive sponsorship.

How does the planner obtain and keep this commitment?

One of the most effective ways to gain and maintain management support is to help educate management as to the risks of not having a continuity planning process in place. If executive management does not understand the impacts that an interruption would have upon time-critical business processes, if is sometimes difficult to attract the attention and support needed to undertake continuity planning. Some suggested steps in obtaining executive management support include:

- Conducting appropriate research to understand:
  Both the mission- and time-critical business processes of the organization
  Management's strategic and tactical initiatives and vision
  The competitive environment in which the organization operates
  The people issues associated with developing a continuity planning process

- Performing a preliminary high-level risk analysis focused on availability vulnerabilities
- Identifying any relevant regulatory or legal requirements
- Building the business case for the continuity planning projects that will ensue
- Obtaining commitment for all the next step activities that will lead to a fully implemented continuity planning infrastructure

121.2.1 Conducting Appropriate Research

The initial step in any continuity planning project undertaking is for the planner to gain a clear idea of the organization's uniqueness, culture, competitive position, and business processes. One challenge plaguing continuity planning industry professionals over the years has been the tendency to be myopic in their view of the individual components of a company. This view has often led planners down a technical course of action that mistakenly focuses attention away from the larger business issues facing the company. The continuity planning business process itself involves more than just continuity of the technical IT and communications infrastructures of the company and therefore requires a broader vision and approach to preparing executive management for what should truly become an enterprise-wide continuity planning process.

121.2.2 Understanding Management's Vision

Aside from understanding the fundamental processes that the enterprise relies upon to conduct its affairs, the planner must also have a clear understanding of executive management's visions for the organization.

What are the strategic and tactical visions, mission, and guiding principles that management is fostering and focusing resources on?

By understanding management's mission, the planner can derive the critical success factors they are striving to achieve. Understanding critical success factors can help the planner appreciate the strategies, tactics, and metrics management is using to achieve and measure success. This information is extremely valuable as it allows customization of the continuity planning processes to dovetail with and support the overall strategies and tactics management is using to achieve success. Matching continuity planning initiatives with enterprise business strategies, as measured by management's own critical success factors, is probably the single best way to ensure that executive management support is obtained. The planner can use this knowledge to identify opportunities for quick-hit continuity planning activities that will be most beneficial to the organization in the short term, while also mapping a longer' term approach to designing a continuity planning solution suited to the company.

Where would the planner obtain this type of information?

Clearly, interviews or discussions with executive management representatives would be a good starting point. Additionally, annual reports, strategic and tactical planning documents, and industry reports that depict the current state of the industry and project future state predictions, as well as the business process maps obtained or developed previously, would all be of vital assistance in understanding management vision.

121.2.3 Understand the Competitive Environment

To understand the strengths and weaknesses of the organization, the planner should have an understanding as to how it compares with the marketplace or competitive environment. Internal sources of competitive marketplace information include information that has probably already been collected by the marketing, research and development, and investment departments, for example. External sources of competitive information include *Standard and Poor's Industry Surveys*, and *Hoover's Online* has information on 14,000 public and private U.S. and non-U.S. companies, which would include competitors. There are many others, of course, including professional, industry, or trade organizations. Competitive information is available and can be had with little effort. The planner who can demonstrate an understanding of the competitive environment has already gone a long way toward helping ensure executive management attention and response when resources are needed for continuity planning purposes.

121.2.4 Understand the People Issues

In today's rapidly shifting business and uncertain political environments, organizations are hurrying to stay abreast of rapidly changing technology, business, and political realities. Unfortunately, many organizations focus tremendous amounts of resources and time on analysis and refinement of technology-related issues, for example, but give little attention to how best to implement or deploy the resulting strategies from a people perspective. The continuity plans may be ready for the enterprise, but is the enterprise ready for the continuity plan?

What should the planner do to ensure that the organization is ready for the continuity planning process?

The planner must understand that the company's culture and people play a significant role in the overall success of any project implementation, including continuity planning. In the past, many well-conceived and well-designed continuity planning process components have fallen short or have cost much more than anticipated because of a lack of appreciation for the people issues, and successful continuity planning is almost entirely people centric; that is, people must take the initiative in the first place to actually perform and develop continuity plans and arrange for the technologies and processes that must be in place to allow the continuity processes to work. Although a continuity planning process certainly has its technical components, it is the people who initiate and facilitate development and implementation of the processes and technologies that must be put into place, and it is the people who have to test, maintain, and measure the performance. Should a disaster or disruption occur, it is the people who will have to execute the recovery effort. When managers do not consider the organization's culture and people impacts, projects fail. The planner must consider the organizational change management issues associated with implementing an appropriately designed continuity planning infrastructure by involving company personnel at an early stage, by setting appropriate expectation levels, and by utilizing a teaming approach in order to minimize resistance to change. The planner should ensure that key stakeholders are identified and utilized from the planning phase forward, clearly articulate benefits and rewards of the process, and emphasize the "what's in it for me" payback.

121.2.5 Business Process Mapping

In preparation for beginning a continuity planning project, whether specifically focused on a limited number of components of the company or for enterprise-wide implementations, the planner must consider and understand the business issues facing the management group. This process begins by gaining a thorough understanding of the business processes of the organization. All organizations in the public and private sectors share similar business processes with other companies or organizations in a similar industry group, A thorough understanding of the enterprise business process allows the planner to see how megaprocesses, major processes, and major subprocesses operate and how they correlate one to another, map across the organization, and interrelate in terms of their availability requirements. The continuity planner can use business process definitions for BCP planning, implementation, training, testing, and measurement and for helping to facilitate the BIA process itself. The planner's ability to speak intelligently about the time-critical needs of precise business processes will enhance executive management communications and confidence in forthcoming recommendations.

121.2.6 Building the Business Case

Armed with this information, the recovery planner can then set out to build the business case for continuity planning. Although some organizations are mandated by regulations to establish a continuity planning process, most are not. The decision to put in place a continuity planning process is a business decision that is measured in terms of expected value-added contributions of the process relative to the commitment of resources required to achieve a successful outcome. As with any business plan, the objective is to identity benefits of having an appropriate continuity planning process. In most cases, the planner is faced with the appearance of having a non-profit-generating project with the goal of offsetting potential losses. Unfortunately, in the past it has been difficult for continuity planners to clearly demonstrate the value-added contribution an effective continuity planning process brings to the organization's people, processes, technology, and mission. In presenting the business case return on investment, it should be measured in more than simply financial information. Qualitative and quantitative measures can be applied to potential loss impacts associated with a disruption in time-critical business processes. Of course, determining the significance of these threats is the purpose of the business impact assessment, so only preliminary business case estimates can be done at this point, awaiting results of the BIA. Preliminary financial estimates can be developed, however, using an interactive and more subjective information gathering process. The planner can estimate a rough order of magnitude (ROM) baseline of resource commitment required to support the case for proceeding with the next phases of the methodology that initially begins with the BIA.

121.3 The BCP Process Development

The BIA is the key to a successful BCP implementation, and understanding and standardizing enterprise business process names is critical to the success of the BIA. By way of background, let's focus on where the BIA fits into the BCP development process. Following is a relatively generic methodology that is commonly used for the development of business unit continuity plans, crisis management plans, and technological platforms and communications network continuity plans.

- *Phase I. BCP Project Scoping and Initiation*—This phase determines the scope of the BCP project and develops the project plan. It examines business operations and information system support services to form a project plan to direct subsequent phases. Project planning must define the precise scope, organization, timing, staffing, and other issues. This enables articulation of project status and requirements throughout the organization, chiefly to those departments and personnel who will be playing the most meaningful roles during the development of the BCP.
- *Phase II. Business Impact and Risk Assessment*—This phase involves identification of time-critical business processes and determines the impact of a significant interruption or disaster. These impacts may be financial, in terms of dollar loss, or operational in nature, such as the ability to deliver and monitor quality customer service.
- *Phase III. Developing Continuity Strategies*—The information collected in phase II is employed to approximate the resources (e.g., business unit or departmental space and resource requirements, technological platform services, communications networks requirements) necessary to support time-critical business processes and subprocesses. During this phase, an appraisal of recovery alternatives and associated cost estimates are prepared and presented to management.
- *Phase IV. Continuity Plan Development*—This phase develops the actual plans (e.g., business unit, crisis management, technology-based plans). Explicit documentation is required for execution of an effective continuity process. The plan must include administrative inventory information and detailed continuity team action plans, among other information.
- *Phase V. Implement, Test, and Maintain the BCP*—This phase establishes a rigorous, ongoing testing and maintenance management program.

- *Phase VI. Implement Awareness and Process Measurement*—The final and probably the most crucial long-term phase establishes a framework for measuring the continuity planning processes against the value they provide the organization. In addition, this phase includes training of personnel in the execution of specific continuity activities and tasks. It is vital that they be aware of their role as members of continuity teams.

121.4 The BIA Process

As mentioned earlier, the intent of the BIA process is to help the organization's management appreciate the magnitude of the operational and financial impacts associated with a disaster or serious disruption. When they understand, management can use this knowledge to calculate the recovery time objective for time-critical support services and resources. For most organizations, these support resources include:

- Facilities
- IT infrastructure (including voice and data communications networks)
- Hardware and software
- Vital records
- Data
- Business partners

The connection is made when each of the time-critical business processes is mapped to the above supporting resources. Every place a time-critical process touches a supporting resource, that resource is a candidate for some level of BCP effort; therefore, the value of a thorough understanding of the company's business processes cannot be overemphasized.

121.4.1 Start with Business Process Maps

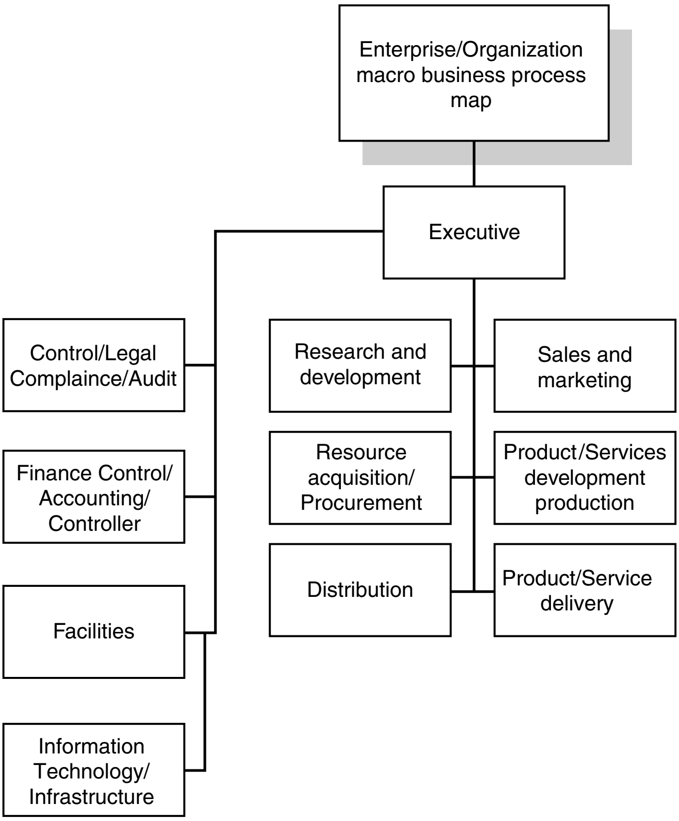
What do we mean when we talk about business process maps? All public and private sector organizations share similar business processes with other companies or organizations in a similar industry group. These business processes can be studied and mapped for the enterprise. The BCP project team can then utilize the business process maps to analyze how mega processes, major process, and major subprocesses operate and interrelate with one another's availability requirements. The continuity planner can use these maps for planning, implementation, training, testing, and measurement. The planner can use the process maps to view the entire organization from the top down and then is able to drill down to identify specific time-critical processes and their supporting resources, to determine single points of failure, and to visualize how the continuity planning process should be constructed to best fit the circumstances. Business process maps help the planner to visualize how the company or organization conducts business; they are essentially a roadmap to the business. They provide a common naming convention for business processes as they interrelate and cross the organizational structure depicted in the company's organization charts. By obtaining or developing process maps, the planner has taken a huge step forward in understanding the true business processes of the enterprise that will be helpful during discussions with executive management regarding continuity planning requirements and investments. As mentioned earlier, the continuity planner's ability to speak intelligently about the time-critical needs of precise business processes will enhance executive management communications and their confidence in forthcoming recommendations.

121.4.2 Business Process Mapping: How To

Caveat: It should be noted from the beginning that business process mapping can and is done differently depending on the mapping purposes. No standard methodology for mapping exists, as many components of the enterprise need to look at the organization differently, thus leaving them to best define their own leading practices for business process mapping. The mapping methods described here have been proven to work best when applied to conducting a BCP business Impact assessment. Exhibit 121.1 is a generic representation of a typical mega business process map that can be used by the planner to standardize business processes among and within individual business units of the enterprise.

121.4.3 Business Process Mapping for the BIA

It is important to limit the population of business processes identified to a workable number. Identification methods should be customized so mega business processes, major business processes, and sub-business processes number anywhere from eight to twelve each. The purpose of breaking up huge business processes into workable and understandable bundles supports efficiency in mapping each across the enterprise. One business process that describes the entire enterprise is not enough, but documenting hundreds of business processes is too many. For purposes of discussion, Exhibit 121.1 illustrates a typical mega process map. The executive, research and development, sales and marketing, procurement, production, distribution, finance, and accounting mega business processes (notice eight mega processes) is a great starting point. By limiting the number of mega processes, the planner has ensured a workable number of business processes that then can be broken down into another eight to twelve major business processes. And, likewise, each of the major business processes that make up each mega process will have eight to twelve subprocesses. Notice that, although the facilities, IT, and compliance business processes are included in the illustration above, these types of business processes



Enterprise/Organization macro business process map
Executive
Control/Legal Complaince/Audit
Finance Control/ Accounting/ Controller
Facilities
Information Technology/ Infrastructure
Research and development
Sales and marketing
Resource acquisition/ Procurement
Product/Services development production
Distribution
Product/Service delivery

EXHIBIT 121.1 Typical mega business process map.

are normally classified as supporting processes required by each of the primary mega processes as support resources and are not considered, in and of themselves, true mega or major business processes.

121.4.4 Business Process Breakdown

Exhibit 121.2 illustrates a typical detailed map that results as the continuity planners identify each individual business process and then break that process down into its constituent parts. This type of map will be replicated many times across a sizeable enterprise but is extremely valuable for continuity planners when attempting to identify and the prioritize time-critical business processes.

121.5 Conducting the BIA

When actually explaining the intent of the BIA to those being interviewed, the following approaches should be observed and topics discussed with the participants:

- *Ask intelligent questions of knowledgeable people.* These questions are based loosely on the concept that, if you ask enough reasonably intelligent people a consistent set of measurable questions, then you will eventually reach a conclusion that is more or less the correct one—very qualitative, in other words. The BIA questions serve to elicit qualitative results from a number of knowledgeable people. The precise number of people interviewed obviously depends on the scope of the BCP activity and the size of the organization; however, when consistently directing a well-developed number of questions to an informed audience, the results will reflect a high degree of reliability.
- *Ask to be directed to the correct people.* As the interview unfolds, it may become evident that the interviewee is the wrong person to be answering the questions. Ask who else within this area

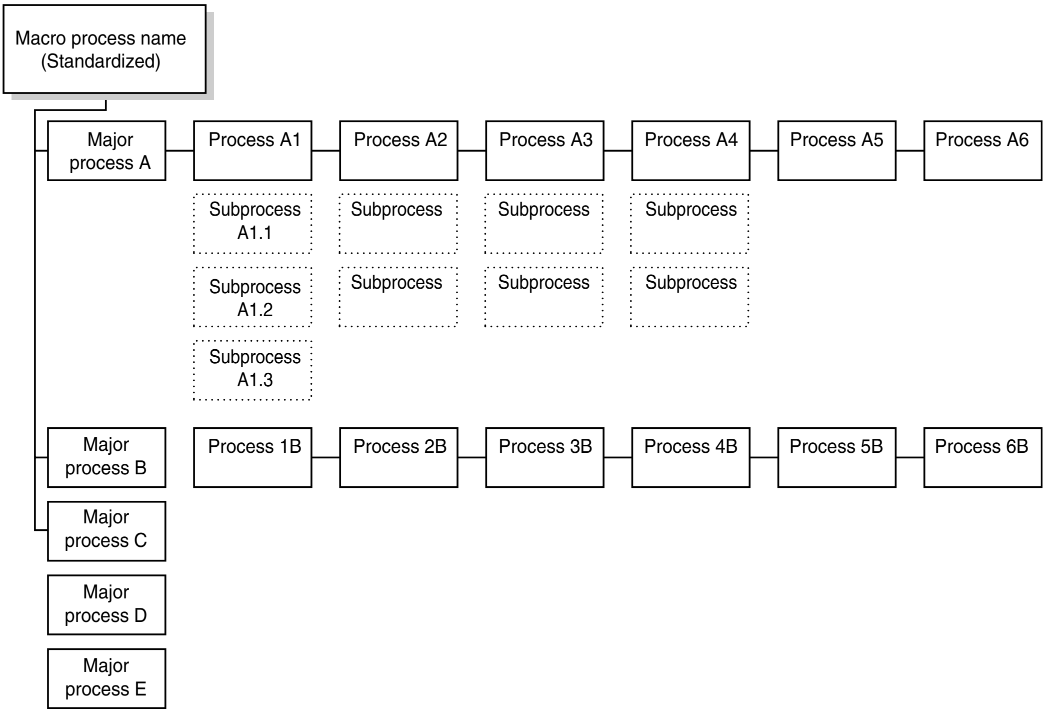


EXHIBIT 121.2 Typical detailed map.

would be better suited to address these issues. They might be invited into the room at that point, or it may be necessary to schedule a meeting with them at another time.

- *Assure them that their contribution is valuable.* A very important way to build the esteem of interviewees is to mention that their input to the process is considered valuable, as it will be used to formulate strategies necessary to recover the organization following a disruption or disaster. Explaining that the purpose of the interview is to obtain their business unit's relevant information for input to planning a continuity strategy can sometimes change the tone of the interview positively.
- *Explain that the plan is not strictly an IT plan.* Even if the purpose of the BIA is for IT continuity, when interviewing business unit management to prepare a technological platform recovery plan, it is sometimes useful to couch the discussion in terms of: "A good IT continuity plan, although helping IT to recover, is really a business unit plan." Why? Because the IT plan will recover the business functionality of the interviewee's business unit as well, and that is the purpose of the interview.
- *Focus on who will really be exercising the plan.* Another technique is to mention that the continuity plan that will eventually be developed can be used by the interviewees but is not necessarily developed for them. Why? Because the people being interviewed probably already understand what to do following a disaster, without referring to extensive written recovery procedures, but the fact of the matter is that following the disruption these people may not be available. It may well be the responsibility of the next generation of management to recover, and it will be the issues identified by this interviewee that will serve as the continuity route map.
- *Focus on time-critical business processes and support resources.* As the BIA interview progresses, it is important to fall back from time to time to reinforce the idea that identifying time-critical functions and processes is the purpose of the interview. Remember to differentiate "mission critical" from "time critical."
- *Assume worst-case disaster.* When faced with the question "When will the disruption occur?" the answer should be "It will occur at the worst possible time for your business unit. If you close your books on December 31, and you need the computer system the most on December 30 and 31, then the disaster will occur on December 29." Only when measuring the impacts of a disruption at the worst time can the interviewer get an idea as to the full impact of the disaster, which allows the impact information to be more meaningfully compared from one business unit to the next.
- *Assume that no continuity capability exists.* To obtain results that are comparable, it is essential that interviewees assume that no continuity capability will exist when they answer the impact questions. The reason for this is that, when they attempt to quantify or qualify the impact potential, they may confuse a preexisting continuity plan or capability with no impact, and that is incorrect. No matter the existing continuity capability, the impact of a loss of services must be measured in raw terms so when the results of the interviews from business unit to business unit are compared, the results are comparable (apples to apples, if you will).
- *Gather order of magnitude numbers and estimates.* Financial impact information is needed in orders of magnitude estimates only. Do not get bogged down in minutia, as it is easy to get lost in the detail. The BIA process is not a quantitative risk assessment! It is not meant to be. It is qualitative in nature, and, as such, orders of magnitude impacts are completely appropriate and even desirable. Why? Because preciseness in estimation of the loss impact almost always will result in arguments about the numbers. When this occurs, the true goal of the BIA is lost, because it turns the discussion into a numbers game, not a balanced discussion concerning financial and operational impact potentials. Because of the unlimited and unknown numbers of varieties of disasters that could possibly befall an organization, the true numbers can never ever be precisely known, at least until after the disaster. The financial impact numbers are merely estimates intended to illustrate degrees of impacts. So, skip the numbers exercise and get to the point.

- *Stay focused on the BCP scope.* Whether the BIA process is for development of technological platforms, end-user facilities continuity, voice network, etc., it is very important not to allow scope creep in the minds of the interviewees. The discussion can become very unwieldy if the focus of the loss impact discussions wanders from the precise scope of the BCP project.
- *Remember that there are no incorrect answers.* Because all the results will be compared with one another before the BIA report is forwarded, it is important to emphasize that interviewees should not worry about wrong numbers. As the BIA process evolves, each business unit's financial and operational impacts will be compared with the others, and any impact estimates that are out of line with the rest will be challenged and adjusted accordingly.
- *Do not insist upon getting the financial information on the spot.* Sometimes the compilation of financial loss impact information requires a little time to accomplish. The author often tells interviewees that we will return within a few days to collect the information, so additional care can be taken in preparation, making sure that we do actually return and pick up the information later.
- *Understand the value of push back.* Do not underestimate the value of push back when conducting BIA interviews. Industry experience has taught us that anywhere from one third to one half of an organization's business processes turn out to be time critical. Business process personnel will, most times, tend to view their activities as extremely time critical, with little or no downtime acceptable. In reality, their operations will be arranged in some priority order with the other business processes of the organization for recovery priority. Realistic recovery time objectives (RTOs) must be reached, and sometimes the interviewer must push back and challenge what may be considered unrealistic recovery requirements. Be realistic in challenging, and request that the interviewee be realistic in estimating their business unit's RTOs. Common ground will eventually be found that will be more meaningful to those who will read the BIA findings and recommendations—the executive management group.

121.5.1 BIA Information-Gathering Techniques

Various schools of thought exist with regard to gathering BIA information. Conducting individual one-on-one BIA interviews is popular, but organizational size and location issues sometimes make conducting one-on-one interviews impossible. Other popular techniques include group sessions or the use of an electronic medium (i.e., data or voice network), or a combination of all of these. The following points highlight the pros and cons of these interviewing techniques:

- *One-on-one BIA interviews*—One-on-one interviews with organizational representatives are the most effective way to gather BIA information. The advantages of this method are the ability to discuss the issues face to face and observe the person. This one-on-one discussion will give the interviewer a great deal of both verbal and visual information concerning the topic at hand. In addition, personal rapport can be built between the interviewee and the BIA team, with the potential for additional assistance and support to follow. This rapport can be very beneficial during later stages of the BCP development effort if those being interviewed understand that the BCP process was undertaken to help them get their jobs done in times of emergency or disaster. The disadvantages of this approach are that it can become very time consuming, and can add time to the critical path of the BIA process.
- *Group BIA interview sessions or exercises*—This type of information gathering activity can be very efficient in ensuring that a lot of data is gathered in a short period of time and can speed the BIA process tremendously. The drawback to this approach is that, if not conducted properly, it can result in a meeting of a number of people without very much useful information being obtained.
- *Executive management mandate*—Although not always recommended, in certain circumstances conducting only selected interviews with very high-level executive management will suffice for

BIA purposes. Such situations might include development of continuous operations and strategies where extremely short recovery timeframes are already obvious or where time for development of appropriate strategies for recovery is severely shortened. The level of confidence is not as high in comparison to performing many more exhaustive sets of interviews (at various levels of the organization, not just with the executive management group), but it does speed up the process.

- *Electronic medium*—Use of voice and data communications technologies, video conferencing, and Web-based technologies and media are becoming increasingly accepted and popular. Many times, the physical or geographical size and diversity as well as the structural complexity of the organization lend itself to this type of information gathering technique. The pros are that distances can be diminished and travel expenses reduced. The use of automated questionnaires and other data gathering methods can facilitate the capture of tabular data and ease consolidation of this information. Less attractive, however, is the fact that this type of communication lacks the human touch and sometimes ignores the importance of the ability of the interviewer to read the verbal and visual communications of the interviewee. *Note*: Especially worrisome is the universal broadcast of BIA-related questionnaires. Uninformed groups of users on a network may supply answers to qualitative and quantitative BIA questions without regard to the point or nuance of the question or the intent of the use of the result. Such practices almost always lend themselves to misleading and downright wrong results. This type of unsupported data gathering technique for purposes of formulating a thoughtful strategy for recovery should be avoided.

Most likely, an organization will need to use a mix of these suggested methods or use others as suited to the situation and culture of the enterprise.

121.5.2 The Use of BIA Questionnaires

Without question, the people-to-people contact of the BIA process is the most important component in understanding the potential impact a disaster will have on an organization. People run the organization, and people can best describe business functionality and their business units' degree of reliance on support services. The issue here, however, is deciding what is the best and most practical technique for gathering information from these people. There are differing schools of thought regarding the use of questionnaires during the BIA process. The author's opinion is that a well-crafted and customized BIA questionnaire will provide the structure necessary to guide the BIA and project teams. This consistent interview structure requires that the same questions be asked of each BIA interviewee. Reliance can then be placed on the results because answers to questions can be compared to one another with assurance that the comparisons are based on the same criterion. Although the questionnaire can be a valuable tool, the structure of the questions is subject to a great deal of customization. This customization of the questions depends largely on the reason why the BIA is being conducted in the first place.

The BIA process can be approached differently depending on the needs of the organization. Each BIA situation should be evaluated in order to properly design the scope and approach of the BIA process. BIAs may be desired for several reasons, including:

- Initiating a BCP process where no BIA has been done before, as part of the phased implementation methodology
- Reinitiating a BCP process where a BIA was performed in the past but now must be brought up to date
- Conducting a BIA in order to incorporate the impacts of a loss of E-commerce-related supply-chain technologies into the overall continuity strategies of the organization
- Conducting a BIA in order to justify BCP activities that have already been undertaken (e.g., acquisition of a hot site or other recovery alternative)

- Simply updating the results of a previous BIA effort to identify changes in the environment and as a basis to plan additional activities
- Initiating a BIA as a prelude to beginning a full BCP process for understanding or as a vehicle to sell management on the need to develop a BCP

121.5.3 Customizing the BIA Questionnaire

A questionnaire can be constructed or customized to serve as an efficient tool for accurately gathering BIA information. The number of BIA questionnaires in use by organizations is nearly unlimited. It should go without saying that any questionnaire, BIA or otherwise, can be constructed so as to elicit the response one would like. It is important that the goal of the BIA be in the mind of the questionnaire developers so the questions asked and the responses collected will meet the objective of the BIA process.

121.5.4 BIA Questionnaire Construction

Exhibit 121.3 is an example of a BIA questionnaire. Basically, the BIA questionnaire is made up of the following types of questions:

- *Quantitative questions*—These questions ask the interviewee to consider and describe the economic or financial impacts of a potential disruption. Measured in monetary terms, an estimation of these impacts will aid the organization in understanding loss potential, in terms of lost income as well as an increase in extraordinary expense. The typical qualitative impact categories might include revenue or sales loss, lost trade discounts, interest paid on borrowed money, interest lost on float, penalties for late payment to vendors or lost discounts, contractual, fines or penalties, unavailability of funds, or canceled orders due to late delivery. Extraordinary expense categories might include

EXHIBIT 121.3 Sample BIA Questionnaire

Introduction

Business unit name:

Date of interview:

Contact name(s):

Identify business process or business unit (BU) function:

Briefly describe the overall business functions of the BU (with a focus on time-critical functions/processes), link each time-critical function or process to the IT application or network, and describe the interrelationships of the business processes and applications or networks:

Financial impacts

Estimate impact of lost revenue (e.g., revenue or sales loss, lost trade discounts, interest paid on borrowed money, interest lost on float, penalties for late payment to vendors or lost discounts, contractual fines or penalties, unavailability of funds, canceled orders due to late delivery):

Estimate impact of extraordinary expenses (e.g., acquisition of outside services, temporary employees, emergency purchases, rental/lease equipment, wages paid to idle staff, temporary relocation of employees):

Operational impacts

Estimate impact of business interruption (e.g., loss of customer service capabilities, inability to serve internal customers/management):

Estimate loss of confidence (e.g., by customers, shareholders, regulatory agencies, employees):

Technological dependence

Describe reliance on systems, business functions, and applications (attempt to identify specific automated systems, processes, and applications that support BU operations):

Describe system interdependencies:

Describe state of existing BCP measures:

Other BIA related discussion issues

"What else should I have asked you that I did not, relative to this process?"

Other questions should be customized to the environment of the organization, as needed acquisition of outside services, temporary employees, emergency purchases, rental/lease equipment, wages paid to idle staff, and temporary relocation of employees.

- *Qualitative questions*—Although the economic impacts can be stated in terms of dollar loss, the qualitative questions ask the participants to estimate potential loss impact in terms of their emotional understanding or feelings. It is surprising how often the qualitative measurements are used to put forth a convincing argument for a shorter recovery window. The typical qualitative impact categories might include loss of customer services capability or loss of confidence.
- *Specialized questions*—Make sure that the questionnaire is customized to the organization. It is especially important to make sure that both the economic and operational impact categories (e.g., lost sales, interest paid on borrowed funds, business interruption, customer inconvenience) are stated in such a way that each interviewee will understand the intent of the measurement. Simple is better here.

Using an automated tool? If an automated tool is being used to collect and correlate the BIA interview information, then make sure that the questions in the database and questions of the questionnaire are synchronized to avoid duplication of effort or going back to interviewees with questions that could have been handled initially.

A word of warning here, however. The author has seen people pick up a BIA questionnaire off the Internet or from a book or periodical (like this one) and use it without regard for the culture and practices of their own organizations. Never, ever use a noncustomized BIA questionnaire. The qualitative and quantitative questions must be structured to the environment and style of the organization. A real opportunity for failure arises if this point is dismissed.

A recent trend in BCP development, by the way, is that organizations seem to be moving away from prepackaged specialized software to the use of a combination of internal technologies that enterprise personnel already know and understand. This cuts down on the training curve and takes a little of the mystery out of the process, in addition to cutting down on front-end purchase and maintenance costs, not to mention technical support from another vendor, etc.

121.6 BIA Interview Logistics and Coordination

This portion of the report will address the logistics and coordination of performing BIA interviews. Having scoped the BIA process, the next step is to determine who and how many people will be interviewed. The following are some techniques that might be used to do so:

- *Methods for identifying appropriate BIA interviewees*—Interviewing everyone in the enterprise is obviously out of the question. A sample of those management and staff personnel who will provide the best information in the shortest period should be chosen. To do that, it is necessary to have a precise feel for the scope of the project (e.g., technological platform continuity, business unit continuity, communications continuity, crisis management plans).
- *Organizational process models*—As was mentioned previously, identification of organizational mega and major business processes is the first place to start. Enterprises that are organized along process lines lend themselves to development of continuity planning strategies that will eventually result in the most efficient continuity infrastructure. Use of or development of models that reflect organizational processes will go a long way toward assisting BIA team members in identifying those personnel crucial to determining time-critical process requirements.
- *Organizational chart reviews*—The use of formal, or sometimes even informal organization charts is a good place to start. This method includes examining the organizational chart of the enterprise to understand those functional positions that should be included. Review the organizational chart to determine which organizational structures will be directly involved in

the overall effort and those that will be the recipients of the benefits of the finished continuity plan.

- *Overlaying systems technology*—Overlaying systems technology (e.g., applications, networks) configuration information over the organization chart will reveal components of the organization that may be affected by an outage of the systems. Mapping applications, systems, and networks to the organization's business functions will aid tremendously when attempting to identify the appropriate names and numbers of people to interview.
- *Executive management interviews*—This method includes conducting introductory interviews with selected executive management representatives to identify critical personnel to be included in the BIA interview process as well as to receive high-level guidance and to raise overall executive level management awareness and support.
- *Coordination with the IT organization*—If the scope of the BIA process is continuity of technological platforms or communications systems, then conducting interviews with a number of IT personnel could help shorten the data gathering effort. Although IT users will certainly need to be interviewed, IT personnel can often provide much valuable information but should not be relied on solely as the primary source of business impact outage information (e.g., revenue loss, extra expense).
- *Sending questionnaire out in advance*—It can be useful to distribute the questionnaire to the interviewees in advance. Whether it is a hardcopy or in an electronic media format, the person being interviewed should have a chance to review the questions, to be able to invite others into the interview or redirect the interview to others, and to begin to develop the responses. Emphasize to the people who receive the questionnaires in advance not to fill them out but simply review them as a way to be prepared to address the questions later.
- *Scheduling interviews*—Ideally, the BIA interview should last from 45 minutes to 1 hour and 15 minutes. The author has found that it sometimes can be advantageous to go longer than this, but if many of the interviews are lasting longer than 1 hour and 15 minutes, then perhaps a BIA scoping issue should be addressed, necessitating the need to schedule and conduct a larger number of additional interviews.
- *Limiting number of interviewees*—It is important to limit the number of interviewees in the session to one, two, or three, but no more. Given the amount and quality of information to be elicited from this group, more than three people can deliver a tremendous amount of good information that unfortunately can be missed when too many people are delivering the message at the same time.
- *Scheduling two interviewers*—When setting up the BIA interview schedule, try to ensure that at least two interviewers can attend and take notes. This will help eliminate the possibility that good information may be missed. Every additional trip back to an interviewee for confirmation of details will add overhead to the process.
- *Validating financial impact thresholds*—An often-overlooked component of the process includes discussing with executive management the thresholds of pain that could be associated with a disaster. Asking the question as to whether a $5 million loss or a $50 million loss would have a significant impact on the long-term bottom line of the organization can lead to interesting results. An understanding on the part of the BIA team as to what financial impacts are acceptable or, conversely, unacceptable is crucial to framing BIA financial loss questions and the final findings and recommendations that the BIA report will reflect.

121.6.1 The Importance of Documenting a Formal RTO Decision

The BIA process concludes when executive management makes a formalized decision as to the RTO they are willing to live with after analyzing the impacts to the business processes due to outages of vital support services. This includes the decision to communicate these RTO decisions to each business unit and support service manager involved.

Why is it so important that a formalized decision be made?

A formalized decision must be clearly communicated by executive management because the failure to document and communicate precise RTO information leaves each manager with imprecise direction on: (1) selection of an appropriate recovery alternative method, and (2) the depth of detail that will be required when developing recovery procedures, including their scope and content. The author has seen many well-executed BIAs with excellent results wasted because executive management failed to articulate their acceptance of the results and communicate to each affected manager that the time requirements had been defined for continuity processes.

121.6.2 Interpreting and Documenting the Results

As the BIA interview information is gathered, considerable tabular and written information will begin to quickly accumulate. This information must be correlated and analyzed. Many issues will arise here which may result in some follow-up interviews or information gathering requirements. The focus at this point in the BIA process should be as follows:

- *Begin documentation of the results immediately.* Even as the initial BIA interviews are being scheduled and completed, it is a good idea to begin preparation of the BIA findings and recommendations and actually begin entering preliminary information. The reason is twofold. The first is that waiting until the end of the process to begin formally documenting the results makes it more difficult to recall details that should be included. Second, as the report begins to evolve, issues will be identified that require immediate additional investigation.
- *Develop individual business unit BIA summary sheets.* Another practical technique is to document each and every BIA interview with its own BIA summary sheet. This information can eventually be used directly by importing it into the BIA findings and recommendations, which can also be distributed back to each particular interviewee to authenticate the results of the interview. The BIA summary sheet contains a summation of all the verbal information that was documented during the interview. This information will be of great value later as the BIA process evolves.
- *Send early results back to interviewees for confirmation.* Returning BIA summary sheets to the interviewees can continue to build consensus for the BCP project and begin to ensure that any future misunderstandings regarding the results can be avoided. Sometimes it may be desirable to get a formal sign-off, but other times the process is simply informal.
- *Make it clear that you are not trying to surprise anyone.* The purpose for diligently pursuing the formalization of the BIA interviews and returning summary sheets to confirm the understandings from the interview process is to prevent any surprises later. This is especially important in large BCP projects where the BIA process takes a substantial amount of time. It is always possible that someone might forget what was said.
- *Define time-critical business functions/processes.* As has been emphasized in this report, all issues should focus back to the true time-critical business processes of the organization. Allowing the attention to be shifted to specific recovery scenarios too early in the BIA phase will result in confusion and lack of attention to what is really important.
- *Tabulate financial impact information.* A tremendous amount of tabular information can be generated through the BIA process. It should be boiled down to its essence and presented in such a way as to support the eventual conclusions of the BIA project team. It is easy to overdo it with numbers. Just be sure that the numbers do not overwhelm the reader and fairly represent the impacts.
- *Understand the implications of the operational impact information.* Often, the weight of evidence and the basis for the recovery alternative decision are based on operational rather than financial

information. Why? Usually the financial impacts are more difficult to accurately quantify, because the precise disaster situation and the recovery circumstances are difficult to visualize. The customer service impact of a fire, for example, is readily apparent, but it would be difficult to determine with any degree of confidence what the revenue loss impact would be for a fire that affects one particular location of the organization. Because the BIA process should provide a qualitative estimate (orders of magnitude), the basis for making the hard decisions regarding acquisition of recovery resources are, in many cases, based on the operational impact estimates rather than hard financial impact information.

121.6.3 Preparing the Management Presentation

Presentation of the results of the BIA to concerned management should result in no surprises for them. If the BIA findings are communicated and adjusted as the process has unfolded, then the management review process should really become more of a formality in most cases. The final presentation meeting with the executive management group is not the time to surface new issues and make public startling results for the first time. To achieve the best results in the management presentation, the following suggestions are offered:

- *Draft report for review internally first.* Begin drafting the report following the initial interviews to capture fresh information. This information will be used to build the tables, graphs, and other visual demonstrations of the results, and it will be used to record the interpretations of the results in the verbiage of the final BIA findings and recommendations report. One method for developing a well-constructed BIA findings and recommendations report from the very beginning is, at the completion of each interview, to record the tabular information into the BIA database or manual filing system. Second, the verbal information should be transcribed into a BIA summary sheet for each interview. This BIA summary sheet should be completed for each interviewee and contain the highlights of the interview in summarized form. As the BIA process continues, the BIA tabular information and the transcribed verbal information can be combined into the draft BIA findings and recommendations report. The table of contents for a BIA report may look like the one in Exhibit 121.4.
- *Schedule individual executive management meetings as necessary.* As the time for the final BIA presentation nears, it is sometimes a good idea to conduct a series of one-on-one meetings with selected executive management representatives to brief them on the results and gather their feedback for inclusion in the final deliverables. In addition, this is a good time to begin building grassroots support for the final recommendations that will come out of the BIA process; at the same time, it provides an opportunity to practice making your points and discussing the pros and cons of the recommendations.

EXHIBIT 121.4 BIA Report Table of Contents

Executive summary
Background
Current state assessment
Threats and vulnerabilities
Time-critical business functions
Business impacts (operational)
Business impacts (financial)
Recovery approach
Next steps/recommendations
Conclusion
Appendices (as needed)

- *Prepare executive management presentation (bullet point).* The author's experience says that most often executive management level presentations are better prepared in a brief and focused manner. It will undoubtedly become necessary to present much of the background information used to make the decisions and recommendations, but the formal presentation should be in a bullet-point format, crisp and to the point. Of course every organization has its own culture, so be sure to understand and comply with the traditional means of making presentations within the organization's own environment. Copies of the report, which have been thoroughly reviewed, corrected, bound, and bundled for delivery, can be distributed at the beginning or the end of the presentation, depending on circumstances. In addition, copies of the bullet-point handouts can be supplied so attendees can make notes and use them for reference at a later time. Remember, the BIA process should end with a formalized agreement as to management's intentions with regard to RTOs, so business unit and support services managers can be guided accordingly. It is here that that formalized agreement should be discussed and the mechanism for acquiring and communicating it determined.
- *Distribute report.* When the management team has had an opportunity to review the contents of the BIA report and have made appropriate decisions or given other input, the final report should be distributed within the organization to the appropriate numbers of interested individuals.

121.7 Next Steps

The BIA is truly completed when formalized executive management decisions have been made regarding: (1) RTOs, (2) priorities for business process and support services continuity, and (3) recovery resource funding sources. The next step is the selection of the most effective recovery alternative. The work gets a little easier here. We know what our recovery windows are, and we understand what our recovery priorities are. We now have to investigate and select recovery alternative solutions that fit the recovery window and recovery priority expectations of the organization. When the alternatives have been agreed upon, the actual continuity plans can be developed and tested, with organization personnel organized and trained to execute the continuity plans when needed.

121.8 Final

The goal of the BIA is to assist the management group in identification of time-critical processes and to determine their degree of reliance upon support services. Business process mapping methods, like those described in this chapter, will go a long way toward making the BIA effort more efficient and will significantly enhance the credibility of the results. When they have been identified, time-critical processes should in turn be mapped to their supporting IT, voice and data networks, facilities; human resources, etc. Time-critical business processes are prioritized in terms of their RTOs, so executive management can make reasonable decisions as to the recovery costs and time frames that they are willing to fund and support. The process of business continuity planning has matured substantially since the 1980s. BCP is no longer viewed as just a technological question. A practical and cost-effective approach toward planning for disruptions or disasters begins with the business impact assessment. Only when executive management formalizes their decisions regarding continuity time frames and priorities can each business unit and support service manager formulate acceptable and efficient plans for recovery of operations in die event of disruption or disaster. It is for this reason that the BIA process is so important when developing efficient and cost-effective business continuity plans and strategies.

121.9 BIA To-Do Checklist

121.9.1 BIA To Do's

- Customize the BIA information gathering tools to suit the organization's customs or culture.
- Focus on time-critical business processes and support resources (e.g., systems, applications, voice and date networks, facilities, people).
- Assume worst-case disaster (e.g., day of week, month of year).
- Assume no recovery capability exists.
- Obtain raw numbers in orders of magnitude.
- Return for financial information.
- Validate BIA data with BIA participants.
- Formalize decisions from executive management (e.g., RTO time frames, scope and depth of recovery procedures) so lower level managers can make precise plans.

121.9.2 Conducting BIA Interviews

- When interviewing business unit personnel, explain that you are here to get the information you need to help IT build their recover plan. Emphasize that the resulting IT recovery is really theirs, but the recovery plan is really yours. We are obtaining their input as an aid to ensuring that information services constructs the proper recovery planning strategy.
- Interviews should last no longer that 45 minutes to 1 hour and 15 minutes.
- The number of interviewees at one session should be at best one and at most two to three. More than that and the ability of the individual to take notes is questionable.
- If possible, at least two BIA representatives should be in attendance at the interview. Each should have a blank copy of the questionnaire on which to take notes.
- One person should probably not perform more than four interviews per day due to the requirement to document the results of each interview as soon as possible and because of fatigue factors.
- Never become confrontational with the interviewees. Interviewees should not be defensive when answering the questions unless they do not properly understand the purpose of the BIA interview.
- Relate to interviewees that their comments will be taken into consideration and documented with the others gathered and that they will be requested to review, at a later date, the output from the process for accuracy and provide their concurrence.

122

Testing Business Continuity and Disaster Recovery Plans

James S. Mitts

122.1 Overview

Everything an information security practitioner deals with requires some form of testing to ensure that the information technology or resource is within configuration specifications. This applies to ensuring that business continuity (BC) and disaster recovery (DR) plans are documented and executable as per the business continuity strategy and that the capabilities are deployed as part of an overall business continuity program for the enterprise. Testing BC/DR plans is done with regard to justifying the economic benefit of having BC/DR capabilities in place. A company that decides not to test its BC/DR plans will not know if those capabilities and documented procedures will work during a disaster and thus jeopardize survivability of the enterprise. The information security professional may be asked to assume the role of testing coordinator or facilitator. This role, in most organizations, is responsible for coordinating and facilitating testing of all BC/DR plans, which requires a thorough understanding of the plans to ensure that the business continuity policy will be met, attaining appropriate funding for the overall testing of these plans, identifying the types of testing that should be conducted, scheduling testing to minimize its impact on business operations, and developing scenario-based test plans that clearly state the scope, purpose, and objective for testing.

122.2 Business Continuity Program Policy Guidelines for Testing

The business continuity program policy should provide basic guidelines for the testing of business continuity and disaster recovery planning. The policy should state the types of accepted tests that can be performed and the number of times tests must be conducted. It should indicate the person or persons responsible for the testing of plans. Although the business continuity program policy may not specify types of tests or the number of tests to be conducted, it is imperative that the information security professional understand the types of test that can be conducted to determine if business continuity plans are viable and executable. Exhibit 122.1 provides an example of a business continuity program policy.

122.3 Obtaining the Funding To Conduct a BC/DR Plan Testing Program

As with anything in business, certain costs are associated with business activities. Testing BC/DR plans is no different. In putting the testing plans together, the information security professional needs to develop a business case that outlines the costs of conducting various testing exercises for each component of the BC/DR plan. The planning stage requires an understanding of the type of test to be conducted, who will be involved, how long the test could take, and what the impact on business operations will be. The individuals doing the planning should not be team leaders or members who will be conducting the test. The impact to business operations can be determined from the business impact assessment that was previously conducted in the BC program methodology. DR plan testing typically deals with recovery of data and systems at an alternate location that typically is not close by. Costs associated with testing the DR plan will tend to be greater because of the scope of activities and resources. The costs for testing components of a BC/DR plan can be identified by understanding the planning considerations noted later.

The costs of testing should be fully described, understood, and approved by management to achieve any level of assurance that the BC/DR plans are viable and executable. Some of the things that the information security professional should consider when estimating costs include:

- Number of participants (e.g., potential loss of productivity during testing, outside resources required)
- Facility expenses for the test (e.g., conference rooms, hot-site testing fees, hotel rooms)
- Food expenses (e.g., meals, snacks, coffee, sodas)
- Communication expenses (e.g., telephone setup, datacom setup, teleconference fees)
- Supply expenses (e.g., paper, pencils, notepads, pens, markers, whiteboards, flip charts)
- Form development and printing expense (e.g., incident, problem/issue, post-exercise evaluation)

EXHIBIT 122.1 Sample Business Continuity Program Policy

It is the policy of ABC Company that a business continuity program shall be established and maintained to protect company assets, employees, stakeholders, and customer relations should a disaster of any manner befall ABC Company. The business continuity program shall establish the creation of business continuity or disaster recovery plans that contain appropriate procedures to sustain and recover critical ABC business operations after a disaster. The business continuity program shall ensure that these plans are assigned to a "plan owner" who shall be responsible for assuring that the plan is executable and capable of sustaining ABC business operations. The business continuity program shall ensure that testing of all components of the plans are conducted by using drills, structured walk-throughs, simulations, and full-interruption tests. Testing of all components of the plans should be conducted at least once a year.

122.4 Types of Tests

The types of tests that can be conducted are many, but for the purposes of this chapter we outline here the major tests that should be conducted as part of an overall BC/DR plan testing program.

122.4.1 Drills

Drills are typically targeted to a specific response and include fire, building evacuation, and bomb threat, to name a few. The purpose of a drill is to have the drill participants follow the designated response activities specified in their plans to become more proficient in executing the response activity. For example, a fire drill is conducted to familiarize building occupants with the response activities necessary to ensure the safety of employees and visitors in a company facility. The fire drill tests the ability of employees to execute their specified response activities when alerted, and it allows observation of those persons managing the response (e.g., floor warden, floor captain) as they perform their specific responsibilities to make sure all persons are evacuated from the facility. Many organizations only conduct these drills during the first shift when most employees are at work. This is a mistake, because it deprives off-hours personnel the benefits of the drill. Cleaning crews, maintenance workers, and guard forces often are overlooked but still need to be familiar with building evacuation and other contingency plans and procedures.

122.4.2 Walk-Through Test

Among the several types of walk-through tests are the orientation walk-through, tabletop walk-through (with or without simulation), and live walk-through.

122.4.2.1 Orientation Walk-Through

An orientation walk-through is a tabletop exercise of a BC/DR plan and is the first test conducted to familiarize the team leader and members with the BC/DR plan. It addresses all components of the BC/DR plan.

122.4.2.2 Tabletop Walk-Through

A tabletop walk-through is one that exercises all or part of the BC/DR plan as specified in the scope of the test plan.

122.4.2.3 Live Walk-Through

A live walk-through is an exercise where the plan is executed as if a real disaster has taken place at a specific point in the facility and is typically conducted with multiple BC/DR teams. This is often called a simulation test.

122.4.2.4 Parallel Test

This operational test is held in parallel with the actual processing of critical systems to ensure that the systems will run correctly at the alternative site.

122.4.2.5 Simulation Test

This test involves all groups that would be involved in an actual recovery to ensure that the plan works and the various groups interface appropriately; it is usually scenario based. Groups have access to only materials in offsite storage to conduct their activities in the simulated recovery.

122.4.2.6 Full Interruption Test

This test is a full-blown, live test. If the plan calls for going to a hot site to recover, then arrangements to travel to the hot site would be made and a live recovery would take place. This type of test could affect the ability of the company's customers to request products or services. This type of test could be dangerous for a large organization because shutting down normal processing has been known to actually precipitate a disaster when restart problems prevented resumption of normal processing on schedule.

122.5 Planning Considerations for Developing a Test Plan

The information security professional should consider the following questions:

- What parts of the company should be tested?
- Who should be involved?
- Should any hazards be anticipated?
- What are the boundaries (physical, geographical) of the test?
- How real should the test be?
- What is the budget for conducting the test?

After addressing these questions, it is time to begin planning the process for testing the BC/DR plan by considering the following aspects of the testing.

122.5.1 Type of Test

The types of test to be conducted will vary with the type and number of procedures or responses contained in the BC/DR plan; for example, if the plan has ten emergency response procedures, each would have to be drilled or walked through, depending on the procedure. If the business continuity program is new, each business unit or department BC/DR plan must have an orientation walk-through conducted to introduce the plan to the recovery team. As planning moves forward, the information security professional would schedule tabletop exercises for individual procedures within each BC/DR plan. As testing matures, the information security professional would then schedule tests that involve more than one BC/DR team. The testing would progress to the point where the company is ready to attempt a full interruption test.

122.5.2 Logistics Support

122.5.2.1 Location

Finding a place to hold a test can be a challenge. Planners need to find a conference room, auditorium, or meeting room of sufficient size to conduct the particular type of test. The location should be away from the work environment of the BC/DR team whenever possible to have the team members' full attention. For tests that involve more then one team, the size of the facility is critical. The location must be comfortable and easy to get to and have sufficient lighting to conduct the test. For tests that involve traveling overnight to an alternative site, the information security professional should identify meeting places, lodging, and restaurants close to the alternative site.

122.5.2.2 Outside Help

As the testing begins to involve a greater number of BC/DR teams, it becomes more difficult for a small group of observers from internal auditing and other departments to oversee the tests. This is when the information security professional should seek outside help in conducting these tests; for example, the internal auditing group could recommend outside auditors, and consulting firms may be able to support the testing efforts. Of course, the use of such resources must be weighed against the testing budget that has been allocated. Other outside help that the information security professional may consider seeking would include organizations that can help with realism.

122.5.2.3 Realism

When conducting walk-through tests, the information security professional must choose how real those tests should be. Realism is not necessary for an orientation walk-through, but as the testing process matures realism becomes more of a factor in the overall effectiveness of the test. Making each test more interesting and challenging is necessary to sustain testing momentum within the organization. Some suggested considerations for adding realism to a tabletop walk-through include:

- Set up a telephone room that team members would call as part of the defined procedure.
- Have local first responders (fire, police, emergency medical services) make appearances as part of the scenario.
- Ask a senior manager to make an appearance to request a status update.
- Have representatives of other BC/DR teams participate in the test to request information.

For live walk-through testing, interaction with other groups is imperative. The more realistic the information security professional can make test, the better prepared the BC/DR team members will be if and when a real emergency or disaster takes place.

Finally, make sure that the company has an interface with local emergency management. At times, local emergency services managers will seek businesses to help them conduct an exercise on a large scale. Participation in such an exercise will benefit the company in several ways:

- It exposes the company to the thought processes that the public sector uses for its testing.
- It provides an added element of realism when the company performs their BC/DR plans during a regional exercise.
- It provides an introduction to other businesses in the area that can be ongoing sources of information and provide opportunities for partnering with regard to emergency response and recovery solutions.

122.5.3 Date and Time of Test

The date and time of a test depend on the scope and impact on operations. Tests can be conducted when convenient for the test participants; however, testing in the off hours should also be conducted as a threat to the organization can happen at any time during the day or week.

122.5.4 Impact on Operations

When planning to test a BC/DR plan, planners need to determine the impact on the company's ability to provide products and service to its customers. Depending on the plan being tested, having an understanding of the potential impact on operations may indicate that only a portion of the BC/DR team should be allowed to participate in the test. Eventually, a test will have to be conducted to evaluate the overall team dynamics in executing the plan. As the testing program matures, the impact on company operations increases due to a greater number of BC/DR teams being tested together to ensure overall business continuity plan integration. Finally, when a full interruption test is conducted, the overall business continuity picture will be observed and the test will have a profound impact on company operations.

122.5.5 Cost

The cost of testing should be determined during the planning of each test. A separate testing cost center should be set up for tracking and budgetary purposes. Utilizing company facilities will keep the cost of a test as low as possible. It is important to track the cost of lost productivity as part of conducting testing. For the testing program to remain viable, it is important to keep costs within the established budget. The information security professional needs to find innovative ways to conduct testing within the corporate culture of the company.

122.6 Elements of a Test Plan

The test plan document describes the planning, execution, and review of the company BC/DR plans. The elements of the test plan are described below:

- *Purpose of the test plan*—This section describes what is expected from the test and document the activities being conducted.

- *Change control history for the test plan*—This section tracks the history of the test plan from the time planning began to completion of the final report.
- *Scheduled date and time of the test*—This section describes when the plan will be conducted.
- *Test type*—This section describes the type of test that is being planned.
- *Test observers*—This section describes who will be observing the test.
- *Test participants*—The section identifies the testing coordinator, supporting test personnel, teams, and the associated team members.
- *Testing objective*—This section describes what specific actions will be tested; multiple objectives can be stated.
- *Event or incident scenario*—This section describes the events or situations that have precipitated execution of the DR/BC plan.
- *Test plan scope*—This section indicates the plan being tested and portions of the plan to be tested.
- *Testing limitations*—This section describes limitations of the test.
- *Testing assumptions*—This section describes assumptions associated with the test.
- *Testing tasks*—This section lists the actual plan or sections to be tested as determined by the testing coordinator/facilitator. The document has subsections for documenting acceptable results, as determined by the testing coordinator or facilitator, and actual results from the test. The actual results are recorded by the test observers.
- *Problems encountered during testing*—This section documents any problems discovered and noted by the coordinator or facilitator and the observers.
- *Post-test review*—This section documents the post-test review session with participants.
- *Corrective action plan for deficiencies*—This section lists deficiencies noted in the test that require improvement. A separate corrective action plan should be developed that identifies the deficiencies and proposes resolutions.
- *Test summary*—The summary is written by the test coordinator or facilitator after the post-test review meeting has been conducted and a corrective action plan has been documented. This summary describes what worked properly and what was deficient and makes general recommendations for improving the plan. These recommendations should be provided to those responsible for plan update and maintenance.

122.7 Creating a Testing Schedule

A testing schedule should be developed that addresses all testing to be conducted on all BC/DR plans within the company for the fiscal year. It should contain the plan being tested, the scope of the test, the type of test to be conducted, coordinator or facilitator name, names of team leaders, dates, and times (see Exhibit 122.2). The use of an overall schedule helps the coordinator or facilitator and team leaders to track all of the testing being conducted throughout the year.

122.8 Practice Case

To see how this all works, we will work through the process of creating a test plan for a finance department response procedure at ABC Company, which is located on the lower floors of a downtown high-rise building in Seattle, WA. The scope of our test will focus on all steps of the finance department's building evacuation procedure. The test will only involve the finance department.

The two objectives of this test are:

- Observe the finance team's execution of the procedure.
- Observe the BC plan team leader's execution and control of the procedure.

EXHIBIT 122.2 Sample Testing Schedule: ABC Testing Schedule for 200x

BC/DR Plan Name	Scope of the Test	Type of Test	Coordinator	Team Leaders	Date and Time of Test
[Insert BC/DR plan name]	[Insert scope of test here]	[Insert type of test here]	[Insert name]	[Insert name]	[Insert MM/DD] [Insert HH:MM to HH:MM]
Finance BC plan	Review accounting BC plan	Orientation walk-through	John Doe	Jack Dane	01/20 08:00 to 09:00
Finance BC plan	Test plan activation procedure	Notification drill	John Doe	Jack Dane	02/12 13:00 to 14:00
Finance BC plan	Test building evacuation procedure	Drill	John Doe	Jack Dane	02/20 11:00 to 11:15

The scenario for this test is a bomb threat to a state agency located on the floor directly above ABC Company. ABC Company receives notice from building management to evacuate the building due to a bomb threat and subsequent discovery of a mysterious package within the State of Washington Agency on the seventh floor. All company personnel are to evacuate the building. To determine what type of test to conduct, we review a particular part of ABC Company's business continuity (BC)/disaster recovery (DR) plan — BC/DR Policy 500.

122.8.1 ABC Company's BC/DR Plan, BC/DR Policy 500

122.8.1.1 Policy Statement

Test disaster recovery plan.

122.8.1.2 Objective

Establish ABC Company policy on disaster recovery plan testing and provide guidelines on determining what to test, types of tests, frequency, and participation levels.

122.8.1.3 Business Drivers

Reduce risk, mitigate loss, maintain continued availability of data. Protecting the availability of company information assets and intellectual property ensures the continued operation of critical functions, meets the company security requirements and that of clients, and mitigates costs associated with data recovery, litigation, and negative public image.

122.8.1.4 Determining Business Processes To Test

To determine which business processes to test, emphasis should be placed on the results of the most current business impact assessment (BIA). Each business-critical process defined in the BC/DR plan should be completely reassessed for currency and prioritized based on the BIA and estimated risk analysis of threats, vulnerabilities, and safeguards. Business processes recognized as critical by the BC/DR plan should be assessed annually and prioritized based on the BIA and the risk factor (RF) determined via the risk analysis of threats, vulnerabilities, and safeguards and should be the primary focus of testing.

122.8.1.5 Types of Test

The ABC testing methodology and implementation schedule should accomplish the following:

- Test the BC/DR plans to the fullest extent possible.
- Incur no prohibitive costs.
- Cause no or minimal service disruptions.

- Provide a high degree of assurance in recovery capabilities.
- Provide quality input for BC/DR plan maintenance.

122.8.1.6 Walk-Through Testing

This is the most recommended testing strategy. Verbally, team members "walk through" the specific steps as documented in the BC/DR plan to confirm effectiveness, identify gaps, bottlenecks, or other weaknesses in the BC/DR plan. Staff should be familiarized with procedures, equipment, and offsite facilities, if required.

122.8.1.7 Simulation Testing

A disaster is simulated, and normal operations should not be interrupted. Hardware, software, personnel, communications, procedures, supplies and forms, documentation, transportation, utilities, and alternative site processing should be thoroughly tested in a simulation test. Extensive travel, moving equipment, and eliminating voice or data communications may not be feasible or practical during a simulated test; however, validated checklists should provide a reasonable level of assurance for many scenarios. The simulation test should be considered and only implemented after the previous checklist and walk-through tests have been validated. The results of previous tests should be analyzed before the proposed simulation to ensure that lessons learned during the previous testing have been remediated.

122.8.1.8 Test Team Participants

Cross-functional staffing is most desirable for testing and should include the following:

- *Management*—Continuous management input through the entire process is vital; the manager who will serve as the emergency response coordinator (ERC) should be involved in planning every test unless the ERC is a participant in the test.
- *Finance*—Finance personnel should assist in providing accurate cost analyses for each phase of the testing process.
- *Internal audit*—Internal audit representatives should advise on contractual and regulatory issues.
- *Legal*—Legal staff should advise on issues involving contractors, unions, or worker rights.
- *Process owners*—Relevant personnel should provide the initial logical breakdown of processes for walk-through and simulation tests and provide realistic scenarios.
- *Security department*—Security staff should maintain business and personnel security throughout the testing process.

122.8.1.9 Testing Frequency

Testing should be performed, at a minimum, on an annual basis. Tests should be documented and audited for appropriateness and results achieved. Lessons learned should also be documented and discussed for future testing implementations.

122.8.2 Selection of Simulation Test

We choose to use a simulation test to test the finance department procedure specified in Section 3.5.1 of its BC plan, outlined below:

1.0 Introduction
2.0 Finance Business Continuity Team
3.0 Emergency Response
  3.1 Overview
  3.2 First Responder Perspective
  3.3 BC Team Leader Perspective
  3.4 Emergency Response Procedures — General

3.5 Emergency Response Procedures — Specific
3.5.1 Emergency Response for Building Evacuation
3.5.2 Emergency Response to a Fire
3.5.3 Emergency Response to a Bomb Threat
3.5.4 Emergency Response to a Chemical Spill
3.5.5 Emergency Response to an Earthquake
3.5.6 Emergency Response to Weapons in the Workplace
3.5.7 Emergency Response to Violence in the Workplace
3.5.8 Emergency Response to an Armed Intruder/Robbery in the Workplace
3.5.9 Emergency Response to Civil Disorder or Public Intrusion
3.5.10 Emergency Response to a Medical Emergency in the Workplace
4.0 Crisis Management
5.0 Business Continuity
5.1 Overview
5.2 Finance BC Team Activation Procedure
5.3 Finance BC Team Business Recovery/Resumption Procedures
6.0 Appendices

122.8.2.1 Response for Building Evacuation

It is apparent that the Building Evacuation Procedure is one of many emergency responses contained within the plan. The Building Evacuation Response for the Finance BC Team is provided in Exhibit 122.3. Note that the table contains two columns at step 2—one for exiting by the men's restroom on the floor and the other for exiting by the women's restroom. So, with this information we can begin to fill in the test plan and continue the planning process. Exhibit 122.4 illustrates the test plan containing the

EXHIBIT 122.3 Response for Building Evacuation

Upon Hearing Fire Alarm or Receiving Notification to Evacuate the Building…

Action	
1 Exit the building at the closest emergency exit. The preferred exit is the exit closest to the men's restroom. *Do not use the elevators to evacuate*	1 *BC team leader:* Check work area to ensure that all personnel in the area or on your team are evacuating the building. Proceed down the stairs to the fifth-floor lobby and make sure that the receptionist has been informed to evacuate. Proceed to the nearest fifth-floor emergency exit and evacuate the building as described in the following steps
Evacuation through exit closest to men's restroom	**Evacuation through exit closest to woman's restroom**
2A Upon reaching the first-floor via the stairs, proceed to the left down the hallway and exit out the door to the alley	2B Upon exiting the emergency stairwell, proceed out the door to the loading dock
3A If safe to do so, turn to the left and proceed south down the alley to L Street, then go to Step 5; otherwise, go to the right down the alley to B Street. Make a left going toward Third Avenue, then left again, around the block toward L Street	3B Go down the stairs on the loading dock and proceed south down the alley to L Street
4A Make left onto L Street and proceed to evacuation assembly point (EAP) located under the overhang next to the Teriyaki restaurant on L Street	4B Turn right at the sidewalk to the evacuation assembly point (EAP) located under the overhang next to the Teriyaki restaurant on L Street
5A Upon arriving at the EAP, remain calm and await further instructions	5B Upon arriving at the EAP, remain calm and await further instructions
6A *BC team leader:* When you arrive at the EAP, account for all personnel on your team and report the team's evacuation status to the emergency response coordinator (ERC). Await additional instructions from the ERC	6B *BC team leader:* When you arrive at the EAP, account for all personnel on your team and report the team's evacuation status to the emergency response coordinator (ERC). Await additional instructions from the ERC

TEST REPORT DOCUMENT
ABC Finance Department
ABC Finance Business Continuity Plan

FinanceBCP_V2.1_2005.doc
TR-1-0-B-Finance-02202005.doc

Table of Contents

[Beginning of main body of the testing document]

1.0 Purpose of This Document

The purpose of this Test Report Document is to enable test planning, test execution, test review, and corrective action for this version of the finance business continuity plan. This document is utilized as a baseline throughout the various phases of the testing process, independent of the type of testing being performed. Items in this Test Report Document marked by “<<>>“ should be updated for the particular plan under test.

2.0 Document Change Control History

This document will be updated as necessary throughout the course of pretest planning, test execution, and post-test review. The version number (left-most digit) indicates the phase of the Test Report Document (1 = pretest; 2 = test; 3 = post-test; 4 = final-report). The issue number (right-most digit) will be incremented by one whole digit if there is a need to reissue this document due to a major change or update within a phase.

TR indicates test report.

D indicates disaster recovery plan (DRP).

B indicates business continuity plan (BCP).

Version and Issue	Date Issued (mmddyyyy)	Phase and Version Description
TR-1-0-B-Finance-02202005.doc	02202005	Pretest version of this document for use during pretest planning meetings
<<Version>>	<<Date>>	Test version of this document for use during testing
<<Version>>	<<Date>>	Post-test version of this document for use during post-test review meetings
<<Version>>	<<Date>>	Final report version of this document with a completed corrective action plan

Note: This is an example of a test report document filename TR-1-1-B-Finance-02212005, Version 1, Issue 1, of the pretest report for the business function BCP for finance.

Exhibit 122.4 (continued)

3.0 Scheduled Date and Time of Test

Start	Finish
<HH:MM am/pm, MM/DD/YYYY>	<HH:MM am/pm, MM/DD/YYYY>

4.0 Type of Test

Darken the box indicating the test being conducted:

❑ Drill

❑ Walk-through (orientation, tabletop, live)

■ Simulation test

❑ Full interruption test

5.0 Test Observers (TOs)

Those individuals involved in observing the expected execution results of the test and documenting the results achieved during the test:[a]

Test Observer Names	Position	Phone	Mail ID
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>

6.0 Test Participants (TPs)

Those individuals involved in executing the plan sections and procedure elements within the BCP being tested:[b]

Test Participant Names	Position	Phone	Mail ID
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>
<<Name>>	<<Position>>	<<Phone>>	<<Mail ID>>

7.0 Testing Objectives

The four objectives of this test are:

Observe the finance team's execution of the procedure.
Observe the BC team leader's execution and control of the procedure.
Identify problems encountered.
Document results and problem resolutions.

8.0 Execution Scenario:

ABC Company has received a notice from building management to evacuate the building due to a bomb threat and subsequent discovery of a mysterious package within the State of Washington Agency office on the seventh floor. All company personnel are to evacuate the building.

Exhibit 122.4 (continued)

9.0 Scope of Testing

Plan Names	Hi-Level Scope of Execution
FinanceBCP_V2.1_2005.doc	Scope of this test focuses on all steps of the finance department's building evacuation procedure.
<<Plan name>>	<<Scope>>
<<Plan name>>	<<Scope>>
<<Plan name>>	<<Scope>>

10.0 Limitations on Test Execution

The test will only involve the finance department.

11.0 Assumptions Related to Test Execution

All test participants have the latest copy of the BC Plan available to them.
All test participants are familiar with the relevant emergency procedures

<<Insert additional assumptions as necessary.>>

11.1 Detailed Business Continuity Plan Testing

<<Insert.>>

12.0 Problems Encountered

<<Insert problems encountered during the test.>>>

13.0 Post-Test Review

<<Insert comments and observations from the post-test review.>>

14.0 Corrective Action Plan for Deficiencies

<<Insert action plan for improving the plan.>>

15.0 Test Summary

<<To be completed by test facilitator after the post-test review has been conducted and a corrective action plan has been documented. Describe what worked properly and what was deficient and make general recommendations for improving the plan.>>

16.0 Appendix: Corrective Action Plan

<<Insert the specific corrective action plan for the test here; address at post-test review meeting.>>

Exhibit 122.4 (continued)

1.1.1 Plan Element[c]	1.1.2 Expected Execution Result[d]	1.1.3 Results Achieved[e]
1. Action: Upon hearing the fire alarm or receiving notification to evacuate the building, exit the building at the closest emergency exit. The preferred exit to take would be the exit closest to the men's restroom. *Do not use the elevators to evacuate.*	Finance team members begin exiting the building using the exits, not the elevators.	<<Insert>>
BC team leader: Check work area to ensure that all personnel in the area or on your team are evacuating the building. Proceed down the stairs to the fifth-floor lobby and make sure that the receptionist has been informed to evacuate. Proceed to the nearest fifth-floor emergency exit and evacuate the building as described in the following steps.	The acting BC team leader executes the procedure as described.	<<Insert>>
Evacuation through exit closest to men's restroom		
2A. Action: Upon reaching the first floor in the stairwell, proceed to the left down the hallway and exit out the door to the alley.	Finance team members that use the men's restroom exit follow the procedure as described.	<<Insert>>
Evacuation through exit closest to woman's restroom		
2B. Action: Upon exiting the emergency stairwell, proceed out the door to the loading dock.	Finance team members that use the women's restroom exit follow the procedure as described.	<<Insert>>
3A. Action: If safe to do so, turn to the left and proceed south down the alley to L Street, then go to Step 5; otherwise, go to the right down the alley to B Street. Make a left going toward Third Avenue, then left again, around the block toward L Street.	Finance team members that use the men's restroom exit follow the procedure as described.	<<Insert>>
3B. Action: Go down the stairs on the loading dock.	Finance team members that use the women's restroom exit follow the procedure as described.	<<Insert>>
4A. Action: Make a left on to L Street and proceed to the evacuation assembly point (EAP) located under the overhang next to the Teriyaki restaurant on L Street.	Finance team members that use the men's restroom exit follow the procedure as described.	<<Insert>>
4B. Action: All employees should proceed south down the alley to L Street. Turn right at the sidewalk to the EAP located under the overhang next to the Teriyaki restaurant on L Street.	Finance team members that use the women's restroom exit follow the procedure as described.	<<Insert>>
5A. Action: Upon arriving at the EAP, remain calm and await further instructions.	Finance team members that use the men's restroom exit follow the procedure as described.	<<Insert>>
5B. Action: Upon arriving at the EAP, remain calm and await further instructions.	Finance team members that use the women's restroom exit follow the procedure as described.	<<Insert>>
BC team leader: When you arrive at the EAP, account for all personnel on your team and report the team's evacuation status to the emergency response coordinator (ERC). Await additional instructions from the ERC.	The acting BC team leader executes the procedure as described.	<<Insert>>

Notes

[a] Test observers, ideally, are individuals not involved in the development of the BC/DR plan under test.

[b] Test participants must be those familiar with the BC/DR plan under test and should specifically be named team members of the BC/DR plan.

[c] As documented in the plan itself.

[d] As defined by members of the planning team.

[e] As documented during the test by the test facilitator and test observers.

[f] Reference the "results achieved" for this plan element during testing, and evaluate for corrective action during the post-test review meeting.

information noted above. Now the information security professional must determine the date and time for the test, identify the test observers who will be involved, insert the finance team members' names from the finance business continuity plan team roster into the test participants section, and make final adjustments to the limitations and assumptions of this test. After all this has been completed, the next steps would be to conduct the test, note any problems encountered, conduct the post-test review with the finance team, determine the need for any corrective actions, and write up the test summary.

122.9 Conclusion

Testing of business continuity and disaster recovery plans are the means of affirming that these plans and their capabilities are viable and executable. Testing allows a company to adjust their overall business continuity strategy through a continuous improvement cycle. The information provided in the article is a baseline that an information security professional can utilize to begin and sustain the testing of business continuity and disaster recovery plans. The Information security professional's involvement in a company's business continuity program should also ensure that the integrity, availability, and confidentiality of the information assets will be maintained even during a disaster.

123

Restoration Component of Business Continuity Planning

John Dorf
Martin Johnson

Everyone understands the importance of developing a business continuity plan (BCP) to ensure the timely recovery of mission-critical business processes following a damaging event. There are two objectives, however, and often, the second objective is overlooked return to normal operations as soon as possible. The reason for the urgency to return to normal operations is that backup and work-around procedures are certainly not "business as usual." Backup capabilities, whether due to the loss of primary premises or primary data, probably only include those business activities that are critical to getting by. The longer a company must operate in this mode, the more difficult the catch-up will be. There are several steps that can be taken in advance to prepare for the timely, efficient return to normalization. The purpose of this chapter is to discuss the steps and resources to ensure total recovery. In addition, it is important to understand how to handle damaged equipment and media in order to minimize the loss associated with a disaster.

Restoration includes the following:

1. Handling damaged equipment and media in order to minimize the loss
2. Salvaging hard copy and electronic media
3. Performing damage assessment and the resulting disposition of damaged facilities and equipment
4. Determining and procuring appropriate property insurance
5. Identifying internal and external resources to perform restoration activities
6. Developing, maintaining, and testing your restoration plan

This chapter will help you understand the issues related to each of these items and be a resource for developing the necessary information for inclusion in your BCP program.

The more time that passes before the salvation of hardcopy and electronic media, the greater the chance that the data or archival records will be permanently lost. However, if you rush to handle, move, dry, etc., media and do not do so in the correct manner, you may worsen the situation. Therefore, to ensure minimizing the damage you must act quickly and correctly to recover data and restore documents. This also applies to the facilities and infrastructure damage.

Having telephone numbers for restoration companies is not enough. The primary reason is in the event of a regional problem like flooding, ice storms, etc., you will have to wait for those companies that have advance commitments from other companies.

Another important issue associated with restoration is insurance. It is imperative you understand what is covered by your insurance policy and what approval procedures must be completed before any restoration work is performed. There are many stories about how insurance companies challenged claims because of disagreements concerning coverage or restoration procedures. Challenges from insurance carriers can hold up restoration for extended periods of time. Following are two examples showing the importance and magnitude of effort involved with restoration after a disaster.

> The 1993 World Trade Center bombing illustrates the potential magnitude of a clean-up effort. Over a 16-day period, 2700 workers hired by a restoration contractor, working round the clock in three shifts, cleaned over 880,000 square feet of space in the twin towers and other interconnected facilities. Ninety percent of the floors in the 110-story towers had light amounts of soot, while 10 percent suffered heavier damage.
>
> In 1995, Contra Costa County, California, suffered almost $15 million in arson-related fire damage to four county courthouses over a three-week period. In all, 124,000 files had to be freeze-dried and restored at an estimated cost of $50 per document.

A good restoration program will not guarantee you will not have a problem with your insurance carrier. The following is an example of how a disagreement between an insured and insurer can delay restoration of your business:

> In 1991, a 19-hour fire at One Meridian Plaza in Philadelphia destroyed eight of the 38 floors in the building. It took 6 years of legal maneuvering to settle the claim between the building owners and the insurers. Each party disagreed with the other over the extent of the restoration. For most of the 6 years, the parties' difference amounted to almost $100 million. The owners believed that the floors above the 19th floor had to be torn down because the steel beams supporting the structure had moved 4 inches and could not be certified as safe. The insurance company disagreed and argued that the building could be repaired without tearing down the floors. The owner and insurer also disagreed over the extent of environmental cleanup caused by the fire. Eventually, the matter was settled out of court for an undisclosed sum.

123.1 Understanding the Issues

For all damaged or destroyed property a company must understand when it needs to try to restore the property, and when the property can just be replaced. A critical issue concerning restoration is really the handling of documents and electronic media. Handling of the physical damage is more easily accomplished and more straightforward. The handling of vital records, however, is more difficult. The vital records may only be needed if an original contract is challenged, or is needed from a corporate entity standpoint. How a company deals with this exposure is not an easy determination. Some companies build facilities that are protected from most hazards to critical documents and data. The issue concerning having both a protected environment and duplication becomes a business issue; how much insurance is enough? Therefore, any time a company only has a single copy of vital documents and data, it must develop a strategy of what it would do if those records are damaged. This is a dilemma for many companies where duplicate copies cannot be maintained. Insurance companies have millions of pages of archived contracts and other legal documents that may not be feasibly copied. Other industries such as financial services handle equity certificates and other legal tender that perhaps cannot be copied as a normal course of business.

A company should develop a restoration plan in conjunction with performing a vital records review. In this way, the restoration of business-critical items can be assessed along with the alternatives of providing replication. Insurance coverage must be evaluated and coordinated with the restoration plan and other components of business continuity planning.

123.2 How to Select Restoration Service Providers

It is not difficult to find a service provider to clean up the rubble following a flood or fire. It is much more difficult to find a service provider that knows how to dry the soaked documents to best ensure their usability. It also takes a lot of expertise to handle fire-damaged documents and magnetic media to restore information.

The normal care for selecting any critical supply chain partner should be used. For a restoration company, however, you don't have the ability to ask for a pilot program. There are many sources of information to identify restoration companies, including local, state, and federal agencies. In addition, the Internet is an excellent source for both planning information, and resources.

Your own insurance carrier is also a good source of service provider information. Additionally, many insurance carriers have a partnership with recovery firms so that a firm is authorized to do certain work and deal directly with the insurance carrier to ensure there are no misunderstandings about the work to be performed.

123.3 Where Does Insurance Coverage Fit into Your Restoration Program?

The subjects of restoration and insurance are closely intertwined as, in most cases, property insurers are expected to pay for the majority of the cost of any restoration. The settlement of a property insurance claim can be a complex, time-consuming, and vexing issue, even for a seasoned insurance professional. The insured often do not understand their coverage and routinely overestimate the amount of the loss or assume that a claim is covered when it is not. Insurers and their representatives may communicate poorly with the insured as to the nature of the coverage, the information required to adjust the claim, and the timetable to be expected. Both sides need to cooperate and communicate clearly so that reasonable expectations are established quickly and conflicts can be resolved in a timely manner.

The discussion on insurance includes a brief overview of standard commercial property insurance policies and common problems during the claim settlements process.

123.3.1 Property Insurance Overview

Property insurance can be purchased with many options, which serve to tailor the standard policy language to the specific needs of the policyholder. Therefore, it is important that business owners take the time to review their needs with their insurance agent, broker, or advisor, so that the resulting insurance purchase reflects those needs before a loss occurs. This will help avoid future misunderstandings with the insurance company in the event of a claim.

Property insurance can be purchased on either a Named Perils or All Risk form. The All Risk form covers all causes of loss that are not specifically excluded in the policy and provides broader protection to the insured than a Named Perils form. Under a Named Perils form, the insured bears the responsibility of proving that damage to the property was caused by one of the enumerated causes of loss. Use of the All Risk form shifts the burden of proof onto the insurer to prove that a particular loss was not covered by the policy. Insurers avoid the use of the phrase "All Risk" and use the phrase "Special Form" to describe this same coverage.

The property policy valuation clause is a second area of frequent misunderstanding by policyholders. That is, if a loss occurs, on what basis will the policyholder be compensated for the loss or damage to the property? Insurers offer two basic valuation choices: actual cash value (ACV) or replacement cost coverage. ACV is defined as the cost to repair or replace the lost or damaged property with property of like kind and quality less physical depreciation. For example, suppose that a commercial refrigerator purchased five years ago and expected to have a useful working life of ten years is burned up in a fire. Assuming that the refrigerator had been well maintained up to the time of the loss, the insurance company adjuster might offer to settle the claim for 50 percent of the cost today of a new refrigerator of similar design, quality, and capacity. It should be noted that the lost or damaged property will be valued as of the date of the loss and not on the basis of the original cost.

Replacement cost valuation means that the policyholder will be compensated on the basis of new for old. That is, the policyholder is entitled to compensation on the basis of the cost to repair or replace the lost or damaged property with property of like kind and quality with no deduction for physical depreciation. As noted above, the determination of the replacement cost of the damaged or lost property takes place as of the actual date of loss.

Regardless of whether ACV or replacement cost valuation is chosen, the policyholder needs to make sure that the amount of insurance purchased accurately reflects the current replacement cost value of the insured property. This is necessary to avoid a coinsurance penalty being applied that could reduce any loss adjustment.

If replacement cost coverage is chosen, then in the event of loss or damage to the covered property, the insured must actually repair or replace the lost or damaged property. Otherwise, the insurance company is usually only required to reimburse the insured on an ACV basis.

Finally, the insurance company will never pay more than the applicable amount of insurance that has been purchased by the policyholder. This last provision underscores the need for business owners to adequately assess the replacement cost value of their property at the time the policy is placed.

We have not included an in-depth discussion of the topics of Business Interruption or Extra Expense insurance in our discussion of property insurance because it is beyond the scope of this chapter. These coverages go hand in hand with adequate property insurance coverage. Business interruption coverage pays for lost earnings and continuing expenses during the period of time the business is shut down. Extra expense coverage pays for the additional costs to maintain business during the shut-down period. The absence or insufficiency of either of these coverages can jeopardize the survival of the business that is jeopardized because of a lack of financial resources during the restoration period. Detailed records of all expenditures to maintain the operations of the business (extra expense) should be kept and included in the claim. The business interruption portion of the claim will be based on the lost earnings of the business as compared with periods preceding the loss.

In addition to standard property insurance coverage, business owners should discuss with their insurance advisors the need for additional insurance coverage in the following areas:

- Boiler and machinery
- Valuable papers
- Accounts receivable
- Electronic data processing (EDP)

Property insurance policies exclude coverage for damage caused by:

- Explosion of steam boilers, steam pipes, steam engines, or steam turbines
- Artificially generated electric current, including electric arcing, that affects electrical devices, appliances, or wire
- Mechanical breakdown, including rupture or bursting caused by centrifugal force

Such damage may be covered under boiler and machinery insurance policies. Boiler and machinery policies have many characteristics similar to property policies. In the event of a loss, these insurers often provide assistance in the repair or replacement of the damaged equipment. They also provide statutorily required inspection services.

Valuable papers coverage under a standard commercial property insurance policy is limited to $2500. Valuable papers coverage may be important for businesses where the destruction of documents would cause the business to suffer a monetary loss or to expend large sums in reconstructing the documents. The limit of insurance under a standard property policy can be increased to meet a desired need. The ISO (Insurance Services Office) valuable papers form defines valuable papers and records as "inscribed, printed, or written documents, manuscripts, or records." Money and securities, data processing programs, media, and converted data are not covered. Coverage for loss or destruction to money and securities can be found in Crime Insurance policies. Data processing programs, media, and data can be covered under EDP policies. Care needs to be exercised in estimating the cost of reconstructing documents so that adequate limits of insurance can be purchased.

If Accounts Receivable records are damaged by an insured cause of loss, this type of coverage will pay the business owner amounts due from customers that he is unable to collect as a result of the damage to his records, collection expenses in excess of normal collection costs, and other reasonable expenses incurred to reestablish records of accounts receivable. This coverage can be purchased as an endorsement to a commercial property insurance policy. Again, care must be exercised in setting an adequate amount of insurance.

Electronic data processing (EDP) coverage is a must for organizations that rely heavily on data processing or electronic means of information storage. EDP coverage can provide All Risk coverage for equipment and data, software and media, including the perils of electrical and magnetic injury, mechanical breakdown, and temperature and humidity changes, which are important to computer operations. In addition, the coverage can include the cost of reproducing lost data, which is not available under a standard commercial property insurance policy.

123.3.2 Property Insurance Claims Settlement Process

Exhibit 123.1 provides a broad overview of the claim settlement process. The exhibit underscores the importance of complete and well-organized documentation and open communication during the claim settlement process. These two factors are major reasons why claims settlements are delayed or even end up in litigation. The items shown in this table are important steps to include in your restoration plan.

The claims settlement process is adversarial by its nature. The insured party is intent on maximizing its potential recovery under its insurance policy, while the insurance company is trying to minimize its exposure to the insured's claim. This does not mean that the claim settlement process must be nasty or unpleasant. The parties should work together in good faith in arriving at a reasonable settlement of a claim. The insurance carrier will be less likely to raise substantive issues if it believes that the insured is not trying to take advantage of the situation. Likewise, if the insurer establishes reasonable ground rules at the beginning of the process, it should expect the insured to be forthcoming with the information requested in a timely manner. Although it is usually in the insured's best interests to provide complete and well-organized documentation, the insured should not overwhelm the insurance company and should only provide the documentation necessary to substantiate the amounts requested,

EXHIBIT 123.1 Overview of the Claim Settlement Process

- Report the event to the property insurance company immediately. Depending on the specific items damaged and the nature of the damage, it may be appropriate to notify the boiler and machinery insurer as well.
- Prevent further damage to covered property.
- Obtain property repair/replacement estimates or appraisals and prepare and document the claim. If business interruption and/or extra expense are going to be claimed, extensive additional documentation may be needed. (If a business interruption loss exceeds $1 million, the insured should consider hiring accountants experienced in documenting such claims.)
- Submit documentation to the insurance company adjuster and cooperate with the adjuster in his investigation and adjustment of the claim.
- Request authorization to proceed with repairs or the purchase of major items.
- If appropriate, request a partial payment of the claim from the insurance company.
- Negotiate the final claim settlement with the insurance company adjuster.
- Submit a sworn proof of loss to the insurance company.
- Receive claim settlement.

keeping ancillary documentation available in the event that the insurance carrier requests additional information.

The insurance adjuster is an individual assigned by the insurance company to handle a claim on its behalf. The adjuster may be an employee of the insurance company or may work for an independent firm hired by the insurance company. Adjusters will be the key contact between the insurer and the insured. Their responsibilities include determining the cause of a loss, the nature and scope of damage to the property, whether the policy covers the damages claimed, to what extent property should be repaired or replaced and the corresponding cost, and finally the amount that the insurance carrier is willing to pay in settlement of the claim. The adjuster also acts as a quarterback in determining whether other specialists need to become involved.

Depending on the size and complexity of the claim, the insurance carrier may selectively involve accountants, lawyers, and other specialists in the claim settlement process. These specialists are working on behalf of the insurance carrier and not the insured. Although the insured should not be unduly alarmed if the insurance company employs such specialists, the insured may be well advised to consider employing his own specialists to work on his behalf in calculating the claim in order to be on a more equal footing with the insurance company.

The agent or broker who placed the insurance can provide guidance and assistance to the insured in handling the claim. This should be expected, because the broker or agent has received compensation to arrange the insurance. Smaller brokers sometimes lack the capability to be of much assistance in a claim situation.

The responsibilities of the policyholder in the event of a loss are spelled out in most insurance policies. They include prompt notification of the insurer, protecting the covered property from further damage, providing detailed inventories of the damaged and undamaged property, allowing the insurance company to inspect the damaged property, take samples, and examine the pertinent records of the company, providing a sworn proof of loss, cooperating with the insurer in the investigation and settlement of the claim, and submitting to examination under oath concerning any matter relating to the insurance or the claim.

Willis Corroon, a large multinational insurance broker, recommends that the following steps be taken immediately following a loss:

- Make sure that the loss area is safe to enter.
- Report the claim to the agent and to the insurer.
- Restore fire protection.
- Take immediate action to minimize the loss.
- Protect undamaged property from loss.

- Take photographs of the damage.
- Identify temporary measures needed to resume operations and maintain safety and security, and the costs of those measures.
- Consult with engineering, operations, and maintenance personnel as well as outside contractors for an initial estimate of the scope and cost of repairs.
- Make plans for repairing the damage.

123.4 What Is Included in a Restoration Plan?

After a disaster such as a fire or hurricane, the natural inclination is to assume that documents, computer records, equipment and machinery, and high-tech computers and other data processing equipment that appear to be unusable or severely damaged should be scrapped and replaced. However, before anything is done, experts should be brought in to assess the damage and determine short- and long-term courses of action. The short-term course of action is intended to stabilize the situation at the disaster location so as to prevent further damage from occurring. The long-term strategy is to determine which items can be salvaged and repaired and which should be replaced.

Although notification to the insurance company should be one of the first steps taken after a disaster has occurred, do not wait for the insurance adjuster to show up before implementing stabilization procedures. It is a common insurance policy requirement that the insured take steps to prevent additional damage from occurring after a disaster. Such post-loss disaster mitigation should be part of a comprehensive business continuity plan. If no plan exists, then common sense should prevail.

Your restoration plan should include the following:

- Ensure life safety at the disaster location.
- Reactivate fire protection and other alarm/life safety systems.
- Establish security at the site to keep out intruders, members of the public, the press, as well as employees who should not be allowed in the disaster area unless they are directly involved in damage assessment or mitigation efforts.
- Cover damaged roofs, doors, windows, and other parts of the structure.
- Arrange for emergency heat, dehumidification, or water extraction.
- Separate damaged components that may interfere with restoration, but do not dispose of these components because restoration experts and the insurance adjuster will want to inspect them.
- Take photographs or videotape of the disaster site as well as damaged and undamaged property.
- Bring in experts in document/records restoration and qualified technical personnel to work on computer and communications equipment and systems, machinery and furniture, wall and floor coverings, and structural elements.
- Maintain a log of all steps taken after a disaster, noting time, location, what has been done, who did it, as well as work orders and invoices of all expenditures relating to the disaster.

After the disaster site has been secured and stabilized and the extent of damage assessed, contracts should be negotiated with qualified restoration contractors. The insurance company adjuster may be able to recommend qualified contractors. The adjuster should be consulted before any contracts are awarded.

The extent of the restoration possibly depends on the type of property damaged, the nature of the damage, and the extent and speed of post-disaster damage minimization. Another factor is the level of expertise brought in to assess and recommend restoration strategies as well as the quality of the restoration contractors brought in to do the work.

Following are some generalized comments on the restoration of paper documents, magnetic media (computer disks and tape), and electronic equipment and machinery.

Water damage is one of the most prevalent forms of damage to paper-based documents. Restoration efforts need to begin immediately if documents are to be saved. Water should be pumped out of the area as quickly as possible. The area also needs to be vented to allow air to circulate. Cool temperatures will help preserve water-soaked documents until actual restoration work can begin. Bringing in a freezer unit such as a refrigerated trailer (capable of being held at 0 degrees F) to store the documents will help slow down mold damage. Before freezing, documents should be cleaned and handled with extreme care. Documents should be kept in blocks (i.e., not pulled apart) as this will prevent additional deterioration. Documents that are not thoroughly soaked can be dried using dehumidification. Freeze-drying water-soaked documents will produce good results. Sterilization and application of a fungicidal buffer will help prevent further mold damage. Dehumidification and freeze-drying can take from one to two weeks to be completed.

Damaged computer tapes and diskettes need to be restored within 72 to 96 hours of a disaster to be effective. Water-damaged diskettes can be opened and dried using isopropyl alcohol and put into new jackets. Then the information is transferred onto new disks. Tapes can be freeze-dried or machine-dried using specialized machinery. The data on the tapes is then transferred to new media. Soot- and smoked-damaged diskettes need to be cleaned by hand, and then data transfer can take place.

Equipment and machines need to be evaluated on a case-by-case basis. There are specialist firms that can evaluate and recommend repair/restoration strategies for equipment. These firms may also do the repairs, or they may recommend shipping the damaged equipment to the manufacturer or utilize other shops to do the restoration. In general, insurance companies will not authorize replacement of damaged equipment with new or refurbished equipment unless the cost to repair the item exceeds 50 percent of its replacement cost. Smoke, soot, and other contaminants can be removed from equipment and replacement parts when damaged parts cannot be adequately cleaned. Occasionally, the original manufacturer may balk at substantially repairing damaged equipment, claiming that the repair will prove inadequate or will void the manufacturer's warranty. They are usually interested in selling new equipment. In such cases, insurance companies may be able to purchase replacement warranties (to replace the original manufacturer's warranty) from a warranty replacement company to satisfy the insured. The replacement warranty will be for the period of time remaining on the original manufacturer's warranty.

123.5 What Are the Costs for a Restoration Program?

The costs associated with restoration are more "at time of disaster" costs and would be covered by insurance. Having a thorough restoration strategy and plan will help to scope the insurance needed, and may even save money for those who are over-insured due to the lack of knowledge.

The primary cost of a program are the people resources necessary to develop and maintain the capability.

An approach to matching insurance needs with the potential cost to restore data and infrastructure is to start with your insurance carrier. Determine the types of restoration covered with different policies and then compare the coverage with restoration company estimates. Costs are usually based on square feet, type of media, etc.

Restoration of critical equipment is usually procured through the source of the equipment. This may include staged replacement parts or quick-ship components. Sometimes there is an incremental charge to maintenance fees to guarantee expedited service or replacement.

123.6 Ensuring Provider Can and Will Perform at Time of Disaster

Restoration is a service not dissimilar to maintenance for critical IT and facility operations. In the event of an emergency, any delay can cause a significant financial impact. You should view restoration in this same light. Therefore, expend the same diligence you would to selecting a service provider for ensuring business continuation, to selecting one for ensuring timely business resumption.

123.7 Testing Your Restoration Plan

Once a restoration plan has been implemented, it should be tested as part of a company's BCP program. The purpose of testing will be to validate that the plan:

1. Meets the business needs in terms of timeframe
2. Reduces the exposure to the loss of documents and data to an acceptable level
3. Remains in compliance with insurance requirements
4. Is current and the level of detail is sufficient to ensure a timely, efficient recovery

Testing is a primary means of keeping the restoration plan current. Regular tests with varying scope and objectives prevent the program from becoming too routine. As with any testing program, you start out simple and build on successes. Initially, it may involve contacting your service providers and verifying the following:

- You would be able to reach them at any hour, on any day
- They should be able to respond within the expected timeframes

Other tests may involve your restoration team members' awareness of the plan, ability to perform the tasks, and coordination with other "recovery and return to normal" activities.

In some cases, a company's need for restoration services actually diminishes. As IT solutions become more robust and the need for nonstop processing increases, more and more companies employ remote, replicated data. In this case, if the primary copy of data is lost, a second, equally current copy is available. Therefore, if a company had services for the restorations of electronic media, it may not be necessary.

123.8 Restoration Plan without a BCP Plan

Even if your company does not have a BCP program, it is still prudent to have ready resources to provide restoration services if needed. A company that does not understand the need for a BCP program will not allocate resources to develop a restoration strategy. A fallback would be to coordinate with your insurance carrier an understanding the critical nature of your vital records and single points of processing failure in order to procure the appropriate resources to get the job done.

123.9 Conclusion

A restoration strategy is one that can be implemented relatively easily and at minimal cost. Have your insurance carrier explain the types of hazards and restoration techniques, and if in a bind, work with the approved service partners.

Because time is of the essence when it comes to recovering damaged vital records and sensitive equipment, a BCP team should be assigned specific restoration responsibilities. Restoration should be a close second when it comes to recovering your business following a disaster.

123.10 Getting Support for Your Restoration Program

The most difficult task in developing a restoration capability and plan is to get internal manpower resources approved to help with the work. There may be some reluctance to go to management and suggest there is a need to prepare for the potential damage to critical property after management has spent money supposedly to eliminate the risk.

Everyone has seen news reports of damage due to floods, fires, and explosions. What most people do not know is that there is significant technology available to recover the critical data from damaged vital records. In addition, there are service providers who will guarantee replacement equipment within preestablished timeframes for a fixed subscription fee.

The important task is for the owner of critical business data and processing equipment to educate himself and his management that preplanning can significantly reduce the impact from potential loss of data.

123.11 Next Steps to Planning for Restoration

Below is an outline of steps to be performed to design and implement a restoration strategy to further protect a company's informational and physical assets.

I. Assess the needs
   A. What insurance coverage currently exists for the recovery and restoration of vital records following an event?
   B. What are the coverage options available for restoration of archival data and documents, as well as data needed to fully recover business processing?
   C. What are the business risks in terms of single copies of vital records?
   D. What are the business risks associated with the loss of equipment and facilities?

II. Develop a restoration strategy
   A. Identify alternatives to either eliminate single points of failure or reduce the impact of lost or damaged property.
   B. Perform a cost/benefit analysis of viable alternatives.
   C. Obtain approval and funding for appropriate alternatives.
   D. Implement the preventive and restoration strategies.

III. Develop a restoration plan and ongoing quality assurance
   A. Incorporate restoration into the existing BCP program.
   B. Assign restoration roles and responsibilities.
   C. Coordinate restoration with the risk management department and other BCP efforts.
   D. Develop ongoing plan maintenance tasks and schedules.
   E. Perform periodic tests of restoration capability.

Business Resumption Planning and Disaster Recovery: A Case History

Kevin Henry

Business resumption and disaster recovery planning is probably the part of information security that is easiest to overlook and postpone. Perhaps that is because few people actually enjoy preparing a business resumption plan. Like insurance, it is something one hopes is never needed; and because it is an inexact science at best, one is rarely sure that it has been completed correctly. More often, however, no one intentionally delays business resumption planning; it just does not happen—because of other job pressures, deadlines, and more seemingly urgent demands on one's time.

It is estimated that fewer than 50 percent of all firms have a reliable, complete, and current business resumption and disaster recovery plan in place.[1] For that reason, many firms are looking at two initiatives to address the lack of viable business resumption plans. The first is establishing a risk manager position within the corporation, a position with the primary responsibility of coordinating the development of business resumption and disaster recovery plans. The second initiative is to build business resumption and disaster recovery plan funding and timelines into every project. This is intended to force the development of plans prior to the project wrapping up and the team members dispersing. The effectiveness of these initiatives will ultimately depend on the leadership of senior management to enforce the mandate of the risk managers and require the completion of these tasks prior to project closure.

Because no organization ever wants to experience either a partial or full interruption of business operations, there is a silver lining in every cloud. The experience of having handled—and survived—a disaster can have a long-term benefit to a company. This chapter examines an actual case history of a computer system failure and the events that contributed to this becoming a disaster. In this particular instance, the business plan was implemented and, as it always seems to be, it was not a complete solution; however, it allowed a measure of the business process to continue to operate.

A business resumption plan is designed to provide an alternate method of continuing business operations in the event that the "normal" processes have been disrupted. A business resumption plan must address all types of scenarios that could disrupt the business process. These can be computer failures, but they are often other internal or external incidents that prevent an operation from continuing its usual practices. Some of these other disruptions may be environmental, such as fire (even if in a nearby structure) or flood, or they may be other external issues such as labor disruptions, gas leaks, or power failures. One notable computer system failure was caused by a watermain break some distance from the data processing site. When the water supply to the air conditioning unit was stopped, the air conditioning unit shut down and the data center overheated within a very short time.

One primary purpose of a business resumption plan and disaster recovery plan is to reduce the likelihood of a disaster occurring. This is a natural by-product of the initial stages of a properly developed business resumption plan. As the business resumption team begins to examine the area that it is developing a plan for, that team will create an awareness of the risks a system or corporation is exposed to. This will also locate and identify the weaknesses that could lead to an operational failure. These weaknesses might be found in a system, a process, hardware, software, lack of training, personnel issues that have not been addressed, or some form of environmental or external threat. Following that, the purpose of the plan is to set up a framework for the business process to be able to resume its usual operations in an alternate manner. The implementation speed of a business resumption plan is primarily dependent on the importance of the system. A critical system (such as 911, hospitals, or air traffic control) must have a plan that can be operational within seconds or minutes, while a less-critical system may be able to slowly come up to speed, over a period of days or even weeks.

An excellent example of a successful business resumption scenario was the ability of United Airlines to continue its operations despite a fire that shut down its operational control center for three weeks in 1999. Despite controlling 2500 flights a day from that site, United was able to resume processing at its backup site in less than one hour, with the result that only one flight had to be canceled and a handful of other flights experienced minor delays. Fortuitously, this backup site was just in the final stages of acceptance testing as part of the development of a new business resumption plan.

Once a disaster has struck, the primary intent of the business groups is to resume operations with as little operational impact on critical systems as possible. Simultaneously, the disaster recovery plan implementation is beginning. The first goal of the disaster recovery plan is to prevent further damage. This means, first and foremost, ensuring personal safety. Then the disaster recovery plan splits into three areas: cleanup of the damaged site (salvage and repair), supporting the alternate business operations, and transition back to normal process.

The ultimate goal of the business resumption and disaster recovery plan is achieved when business operations are able to resume their normal or predisaster state. Failure to be able to maintain or resume operations in a timely manner results in a devastating statistic of nearly 50 percent total business failure.

To be effective, a business resumption and disaster recovery plan must be fully documented. Every responsibility and task, all software and hardware, communications links, and security requirements must be written out and available immediately when required. It is not sufficient to rely on personnel with a wealth of experience or understanding of the operations to be available for consultation in the middle of the disaster. When properly documented, any two people reading the document will reach the same conclusions and take the same actions. When this can be proven to be the case, then one can be assured that the documentation is thorough and clear.

124.1 A Case History

This case history is an actual sequence of events experienced by Serv-co (a fictitious name). There is a tremendous amount of information to be learned from this disaster—both to see the sequence of events that led up to and contributed to the disaster itself, and the lessons learned through the handling of the disaster.

Serv-co had a payments processing system (see Exhibit 124.1) that handled all of the incoming payments to the company—mailed checks, Internet payments, and payments handled by agents of Serv-co, including local banks and independent agents and representatives. The payment processing system handled in excess of 25,000 payments daily. The incoming payments were handled at three separate workstations (see Exhibit 124.1). The workstation operators would enter the payment amount and account number into the workstation. Once a thousand payments had been entered, the file was closed and transmitted to a central server. Attached to the file were control totals to assist in verification of file integrity and error detection. Once a day, the area manager would log on to the server and group all of the day's transaction files into one large file. Once some preliminary balancing had been done, the manager would establish a communications link to the legacy mainframe system that handled all customer account management and invoicing. The manager would transmit the cumulative file to the legacy system. Once received by the mainframe system, batch processes would be run that posted all of the payment activity to the individual customer accounts.

Unfortunately, one day the payment processing system failed.

The failure of the payment processing system happened, as most failures seem to do, on a Friday afternoon in mid-summer when most people's minds are already at the beach. The area manager called the support vendor and reported a strange error code that had been encountered when she tried to transfer the day's payments summary file to the mainframe system.

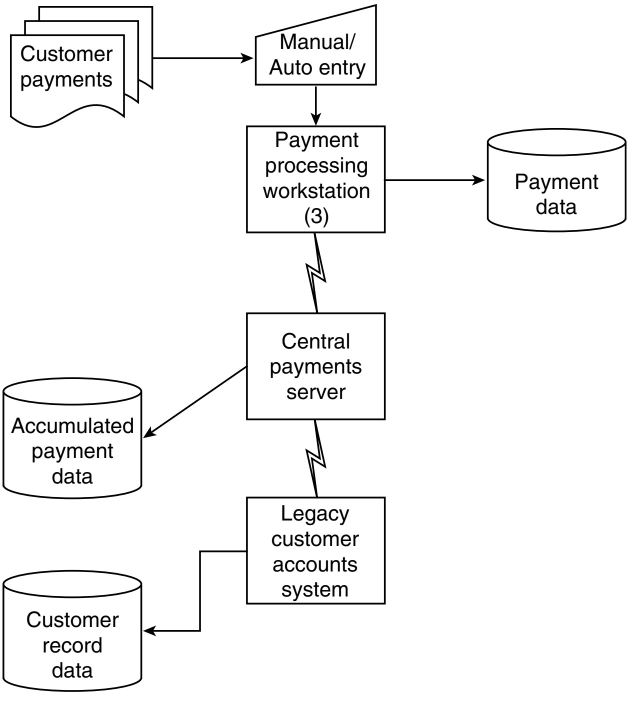

EXHIBIT 124.1 Payments system layout.

Being late on a Friday, it was agreed that the support company, referred to as Maint Group, would come out to Serv-co's location first thing Monday morning to investigate and correct the problem. This was not considered a serious problem. In the past, it had happened that minor system failures or file errors and imbalances would delay the posting of customer payments to their accounts by a day or two.

With his usually cheerful greeting, Maint Group's technician arrived early Monday morning to repair the problem. It should be noted that Maint Group was not the original vendor of the equipment; Maint Group had assumed the maintenance contract when the original vendor failed and went out of business. Within moments, the helpful grin of the technician faded as he realized that despite his years of experience with this equipment, he had never encountered this error condition. At this point, the value of a large vendor with a network of offices and a second-tier support group became apparent. Although this was not a common error, the technician was able to obtain assistance through contact with another branch (see Exhibit 124.2).

The error turned out to be a hard drive disk failure requiring the replacement of the hard drive. Here the first major deficiencies of the Serv-co payment processing system became clear. When Serv-co had purchased the system, instead of purchasing a server-class machine, the system server only included one hard drive and one power supply. Because of this, Serv-co's own Information Systems Standards Group had refused to accept the maintenance and oversight of the system.

Since the original purchase, the Payment Processing group had also moved to a new location. This meant a move of their workstations and server to a new facility. The equipment was located in a secure room; however, no provisions had been made for a proper power supply (UPS), nor were the proper environmental conditions provided for the equipment. This included mounting the server itself on a shelf over a desk. In addition, no secure and organized storage facility was provided for the backup tapes. The Payments Processing workgroup had several employees who had a keen interest in computers and were enthusiastic about looking after the equipment; however, without proper training and knowledge, they were unable to identify some of the basic deficiencies in the setup of the system.

As with many corporations, Serv-co had undergone some major restructuring a few years earlier. As part of this, several of the employees who were most knowledgeable about the system were released from Serv-co as part of a downsizing initiative. Because there was little or no documentation for the system, much of the practical knowledge of the system departed with these individuals (see Exhibit 124.3).

Back to the case history. The technician now had to find a new hard drive for the server. Because the equipment was now more than 12 years old, it was obsolete and piece parts were becoming increasingly difficult to find. In fact, Maint Group had sent a note to Serv-co two years earlier, indicating that the hard drive for this system was manufacturer discontinued and had exceeded its life expectancy. Maint Group recommended immediate replacement of the equipment. As a part of this notice, Maint Group also indicated that because of these limitations, it would only be able to continue to support the equipment on a "best effort" basis.

The technician was able to locate a hard drive in another city and arrangements were made to courier the hard drive to Serv-co for delivery first thing the next morning (Tuesday).

EXHIBIT 124.2 Vendor Selection

When making a new purchase of hardware or software, or making the decision about in-house support or outsourced maintenance agreements, the choice of vendor is critical. Many times, the number of firms to choose from may be limited, especially when proprietary products are involved. However, where possible, a company or agency should ensure that it retains sufficient skills in-house to be able to perform or oversee basic updates and tasks. This is a safeguard against vendor failure or vendor labor disruption. Also, the choice of a large vendor may be more expensive than a local, smaller vendor. The larger vendor may have more technical and equipment support available for that price, whereas the smaller vendor may be able to provide faster or a more-personal level of service. Ensure that the choice of vendor includes a review of whether the vendor has adequate support systems in place to deal with abstract or custom problems and has ready access to spare components; although there may be a higher cost for such support, it can be critical in a disaster scenario.

EXHIBIT 124.3 Documentation

Documentation is perhaps the most critical resource in a disaster situation. When properly prepared, documentation allows all personnel involved to understand their tasks and responsibilities and how those tasks fit into the other activities surrounding the disaster. Ideally, documentation should be written in a clear, standard format so that no time or effort is lost trying to understand the flow of the documents. This means that any two people who read the documents will come to the same conclusion and undertake the same actions

Documentation must be written for all processes and tasks surrounding a system, especially the routine or mundane daily tasks. Often, it is these tasks that no one knows how to do, or forgets, when the "expert" is sick or on vacation

Tuesday morning the package arrived; the drive it contained was not the same one indicated by the label on the outside of the package. (Obviously, whenever a critical delivery of this type is required, the sender should take the necessary steps to verify the contents of the delivery.)

At this point, Serv-co had begun the transition from a minor inconvenience to a major disaster. Every day that passed caused an increase in the number of customers who have made payments to Serv-co and they received bills that did not reflect those payments. Moreover, these bills assessed the customers with an invalid late payment charge. This began to cause increased workload for the Customer Service Representatives and lead to poor customer relations and possibly even unwelcome media attention. By the end of this disaster, more than 15,000 customers had been affected.

Maint Group located two more hard drives in other parts of the country and arranged to have both sent to Serv-co for delivery the next morning. However, Wednesday morning arrived with no deliveries. Because of a labor disruption at the airline, the packages had been bumped off their flights and consequently did not arrive.

Thursday morning a replacement hard drive arrived and, with a great sense of relief, the technician began to install it. Once installed, the technician asked the local manager for the copies of the system backups so that he could begin to load the operating system onto the new drive. The manager reached across the shelf and passed the technician a stack of old tape cartridges. For several years since the downsizing of the "computer support" person for the group, the manager had faithfully been taking daily backups and storing them on these tapes. What she did not realize was that all she was backing up were the daily transaction files, not the operating system. Serv-co had no viable backup copy of its operating system.

The Maint Group technician called his technical support personnel and was told that a generic copy of the operating system was available, but that it would not contain any customization that had been built into the operating system by the original vendor (who, as one remembers, had since gone out of business). This generic copy was installed but it was not useable in its current state. Maint Group immediately began the task of writing patches to the operating system to meet the requirements of the Serv-co application. These patches were promised to be ready by the following Tuesday.

At this point, the customer impact had become critical and Serv-co began to examine its business continuity program. As a proper program should, it reflected the critical time factors that applied to this group. Management had accepted that payments processing was not as critical as some other services provided by Serv-co and rightfully had designed the plan to allow for a few days' delay before business process resumption. The business resumption plan prescribed a manual work-around of entering the payments into financial spreadsheets. These spreadsheets would then be FTP'd to the legacy mainframe systems and the batch processes adapted to read the new files. This was a tremendously labor-intensive operation, and a call went out to the various departments within Serv-co to provide personnel to work over the long holiday weekend to input these payments.

Because of the manual effort involved, more personnel were also required to examine the completed spreadsheets to detect errors. In fact, of the many spreadsheets created, only one was found to be totally error-free. The local Payments Processing manager called the Risk Management group to alert them of the implementation of their business continuity plan and was advised to "keep them posted." This was a breakdown in the role of the Risk Management group. With their knowledge of crisis management and process flow and their familiarity with contacting other groups such as Human Resources, Legal, and Corporate Communications, they could have provided a substantial level of assistance in handling this disaster. But like so many departments, Risk Management was short staffed due to vacations. Without this assistance and coordination, the local manager in Payments Processing was soon overwhelmed with calls from other groups for scheduling and recovery operations. The demands of this activity on the manager's time and the time of the other people in her group further impacted their ability to respond to the business needs. The other result of the lack of input from Risk Management was that proper communication with the unions on the property were not established and, instead of receiving support for their recovery efforts, the manager was soon faced with several grievances pertaining to people from the wrong jurisdiction doing another bargaining unit's work. This may not have been avoidable, depending on the overall tone of labor/management relations, but proper communication and involvement may have prevented further animosity and stress in an already tense situation.

On Tuesday morning, the Maint Group technician arrived with the patches for the operating system. Once installed, these patches provided some functionality but many of the error-detection and balancing controls were absent. Also, the server was unable to establish a communications link with the mainframe. The last time this link had been set up, it had taken two technicians three days to determine the correct settings. Once again, the documentation was missing, and with it, this critical piece of information. Fortunately, a copy of the configuration was found in the recycling bin by a LAN support person who had been doing an inventory of communications links several months earlier.

Over the next week, Serv-co was able to catch up on its payments processing, but the cost in manpower and goodwill was extensive.

It is noteworthy that at the time of this failure, Serv-co had already bought a replacement system but it had not yet been delivered by the vendor. This process had started more than two years earlier with the notification of the obsolete equipment, but it had encountered several hurdles along the way. Management had twice sent the purchase proposal back to the Payment Processing department to explore other options (such as outsourcing) and less-expensive solutions. This delayed the replacement long enough for the existing equipment to finally fail.

Once again, however, the Payments Processing area had purchased the replacement equipment without the input and oversight of the Information Systems Standards group. As a result, the new equipment was similar to the old equipment in that it only had a single hard drive and a single power supply. It was also designed as a stand-alone system and plans had not been made to back it up to the corporate enterprise storage system. In fact, the Information Systems Standards group had once again declared that it would not support the new system, and its only concern with the project was that the interface to its legacy systems would work correctly.

So, what did Serv-co learn from this disaster? And what can the reader learn? A lot.

124.2 Professional Support

Ensure that all systems are installed with the oversight of information systems (IS) professionals and according to corporate standards. The active involvement of the IS staff in the procurement and support of stand-alone systems will prevent many minor errors from turning into major disasters. If the corporation does not have the standards it needs to develop them, this will also prevent further holes from developing in the security infrastructure through incompatible equipment. The more standard the equipment is, the easier it is to have in-house knowledge and keep the correct operating system patches up to date. Standard equipment also allows for easier load sharing and minimizes single points of failure. As a part of this, all companies should ensure that they have knowledgeable support for all of their systems. Especially when a system has been developed by an outside contractor, ensure that the knowledge of the system is not lost at the completion of the project. Once this disaster was resolved, Serv-co's Payments Processing and IS departments began to cooperate and redesign the replacement system. This included a regular backup to the enterprise storage system and the purchase of server-class equipment.

124.2.1 Backups

It goes without saying that proper backups must be done on all operating systems. Often, it is configurations (communications, routers, etc.) and rule bases (firewalls) that are overlooked. In all cases, backups should be done often enough to ensure that a processing cycle can be rebuilt if necessary. There are many examples of situations in which a system has only kept two or three generations of certain files. In the event of a failure (especially when the failure was related to application program change), the on-call programmer tries to rerun the job. If the subsequent rerun fails, it could happen that the last good backup has already been aged off and deleted before the problem is corrected. It is also important to ensure that all legal requirements for backups are met, such as long-term retention of financial records.

There are many different types of backup media available these days, including various tape products and CDs. The latest documentation on CDs indicates that they have a life expectancy even in adverse conditions of up to 200 years. In that case, the lifespan of the product is not the problem; the challenge is to ensure that any encryption keys are securely stored and available, and the software needed to read the CDs is also available the day that the data is required.

When recording backups, always ensure that the backup copy is readable. One company recently attempted to recover from a disk-head write failure only to discover that four of its 20 newly purchased tape cartridges were faulty. When it comes to the point of needing to recover from a backup, if the backup is faulty, the extent of the problem grows exponentially.

124.2.2 Equipment Aging

More and more of the equipment in use in corporations and agencies these days has already exceeded its lifespan. This is especially true for hard drives, power supplies, and tapes. A regular inventory of all equipment should be taken and the equipment specifications reviewed to ensure that the equipment is still reliable.

124.2.3 Dependencies

Many systems and business processes are not even aware of the other systems that depend on them, and that they themselves depend on for processing. Detailed data flow diagrams showing all internal and external system dependencies should be drawn up so that if a system fails, it is immediately apparent who else has been affected. This is especially important for financial systems and areas subject to regulatory requirements where the absence of a file may not be noticed but could have significant impact on processing or legal penalties.

124.2.4 Encryption

If the system has any form of encryption, it is necessary to keep all keys in a secure place for retrieval. Often, once a system has been operating for some period of time, the keys are forgotten; and when the system experiences a failure, it can be extremely dangerous if the keys are unavailable. Whenever an employee is using encryption for company documents or files, a copy of the keys should be retained in a secure, trusted location. It has happened that the loss of an employee through accident or termination has left a company unable to recover critical files. In one recent case, an employee who was about to be terminated for inappropriate behavior was able to hold the company "hostage" by refusing to disclose his keys and the administrative passwords to several key systems.

124.2.5 Vendor Failure

One of the most prevalent characteristics of the entire information processing field has to be vendor change. On a nearly daily basis, vendors are opening, closing, merging, or changing business direction. When this is accompanied by the rapid replacement of one technology with a newer product, this can have a significant impact on business resumption plans. Information systems professionals need to be continuously aware of the state of their vendor support network. A list of vendor phone numbers and contact lists must be kept together with the business resumption plan, and many plans should also include a commitment from vendors to supply new equipment on a priority basis in the event of a major failure.

Vendor-supplied software should be kept in escrow (held in trust by a third party) so that it is available if the vendor is unable to meet its maintenance or upgrade contractual conditions.

When purchasing new equipment, the risk is always whether it will continue to be manufactured and supported. More than one company has been unable to obtain a maintenance agreement for equipment that it had recently purchased because the vendor moved to a new line of business and abandoned a certain product line.

When selecting a vendor, the decision must be made whether to go with a possibly higher-priced vendor that has a large network of support and spare equipment availability, or with a smaller or local vendor and mitigate the risk through the purchase of spare parts or retaining greater in-house expertise.

124.3 BCP: Up to Date

To get a comprehensive and complete business resumption plan set up is difficult, but the effort does not stop there. A corporation, department, or agency still needs to identify the person responsible for the plan on an ongoing basis. Plans need to be reviewed at least once a year and after any major change in departmental structure. This responsibility should be built into the job description of the person who will maintain the business resumption plan and represent the department on the corporate Risk Management team. If the department does routine job reviews, the adherence to this responsibility should also be reviewed.

124.4 Union

Unions are a fact of life in many companies and agencies these days, and that places certain legal restrictions on the employees and managers. In most jurisdictions, it is illegal to negotiate a separate agreement with an individual who is represented by a union. Often in a crisis, a manager has attempted to negotiate a separate pay or compensation agreement directly with employees. This may seem practical but it can also be illegal and unenforceable. The business resumption plan must include a method of contacting a union representative for a unionized group that could be involved or affected by a business interruption. Hopefully, through prompt communication, the union can be available to assist in the recovery and personnel coordination activity, rather than add increased complexity to the disaster through labor disruption.

Whether or not there is a union on the property, the Human Resources department should be involved in the recovery efforts to ensure that any applicable labor codes or laws are being followed.

124.5 Risk Management Involvement

Many corporations and agencies now have a Risk Management group that has overall responsibility for coordinating the departmental plans, liason with external and internal groups, and leadership in a crisis. This group needs to have unrestricted access to the senior management of the company and must have the mandate to assist or lead in any business disruption. Without this mandate, Risk Management groups often have difficulty obtaining the subject matter experts (SMEs) to assist in a crisis because a manager in another group has refused to release them from their regular duties.

The focus areas of this group in a crisis are communication, collaboration, control, and coordination (the 4 Cs). With a properly set up group, a corporation will avoid the "Alexander Haig syndrome" of competing groups unsure of who is in charge and delivering conflicting statements.

One of the members of this group, on an as-needed basis, should be a member of the Health and Safety group of the company. This is to ensure that proper attention is being paid to the health issues, both mental and physical, of individual workers in a crisis scenario.

In a disaster, the Risk Management group should also ensure that all advertising campaigns related to the company or the disaster are halted or amended, and that a separate individual or organization is monitoring the media and providing feedback on how the corporation's statement or message is being received in the community.

Two factors that can be missed in many Risk Management groups are housekeeping and security of the Emergency Operations Center (EOC) and the site of the failure during disaster recovery efforts. Limiting access to the EOC and keeping it clean and uncluttered will aid in the smooth operation of the center.

The EOC should have separate access lines for the families of employees that are involved in the recovery operation so that they can pass on messages or receive updates. The understanding and resolution of family issues are critical to the involved individuals being able to focus on the recovery efforts. In addition, the company should have a telephone line with an answering machine that provides regular updates to other employees not directly related to the crisis. This can also be used to relay worksite and reporting information to the employees.

A disaster recovery operation often includes the disbursement of funds that exceeds the normal limit of local managers. A chain of command that accelerates the approval process or grants an increased spending limit on a temporary basis should be developed. There also needs to be a payroll process or provision for advance funds to be released to the families and individuals affected by the crisis.

The Risk Management group should have a list of the major customers of a company so that calls can immediately be made to these firms indicating that the company is still operational and outlining revised contact methods. This may prevent the loss of contracts or eroded confidence by the client community.

124.6 Downsizing

Downsizing has had a devastating effect on information systems security. It has led to the amalgamation of many functions, thereby removing separation of duties, and it has led to many individuals assuming responsibility for many tasks for which they have not received adequate training or experience. This is where inadequate documentation can harm a corporation. Often, many of the little jobs that were being done and the reasons for those actions are lost once a person has been released. Support people are especially vulnerable to downsizing because the benefit and importance of their work is not realized.

Downsizing also impacts morale and loyalty to the corporation. It has been estimated that a downsizing initiative deprives a corporation of four week's worth of productivity. Increased attention to security risks and possible malicious behavior must be included in the activity of the information systems security professional at this time. Most estimates are that 10 percent of an employee base will take advantage of an opportunity to defraud a corporation at any time. During a period of downsizing, this will usually rise to approximately 30 percent.

124.7 Documentation

Although documention was previously discussed, it is timely to add one further comment. Following any failure or test of the business resumption plan or a disaster recovery effort, review all documentation promptly to record all improvements and amendments to the documentation. Ensure that only the latest version of documentation is available (this can be accomplished by numbering the documents).

124.8 Partial Processing: Who Gets Priority

During a disaster every department wants priority service. This is not the time to make these decisions or to try to juggle multiple tasks. An integral part of developing business resumption and disaster recovery plans is to determine which areas of the company get first attention. In many plans, the plan does not include enough hardware or processing power to recover all business processes. Ensure that the correct ones are the ones that are recovered. Once a plan has been developed, have all managers sign off on it so that they realize and accept who will get first priority in the event of an incident.

124.9 Multiple Disasters: Be Aware of Other Disasters that May Impact the Primary Recovery Site

A daily task of the Risk Management group, and all business resumption planners, has to be monitoring of ongoing events that could affect a corporation's business processes or disaster recovery plans. For example, a corporation should attempt never to be surprised by an event at a neighboring facility or an environmental hazard that affects its ability to operate. This includes an awareness of ongoing disasters that may be affecting its disaster plan. An example of this was experienced following the World Trade Center bombing. A few weeks later, another company that lost its data center due to a structural failure (heavy snow load on the roof) was unable to move into its contracted hot site as planned because it was already in use by companies displaced from the World Trade Center. If that company had been attentive to this, it could have realized that this would have an effect on its disaster recovery plans and taken measures to arrange for an alternate site if necessary prior to its own failure.

A disaster recovery plan may be needed for an extended period of time; recent ice storms, for example, have disrupted commercial power for some firms for several weeks. Despite the fact that they were able to initially resume business operations, they were unable to continue because they only planned for providing alternate power for a few days.

124.10 Summary

Information systems security professionals have become keys players in the whole field of business resumption planning and disaster recovery. This is a radical departure from the normal duties of most information systems security personnel. Rather than a strictly technical or systems understanding, it requires them to gain an understanding of the entire business process and how they can support and enable those processes in a disaster scenario. The knowledgeable and professional advice that information systems security professionals provide will also significantly enhance the ability of most organizations, corporations, and agencies to prepare for and react to any incidents that could impair their business processes or threaten their very survival in a competitive and fast-moving marketplace.

Business Continuity Planning: A Collaborative Approach

Kevin Henry

Business continuity planning (BCP) has received more attention and emphasis in the past year than it has probably had cumulatively during the past several decades. This is an opportune time for organizations to leverage this attention into adequate resourcing, proper preparation, and workable business continuity plans. Business continuity planning is not glamorous, not usually considered to be fun, and often a little mundane. It can have all the appeal of planning how to get home from the airport at the end of an all-too-short vacation.

This chapter examines some of the factors involved in setting up a credible, useful, and maintainable business continuity program. From executive support through good leadership, proper risk analysis and a structured methodology, business continuity planning depends on key personnel making business-oriented and wise decisions, involving user departments and supporting services.

Business continuity planning can be defined as preparing for any incident that could affect business operations. The objective of such planning is to maintain or resume business operations despite the possible disruption. BCP is a preincident activity, working closely with risk management to identify threats and risks and reducing the likelihood or impact of any of these risks occurring. Many such incidents develop into a crisis, and the focus of the effort turns to crisis management. It is at this time that the value of prior planning becomes apparent.

The format of this chapter is to outline the responsibilities of information systems security personnel and information systems auditors in the BCP process. A successful BCP program is one that will work when needed and is built on a process of involvement, input, review, testing, and maintenance. The challenge is that a BCP program is developed in times of relative calm and stability, and yet it needs to operate in times of extreme stress and uncertainty. As we look further into the role of leadership in this chapter, we will see the key role that the leader has in times of crisis and the importance of the leader's ability to handle the extreme stress and pressures of a crisis situation.

A significant role of the BCP program is to develop a trained and committed team to lead, manage, and direct the organization through the crisis.

Through this chapter we will examine the aspects of crisis development, risk management, information gathering, and plan preparation. We will not go into as much detail about the plan development framework because this is not normally a function of IT or security professionals, yet understanding the role and intent of the business continuity program coordinator will permit IT professionals to provide effective and valued assistance to the BCP team.

So what is the purpose of the BCP program? It is to be prepared to meet any potential disruption to a business process with an effective plan, the best decisions, and a minimization of interruption.

A BCP program is developed to prepare a company to recover from a crisis—an event that may have serious impact on the organization, up to threatening the survival of the organization itself. Therefore, BCP is a process that must be taken seriously, must be thorough, and must be designed to handle any form of crisis that may occur. Let us therefore look at the elements of a crisis so that our BCP program will address it properly.

125.1 The Crisis

A crisis does not happen in isolation. It is usually the combination of a number of events or risks that, although they may not be catastrophic in themselves, in combination they may have catastrophic results. It has sometimes been said that it takes three mistakes to kill you, and any interruption in this series of events may prevent the catastrophe from taking place. These events can be the result of preexisting conditions or weaknesses that, when combined with the correct timing and business environment, initiate the crisis. This can be called a "catalyst" or "crisis trigger."

Once the crisis has begun, it evolves and grows, often impacting other areas beyond its original scope and influence. This growth of the crisis is the most stressful period for the people and the organization. This is the commencement of the crisis management phase and the transition from a preparatory environment to a reactionary environment. Decisions must be made on incomplete information amid demands and pressure from management and outside groups such as the media and customers. An organization with an effective plan will be in the best position to survive the disaster and recover; however, many organizations find that their plan is not adequate and are forced to make numerous decisions and consider plans of action not previously contemplated. Unfortunately, most people find that Rudin's Law begins to take effect:

> When a crisis forces choosing among alternatives, most people will choose the worst possible one.
>
> **—Rudin's Law.**

Let us take a closer look at each of these phases of a crisis and how we can ensure that our BCP program addresses each phase in an effective and timely manner.

125.1.1 Preexisting Conditions

In a sporting event, the opposition scores; when reviewing the video tapes later, the coach can clearly see the defensive breakdowns that led to the goal. A player out of position, a good "deke" by the opponent (used in hockey and soccer when an opposing player fools the goalie into believing that he is going in one direction and yet he actually goes in a different direction, thereby pulling the goaltender out of position and potentially setting up a good opportunity to score), a player too tired to keep pace—each contributing to the ability of the unwanted event to occur. Reviewing tapes is a good postevent procedure. A lot can be learned from previous incidents. Preparations can be made to prevent recurrence by improvements to the training of the players, reduction of weakness (maybe through replacing or trading players), and knowledge of the techniques of the opponents.

In business we are in a similar situation. All too often organizations have experienced a series of minor breakdowns. Perhaps they never became catastrophes or crises, and in many cases they may have been covered up or downplayed. These are the best learning events available for the organization. They need to be uncovered and examined. What led to the breakdown or near-catastrophe, what was the best response technique, who were the key players involved—who was a star, and who, unfortunately, did not measure up in times of crisis? These incidents uncover the preexisting conditions that may lead to a much more serious event in the future. Examining these events, documenting effective response techniques, listing affected areas, all provide input to a program that may reduce the preexisting conditions and thereby avert a catastrophe—or at least assist in the creation of a BCP that will be effective.

Other methods of detecting preexisting conditions are through tests and audits, interviewing the people on the floor, and measuring the culture of the organization. We often hear of penetration tests—what are they designed to do? Find a weakness before a hostile party does. What can an audit do? Find a lack of internal control or a process weakness before it is exploited. Why do we talk to the people on the floor? In many cases, simply reading the policy and procedure manuals does not give a true sense of the culture of the organization. One organization that recently received an award for its E-commerce site was immediately approached by several other organizations for a description of its procedure for developing the Web site. This was willingly provided—except that in conversation with the people involved, it was discovered that in actual fact the process was never followed. It looked good on paper, and a lot of administrative time and effort had gone into laying out this program; but the award-winning site was not based on this program. It was found to be too cumbersome, theoretical, and, for all intents and purposes, useless. Often, merely reviewing the policy will never give the reader a sense of the true culture of the organization. For an effective crisis management program and therefore a solid, useable BCP program, it is important to know the true culture, process, and environment—not only the theoretical, documented version.

One telecommunications organization was considering designing its BCP for the customer service area based on the training program given to the customer service representatives. In fact, even during the training the instructors would repeatedly say, “This may not be the way things will be done back in your business unit, this is the ideal or theoretical way to do things; but you will need to learn the real way things are done when you get back to your group.” Therefore, a BCP program that was designed according to the training manual would not be workable if needed in a crisis. The BCP needs to reflect the group for which it is designed. This also highlighted another risk or preexisting condition. The lack of standardization was a risk in that multiple BCP programs had to be developed for each business operation, and personnel from one group may not be able to quickly assume the work or personnel of another group that has been displaced by a crisis. Detecting this prior to a catastrophe may allow the organization to adjust its culture and reduce this threat through standardization and process streamlining.

One of the main ways to find preexisting conditions is through the risk analysis and management process. This is often done by other groups within and outside the organization as well—the insurance company, the risk management group, internal and external audit groups, security, and human resources. The BCP team needs to coordinate its efforts with each of these groups—a collaborative approach so that as much information is provided as possible to design and develop a solid, workable BCP program. The human resources group in particular is often looking at risks such as labor difficulties, executive succession, adequate policy, and loss of key personnel. These areas also need to be incorporated into a BCP program.

The IT group plays a key role in discovering preexisting conditions. Nearly every business process today relies on, and in many cases cannot operate without, some form of IT infrastructure. For most organizations this infrastructure has grown, evolved, and changed at a tremendous rate. Keeping an inventory of IT equipment and network layouts is nearly impossible. However, because the business units rely so heavily on this infrastructure, no BCP program can work without the assistance and planning of the IT group. From an IT perspective, there are many areas to be considered in detecting preexisting conditions: applications, operating systems, hardware, communications networks, remote access, printers, telecommunications systems, databases, Internet links, stand-alone or desktop-based systems, defense systems, components such as anti-virus tools, firewalls, and intrusion detection systems, and interfaces to other organizations such as suppliers and customers.

For each component, the IT group must examine whether there are single points of failure, documented lists of equipment including vendors, operating version, patches installed, users, configuration tables, backups, communications protocols and setups, software versions, and desktop configurations. When the IT group has detected possible weaknesses, it may be possible to alert management to this condition as a part of the BCP process in order to gain additional support for new resources, equipment, or support for standardization or centralized control.

The risk in many organizations is the fear of a "shoot the messenger" reaction from management when a potential threat has been brought to the attention of management. We all like to hear good news, and few managers really appreciate hearing about vulnerabilities and recommendations for increased expenditures in the few moments they have between budget meetings. For that reason, a unified approach using credible facts, proposals, solutions, and costs, presented by several departments and project teams, may assist the IT group in achieving greater standards of security and disaster preparedness. The unfortunate reality is that many of the most serious events that have occurred in the past few years could have been averted if organizations had fostered a culture of accurate reporting, honesty, and integrity instead of hiding behind inaccurate statistics or encouraging personnel to report what they thought management wanted to hear instead of the true state of the situation. This includes incidents that have led to loss of life or financial collapse of large organizations through city water contamination, misleading financial records, or quality-of-service reporting.

It is important to note the impact that terrorist activity has had on the BCP process. Risks that had never before been seriously considered now have to be contemplated in a BCP process. One of the weaknesses in some former plans involved reliance on in-office fireproof safes, air transit for key data and personnel, and proximity to high-risk targets. An organization not even directly impacted by the actual crisis may not be able to get access to its location because of crime-scene access limitations, clean-up activity, and infrastructure breakdowns. Since the terrorist actions in New York, several firms have identified the area as a high-risk location and chosen to relocate to sites outside the core business area. One firm had recently completed construction of a new office complex close to the site of the terrorist activity and has subsequently chosen to sell the complex and relocate to another area.

On the other hand, there are several examples of BCP programs that worked properly during the September 11, 2001, crisis, including tragic incidents where key personnel were lost. A BCP program that is properly designed will operate effectively regardless of the reason for the loss of the facility, and all BCP programs should contemplate and prepare for such an event.

125.1.2 Crisis Triggers

The next step in a crisis situation is the catalyst that sets off the chain of events that leads to the crisis. The trigger may be anything from a minor incident to a major event such as a weather-related or natural disaster, a human error or malicious attack, or a fire or utility failure. In any event, the trigger is not the real problem. An organization that has properly considered the preconditions that may lead to a crisis will have taken all precautions to limit the amount of damage from the trigger and hopefully prevent the next phase of the crisis—the crisis expansion phase—from growing out of control. Far too often, in a *post mortem* analysis of a crisis, it is too easy to focus on the trigger for the event and look for ways to prevent the trigger from occurring—instead of focusing on the preconditions that led to the extended impact of the crisis.

When all attempts have been made to eliminate the weaknesses and vulnerabilities in the system, then attention can be given to preventing the triggers from occurring.

125.1.3 Crisis Management/Crisis Expansion

As the crisis begins to unfold, the organization transitions from a preparatory stage, where the focus is on preventing and preparing for a disaster, to a reactionary stage, where efforts are needed to contain the damage, recover business operations, limit corporate exposure to liability and loss, prevent fraud or looting, begin to assess the overall impact, and commence a recovery process toward the ultimate goal of resumption of normal operations. Often, the organization is faced with incomplete information, inadequate coordinating efforts, complications from outside agencies or organizations, queries and investigations by the media, unavailability of key personnel, interrupted communications, and personnel who may not be able to work together under pressure and uncertainty.

During a time of crisis, key personnel will rise to the occasion and produce the extra effort, clarity of focus and thought, and energy and attitude to lead other personnel and the organization through the incident, These people need to be noticed and marked for involvement in future incident preparation handling. Leadership is a skill, an art, and a talent. Henry Kissinger defines leadership as the ability to "take people from where they are to places where they have never been." Like any other talent, leadership is also a learned art. No one is born a perfect leader, just as no one is born the world's best golfer. Just as every professional athlete has worked hard and received coaching and guidance to perfect and refine his ability, so a leader needs training in leadership style, attention to human issues, and project planning and management.

One of the most commonly overlooked aspects of a BCP program is the human impact. Unlike hardware and software components that can be counted, purchased, and discarded, the employees, customers, and families impacted by the crisis must be considered. No employee is going to be able to provide unlimited support—there must be provisions for rest, nourishment, support, and security for the employees and their families.

The crisis may quickly expand to several departments, other organizations, the stock market, and community security. Through all of this the organization must rapidly recognize the growth of the disaster and be ready to respond appropriately.

The organization must be able to provide reassurance and factual information to the media, families, shareholders, customers, employees, and vendors. Part of this is accomplished through knowing how to disseminate information accurately, representing the organization with credible and knowledgeable representatives, and restricting the uncontrolled release of speculation and rumor. During any crisis, people are looking for answers, and they will often grasp and believe the most unbelievable and ridiculous rumors if there is no access to reliable sources of information. Working recovery programs have even been interrupted and halted by the spread of inaccurate information or rumors.

Leadership is the ability to remain effective despite a stressful situation; remain composed, reliable, able to accept criticism (much of it personally directed); handle multiple sources of information; multitask and delegate; provide careful analysis and recommendations; and inspire confidence. Not a simple or small task by any means.

In many cases the secret to a good BCP program is not the plan itself, but the understanding of the needs of the business and providing the leadership and coordination to make the plan a reality.

Some organizations have been dismayed to discover that the people who had worked diligently to prepare a BCP program, coordinating endless meetings and shuffling paperwork like a Las Vegas blackjack dealer, were totally unsuited to execute the very plans they had developed.

The leader of a disaster recovery team must be able to be both flexible and creative. No disaster or crisis will happen "by the book." The plan will always have some deficiencies or invalid assumptions. There may be excellent and creative responses and answers to the crisis that had not been considered; and, although this is not the time to rewrite the plan, accepting and embracing new solutions may well save the organization considerable expense, downtime, and embarrassment. One approach may be the use of wireless technology to get a LAN up and running in a minimal amount of time without reliance on traditional cable. Another example is the use of microwave to link to another site without the delay of waiting for establishment of a new T1 line. These are only suggestions, and they have limitations—especially in regard to security—but they may also provide new and rapid answers to a crisis. This is often a time to consider a new technological approach to the crisis—use of Voice-over-IP to replace a telecommunications switch that has been lost, or use of remote access via the Internet so employees can operate from home until new facilities are operational.

Business resumption or business continuity planning can be described as the ability to continue business operations while in the process of recovering from a disaster.

The ability to see the whole picture and understand hidden relationships among processes, organizations, and work are critical to stopping the expansion of the crisis and disaster. Determining how to respond is a skill. The leaders in the crisis must know who to call and alert, on whom to rely, and when to initiate alternate processing programs and recovery procedures. They need to accurately assess the extent of the damage and expansion rate of the crisis. They need to react swiftly and decisively without overreacting and yet need to ensure that all affected areas have been alerted.

The disaster recovery team must be able to assure the employees, customers, management team, and shareholders that, despite the confusion, uncertainty, and risks associated with a disaster, the organization is competently responding to, managing, and recovering from the failure.

125.1.4 Crisis Resolution

The final phase of a crisis is when the issue is resolved and the organization has recovered from the incident. This is not the same as when normal operations have recommenced. It may be weeks or years that the impact is felt financially or emotionally. The loss of credibility or trust may take months to rebuild. The recovery of lost customers may be nearly impossible; and when data is lost, it may well be that no amount of money or effort will recover the lost information. Some corporations have found that an interruption in processing for several days may be nearly impossible to recover because there is not enough processing time or capacity to catch up.

The crisis resolution phase is a critical period in the organization. It pays to reflect on what went well, what lessons were learned, who were the key personnel, and which processes and assumptions were found to be missed or contrarily invalid. One organization, having gone through an extended labor disruption, found that many job functions were no longer needed or terribly inefficient. This was a valuable learning experience for the organization. First, many unnecessary functions and efforts could be eliminated; but second, why was the management unable to identify these unnecessary functions earlier? It indicated a poor management structure and job monitoring.

125.2 The Business Continuity Process

Now that we have examined the scenarios where we require a workable business continuity plan, we can begin to explore how to build a workable program. It is good to have the end result in mind when building the program. We need to build with the thought to respond to actual incidents—not only to develop a plan from a theoretical approach.

A business continuity plan must consider all areas of the organization. Therefore, all areas of the organization must be involved in developing the plan. Some areas may require a very elementary plan—others require a highly detailed and precise plan with strict timelines and measurable objectives. For this reason, many BCP programs available today are ineffective. They take a standard one-size-fits-all approach to constructing a program. This leads to frustration in areas that are overplanned and ineffectiveness in areas that are not taken seriously enough.

There are several excellent Web sites and organizations that can assist a corporation in BCP training, designing an effective BCP, and certification of BCP project leaders. Several sites also offer regular trade journals that are full of valuable information, examples of BCP implementations, and disaster recovery situations. Some of these include:

- Disaster Recovery Journal, www.drj.com
- Disaster Recovery Institute Canada, www.dri.ca

- Disaster Recovery Information Exchange, www.drie.org
- American Society for Industrial Security, www.asisonline.org
- Disaster Recovery Institute International, www.dr.org
- Business Continuity Institute, www.thebci.org
- International Association of Emergency Managers, www.nccem.org
- Survive—The Business Continuity Group, www.survive.com

There are also numerous sites and organizations offering tools, checklists, and software to assist in establishing or upgrading a BCP program.

Regardless of the Web site accessed by a BCP team member, the underlying process in establishing a BCP program is relatively the same.

- Risk and business impact analysis
- Plan development
- Plan testing
- Maintenance

The Disaster Recovery Institute recommends an excellent ten-step methodology for preparing a BCP program. The *Disaster Recovery Journal* Web site presents a seven-step model based on the DRI model, and also lists the articles published in its newsletters that provide education and examples of each step. Regardless of the type of methodology an organization chooses to use, the core concepts remain the same, Sample core steps are:

- Project initiation (setting the groundwork)
- Business impact analysis (project requirements definition)
- Design and development (exploring alternatives and putting the pieces together)
- Implementation (producing a workable result)
- Testing (proving that it is a feasible plan and finding weaknesses)
- Maintenance and update (preserving the value of the investment)
- Execution (where the rubber meets the road—a disaster strikes)

As previously stated, the intent of this chapter is not to provide in-depth training in establishing a BCP program. Rather, it is to present the overall objectives of the BCP initiative so that, as information systems security personnel or auditors, we can provide assistance and understand our role in creating a workable and effective business continuity plan.

Let us look at the high-level objectives of each step in a BCP program methodology.

125.2.1 Project Initiation

Without clearly defined objectives, goals, and timelines, most projects flounder, receive reduced funding, are appraised skeptically by management, and never come to completion or delivery of a sound product. This is especially true in an administrative project like a BCP program. Although the awareness has been raised about BCP due to recent events, this attention will only last as long as other financial pressures do not erode the confidence that management has in realizing worthwhile results from the project.

A BCP project needs clearly defined mandates and deliverables. Does it include the entire corporation or only a few of the more critical areas to start with? Is the funding provided at a centrally based corporate level or departmentally? When should the plans be provided? Does the project have the support of senior management to the extent that time, resources, and cooperation will be provided on request as needed by the BCP project team?

Without the support of the local business units, the project will suffer from lack of good foundational understanding of business operations. Therefore, as discussed earlier it is doubtful that the resulting plan will accurately reflect the business needs of the business units.

Without clearly defined timelines, the project may tend to take on a life of its own, with never-ending meetings, discussions, and checklists, but never providing a measurable result.

Security professionals need to realize the importance of providing good support for this initial phase—recommending and describing the benefits of a good BCP program and explaining the technical challenges related to providing rapid data or processing recovery. As auditors, the emphasis is on having a solid project plan and budget responsibility so that the project meets its objectives within budget and on time.

125.2.2 Business Impact Analysis

The business impact analysis (BIA) phase examines each business unit to determine what impact a disaster or crisis may have on its operations. This means the business unit must define its core operations and, together with the IT group, outline its reliance on technology, the minimum requirements to maintain operations, and the maximum tolerable downtime (MTD) for its operations. The results of this effort are usually unique to each business unit within the corporation. The MTD can be dependant on costs (costs may begin to increase exponentially as the downtime increases), reputation (loss of credibility among customers, shareholders, regulatory agencies), or even technical issues (manufacturing equipment or data may be damaged or corrupted by an interruption in operations).

The IT group needs to work closely during this phase to understand the technological requirements of the business unit. From this knowledge, a list of alternatives for recovery processing can be established.

The audit group needs to ensure that proper focus is placed on the importance of each function. Not all departments are equally critical, and not all systems within a department are equally important. E-mail or Internet access may not be as important as availability of the customer database. The accounting department—despite its loud objections—may not need all of its functionality prioritized and provided the same day as the core customer support group. Audit can provide some balance and objective input to the recovery strategy and time frames through analysis and review of critical systems, highest impact areas, and objective consideration.

125.2.3 Design and Development

Once the BCP team understands the most critical needs of the business from both an operational and technology standpoint, it must consider how to provide a plan that will meet these needs within the critical timeframes of the MTD. There are several alternatives, depending on the type of disaster that occurs, but one alternative that should be considered is outsourcing of some operations. This can be the outsourcing of customer calls such as warranty claims to a call center, or outsourcing payroll or basic accounting functions.

Many organizations rely on a hot site or alternate processing facility to accommodate their information processing requirements. The IT group needs to be especially involved in working together with the business units to ensure that the most critical processing is provided at such a site without incurring expense for the usage of unnecessary processing or storage capability.

The audit group needs to ensure that the proper cost/benefit analysis has been done and that the provisions of the contract with the hot site are fulfilled and reasonable for the business needs.

The development of the business continuity plan must be reviewed and approved by the managers and representatives in the local business groups. This is where the continuous involvement of key people within these groups is beneficial. The ideal is to prepare a plan that is workable, simple, and timely. A plan that is too cumbersome, theoretical, or unrelated to true business needs may well make recovery operations more difficult rather than expedite operational recovery.

During this phase is it noticed that, if the BCP process does not have an effective leader, key personnel will begin to drop out. No one has time for meaningless and endless meetings, and the key personnel from the business units need to be assured that their investment of time and input to the BCP project is time well spent.

125.2.4 Implementation of the Business Continuity Plan

All of the prior effort has been aimed at this point in time—the production of a workable result. That is, the production of a plan that can be relied on in a crisis to provide a framework for action, decision making, and definition of roles and responsibilities.

IT needs to review this plan to see its role. Can IT meet its objectives for providing supporting infrastructures? Does IT have access to equipment, backups, configurations, and personnel to make it all happen? Does IT have the contact numbers of vendors, suppliers, and key employees in off-site locations? Does the business unit know who to call in the area for support and interaction?

The audit group should review the finished product for consistency, completeness, management review, testing schedules, maintenance plans, and reasonable assumptions. This should ensure that the final product is reliable, that everyone is using the same version, that the plan is protected from destruction or tampering, and that it is kept in a secure format with copies available off-site.

125.2.5 Testing the Plans

Almost no organization can have just one recovery strategy. It is usual to have several recovery strategies based on the type of incident or crisis that affects the business. These plans need to be tested. Tests are verification of the assumptions, timelines, strategies, and responsibilities of the personnel tasked with executing a business continuity plan. Tests should not only consist of checks to see if the plan will work under ideal circumstances. Tests should stress the plan through unavailability of some key personnel and loss of use of facilities. The testing should be focused on finding weaknesses or errors in the plan structure. It is far better to find these problems in a sterile test environment than to experience them in the midst of a crisis.

The IT staff should especially test for validity of assumptions regarding providing or restoring equipment, data links, and communications links. They need to ensure that they have the trained people and plans to meet the restoration objectives of the plan.

Auditors should ensure that weaknesses found in the plans through testing are documented and addressed. The auditors should routinely sit in on tests to verify that the test scenario is realistic and that no shortcuts or compromises are made that could impair the validity of the test.

125.2.6 Maintenance of the BCP (Preserving the Value of the Investment)

A lot of money and time goes into the establishment of a good BCP program. The resulting plans are key components of an organization's survival plan. However, organizations and personnel change so rapidly that almost any BCP is out of date within a very short timeframe. It needs to be defined in the job descriptions of the BCP team members—especially the representatives from the business units—to provide continuous updates and modifications to the plan as changes occur in business unit structure, location, operating procedures, or personnel.

The IT group is especially vulnerable to outdating plans. Hardware and software change rapidly, and procurement of new products needs to trigger an update to the plan. When new products are purchased, consideration must be given to ensuring that the new products will not impede recovery efforts through unavailability of replacements, lack of standardization, or lack of knowledgeable support personnel.

Audit must review plans on a regular basis to see that the business units have maintained the plans and that they reflect the real-world environment for which the plans are designed. Audit should also ensure that adequate funding and support is given to the BCP project on an ongoing basis so that a workable plan is available when required.

125.3 Conclusion

A business continuity plan is a form of insurance for an organization—and, like insurance, we all hope that we never have to rely on it. However, proper preparation and training will provide the organization with a plan that should hold up and ease the pressures related to a crisis. A good plan should minimize the need to make decisions in the midst of a crisis and outline the roles and responsibilities of each team member so that the business can resume operations, restore damaged or corrupted equipment or data, and return to normal processing as rapidly and painlessly as possible.

126

The Business Impact Assessment Process

Carl B. Jackson

The initial version of this chapter was written for the 1999 edition of the *Handbook of Information Security Management*. Since then, Y2K has come and gone, E-commerce has seized the spotlight, and Web-based technologies are the emerging solution for almost everything. The constant throughout these occurrences is that no matter what the climate, fundamental business processes have changed little. And, as always, the focus of any business impact assessment is to assess the time-critical priority of these business processes. With these more recent realities in mind, this chapter has been updated and is now offered for your consideration.

The objective of this chapter is to examine the business impact assessment (BIA) process in detail and focus on the fundamentals of a successful BIA.

There is no question that business continuity planning (BCP) is a business process issue, not a technical one. Although each critical component of the enterprise must participate during the development, testing, and maintenance of the BCP process, it is the results of the business impact assessment (BIA) that will be used to make a case for further action.

Why perform a business impact assessment? The author's experiences in this area have shown that all too often, recovery strategies, such as hot sites, duplicate facilities, material or inventory stockpiling, etc., are based on emotional motivations rather than the results of a thorough business impact assessment. The key to success in performing BIAs lies in obtaining a firm and formal agreement from management as to the precise maximum tolerable downtimes (MTDs), also referred to in some circles as recovery time objectives (RTOs), for each critical business process. The formalized MTDs/RTOs, once determined, must be validated by each business unit, then communicated to the service organizations (i.e., IT, Network Management, Facilities, HR, etc.) that support the business units. This process helps ensure that realistic recovery alternatives are acquired and recovery measures are developed and deployed.

There are several reasons why a properly conducted and communicated BIA is so valuable to the organization. These include: (1) identifying and prioritizing time-critical business processes; (2) determining MTDs/RTOs for these processes and associated supporting resources, (3) raising positive awareness as to the importance of business continuity, and (4) providing empirical data upon which management can base its decision for establishing overall continuous operations and recovery strategies and acquiring supporting resources. Therefore, the significance of the BIA is that it sets the stage for shaping a business-oriented judgment concerning the appropriation of resources for recovery planning and continuous operations. (E-commerce—see below).

126.1 The Impact of the Internet and E-Commerce on Traditional BCP

Internet-enabled E-commerce has profoundly influenced the way organizations do business. This paradigm shift has dramatically affected how technology is used to support the organization's supply chain, and because of this, will also have a significant effect on the manner in which the organization views and undertakes business continuity planning. It is no longer a matter of just preparing to recover from a serious disaster or disruption. It is now incumbent upon technology management to do all it can to avoid any kind of outage whatsoever. The technical disciplines necessary to ensure continuous operations or E-availability include building redundancy, diversity, and security into the E-commerce-related supply-chain technologies (e.g., hardware, software, systems, and communications networks) (see Exhibit 126.1).

This framework attempts to focus attention on the traditional recovery planning process components as well as to highlight those process steps that are unique to the continuous operations/ E-availability process.

The BCP professional must become conversant with the disciplines associated with continuous operations/E-availability in order to ensure that organizational E-availability and recovery objectives are met.

126.2 The BCP Process Approach

The BIA process is only one phase of recovery planning and E-availability. The following is a brief description of a six-phase methodological approach. This approach is commonly used for development of business unit continuity plans, crisis management plans, technological platform, and communications network recovery plans.

- Phase I—Determine scope of BCP project and develop project plan. This phase examines business operations and information system support services, in order to form a project plan to direct subsequent phases. Project planning must define the precise scope, organization, timing, staffing, and other issues. This enables articulation of project status and requirements throughout the organization, chiefly to those departments and personnel who will be playing the most meaningful roles during the development of the BCP.
- Phase II—Conduct business impact assessment. This phase involves identification of time-critical business processes, and determines the impact of a significant interruption or disaster. These impacts may be financial in terms of dollar loss, or operational in nature, such as the ability to deliver and monitor quality customer service, etc.
- Phase III—Develop recovery/E-availability strategies. The information collected in Phase II is employed to approximate the recovery resources (i.e., business unit or departmental space and resource requirements, technological platform services, and communications networks requirements) necessary to support time-critical business processes and sub-processes. During this phase, an appraisal of E-availability/recovery alternatives and associated cost estimates are prepared and presented to management.

EXHIBIT 126.1 Continuous Availability/Recovery Planning Component Framework

Continuous Operations/Availability Disciplines	**Traditional Recovery/BCP Disciplines**
Current state assessment	Current state assessment
Business impact assessment	Business impact assessment
Leading practices/benchmarking	Leading practices/benchmarking
Continuous operations strategy development	Recovery strategy development
Continuous operations strategy deployment	Recovery plan development/deployment
Testing/maintenance	Testing/maintenance
Awareness/training	Awareness/training
Process measurement/metrics/value	Process measurement/metrics/value

- Phase IV—Perform recovery plan development. This phase develops the actual plans (i.e., business unit, E-availability, crisis management, technology-based plans). Explicit documentation is required for execution of an effective recovery process. The plan must include administrative inventory information and detailed recovery team action plans, among other information.
- Phase V—Implement, test, and maintain the BCP. This phase establishes a rigorous, ongoing testing and maintenance management program.
- Phase VI—Implement awareness and process measurement. The final and probably the most crucial long-term phase establishes a framework for measuring the recovery planning and E-availability processes against the value they provide the organization. In addition, this phase includes training of personnel in the execution of specific continuity/recovery activities and tasks. It is vital that they are aware of their role as members of E-availability/recovery teams.

126.3 BIA Process Description

As mentioned above, the intent of the BIA process is to assist the organization's management in understanding the impacts associated with possible threats. Management must then employ that intelligence to calculate the maximum tolerable downtime (MTD) for time-critical support services and resources. For most organizations, these resources include:

1. Personnel
2. Facilities
3. Technological platforms (traditional and E-commerce-related systems)
4. Software
5. Data networks and equipment
6. Voice networks and equipment
7. Vital records
8. Data
9. Supply chain partners

126.4 The Importance of Documenting a Formal MTD/RTO Decision

The BIA process concludes when executive management makes a formalized decision as to the MTD it is willing to live with after analyzing the impacts to the business processes due to outages of vital support services. This includes the decision to communicate these MTD decision(s) to each business unit and support service manager involved.

126.4.1 The Importance of a Formalized Decision

A formalized decision must be clearly communicated by senior management because the failure to document and communicate precise MTD information leaves each manager with imprecise direction on: (1) selection of an appropriate recovery alternative method; and (2) the depth of detail that will be required when developing recovery procedures, including their scope and content.

The author has seen many well-executed BIAs with excellent results wasted because senior management failed to articulate its acceptance of the results and communicate to each affected manager that the time requirements had been defined for recovery processes.

126.5 BIA Information-Gathering Techniques

There are various schools of thought regarding how best to gather BIA information. Conducting individual one-on-one BIA interviews is popular, but organizational size and location issues sometimes make conducting one-on-one interviews impossible. Other popular techniques include group sessions, the use of an electronic medium (i.e., data or voice network), or a combination of all of these. Exhibit 126.2 is a BIA checklist. The following points highlight the pros and cons of these interviewing techniques:

1. *One-on-one BIA interviews*. In the author's opinion, the one-on-one interview with organizational representatives is the preferred manner in which to gather BIA information. The advantages of this method are the ability to discuss the issues face-to-face and observe the person. This one-on-one discussion will give the interviewer a great deal of both verbal and visual information concerning the topic at hand. In addition, personal rapport can be built between the interviewee and the BIA team, with the potential for additional assistance and support to follow. This rapport can be very beneficial during later stages of the BCP development effort if the person being interviewed understands that the BCP process was undertaken to help them get the job done in times of emergency or disaster. The disadvantages of this approach are that it can become very time-consuming, and can add time to the critical path of the BIA process.
2. *Group BIA interview sessions or exercises*. This type of information-gathering activity can be very efficient in ensuring that a lot of data is gathered in a short period of time and can speed the BIA process tremendously. The drawback to this approach is that if not conducted properly, it can result in a meeting of a number of people without very much useful information being obtained.
3. *Executive management mandate*. Although not always recommended, there may be certain circumstances where conducting only selected interviews with very high-level executive

EXHIBIT 126.2 BIA Dos Checklist

BIA To Dos

- Customize the BIA information-gathering tools questions to suit the organization's customs/culture.
- Focus on time-critical business processes and support resources (i.e., systems, applications, voice and date networks, facilities, people, etc.).
- Assume worst-case disaster (day of week, month of year, etc.).
- Assume no recovery capability exists.
- Obtain raw numbers in orders of magnitude.
- Return for financial information.
- Validate BIA data with BIA participants.
- Formalize decision from senior management so lower-level managers (MTD timeframes, scope, and depth of recovery procedures, etc.) can make precise plans.

Conducting BIA Interviews

- When interviewing business unit personnel, explain that you are here to get the information you need to help IT build their recovery plan. But emphasize that the resulting IT recovery is really theirs, and the recovery plan is really yours. One is obtaining their input as an aid in ensuring that MIS constructs the proper recovery planning strategy.
- Interviews last no longer that 45 minutes to 1 hour and 15 minutes.
- The number of interviewees at one session should be at best one, and at worst two to three. More than that and the ability of the individual to take notes is questionable.
- If possible, at least two personnel should be in attendance at the interview. Each should have a blank copy of the questionnaire on which to take notes.
- One person should probably not perform more than four interviews per day. This is due to the requirement to successfully document the results of each interview as soon as possible and because of fatigue factors.
- Never become confrontational with the interviewees. There is no reason that interviewees should be defensive in their answers unless they do not properly understand the purpose of the BIA interview.
- Relate to interviewees that their comments will be taken into consideration and documented with the others gathered. And that they will be requested to review, at a later date, the output from the process for accuracy and provide their concurrence.

management will suffice for BIA purposes. Such situations might include development of continuous operations/E-availability strategies where extremely short recovery timeframes are already obvious, or where times for development of appropriate strategies for recovery are severely shortened (as in the Y2K recovery plan development example). The level of confidence is not as high in comparison to performing many more exhaustive sets of interviews (at various levels of the organization, not just with the senior management group), but it does speed up the process.

4. *Electronic medium*. Use of voice and data communications technologies, videoconferencing, and Web-based technologies and media are becoming increasingly accepted and popular. Many times, the physical or geographical size and diversity, as well as the structural complexity of the organization, lends itself to this type of information-gathering technique. The pros are that distances can be diminished and travel expenses reduced. The use of automated questionnaires and other data-gathering methods can facilitate the capture of tabular data and ease consolidation of this information. Less attractive, however, is the fact that this type of communication lacks the human touch, and sometimes ignores the importance of the ability of the interviewer to read the verbal and visual communications of the interviewee. *Note*: Especially worrisome is the universal broadcast of BIA-related questionnaires. These inquiries are sent to uninformed groups of users on a network, whereby they are asked to supply answers to qualitative and quantitative BIA questions without regard to the point or nuance of the question or the intent of the use of the result. Such practices almost always lend themselves to misleading and downright wrong results. This type of unsupported data-gathering technique for purposes of formulating a thoughtful strategy for recovery should be avoided.

Most likely, an organization will need to use a mix of these suggested methods, or use others as suited to the situation and culture of the enterprise.

126.6 The Use of BIA Questionnaires

There is no question that the people-to-people contact of the BIA process is *the* most important component in understanding the potential a disaster will have on an organization. People run the organization, and people can best describe business functionality and their business unit's degree of reliance on support services. The issue here, however, is deciding what is the best and most practical technique for gathering information from these people.

There are differing schools of thought regarding the use of questionnaires during the BIA process. The author's opinion is that a well-crafted and customized BIA questionnaire will provide the structure needed to guide the BIA and E-availability project team(s). This consistent interview structure requires that the same questions be asked of each BIA interviewee. Reliance can then be placed on the results because answers to questions can be compared to one another with assurance that the comparisons are based on the same criterion.

Although a questionnaire is a valuable tool, the structure of the questions is subject to a great deal of customization. This customization of the questions depends largely on the reason why the BIA is being conducted in the first place.

The BIA process can be approached differently, depending on the needs of the organization. Each BIA situation should be evaluated in order to properly design the scope and approach of the BIA process. BIAs are desirable for several reasons, including:

1. Initiation of a BCP process where no BIA has been done before, as part of the phased implementation methodology
2. Reinitiating a BCP process where there was a BIA performed in the past, but now it needs to be brought up to date

3. Conducting a BIA in order to incorporate the impacts of a loss of E-commerce-related supply-chain technologies into the overall recovery strategies of the organization
4. Conducting a BIA in order to justify BCP activities that have already been undertaken (i.e., the acquisition of a hotsite or other recovery alternative)
5. Initiating a BIA as a prelude to beginning a full BCP process for understanding or as a vehicle to sell management on the need to develop a BCP

126.7 Customizing the BIA Questionnaire

There are a number of ways that a questionnaire can be constructed or customized to adapt itself for the purpose of serving as an efficient tool for accurately gathering BIA information. There are also an unlimited number of examples of BIA questionnaires in use by organizations. It should go without saying that any questionnaire—BIA or otherwise—can be constructed so as to elicit the response one would like. It is important that the goal of the BIA be in the mind of the questionnaire developers so that the questions asked and the responses collected will meet the objective of the BIA process.

126.7.1 BIA Questionnaire Construction

Exhibit 126.3 is an example of a BIA questionnaire. Basically, the BIA questionnaire is made up of the following types of questions:

- *Quantitative questions*. These are the questions asked the interviewee to consider and describe the economic or financial impacts of a potential disruption. Measured in monetary terms, an estimation of these impacts will aid the organization in understanding loss potential, in terms of lost income as well as in an increase in extraordinary expense. The typical quantitative impact

EXHIBIT 126.3 Sample BIA Questionnaire

Introduction
Business Unit Name:
Date of Interview:
Contact Name(s):
Identification of business process and/or business unit (BU) function:
Briefly describe the overall business functions of the BU (with focus on time-critical functions/processes, and link each time-critical function/process to the IT application/ network, etc.) and understanding of business process and applications/networks, etc. interrelationships:
Financial Impacts
Revenue Loss Impacts Estimations (revenue or sales loss, lost trade discounts, interest paid on borrowed money, interest lost on float, penalties for late payment to vendors or lost discounts, contractual fines or penalties, unavailability of funds, canceled orders due to late delivery, etc.):
Extraordinary expense impact estimations (acquisition of outside services, temporary employees, emergency purchases, rental/lease equipment, wages paid to idle staff, temporary relocation of employees, etc.):
Operational Impacts
Business interruption impact estimations (loss of customer service capabilities, inability to serve internal customers/management/etc.):
Loss of confidence estimations (loss of confidence on behalf of customers/shareholders/regulatory agencies/employees, etc.):
Technological Dependence
Systems/business functions/applications reliance description (attempt to identify specific automated systems/processes/applications that support BU operations):
Systems interdependencies descriptions:
State of existing BCP measures:
Other BIA-related discussion issues:
First question phrased: “What else should I have asked you that I did not, relative to this process?”
Other questions customized to environment of the organization, as needed:

categories might include revenue or sales loss, lost trade discounts, interest paid on borrowed money, interest lost on float, penalties for late payment to vendors or lost discounts, contractual fines or penalties, unavailability of funds, canceled orders due to late delivery, etc. Extraordinary expense categories might include acquisition of outside services, temporary employees, emergency purchases, rental/lease equipment, wages paid to idle staff, and temporary relocation of employees.

- *Qualitative questions*. Although the economic impacts can be stated in terms of dollar loss, the qualitative questions ask the participants to estimate potential loss impact in terms of their emotional understanding or feelings. It is surprising how often the qualitative measurements are used to put forth a convincing argument for a shorter recovery window. The typical qualitative impact categories might include loss of customer services capability, loss of confidence, etc.
- *Specialized questions*. Make sure that the questionnaire is customized to the organization. It is especially important to make sure that both the economic and operational impact categories (lost sales, interest paid on borrowed funds, business interruption, customer inconvenience, etc.) are stated in such a way that each interviewee will understand the intent of the measurement. Simple is better here.

126.7.2 Using an Automated Tool

If an automated tool is being used to collect and correlate the BIA interview information, make sure that the questions in the database and questions of the questionnaire are synchronized to avoid duplication of effort or going back to interviewees with questions that might have been handled initially.

A word of warning here, however. This author has seen people pick up a BIA questionnaire off the Internet or from book or periodical (like this one) and use it without regard to the culture and practices of their own organization. Never, ever, use a noncustomized BIA questionnaire. The qualitative and quantitative questions must be structured to the environment and style of the organization. There is a real opportunity for failure should this point be dismissed.

126.8 BIA Interview Logistics and Coordination

This portion of the report will address the logistics and coordination while performing the BIA interviews themselves. Having scoped the BIA process, the next step is to determine who and how many people one is going to interview. To do this, here are some techniques that one might use.

126.8.1 Methods for Identifying Appropriate BIA Interviewees

One certainly is not going to interview everyone in the organization. One must select a sample of those management and staff personnel who will provide the best information in the shortest period. To do that, one must have a precise feel for the scope of the project (i.e., technological platform recovery, business unit recovery, communications recovery, crisis management plans, etc.) and with that understanding one can use:

- *Organizational process models*. Identification of organizational mega and major business processes is the first place to start. Enterprises that are organized along process lines lend themselves to development of recovery planning strategies that will eventually result in the most efficient recovery infrastructure. Use of or development of models that reflect organizational processes will go a long way toward assisting BIA team members in identifying those personnel crucial to determining time-critical process requirements. Exhibit 126.4 attempts to demonstrate that while the enterprisewide recovery planning/E-continuity infrastructure includes consideration of crisis management, technology disaster recovery, business unit resumption, and E-commerce

• Disaster avoidance
• eTechnologies redundancy and diversity
• eRisk mitigation and control
Technology infrastructure recovery planning and execution teams
• Strategy implementation assistance
• Plan development
• Plan excercise
• Quality assurance
• Change management

EXHIBIT 126.4 Enterprisewide BCP/E-continuity infrastructure.

E-availability components, all aspects of the resulting infrastructure flow from proper identification of time-critical business processes.

- *Organizational chart reviews*. The use of formal, or sometimes even informal organization charts is the first place to start. This method includes examining the organizational chart of the enterprise to understand those functional positions that should be included. Review the organizational chart to determine which organizational structures will be directly involved in the overall effort as well as those that will be the recipients of the benefits of the finished recovery plan.
- *Overlaying systems technology*. Overlay systems technology (applications, networks, etc.) configuration information over the organization chart to understand the components of the organization that may be affected by an outage of the systems. Mapping applications, systems, and networks to the organizations business functions will help tremendously when attempting to identify the appropriate names and numbers of people to interview.
- *Executive management interviews*. This method includes conducting introductory interviews with selected senior management representatives in order to identify critical personnel to be included in the BIA interview process, as well as to receive high-level guidance and to raise overall executive-level management awareness and support.

126.8.2 Coordinate with the IT Group

If the scope of the BIA process is recovery of technological platforms or communications systems, then conducting interviews with a number of IT personnel could help shorten the data-gathering effort. Although IT users will certainly need to be spoken to, IT personnel can often provide much valuable information, but should not be solely relied on as the primary source of business impact outage information (i.e., revenue loss, extra expense, etc.).

126.8.3 Send Questionnaire Out in Advance

It is a useful technique to distribute the questionnaire to the interviewees in advance. Whether in hardcopy or electronic media format, the person being interviewed should have a chance to review the questions, and be able to invite others into the interview or redirect the interview to others, and begin to develop the responses. One should emphasize to the people who receive the questionnaire in advance to not fill it out, but to simply review it and be prepared to address the questions.

126.8.4 Scheduling of Interviews

Ideally, the BIA interview should last between 45 minutes and 1 hour and 15 minutes. It sometimes can be an advantage to go longer than this; but if one sees many of the interviews lasting longer than the 1 hour, 15 minute window, there may be a BIA scoping issue that should be addressed, necessitating the need to schedule and conduct a larger number of additional interviews.

126.8.5 Limit Number of Interviewees

It is important to limit the number of interviewees in the session to one, two, or three, but no more. Given the amount and quality of information one is hoping to elicit from this group, more than three people can deliver a tremendous amount of good information that can be missed when too many people are delivering the message at the same time.

126.8.6 Try to Schedule Two Interviewers

When setting up the BIA interview schedule, try to ensure that at least two interviewers can attend and take notes. This will help eliminate the possibility that good information may be missed. Every additional trip back to an interviewee for confirmation of details will add overhead to the process.

126.8.7 Validate Financial Impact Thresholds

An often-overlooked component of the process includes discussing with executive management the thresholds of pain that could be associated with a disaster. Asking the question as to whether a $5 million loss or a $50 million loss impact has enough significance to the long-term bottom line of the organization can lead to interesting results. A lack of understanding on the BIA team's part as to what financial impacts are acceptable, or conversely unacceptable, is crucial to framing BIA financial loss questions and the final findings and recommendations that the BIA report will reflect.

126.9 Conducting the BIA

When actually explaining the intent of the BIA to those being interviewed, the following concepts should be observed and perhaps discussed with the participants.

126.9.1 Intelligent Questions Asked of Knowledgeable People

Based loosely on the concept that if one asks enough reasonably intelligent people a consistent set of measurable questions, one will eventually reach a conclusion that is more or less correct. The BIA questions serve to elicit qualitative results from a number of knowledgeable people. The precise number of people interviewed obviously depends on the scope of the BCP activity and the size of the organization. However, when consistently directing a well-developed number of questions to an informed audience, the results will reflect a high degree of reliability. This is the point when conducting qualitatively oriented BIA: ask the right people good questions and one will come up with the right results.

126.9.2 Ask to Be Directed to the Correct People

As the interview unfolds, it may become evident that the interviewee is the wrong person to be answering the questions. One should ask who else within this area would be better suited to address these issues. They might be invited into the room at that point, or one may want to schedule a meeting with them at another time.

126.9.3 Assure Them that Their Contribution Is Valuable

A very important way to build the esteem of the interviewee is to mention that their input to this process is considered valuable, as it will be used to formulate strategies necessary to recover the organization following a disruption or disaster. Explaining to them that one is there to help by getting their business unit's relevant information for input to planning a recovery strategy can sometimes change the tone of the interview in a positive manner.

126.9.4 Explain that the Plan Is Not Strictly an IT Plan

Even if the purpose of the BIA is for IT recovery and, when interviewing business unit management for the process of preparing a technological platform recovery plan, it is sometimes useful to couch the discussion in terms of … "a good IT recovery plan, while helping IT recover, is really a business unit plan … Why? … Because the IT plan will recover the business functionality of the interviewees business unit as well, and that is why one is there."

126.9.5 Focus on Who Will Really Be Exercising the Plan

Another technique is to mention that the recovery plan that will eventually be developed can be used by the interviewees, but is not necessarily developed for them. Why? Because the people being interviewed probably already understand what to do following a disaster, without having to refer to extensive written recovery procedures. But the fact of the matter is that following the disruption, these people may not be available. It may well be the responsibility of the next generation of management to recover, and it will be the issues identified by this interviewee that will serve as the recovery roadmap.

126.9.6 Focus on Time-Critical Business Processes and Support Resources

As the BIA interview progresses, it is important to fall back from time to time and reinforce the concept of being interested in the identification of time-critical functions and processes.

126.9.7 Assume Worst-Case Disaster

When faced with the question as to when the disruption will occur, the answer should be: "It will occur at the worst possible time for your business unit. If you close your books on 12/31, and you need the computer system the most on 12/30 and 12/31, the disaster will occur on 12/29." Only when measuring the impacts of a disruption at the worst time can the interviewer get an idea as to the full impact of the disaster, and so that the impact information can be meaningfully compared from one business unit to the next.

126.9.8 Assume No Recovery Capability Exists

To reach results that are comparable, it is essential to insist that the interviewee assume that no recovery capability will exist as they answer the impact questions. The reason for this is that when they attempt to

EXHIBIT 126.5 Comparing the Results of the Interviews

Interviewee	Total Loss Impact if Disaster?	Preconceived Recovery Alternative?	Resulting Estimated Loss Potential	No Allowance for Preconceived Recovery Alternative
#1	$20K per day	No	$20,000	$20,000
#2	$20K per day	Yes	0	20,000
#3	$20K per day	No	20,000	20,000
#4	$20K per day	Yes	0	20,000
Totals	—	—	$40,000[a]	$80,000[b]

[a] Incorrect estimate, as one should not allow the interviewee to assume a recovery alternative exists (although one may very well exist).

[b] Correct estimate, based on raw loss potential regardless of preexisting recovery alternatives (which may or may not be valid should a disruption or disaster occur).

quantify or qualify the impact potential, they may confuse a preexisting recovery plan or capability with no impact, and that is incorrect. No matter the existing recovery capability, the impact of a loss of services must be measured in raw terms so that as one compares the results of the interviews from business unit to business unit, the results are comparable (apples to apples, so to speak). Exhibit 126.5 provides an example. In this example, if one allows Interviewees #2 and #4 to assume that they can go somewhere else and use an alternate resource to support their process, the true impact of the potential disruption is reduced by one-half ($40 vs. $80K). By not allowing them to assume that an appropriate recovery alternative exists, one will recognize the true impact of a disruption, that of $80,000 per-day. The $80,000-per day impact is what one is trying to understand, whether or not a recovery alternative already exists.

126.9.9 Order-of-Magnitude Numbers and Estimates

The financial impact information is needed in orders-of-magnitude estimates only. Do not get bogged down in minutia, as it is easy to get lost in the detail. The BIA process is not a quantitative risk assessment. It is not meant to be. It is qualitative in nature and, as such, orders-of-magnitude impacts are completely appropriate and even desirable. Why? Because preciseness in estimation of loss impact almost always results in arguments about the numbers. When this occurs, the true goal of the BIA is lost, because it turns the discussion into a numbers game, not a balanced discussion concerning financial and operational impact potentials. Because of the unlimited and unknown numbers of varieties of disasters that could possibly befall an organization, the true numbers can never ever be precisely known, at least until after the disaster. The financial impact numbers are merely estimates intended to illustrate degrees of impacts. So skip the numbers exercise and get to the point.

126.9.10 Stay Focused on the BCP Scope

Whether the BIA process is for development of technological platforms, end user, facilities recovery, voice network, etc., it is very important that one not allow scope creep in the minds of the interviewees. The discussion can become very unwieldy if one does not hold the focus of the loss impact discussions on the precise scope of the BCP project.

126.9.11 There Are No Wrong Answers

Because all the results will be compared with one another before the BIA report is forwarded, one can emphasize that the interviewee should not worry about wrong numbers. As the BIA process evolves, each business unit's financial and operational impacts will be compared with the others, and those impact estimates that are out of line with the rest will be challenged and adjusted accordingly.

126.9.12 Do Not Insist on Getting the Financial Information on the Spot

Sometimes, the compilation of financial loss impact information requires a little time to accomplish. The author often tells the interviewee that he will return within a few days to collect the information, so that additional care can be taken in preparation, making sure that he does actually return and picks up the information later.

126.9.13 The Value of Pushback

Do not underestimate the value of pushback when conducting BIA interviews. Business unit personnel will, most times, tend to view their activities as extremely time-critical, with little or no downtime acceptable. In reality, their operations will be arranged in some priority order with the other business processes of the organization for recovery priority. Realistic MTDs must be reached, and sometimes the interviewer must push back and challenge what may be considered unrealistic recovery requirements. Be realistic in challenging, and request that the interviewee be realistic in estimating their business unit's MTDs. Common ground will eventually be found that will be more meaningful to those who will read the *BIA Findings and Recommendations*—the senior management group.

126.10 Interpreting and Documenting the Results

As the BIA interview information is gathered, there is a considerable tabular and written information that begins to quickly accumulate. This information must be correlated and analyzed. Many issues will arise here that may result in some follow-up interviews or information-gathering requirements. The focus at this point in the BIA process should be as follows.

126.10.1 Begin Documentation of the Results Immediately

Even as the initial BIA interviews are being scheduled and completed, it is a good idea to begin preparation of the *BIA Findings and Recommendations* and actually start entering preliminary information. The reason is twofold. The first is that if one waits to the end of the process to start formally documenting the results, it is going to be more difficult to recall details that should be included. Second, as the report begins to evolve, there will be issues that arise where one will want to perform additional investigation, while one still has time to ensure the investigation can be thoroughly performed.

126.10.2 Develop Individual Business Unit BIA Summary Sheets

Another practical technique is to document each and every BIA interview with its own *BIA Summary Sheet*. This information can eventually be used directly by importing it into the *BIA Findings and Recommendations*, and can also be distributed back out to each particular interviewee to authenticate the results of the interview. The *BIA Summary Sheet* contains a summation of all the verbal information that was documented during the interview. This information will be of great value later as the BIA process evolves.

126.10.3 Send Early Results Back to Interviewees for Confirmation

By returning the *BIA Summary Sheet* for each of the interviews back to the interviewee, one can continue to build consensus for the BCP project and begin to ensure that any future misunderstandings regarding the results can be avoided. Sometimes, one may want to get a formal sign-off, and other times the process is simply informal.

126.10.4 We Are Not Trying to Surprise Anyone

The purpose for diligently pursuing the formalization of the BIA interviews and returning to confirm the understandings from the interview process is to make very sure that there are no surprises later. This is especially important in large BCP projects where the BIA process takes a substantial amount of time. There is always a possibility that someone might forget what was said.

126.10.5 Definition of Time-Critical Business Functions/Processes

As has been emphasized, all issues should focus back to the true time-critical business processes of the organization. Allowing the attention to be shifted to specific recovery scenarios too early in the BIA phase will result in confusion and lack of attention toward what is really important.

126.10.6 Tabulation of Financial Impact Information

There can be a tremendous amount of tabular information generated through the BIA process. It should be boiled down to its essence and presented in such a way as to support the eventual conclusions of the BIA project team. It is easy to overdo it with numbers. Just ensure that the numbers do not overwhelm the reader and that they fairly represent the impacts.

126.10.7 Understanding the Implications of the Operational Impact Information

Often times, the weight of evidence and the basis for the recovery alternative decision are based on operational rather than the financial information. Why? Usually, the financial impacts are more difficult to accurately quantify because the precise disaster situation and the recovery circumstances are difficult to visualize. One knows that there will be a customer service impact because of a fire, for example. But one would have a difficult time telling someone, with any degree of confidence, what the revenue loss impact would be for a fire that affects one particular location of the organization. Because the BIA process should provide a qualitative estimate (orders of magnitude), the basis for making the difficult decisions regarding acquisition of recovery resources are, in many cases, based on the operational impact estimates rather than hard financial impact information.

126.11 Preparing the Management Presentation

Presentation of the results of the BIA to concerned management should result in no surprises for them. If one is careful to ensure that the BIA findings are communicated and adjusted as the process has unfolded, then the management review process should really become more of a formality in most cases. The final presentation meeting with the senior management group is not the time to surface new issues and make public startling results for the first time.

To achieve the best results in the management presentation, the following suggestions are offered.

126.11.1 Draft Report for Review Internally First

Begin drafting the report following the initial interviews. By doing this, one captures fresh information. This information will be used to build the tables, graphs, and other visual demonstrations of the results, and it will be used to record the interpretations of the results in the verbiage of the final *BIA Findings and Recommendations Report*. One method for accomplishing a well-constructed *BIA Findings and Recommendations* from the very beginning is to, at the completion of each interview, record the tabular information into the BIA database or manual filing system in use to record this information. Second, the verbal information should be transcribed into a *BIA Summary*

EXHIBIT 126.6 BIA Report Table of Contents

1. Executive Summary
2. Background
3. Current State Assessment
4. Threats and Vulnerabilities
5. Time-Critical Business Functions
6. Business Impacts (Operational)
7. Business Impacts (Financial)
8. Recovery Approach
9. Next Steps/Recommendations
10. Conclusion
11. Appendices (as needed)

Sheet for each interview. This *BIA Summary Sheet* should be completed for each interviewee and contain the highlights of the interview in summarized form. As the BIA process continues, the BIA tabular information and the transcribed verbal information can be combined into the draft *BIA Findings and Recommendations*. The table of contents for a BIA Report might look like the one depicted in Exhibit 126.6.

126.11.2 Schedule Individual Senior Management Meetings as Necessary

Near the time for final BIA presentation, it is sometimes a good idea to conduct a series of one-on-one meetings with selected senior management representatives in order to brief them on the results and gather their feedback for inclusion in the final deliverables. In addition, this is a good time to begin building grassroots support for the final recommendations that will come out of the BIA process and at the same time provide an opportunity to practice making one's points and discussing the pros and cons of the recommendations.

126.11.3 Prepare Senior Management Presentation (Bullet Point)

The author's experience reveals that senior management-level presentations, most often, are better prepared in a brief and focused manner. It will undoubtedly become necessary to present much of the background information used to make the decisions and recommendations, but the formal presentation should be in bullet-point format, crisp, and to the point. Of course, every organization has its own culture, so be sure to understand and comply with the traditional means of making presentations within that environment. Copies of the report, which have been thoroughly reviewed, corrected, bound, and bundled for delivery, can be distributed at the beginning or end of the presentation, depending on circumstances. In addition, copies of the bullet-point handouts can also be supplied so attendees can make notes and for reference at a later time. Remember, the BIA process should end with a formalized agreement as to management's intentions with regard to MTDs, so that business unit and support services managers can be guided accordingly. It is here that that formalized agreement should be discussed and the mechanism for acquiring and communicating it determined.

126.11.4 Distribute Report

Once the management team has had an opportunity to review the contents of the BIA Report and made appropriate decisions or given other input, the final report should be distributed within the organization to the appropriate numbers of interested individuals.

126.11.5 Past Y2K and Current E-availability Considerations

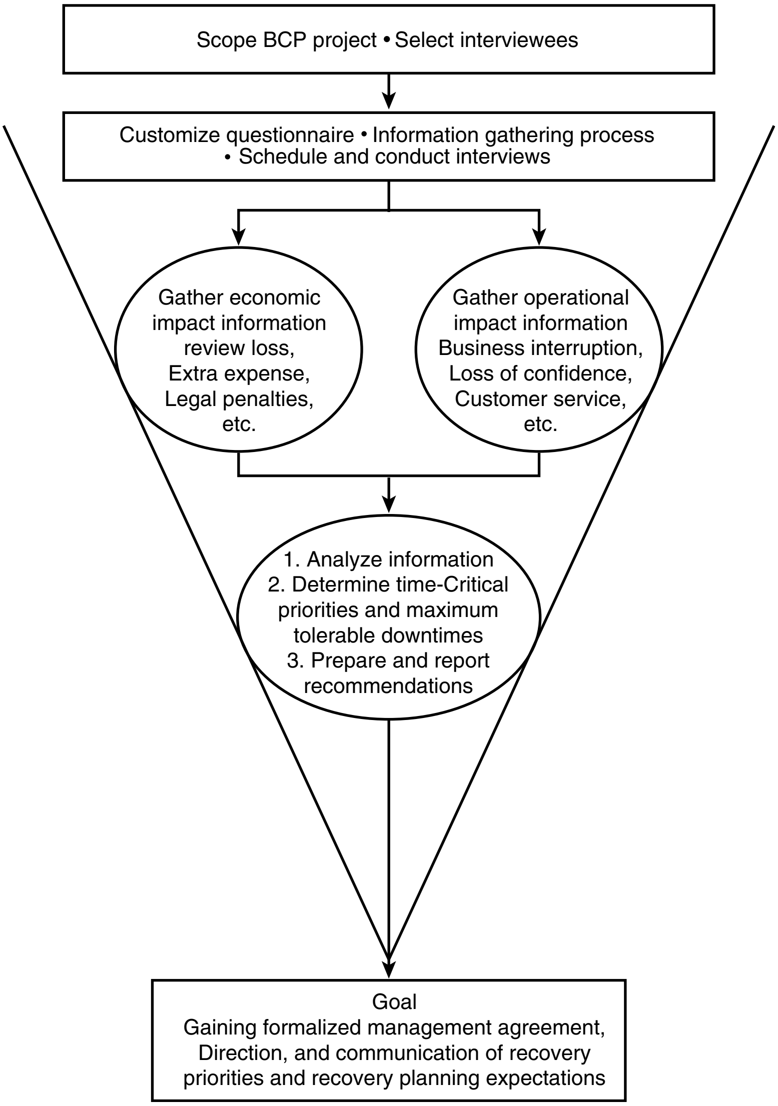
The author's experience with development of Y2K-related recovery plans was that time was of the essence. Because of the constricted timeframe for development of Y2K plans, it was necessary to truncate the BIA process as much as possible to meet timelines. Modification of the process to shorten the critical path was necessary—resulting in several group meetings focusing on a very selective set of BIA criteria.

126.11.6 Limit Interviews and Focus on Upper-Level Management

To become a little creative in obtaining BIA information in this Y2K example, it was necessary to severely limit the number of interviews and to interview higher-level executives to receive overall guidance, and then move to recovery alternative selection and implementation rapidly.

126.11.7 Truncated BIAs for E-availability Application

Additionally, when considering gathering BIA information during an E-availability application, it is important to remember that delivery of E-commerce-related services through the Internet means that



Scope BCP project • Select interviewees
Customize questionnaire • Information gathering process • Schedule and conduct interviews
Gather economic impact information review loss, Extra expense, Legal penalties, etc.
Gather operational impact information Business interruption, Loss of confidence, Customer service, etc.
1. Analyze information
2. Determine time-Critical priorities and maximum tolerable downtimes
3. Prepare and report recommendations
Goal
Gaining formalized management agreement, Direction, and communication of recovery priorities and recovery planning expectations

EXHIBIT 126.7 Business continuity planning route map.

supply-chain downtime tolerances—including E-commerce technologies and channels—are usually extremely short (minutes or even seconds), and that it may not be necessary to perform an exhaustive BIA to determine the MTD/RTO only. What is necessary for a BIA under these circumstances, however, is that it helps to determine which business processes truly rely on E-commerce technologies and channels so that they (business unit personnel) can be prepared to react in a timely manner should E-commerce technologies be impacted by a disruption or disaster.

126.12 Next Steps

The BIA is truly completed when formalized senior management decisions have been made regarding: (1) MTDs/RTOs, (2) priorities for business process and support services recovery, and (3) recovery/E-availability resource funding sources.

The next step is the selection of the most effective recovery alternative. The work gets a little easier here. One knows what the recovery windows are, and one understands what the recovery priorities are. One must now investigate and select recovery alternative solutions that fit the recovery window and recovery priority expectations of the organization. Once the alternatives have been agreed upon, the actual recovery plans can be developed and tested, with organization personnel organized and trained to execute the recovery plans when needed.

126.13 Summary

The process of business continuity planning has matured substantially since the 1980s. BCP is no longer viewed as just a technological question. A practical and cost-effective approach toward planning for disruptions or disasters begins with the business impact assessment. In addition, the rapidly evolving dependence on E-commerce-related supply-chain technologies has caused a refocus of the traditional BCP professional on not only recovery, but also continuous operations or E-availability imperatives.

The goal of the BIA is to assist the management group in identifying time-critical processes, and determining their degree of reliance on support services. Then, map these processes to supporting IT, voice and data networks, facilities, human resources, E-commerce initiatives, etc. Time-critical business processes are prioritized in terms of their MTDs/RTOs, so that executive management can make reasonable decisions as to the recovery costs and timeframes that it is willing to fund and support.

This chapter has focused on how organizations can facilitate the BIA process. See the BCP Route Map in Exhibit 126.7 for a pictorial representation of the BIA process. Understanding and applying the various methods and techniques for gathering the BIA information is the key to success.

Only when executive management formalizes its decisions regarding recovery timeframes and priorities can each business unit and support service manager formulate acceptable and efficient plans for recovery of operations in the event of disruption or disaster. It is for this reason that the BIA process is so important when developing efficient and cost-effective business continuity plans and E-availability strategies.

Network Security Utilizing an Adaptable Protocol Framework

Robby Fussell

Network security is a research topic that is being continually explored. Various network-centric mechanisms are being developed to mitigate vulnerabilities. Firewalls, IDS and IPS, and anti-virus software are just a few. These solutions provide significant security measures for their specific area; however, as networks continue to grow and become more complex, the network becomes vulnerable in different areas void of these security measures. Typically, the processes deployed to monitor these network changes are lacking and many companies do not employ enough security personnel to monitor all of the security devices within the network. Therefore, to provide a more effective security solution, an adaptive conceptual framework needs to be devised that will automate the security measures within a constantly changing network environment. This adaptive framework will utilize intelligent agents.

127.1 Introduction

With the development and deployment of various information assurance (IA) tools like firewalls, IDS/IPS, and anti-virus systems, computer networks still have the problem of being attacked and vulnerable to methods defended by the aforementioned IA tools. The significant problem is the lack of communication of these tools with other devices within the network.

Networks have become extremely complex and yet the defenses employed do not protect the entire network. Some areas of the network might have firewalls in place while other areas of the network do not have any preventive measures. The issue is that there are too many components in numerous locations running various operating systems that contribute to the problem [1]. For example, any corporation that deploys a network infrastructure must have a security person or team that is responsible for mitigating network and system vulnerabilities. Typically, these security teams are understaffed and uninformed in regards to the network structure.

Corporate networks continually expand through the addition of new components or the reduction of legacy components. The process of notifying the security team of the modified network structure is lacking and deficient, at best. A solution is needed that will remove the human responsibility component from this security infrastructure. However, human interaction will always be needed for various security related issues, but not at the expense of a change notification process.

Firewalls are utilized to prevent and allow traffic flow based on a predetermined policy. Firewalls need to work in conjunction with IDS/IPS systems to modify its rule set based on perceived intrusions. Much research and development has made this approach realizable; however, because the network changes with the addition of new links and new components, this firewall solution might not be implemented at the modified network area. Therefore, a solution is needed that automatically produces a change notification when the network and protective measures are deployed. This chapter examines the implementation of intelligent agents as a solution.

127.2 Background: Prior Research and Significance

The research of network-centric mechanisms [1,2] demonstrates the significance for the deployment of security measures. These network-centric mechanisms include firewalls, IDS/IPS, and anti-virus mechanisms, among others. Each of these mechanisms is tailored for a specific area of network security and defense. However, the issues that arise are the complexity of such a diverse and widespread number of mechanisms deployed through out the network along with the lack of communication among the various mechanisms.

Representation, management, and maintenance have also been a problem with the implementation of various network-centric security mechanisms [3]. Other research has shown that the vast amount of critical information that must be processed is typically overwhelming for the system operators due to their stress and high workload [1]. Therefore, an automated and intelligent solution needs to be researched for possible deployment.

The shortcomings of the prior research involve the lack of automation between various security mechanisms deployed throughout the network. The objective of this research is to construct an adaptive communications network using intelligent agents to provide continuous security modifications.

127.3 Intelligent Agents: Methodology

An overlapping network of intelligent agents is needed that communicates various security concerns and provides the ability for the device to self-protect itself from the communicated vulnerability (see Exhibit 127.1). In addition, this overlapping infrastructure of intelligent agents will provide proof of concept of a self-aware network. The ability for the network to be self-aware indicates that the network will generate an alert for any newly added IP-based devices to the network, including updates to the devices in which the agents are paired. In addition, agents that are aware of surrounding agents and their security policy provide the ability for the intelligent agents to identify any vulnerability that occurs within their neighborhood.

This network will contain a standard protocol for all the agents in the network. The agents will need to be able to recognize the function of the network-centric security mechanism and translate that security modification into the dedicated protocol to be transmitted to the other agents. After the agents receive the security modifications, they will need to be able to determine if the modification is applicable to their system and, if so, make the necessary modification.

The framework is based on the concept of adaptation [4]. As stated by Badrinath et al. [4], “Application adaptivity implies that applications must be structured to receive notifications about any

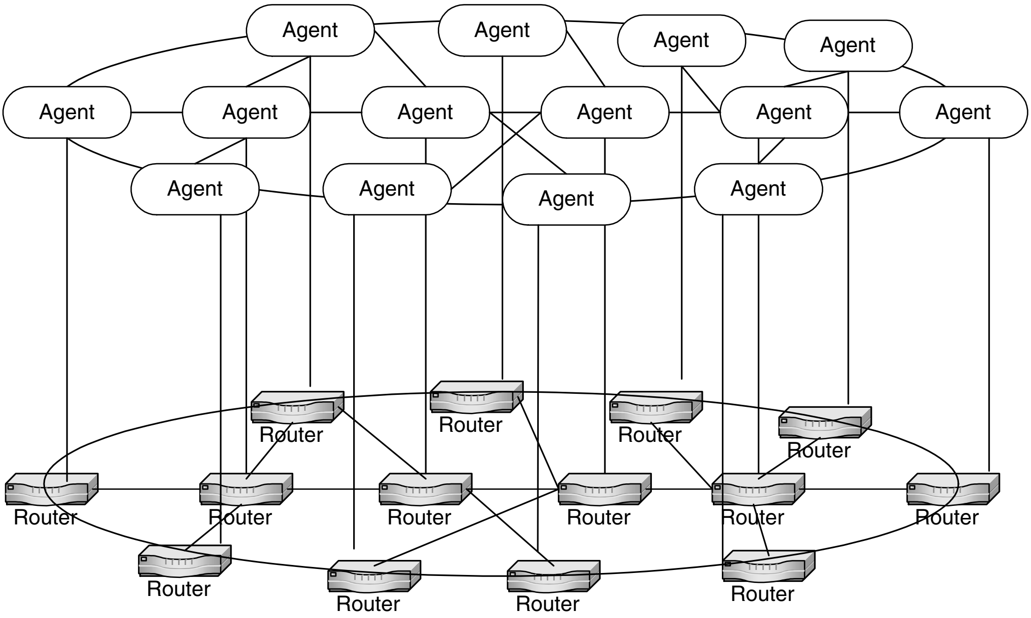

EXHIBIT 127.1 Intelligent agent overlay network.

changes in the environmental state and to react appropriately. Since the network state is complex, the applications must interact with many environmental conditions, sources, and possible reactions." This provides the conceptual framework for developing the network of intelligent agents. The agents and the network will provide the ability of adaptation [5–8].

The method to provide the agents and the network with the ability to adapt will be drawn from the research of Badrinath et al. [4] and Holland [9]. These researchers have discovered the common framework for incorporating adaptability within agents and complex systems. The framework will be modeled after a three-tier architecture, where there will be one central server that receives and transmits all security and IP address modifications.

127.4 Architecture

The three-tier architecture is comprised of the following three components:

1. The intelligent agents
2. The centralized manager (CM)
3. The system console

Each component will be briefly described in the following sections. Along with providing a framework that will allow agents to modify their collocated application, the CM, and in essence the security team, must know the devices that are currently deployed on the network. Therefore, this framework will include two primary objectives:

1. Modify currently deployed components with security modifications.
2. Maintain a centralized repository of devices deployed throughout the network.

The second objective will be somewhat limited because of the difficulties of identifying deployed devices that are communicating via a proxy, virtual private network (VPN), or any other type of masking or translation protocol. Exhibit 127.2 illustrates the conceptual three-tier network.

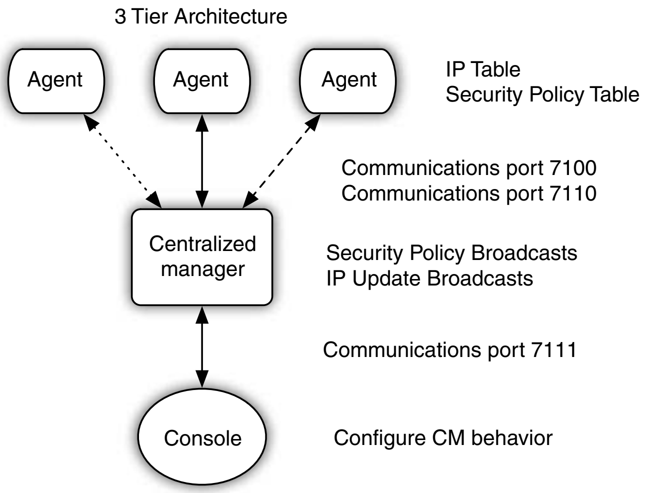

EXHIBIT 127.2 Three-tier architecture.

127.4.1 Intelligent Agents

The intelligent agents are built upon the concepts of artificial intelligence [10] where software-based agents, or softbots, can be utilized to provide intelligent decision making founded on a predetermined model. In this scenario, the intelligent agents will utilize the conceptual model of an expert system [10]. Each agent will have a predefined rule set that it will use to determine its actions [9].

In this solution, each agent has been coded in the Java programming language and each expert system within the agent is based on "if then else" statements to perform its events. The IP table and the security policy table are the main elements of the intelligent agents and the CM.

- The IP table is a file that contains all the identified IP addresses currently deployed on the network.
- The security policy table is a file that contains a device identifier and the device's security rule.

Each agent will possess an IP table file. The agent is responsible for monitoring the network traffic and updating its IP table in the event that an IP address is not listed. After the IP address is added to the agent's IP table, it then generates an alert to the CM of the new IP address. The CM is then responsible for generating an email alert or some other notification to security personnel for attention. Maintaining an IP table on each agent will minimize the overall alerts that may be generated after a period of monitoring or learning. This learning process can be accelerated by manually inputting all of the current IP addresses on the network and having the centralize manager broadcast a new IP table to all agents. In addition, having the numerous agents deployed throughout the network will provide significant coverage for identifying newly added IP addresses. This provides the self-aware concept of network security.

The second essential element contained in the agent is the security policy table. This provides the ability of a CM to remotely update a device's security rule set from a central location. The agent determines, via the identifier on the security policy updates, if the security statement is targeted for its associated device. This concept goes beyond the scope of this project. This function will provide the ability of the agent to interact with its associated device or devices to update their rule sets based on the updates received from the CM. This function will require cooperation from various vendors to provide application-programming interfaces (API) for each device utilized in the network. This project implemented a basic security policy update function for testing and verification purposes.

127.4.2 Centralized Manager

The centralized manager (CM) is the second tier of this conceptual architecture. Its main functions include the following:

1. To receive agent updates of newly discovered IP addresses
2. To update the central IP table with new IP addresses
3. To send out new IP address information to all agents
4. To send out security policy information
5. To generate alerts via email to notify security personnel of new IP addresses discovered on the network
6. To maintain a list of agents not communicating.

The CM is the focal point of this architecture. It maintains an IP table of all authorized IP addresses on the network. If a new IP address is discovered via an intelligent agent, the CM is responsible for notifying the security administrator. The CM is also needed to update the individual agents on the network. Therefore, firewalls and routers that filter segments of the network must allow traffic to and from the CM on port 7110 and from the agents on port 7100. The CM must also be able to identify agents with which it has adrift communications and generate an alert for these agents.

127.4.3 Console

The console application in the three-tier architecture will be used to configure the CM remotely. In this project, the console was not be implemented. The entire CM configuration was applied directly to the CM Java code. The following are some of the projected functions of the console:

1. To configure the CM
2. To generate reports
3. To add or delete IP addresses from the CM

These are some of the basic functions that would be provided by the console in the three-tier architecture. Because the functionality of the console was not an influence on this project, it was omitted from the implementation testing.

127.4.4 Communications Protocol

The policy table, which is composed of device identifier and policy string, is used to perform security policy updates on the corresponding system. The IP table is utilized to maintain authorized IP addresses on the network. This table is modified via CM updates and any new IP addresses that are unidentified are relayed to the CM for notification purposes. The communications with the intelligent agents utilize TCP/IP on port 7100. The communications with the CM utilizes TCP/IP on port 7110.

Exhibit 127.3 depicts the various communications that occur based on function processes between the agents and the CM. In the first scenario, the intelligent agent has detected a new IP address on the network and opens communications with the CM to inform the manager of the newly detected IP address. The CM responds to the agent that it has received the IP notification. In the second scenario, the agent is requesting a new IP table from the CM. This occurs if a new agent is brought online or if the IP table becomes corrupted on the agent. The CM responds to the request with the IP table that resides on the CM and the agent confirms that it has received the IP table. If the agent does not respond in a timely fashion that it has received the IP table from the CM, the CM will resend the IP table. In the third scenario, the CM is performing an IP table broadcast. This occurs when the console configures new IP addresses on the CM causing additions or deletions to be made on the CM IP table. These changes need

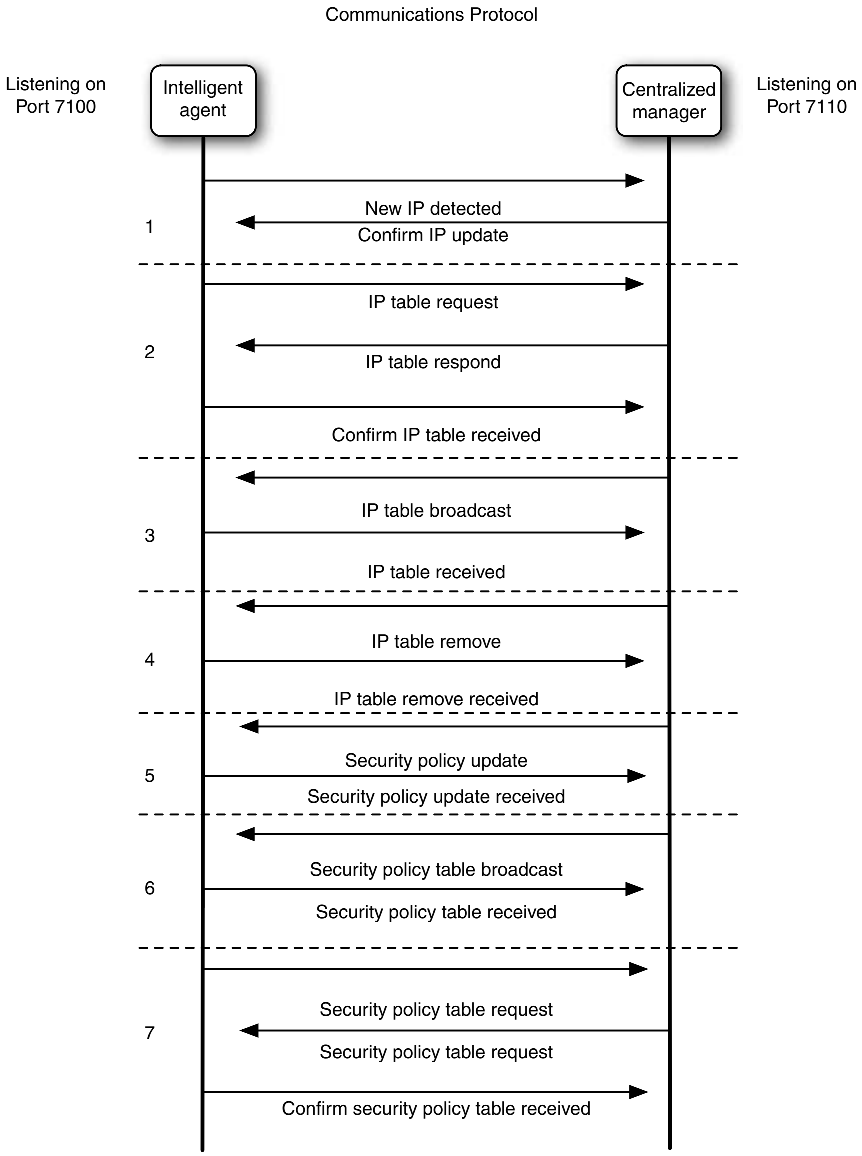

EXHIBIT 127.3 Communications protocol.

to be communicated to all the agents to reduce traffic flow based on new authorized IP addresses appearing on the network and the agents generating new IP address alerts.

In the fourth scenario, the console has configured the CM by the removing of an IP address or range. Instead of the CM broadcasting the entire IP table, which would increase network traffic depending on the size of the table, the CM only communicates an IP table remove for the newly removed IP addresses. The intelligent agents will then perform a remove function and remove the indicated IP addresses from its local IP table. In the fifth scenario, the CM communicates a security policy update broadcast. The agents receive the broadcast and determine, via the device identifier field, whether or not to process the request on its associated device. The agent's respond with a security policy update received response. The sixth scenario depicts the communications related with the security policy broadcast. Like the IP table broadcast, the same communication functions are performed, but only on the security policy table file. Finally, the last communications scenario demonstrates the protocol for a security policy request. Like the IP table request, the same general functions are also performed here, but only to the security policy file.

127.5 Results

The objective of this project was to build and test the foundational framework for this conceptual infrastructure. Additional research must be performed to monitor the self-awareness functionality of the intelligent overlay network. This typically includes the use of network simulation software that can simulate a multinode/multiagent network. The testing of the conceptual framework involved monitoring network traffic requests and responses in different situations.

One of the tests results verified that the agents were able to identify if a security policy update was needed for their corresponding system. The CM was able to generate a packet with the appropriate identifier tag and policy string and communicate that packet of information to the agent. The CM and agent both were able to respond in the designated communication protocol. This was verified by monitoring the transmitted packets via sniffer software.

The next test involved the removing of an IP address from the agent's IP table. The agents were able to remove IP addresses from their IP table when the CM broadcasted an IP remove call. The network communications were monitored and provided evidence that the communications protocol was correctly performed. The removal process was verified by examining the IP address table before and after the IP removal call. The test verified two different scenarios. The first scenario was to verify that the IP address that was to be removed was actually defined in the agent's IP table and then verify that it was removed. The second scenario involved having the IP address absent from the agent's IP table and verify that no action was performed.

The next test was to verify that the agent could perform a successful IP add. The intelligent agents were able to perform an IP add based on the CM broadcast of an IP add through the network. The CM was able to construct the appropriate IP packet that contained the function identifier and IP address. The communications was monitored and verified that the communications protocol was performed as designed and that the packet information was correct. This test was also conducted using two different scenarios. The first scenario verified that the IP address to be added was already present in the agent's IP table. When the agent received the IP address to add, it was able to determine that IP address already resided in the IP table and ignored the add function call. The second scenario verified the agent's ability to add the IP address to its IP table. The agent's IP table was observed to verify that the IP address to add was indeed absent. After the communications process was complete, the agent's IP table was examined and the IP address insertion was verified.

The final examination was to test the agent's ability to notify the CM in the case of a new IP address discovered on the network. The agents were able to notify the CM when it observed a new IP address transmitted on the network by verifying the communications between the agent and CM. The communications were confirmed to be correct in the area of request and response. Also, the agent was able to produce a packet containing the new IP address and transmit it successfully to the CM. This test also contained two different scenarios. The first scenario utilized an IP address that did not reside in the CM IP table. The process was executed and the CM IP table was examined. It was verified that the IP was added to the CM IP table successfully. The second scenario consisted of executing the new IP process with the IP address residing in the CM IP table. It was verified that the CM did not include the existing IP address to its IP table.

These results validate the success of the core foundational components of the three-tier architecture. This demonstrates the foundational theory of adaptation. For systems to survive, they must be self-aware to defend their existence. They accomplish this task of continued propagation by adapting to the changes in their environment. The adaptation techniques utilized are simple “if then else” statements, but with expert judgment built into the decision making process.

127.6 Future Considerations

One area that can be considered for improvement is that of the IP table. The IP table contains the IP addresses on the network, but only in host-specific formation. This can produce a large file that must be maintained by the intelligent agents and the CM. In addition of minimizing the IP table with suitable IP ranges, the use of a more advanced search algorithm would be beneficial. The current search algorithm searches the IP table line by line for a match. This type of searching produces significant lag time in the processing of the IP table. Along with the need for a better searching algorithm, a better sorting algorithm should be utilized to assist the search process.

Another consideration would be using a holding space for IP addresses to be processed. Many IP packets could be transmitted through the network while the agent is preoccupied processing an IP address for verification. This indicates that the agent could miss other IP addresses. A separate process should be implemented to buffer the sniffed IP addresses into a file for future processing. This would help to ensure that all IP packets are being monitored without delaying network traffic or agent processing time. There are other small items that can be implemented to improve this architecture like the limit on the IP and policy array size. Currently, the array size limits the number of IP addresses and security policy information to a maximum of 200 lines. The array size should be dynamic.

Agents must be tailored for each device with which they associate. This is a major undertaking because each agent will be responsible for monitoring the security updates for a particular network device. This will necessitate that each agent have the ability to modify the network device’s security rule set through an API. This task could be quite difficult, depending on the number a various vendor devices deployed throughout the network.

Because agents maintain security policy information regarding other agents, then the agents are self-aware of the configurations of other devices and could have a monitoring function for basic violations that occur within the network and could notify the CM. This would require each agent being aware of its immediate neighbors and their functionality based on the rule sets defined in the policy table. The agents would then monitor the network traffic and would be able to identify any immediate security policy violations with neighboring agents. This would also improve the concept of an IDS, where many deployed agents would be providing an IDS capability and the ability for an intruder to circumvent the numerous IDS agents would be difficult.

Finally, there is a problem where the IP table and security policy table can grow in size depending on the size of the network and number of deployed agents. This could be solved with a function imbedded in each agent that executes when the agent’s associated device is taken offline permanently. The agent would issue a permanent removal request to the CM. The CM would then completely remove that agent, associated device, related security policy, and corresponding IP address from its table information. Indeed, there are other areas in which improvement can be made on this architecture; however, these provide some immediate issues to be considered for advancing this concept.

127.7 Conclusion

As stated by Atighetchi et al. [2], “Adaptive use of network-based capabilities is key to successful and effective defense.” This provides the motivation behind this research. The reason for this research was to search for a solution to the problem of illegal misuse, theft, or tampering of another’s data and/or communication equipment. Many network-centric security measures mitigate this problem but only to a certain degree. The complexity of the network and devices along with the stress and high workload of the security personnel, make the solution of network-centric measures fall short of their goal.

The process of notification of when the network is modified also complicates the problem. Therefore, this research takes the approach of relieving the human factor from the equation by utilizing intelligent agents and an adaptive conceptual framework to provide an automated solution. This automated solution must have some type of human factor to receive and process alerts generated by this framework. However, instead of alerts possibly being generated in various areas of the network, this framework provides one centralized location to receive the alerts to be processed. This reduces the problem of the complexity of the network environment.

Acknowledgments

This work was provided for the project course of information security at Nova Southeastern University. I would like to thank God, Dr. James Cannady, and Dr. Albert-László Barabási for their presentations and insight on the topics concerning artificial intelligence, information security, chaos theory, complexity theory, adaptation, and scale-free networks.

The Five W's and Designing a Secure, Identity-Based, Self-Defending Network (5W Network)

Samuel W. Chun

128.1 Introduction

The amazing advances in networking and networking technologies over the last 25 years have come from a variety of different perspectives. Disparate groups such as government research labs, the military, universities, large corporations, and countless enterprising individuals have all played a part in advancing networking technologies at a breathtaking level; however, these individual and group innovations have rarely coordinated their efforts, resulting in various camps of advancement. Some, such as IBM, Banyan, Microsoft, and Novell, focused on the development of network and desktop operating systems (and directory service) while others, such as Synoptics, Alantec, 3Com, and Cisco Systems, put their primary research efforts on high-speed network infrastructures. In the early 1990s, the very first commercially available firewalls began to be offered to organizations by companies such as Check Point Software Technologies. Only within the last few years have enterprise-class intrusion detection and prevention systems finally become commonly available to those who have the resources to acquire and manage them.

Although technological advances in directory services, firewalls, switches, and routers have come at an astounding level, scant attention has been paid in the past to integrating these advances into a singular entity that serves as a critical asset for organizational productivity. The growing emphasis on the importance of information security has been accompanied by intense interest recently in technology *convergence* with the goal of developing a new model for a secure, identity-based, self-defending network.

This chapter addresses this new emerging model of secure networking by discussing the five basic requirements of all networking systems: who, why, what, where, and when. The chapter also provides a comparison between current networks found in most environments today with the new secure, identitybased, self-defending model (referred to by the author as the “5W Network” for brevity). The hypothetical architecture of a 5W Network in a large distributed medical setting follows a discussion of the various characteristics and components of the secure, identity-based, self-defending network. The chapter concludes with a discussion of what the future holds for the 5W Network and in what environments it would be a likely fit.

128.2 The Five W’s of Secure Networking

Even nonpractitioners of information security will readily agree that access to an organization’s private resources, regardless of what it is, should only be allowed when some very basic questions have been answered. Whether it is physical access to a building, use of a company directory, or connection to a server or network, it is essential to ask several questions before granting access, such as “Who are you?” “What are you going to do?” “Why are you here?” It is just common sense that access should only be allowed based on receiving appropriate answers to these simple questions.

That is why it is so surprising that even today the vast majority of networks fail to ask more than one question before granting access to a connection. For example, how many times has the reader been in a facility where the only requirement for network connectivity—Internet Protocol (IP) address via Dynamic Host Control Protocol (DHCP)—was physical access to a wall jack? In most environments today, connectivity (and the ability to do harm to the network and organization) is usually based on only one question: “Where?” (physical access). Where the user sits and where the user connects will almost always result in a connection appropriate for that location.

Network access, however, should be dependent on more. It is just not enough to rely on physical access to maintain the enterprise’s network security. Ideally, five questions should be answered *before* being granting a network connection:

128.2.1 Identity: Who Are You?

Before anything else, the identity of the person or object attempting to connect to the network should be established. It is not enough simply to know the network jack, IP address, or message authentication code (MAC) when someone has connected to the wall jack to gain access to the network. It is important to establish true identity via some authentication system before granting a useful connection. Ideally, when a person plugs a laptop (could be wireless) into a network, access to the network resources should be denied unless an authentication challenge is met.

128.2.2 Role: Why Are You Here?

When the identity of the object has been verified via authentication, the network should know why the person or object requires access. The network infrastructure should know the role of the person or object within the organization (e.g., printer, network administrator, regular user). This is a function common in most network operating systems. Group-based access policies for server-based resources have been around for many years. Unfortunately, implementation of role-based access to the network infrastructure at OSI layers two and three is almost nonexistent. It is very rare to find a network that requires authentication before granting port-level access to Transmission Control Protocol/Internet Protocol (TCP/IP) or other network services.

128.2.3 Appropriate Access: What Should You Have Access to?

Being cognizant of the identity and role of the requesting object or person should result in the network determining appropriate and inappropriate access. For example, a finance department employee on a roving laptop at a company should only have access to services (e.g., TCP/IP ports, servers, printers) that are appropriate to people working in the finance department, regardless of location. Conversely, the network should also be able to recognize inappropriate actions for particular roles. For example, if the same authenticated finance department employee attempts to perform a port scan or attempts a distributed denial of service (DDoS) attack on a server, the network should recognize that as inappropriate behavior and deny that action (e.g., port shutdown, connection reset).

128.2.4 Location: Where Should You Be?

Telecommunications advances have allowed organizations to grow beyond their geographical locations with impunity over the last 30 years. With inexpensive wide area solutions readily available, setting up remote offices with unfettered access to organizational information technology (IT) resources across the world has never been easier. The good news is that the question of where a person or object should have access has been thoroughly explored. Network segregation via routers (access control lists) and firewalls actually can be used (with considerable effort) to manage access based on location. The bad news is that doing so requires network segmentation (routing) and numerous configurations of routers and firewalls, which requires considerable effort to result in any type of success. It is accepted and very common practice for large organizations to have an "all locations, all access" network policy. The overwhelming need for access regardless of location (and risk) has proliferated these types of networks. In many environments, it is possible (and often easy) to attack servers in data centers halfway across the world just by gaining physical access to a small remote field office. As a result of globalization, location is becoming less and less of a factor in access. This, unfortunately, allows intruders to target resources in an enterprise across the globe.

128.2.5 Time: When Can You Have Access?

Recent studies suggest that there is no real prime time for security incidents. Intrusions are just as likely to happen during the business day (an in-house event) as after hours; however, logical rhythms or cycles of access should not be ignored. Network access policy at the port level should be exercised with time constraints when available. For example, if a company's office is closed over the weekend with no need for user-level access, it would be ideal for all user network ports to be shut down with the exception of network management traffic (e.g., antivirus updates, OS updates and patches).

128.3 The Modern-Day Network: The One "W" Pony

The need for fast access, not secure access, has been the primary motivator for the development of networking technologies over the last 25 years. From 2-Mbps Thinnet to 4/16-Mbps Token Ring to

today's 10-Gbps Ethernet, networking vendors and consequently network implementations have focused on providing unparalleled access. From the pure networking perspective, the questions of who should have access, why they should have access, and where they should have access have been a function left up to the administrators that manage directory services and server-based resources. The serious problem with this is that authentication happens *after* network access. As shown in Exhibit 128.1, when an intruder gains physical access to a network jack in any location (such as a field office), that intruder is free to perform malicious acts (e.g., DoS, Port Scan, malware, sending spam) on the entire network without ever having to authenticate to resources.

The single question that these common networks asks is "Where?" Where users plug in their PCs or laptops will determine what network address they will receive and what access they may be granted based on their connection point. In Exhibit 128.1, the router that connects to two sites is a logical place for an Access Control List. Unfortunately, location is rarely used to limit access due to the trend of mobilization of the work place. From a networking perspective, it is difficult to use physical location as a means for controlling access when the users are moving around from one site to the next; consequently, it is easier to provide a connection and full network access and then let authentication occur when the user attempts to connect to resources. This is most commonly done by asking the user to enter a username and password on the log-in screen; however, this is where serious trouble lurks. After connecting to a physical jack, an intruder can carry out network-based attacks without even attempting to access any of the server-based resources.

128.3.1 Characteristics

The most common characteristics of modern-day networks are easy and fast access. Wherever an employee goes within the company or around the world, that employee needs access to the company's network. The goal of modern-day networks is to provide such a connection with the least amount of effort. These networks tend to be simple and usually flat with little segmentation. Network traffic is generally switched with routers that only perform routing between wide area connections.

128.3.2 Common Components

The single most common component seen in modern-day networks is the Ethernet switch. The exponential advances in switching speed and technology have allowed organizations to deploy large unsegmented networks on an unprecedented scale. With switches that have system backplanes that can handle terabytes per second of information, entire campuses can be connected into a single network with automatic and instant assignment of network addresses.

128.3.3 Benefits

The benefits of these types of networks are clear. They are easy to deploy, manage, and administer because all the users have access to every network service they need. The network performs quickly because little overhead is wasted on such activities as verification of identity and monitoring. This type of solution also has the unfortunate appeal of requiring low capital investment.

128.3.4 Vulnerabilities

A fast, easy access network comes with many vulnerabilities and high risks. Allowing easy, unfettered network access for the end-user community also extends the same access to potentially malicious programs, intruders, and disgruntled internal employees. Reacting to security events, rather than preventing them, is likely to be normal for these types of networks. In addition, post-incident forensic analyses are hindered by the fact that attacks or incidents are likely only to be traceable by IP addresses, host names, and MAC addresses, yielding very little information about the identity of the intruder.

128.3.5 Future

Unfortunately, the vast majority of networks in existence, with the exception of highly secure government and defense environments, are configured and deployed in this manner. This pattern is not likely to change significantly due mainly to the ignorance of the risks posed by having these open access networks. In addition, the simplicity of this architecture coupled with the very low cost of ownership ensures that these types of networks will be implemented well into the future by those that do not consider security a priority.

128.4 The Secure, Identity-Based, Self-Defending Network (5W Network)

In recent years, there has been intense interest in developing not only fast network access but secure access as well. Security breaches by hackers and improper acts performed by disgruntled insiders have resulted in several high-profile cases that have made the headlines in the last few years. Consider these following cases (excerpted from official press releases) from the U.S. Department of Justice Computer Crime and Intellectual Property Section (CCIPS):

- *United States v Meydbray*—The U.S. Attorney's Office for the Northern District of California announced that the former Information Technology Manager of Creative Explosions, Inc., a Silicon Valley software firm, was indicted today by a federal grand jury on charges that he gained unauthorized access to the computer system of his former employer, reading e-mail of the company's president and damaging the company's computer network.
- *United States v Smith*—The New Jersey man accused of unleashing the "Melissa" computer virus in 1999, causing millions of dollars in damage and infecting untold numbers of computers and computer networks, was sentenced today to 20 months in federal prison.

- *United States v Dopps*—A San Dimas man pleaded guilty this afternoon to illegally accessing the computer system of his former employer and reading the e-mail messages of company executives for the purpose of gaining a commercial advantage at his new job at a competitor.

These examples are a small sample of the thousands of cases of computer-related crimes that are investigated by state, local, and federal authorities each year. It is not surprising that there has been a renewed interest in designing networks that are not just fast but also cognizant of the various threats they are likely to face.

An ideal network should do the following each and every time a person or object plugs into a jack:

- *Issue an immediate authentication challenge.*The network should establish who the person or object is before allowing any type of access to occur (i.e., it asks "Who or what are you?").
- *Grant appropriate access based on the identity.* The network should allow access to services (e.g., Web, network, database, FTP site) and resources (e.g., servers, printers, directories, files) based on identity, role, or business policy of the organization (i.e., access is based on "What? Where? When?").
- *Monitor, react, and defend against inappropriate actions.* The network should monitor the connection granted for identity- or role-appropriate activity. If an authenticated user performs an action that is inappropriate for the role (e.g., port scan, multiple connections), the network should autonomously react in a predetermined manner (i.e., access is based on "Why are you here?").

A secure, identity-based, self-defending network (or 5W Network) is a network that asks five very important questions: Who? What? Where? When? Why? It then ensures that access is always granted based on the answers to these questions. After all, all organization should ask these questions when anyone enters their premises, so is it not reasonable to ask these same questions of users connecting to their networks?

128.5 Characteristics: Designing a 5W Network

Designing a network architecture that grants, monitors, and ensures access based on functional roles is not a trivial or easy task. It requires the careful integration of different technologies that have traditionally evolved separately. No single manufacturer, technology, or product will result in a secure network. It is the *convergence* of these infused with good old-fashioned people-generated business policies that will ultimately result in a safe, secure network that is situationally aware. To accomplish this, we must first turn the paradigm of networking upside down: Authentication should happen *before* network access.

The only access that a network port should have enabled by default should be the ones that are required to verify identity. As shown in Exhibit 128.2 (similar to Exhibit 128.1), every time someone plugs a PC, printer, or laptop into a switch port, that person should be challenged for credentials. Only when appropriate credentials have been supplied is network access granted based on a combination of user identity, business policy, and business rules. Then, an automatic self-defense system (an intrusion detection system [IDS]) monitors the activity of the connection so it is ready to react if the connection deviates from identityor role-appropriate behavior. For example, if the user makes sequential successive connections to other PCs (a sign of a virus) or begins to attempt to access servers that it should not (unauthorized access), the self-defense system should automatically issue reaction commands based on a predetermined incident management policy.

Based on preset rules, the self-defense system should be able to reset user connections, shut down ports, write logs, and send security event alerts. All of these actions should be performed autonomously so the network itself is preventing and managing incidents. The security and network administrators are then freed from the mundane burden of chasing down problem cases, allowing more time for strategic activities such as reviewing policies and roles.

128.6 Common Components: Convergence

A secure, identity-based, self-defending network is naturally complex. It requires not only the integration of several different technologies but also the definitions of user, group, and access policies that will be applied in granting network connectivity. The best-designed systems are almost always a result of combining the best technologies, hard work, and carefully considered policies. A truly secure network that is able to defend itself and its organization's most trusted assets is no exception. Five logical components of the 5W Network function together to protect the organization from internal and external threats. Each component can be a physically separate system but not necessarily so. Some manufacturers, such as Enterasys Networks, integrate some of these components and functions into their network equipment. Regardless of whether these components exist as separate systems or are integrated into a large chassis, they must always work together with the goal of security. These logical components are:

- *Authentication system*—The authentication system verifies the identity of the user and objects to the network. It requires that users (and objects) provide credentials for any type of network access. Authentication systems are common in most network environments in the form of directory services. Some of the most commonly used authentication systems are Microsoft Active Directory, Novell eDirectory, and RADIUS. Other more advanced authentication systems, such as biometrics, can also be used for identity verification. This authentication system must be able to communicate in some form with the access control component of the network.
- *Access control system*—The access control component contains the specific user, group, and access policies of the network and serves as a gateway for network access. It takes the authenticated user information and reviews the individual and group rights to resources that the connection should

have. It then issues commands to the network infrastructure equipment to grant specific access to the appropriate resources.

- *Network infrastructure*—The switches, routers, and firewalls should by default grant rights only to the services necessary to achieve authentication. Some of the competing protocols for transporting authentication data include Extensible Authentication Protocol (EAP), Protected EAP (PEAP), Lightweight and Efficient Application Protocol (LEAP), and Tunneled Transport Layer Security (TTLS). Whatever the method, the network infrastructure equipment should grant access to appropriate network services and resources only after successful authentication and access validation. The IEEE 802.1x standard—also known as EAPoL (EAP encapsulation over wired or wireless Ethernet), is commonly used to accomplish port-based network access control.
- *Intrusion detection and prevention systems*—Intrusion detection and prevention systems serve as the watch dogs of the network. They should, of course, monitor the network for suspicious traffic, but they should also serve the vital function of monitoring each connection to ensure that traffic on the connection is appropriate for the role determined by the access control system. If the network activity of a specific connection is questionable or contrary to the authenticated role, they should react based on predetermined incident policies. For example, an authenticated user who browses to a wrong server can result in an alert, but a "Ping of Death" from the same user can result in the IDS issuing a port shutdown command to the switch to which the user is connected.
- *User, group, access, and incident management policies*—Although the various systems in the 5W Network perform the mechanics of security policy enforcement on their own, the network still requires instructions on how to protect itself. These instructions come in the form of policies. The user, group, and access policies determine what role the requester plays in the organization and to what services they should have access. Incident management policies tell the network what it should do when there is activity that violates the role determined by the policies. In the 5W Network, the development of sound, effective policies is where the security practitioner can have the highest impact on the overall network security posture of an organization. Well-developed access and incident management policies, when applied objectively and evenly, reduce the total cost of ownership of a network by reducing the manual intervention required by the IT staff for security incidents.

128.7 Benefits

The benefits of a secure, identity-based, self-defending network are obvious. It achieves access without compromising security. The 5W Network provides objective (policy-based) access based on business role rather than physical location. It also has the ability to lower administration and security costs by being preventive and self-reacting, thus freeing up staff to perform more meaningful tasks.

128.8 Disadvantages

Unfortunately, 5W Networks are not all that common. The convergence of the technologies necessary for true interoperability and the standards (such as 802.1x) that allow for the various components to work with each other are fairly new. Not very many networking vendors produce and market their equipment with secure, identity-based networking in mind. In addition, the complexity of the overall 5W solution, even though it achieves an unprecedented level of security, requires expertise in a variety of IT disciplines that is not always readily available. Cost is also a major factor as the 5W Network requires more equipment of a higher class, expert labor, and greater effort in creating effective policies, none of which is necessary to deploy a traditional switched, easy-access network.

128.9 Future

Currently, a fully role-based, self-defending network is relatively rare. It is generally deployed in large environments that can afford the very best in technology or require such a network due to sensitive information. It is almost impossible to find these networks in small to mid-sized businesses, which cannot afford to invest in these new technologies. As the demand for secure access grows, however, so will the number of networks that integrate the various components described in the previous sections. Research and development efforts by various networking vendors are focusing on making integrative security an important feature of their products, in addition to performance. As of the writing of this chapter, only one vendor, Enterasys Networks, offered a complete suite of networking equipment, including switches, routers, and IDSs, capable of integrating with existing authentication systems to offer true identity-based, self-defending capabilities. Other vendors, such as Cisco Systems, are not far behind in introducing products that have the same capability. As the demand increases and the technology matures, resulting in lower prices, it is expected that more organizations will choose to implement these networks.

128.10 Application of the 5W Network: A Sample Architecture

Environments exist today that have invested in deploying a secure, identity-based, self-defending network. Unfortunately, these organizations are generally not amenable to sharing the details of their architecture to the public, fearing a compromise of a network they have invested so heavily in. So, instead of presenting a case study of an architecture that actually exists today, this section presents a theoretical application of a 5W Network in the setting of a large metropolitan hospital system.

128.10.1 Environment Overview

The MetroHealth Hospital System is a not-for-profit healthcare provider in the Washington, D.C., Metro area. It operates four large hospitals in Virginia, Maryland, and Washington, D.C. Each hospital operates as a separate facility with its own administration that reports to a centralized executive structure of the overall MetroHealth System. In the hospitals, all of the patient care providers (doctors, nurses, and allied health professionals) need access to patient records, regardless of the facility or unit where they are working. A centralized medical record database stores all patient information in MetroHealth's administrative office building (which contains the hospital system's data center). Each hospital has an administration department that stores their own payroll, human resources, and operations information in servers that are dedicated to that hospital. The servers themselves are also located in MetroHealth's data center, but the administration staffs of the hospitals are mobile, working out of the administrative office building and their respective hospitals. All Internet access to the MetroHealth system, including Web browsing and e-mail, is provided through the datacenter in the administrative office building. The MetroHealth enterprise network must provide the following functions:

- Limit access to anyone not authorized by the hospital.
- Provide access to patient records to healthcare providers regardless of the facility where they are working.
- Provide business-hours' access (Monday through Friday, 8:00 a.m. to 5:00 p.m.) to administrative staff to only resources and services dedicated to that particular hospital, regardless of the facility.
- Provide all administrative staff safe access to Internet and e-mail, but limit access to the medical records database, regardless of the facility.
- Prevent threats, including intruders and viruses, from spreading from one hospital to another or to the administrative office center.

128.10.2 Authentication System

An enterprise-wide authentication system should be implemented at MetroHealth (see Exhibit 128.3). In this example, a single Microsoft Active Directory forest domain can be deployed, and each hospital and the administrative office center can be designated as an Organizational Unit (OU). Within each OU, user and role groups, such as doctors, nurses, allied health, payroll, human resources, and administration, can be created so a site-appropriate group is contained within each OU. Of course, redundant domain controllers will have to be deployed at each site to provide local authentication to resources in each hospital. In addition, Microsoft's implementation of RADIUS, an Internet Authentication Service (IAS), will need to be configured and running on the domain controllers so that an access control system can communicate with the authentication system.

128.10.3 Network Infrastructure

The network infrastructure, all of the switches, will have to support role-based networking at the port level. In this example, Enterasys Network's Matrix series will serve as the core, edge, and distribution layer switches for MetroHealth. Currently, Enterasys Networks is the only manufacturer that produces port-level security features (via their user private network [UPN] capability) embedded within their layer two and three devices. By default, all of the ports on the MetroHealth network will allow access to a single service—authentication. All other ports will be closed.

128.10.4 Access Control System

The logical access control system will be comprised of the Microsoft Active Directory Infrastructure (with RADIUS) working in conjunction with the embedded security features of the Matrix switches (UPN enabled) via the IEEE 802.1x communication standard. The 802.1x standard for port-level access control will be used to authenticate end users and provide policy-based networking access for the authenticated users. The Microsoft 802.1x Authentication Client will be used at all of the desktops and laptops at MetroHealth to provide for authentication challenge at connection. The peripheral authorization will occur via hardware MAC addresses so only devices that have been predefined within the MetroHealth network can gain network access. The logical access control system components will ensure that enduser, port-level access is consistent with predefined access policies that are assigned to each MetroHealth Active

Directory role group. The access control system focuses on the prevention of unauthenticated and unauthorized access on the entire network.

128.10.5 Intrusion Detection and Prevention Systems

The Enterasys Dragon Intrusion Response system will serve as the intrusion detection and prevention system. The entire MetroHealth network will be monitored by Dragon sensors. These sensors will monitor the network for aberrant network traffic and abnormal end-user behavior by authenticated end users. If it detects any issues with a specific user or a port, such as scans or DDoS attack attempts, it can perform actions such as quarantine or port shutdown based on predefined incident management policies. This system will focus on the enforcement of network security policies on authenticated users and systems so the risk of incidents from trusted sources is also mitigated.

128.10.6 Access and Incident Management Policies

One of the most important aspects of designing a secure network is documenting access and incident management policies. With the help of business analysts who understand explicitly the requirements of the organization, access policies should be written so network access is only granted to services required by the functional group within the organization. For example, MetroHealth access policies should state that, regardless of which OU healthcare providers are members of, regardless of the facility they are in, they should have network access to the medical records system located in the administrative office building. In addition, they will need to be granted access to other services (e-mail, Web access) when required. On the other hand, the access policies should restrict hospital- or OU-specific administrative users to their dedicated servers regardless of what facility they are logging in from. Access to the medical records system should only be granted to subgroups within administration, such as claims and billing, who use this information for their functional business roles. Because business roles play such a critical part in determining access, network architects need to work with business analysts carefully so the access policies assigned to groups within the Active Directory (or authentication systems) allow the appropriate level of access required for the role.

It is also important to document and implement incident management policies within the IDS that will minimize administrator intervention. Whether the response to the incident is user-level quarantine or immediate reset of a connection, the appropriate responses to events should be predetermined based on the level of seriousness of the incident. The IDS system should be preconfigured so it is enforcing a set of incident management rules rather than performing an alert. This will allow hospital engineering staff to focus on incident policies rather than incident response, which has a much greater value to the organization.

128.11 Summary

This chapter presented an emerging concept of networking based on business role and self defense. It provided a discussion of questions ("Who?" "What?" "Why?" "Where?" "When?") that should be asked before granting access to organizational resources, including networks. A brief introduction into the origins of modern-day networks was followed by a description of their features, benefits, and weaknesses, and they were compared against a new model of networking based on identity, role, and self-defense. This new model—the secure, identity-based, self-defending network (5W Network)—was discussed thoroughly with regard to its features, benefits, strengths, and weaknesses, as well as practical applications. It is expected that, as interest in security grows in enterprise environments, this type of networking, which balances access, security, and management, will become the standard for large organizations.

129

Maintaining Network Security: Availability via Intelligent Agents

Robby Fussell

129.1 Introduction

The information security model is composed of confidentiality, integrity, and availability. Availability is the area of information security that requires services and network components to be continuously available for the user community. If a service or component is unavailable, confidentiality and integrity are meaningless. Network availability is the underlying component that must be present in order for services to be accessible for end users. Developers have used redundancy to assist in ensuring that an application or network is available; however, this is an expensive solution if several network components and services are involved. Computer networks, the electrical power grid, the protein network of a cell, and many other scale-free networks have inherent problems. In order to understand the problems that reside within scale-free networks, an understanding of the concept of scale-free network construction must be observed. Discovered by the research performed by Barabási and his team (2003), scale-free networks are first identified by the characteristic of power laws. By examining a power law histogram (Exhibit 129.1), the components of the power law follow a downward decline, indicating the presence of many small nodes and a few large nodes.

Nodes, in the case of the Internet scale-free computer network, can be described as subnetworks with a defined number of connections to other subnetworks; therefore, a power law distribution of nodes on the Internet would confirm that Internet nodes are primarily nodes having a small amount of connections, with only a few nodes having a large number of connections. This illustration of the power law configuration of the Internet exposes a significant problem that the hacker Mafia Boy almost exploited on a grand scale when he brought down some significant routers segmenting numerous networks. Scale-free networks have a remarkable tolerance against failure. For example, research by Barabási (2003) has shown that the removal of 80 percent of the nodes within a scale-free computer network allowed for the remaining 20 percent of the nodes to maintain the network's connectivity; however, the nodes removed

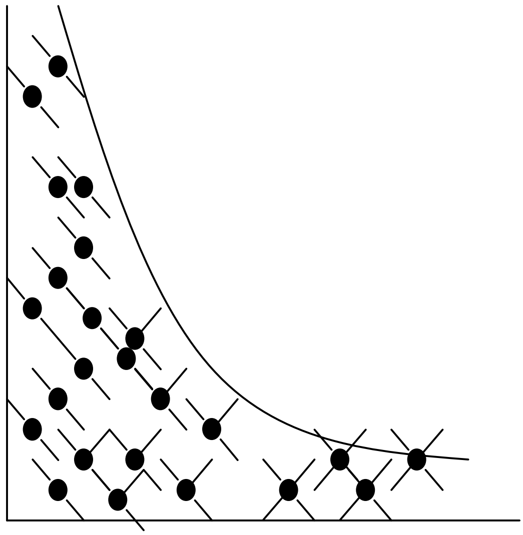

EXHIBIT 129.1 Power law distribution.

were those with a small number of connections. On the other hand, he demonstrated that removing only a few of the nodes having an abundance of connections quickly rendered the network inoperable.

Scale-free networks provide a significant amount of robustness at the cost of having many nodes, and removal of the highly connected nodes is the Achilles' heel of scale-free networks. One method for identifying the key nodes in a scale-free network is the use of nonlinear mathematics, also encompassing chaos theory. Using chaos theory could provide a means for identifying the probability factor that one node is subject to failure within the system. Knowing the probability of failure for each key node would allow the implementation of redundancy measures; however, determining the probability factor for a chaotic and complex system remains a challenge. Because an accurate nonlinear equation that depicts the framework of the Internet does not exist at the time of this report, the failure of nodes within a scale-free network is chaotic, and predicting which nodes will fail is not possible.

129.2 Problem

Identification of the problem is difficult. Node failure within scale-free networks can produce different effects. As stated earlier, the failure of many small nodes will not affect network performance; however, if a few large nodes fail, then the network can be severely crippled. A solution would be to identify the large nodes and protect them. This is not an easy task because each individual network that comprises the Internet could have unidentified large nodes, and the classification task would be complicated; however, the problem itself is not simply the failure of nodes but rather the cascading failure of nodes. Without a doubt, failure of the main node router that connects a company to the Internet is a problem for that company and its customers, but failure of the main large node routers on the Internet is a problem for everybody. Cascading failure occurs when one node fails and the load from that node is shifted to another node, which causes that node to fail and that load gets shifted to the next node, causing it to fail, and so forth, like a domino effect. Causing the appropriate nodes to fail could eventually lead to failure of all of the main large nodes within the network, in turn disabling the entire Internet. Thus, the big problem to be solved is cascading failures.

129.3 Concept

Cascading failures within a scale-free network can isolate network segments from communication. Several approaches for solving the problem of cascading failures within scale-free networks and maintaining network availability have been examined; however, the use of artificial intelligence in the design of network availability looks most promising and seems to be the answer for providing significant computer security. An adaptive agent approach has been studied. This approach is a subset of a network security approach. Network security encompasses the area of security in dealing with networks. It covers methods that provide ways of securing the network by means of redundancy and monitoring. Further dissecting the problem of cascading failures points to the main cause of the problem as being excessive amounts of network traffic load. A method for monitoring and throttling network traffic could provide a measure of security. Many solutions have been developed for balancing traffic loads but only at a sublevel; these solutions target specific routers or aim to provide specific services, such as in quality of service (QoS) agreements. The use of artificial intelligence (i.e., intelligent agents) is intended to provide a solution for the entire network; this approach arose from the idea of self-healing networks, which attempt to correct a problem after the damage has occurred. The adaptive-agent network strives to be a proactive solution for continuous network availability.

Adaptive agents monitor the complex network environment and, based on condition/response rules, determine which actions to perform. The agent code designed to solve the problem of cascading failures would monitor the incoming network traffic load and, based on the load of the current agent, weights assigned to the load levels, and destination or upstream agent loads, would determine how to handle the traffic by either passing the traffic or halting the traffic. This approach maintains load levels to prevent node failure and subsequent cascading failures.

129.4 Problem-Solving Methodology

To solve the problem of cascading failures, a network must be monitored and loads altered to prevent the failure of nodes. Agents deployed throughout the network would be responsible for communicating with their neighboring agents along with providing feedback on load levels. This feedback would be utilized to direct positive or negative responses. This concept is also known as reinforcement learning. Each agent would be responsible for monitoring its own load level and incoming traffic load in order to maintain its own stability. Solving the problem requires all of the following:

- *Define the problem*. The problem is cascading failures in scale-free networks, where the scale-free network environment is computer networks.
- *Identify key issues*. The primary reason for network node failure is typically traffic load on the network. Traffic loads in combination with current processing loads represent the total loads handled by the nodes. Feedback is another issue to be considered. Feedback assists each agent in developing weights for condition/action rules. The weights will have to be adjusted by each agent based on the feedback given because of transmitted traffic loads. This feedback and weighting process will generate better condition/action rules based on fluctuations in the complex system.
- *Collect information*. A variety of information must be collected relating to scale-free networks and electrical power grid blackouts.
- *Make key assumptions*. One key assumption is that communication of feedback between agents will be available. The solution will depend on feedback from neighboring agents in order to maintain optimum weight values, which will produce optimally adapted condition/action rules. It is also assumed that the simulated network environment will have the characteristics of the real environment.
- *Segment the problem*. Cascading failures can be reduced to one general failure. The objective is to prevent a failure from occurring. The cause of the problem of cascading failures has been identified as overload. The problem of overload can be further segmented into overload caused by the current agent operating at a level where the incoming traffic load causes the total load to be over capacity. Overload will have to be monitored for both the current agent and the neighboring agents.

- *Solution integration*. The solution to the problem of overload can be identified by the condition/response rules of an agent. The agent monitors incoming traffic loads, then:
  - It determines if the incoming traffic load will exceed load capacity, based on the load of the current agent.
  - If it can accept the incoming traffic load, the current agent determines whether or not it can pass the traffic load onto the neighboring agent, based on its load capacity and rule weights.
  - After passing traffic load to the neighboring agent, the neighboring agent sends back a positive or negative feedback code.
  - The current agent, based on the neighboring agent's feedback, updates its weights table (an adaptive process).
- *Validate test results*—The solution produces an agent that can adapt to the feedback generated by the neighboring agents. Based on the assumption that the current agent can update its weights table from the responses of neighboring agents, the current agent should be able to throttle the network traffic as necessary to prevent cascading failures.

129.5 Design Specifications

129.5.1 Knowledge Representation

According to Davis, Shrobe, and Szolovits (1993), knowledge representation (KR) is a surrogate for the real world. It is the process of creating a representation of a real-world environment and testing on that simulation instead of acting on the real-world object itself. Knowledge representation technologies are the tools utilized to perform in a simulated environment. In this model, condition/action rules are utilized. When performing knowledge representation, one must remember that a knowledge representation does not fully substitute for the real-world object. The surrogate will inevitably overlook some factors. The complexity of the world requires the KR to be a more focused substitution of the real world that disregards parts of the real-world environment. By defining a KR, results are really only significant for the defined KR. It is possible that the logic gleaned from the knowledge representation will fail in the real-world environment due to its complexity.

The KR of the complex environment of a network will be that a node communicates to another node and, as long as a node remains below it internal capacity, it will continue to communicate. If the node reaches or exceeds its capacity, it will cease to operate. Here, the nodes are referred to as agents. The agents will receive traffic and will send traffic. Traffic data will be represented by a file of values. The adaptation weight values used for logical flow are contained in a file and are arbitrary at onset. Thus, the complex adaptive network will consist of agents and data input files for evaluation. The traffic data is a representation of varying network traffic load. The adaptation weights are used to represent a factor for sending or not sending network traffic.

The KR of intelligent reasoning is the key component. Based on the KR, intelligent-based reasoning will provide the logic for a desired outcome in solving the stated problem. As stated by Davis, Shrobe, and Szolovits (1993), intelligent reasoning contains three elements:

- What is intelligent reasoning?
- What can be obtained from what is known?
- What should be obtained from what is known?

The representation of intelligent reasoning for this model is based on condition/action or, as defined by Holland (1995), stimulus/response. The mathematical logic/algorithm is structured on condition/action rules coded in Java using "if…then" statements. The second question focuses on appropriate conclusions based on real-world information. The intelligent reasoning approach assumes that any load greater than 95 percent capacity will be released in order to avoid a node failure. In addition, any weight range that falls below 55 percent will not pass network traffic. These values have been obtained from real-world observances of network flow. This logic tells the system what to perform. It provides a baseline for intelligent reasoning. Finally, the involvement of feedback in the form of a file containing positive and negative values pertaining to responses given by upstream nodes and the process of updating the weight values after receiving feedback provide a means for intelligent action determination.

129.5.2 Algorithms and Strategies

The solution strategy, then, is to use adaptive agents to monitor network traffic and, based on the network traffic load, direct traffic toward a specific neighboring node. The adaptive agents determine if the traffic load should be transmitted to the neighboring agent based on the load of the neighboring agent, traffic load, and rule set baseline ratio. The agent also evaluate its current load. If the load of the current agent plus the network traffic load exceed capacity, then the current agent would dismiss the network traffic. The agent also receives feedback from the neighboring agent that gives the current agent a measure for how well the rule worked for the transmittal of traffic. Weight evaluation procedures utilize the high-and low-end ranges in the adaptation weights file based on the total load, which is the traffic load plus the neighboring agent load. The Java agent code utilizes the following three algorithms:

- Rule set baseline algorithm (sanctioned inference)

  If incoming traffic load + current agent load > current agent load capacity, throttle traffic. This prevents the possible failure of the current agent based on the high load for processing.

  If incoming traffic load + neighboring agent load > neighboring agent load capacity, throttle traffic. This means that the neighboring agent would not be able to process the traffic and would probably fail if required to do so.

- Load/weight evaluation algorithm (recommended inference)

  If the above rules are not satisfied, the agent will pass the network traffic based on the following algorithm: (high-end range weight + low-end range weight)/200 = test ratio.

  If test ratio < 0.55, then the current agent throttles traffic load and reads feedback from the upstream agent.

  If test ratio > 0.55, then the current agent passes traffic load to the upstream agent and reads feedback from the upstream agent. The evaluation algorithm contains parameters that can be adjusted for a better evaluation outcome.

- Weights update process (adaptation)

  Adapted high-end range weight = current high-end range weight + feedback score.

  Adapted low-end range weight = current low-end range weight + feedback score.

  This process provides a means for placing higher significance on positively reinforced load ranges.

129.6 Test Results

This simulated system environment was based on an adaptive agent artificial intelligence approach. In order for the adaptive agent to be successful, three requirements must be satisfied:

- All the agents in the complex adaptive system must utilize the same syntax in the rule set.
- The rule set will be used to provide information among agents.
- The adaptive agent must contain an adaptive method for modifying the rule set.

EXHIBIT 129.2 Traffic_data.txt

Neighbor Agent Load	Current Agent Load	Traffic Load
50	25	35
25	75	50
90	20	60
50	20	30
90	12	10
90	25	4
80	15	14
30	30	10
10	10	5
15	70	30

In accordance with the first item, the rule set utilizes condition/response rules in the form of "if…then" statements within the Java agent code. The "if…then" statements construct the algorithm that determines how the agent throttles traffic load.

With regard to the second item, the agents are responsible for communicating to neighboring agents using feedback values of 1 and −1. If an agent encounters an increase in load before the neighboring traffic load is received, it can send back a negative feedback code for the original load, and the neighboring agent can update its weights table. Thus, the new weights table will contain the newly adapted weight for future incoming traffic load.

Finally, for item three, the updated weights method in the Java agent code is the process that modifies the weight table and in essence modifies the rules. It is a method for providing for nonstatic decision making. The agent employs the weights table to adapt its behavior. The environment uses files that are read by the Java agent code. One file is used for incoming traffic load: traffic_data.txt. In Exhibit 129.2, the first column of the data represents the load of the neighboring agent. The second column represents the load on the current agent. The third column represents the incoming traffic load.

Another file is used to contain the weight values for a load range: adaptation_weights.txt. In Exhibit 129.3, the first column of this data represents the load values of the neighboring agent plus the traffic load to be passed, and the second column represents the weight values. For testing purposes, both the traffic_data.txt and adaptation_weights.txt files were populated with arbitrary data. The purpose was to examine the adaptation rules to verify if the Java agent code would correctly update the adaptation weight values based on feedback codes. The feedback codes were read in from the file neighboring_agent_responses.txt (see Exhibit 129.4). The data contained in this file was either 1 or −1. The responses were read after each traffic load was processed and transmitted. If the traffic load was throttled, the response table was not read.

EXHIBIT 129.3 Adaptation_weights.txt

Total Load	Weight
95	0
90	0
80	0
70	72
60	75
50	100
40	100
30	85
20	100
10	100

EXHIBIT 129.4 Neighboring_agent_responses.txt

Neighbor Agent Responses
−1
−1
−1
−1
1
1

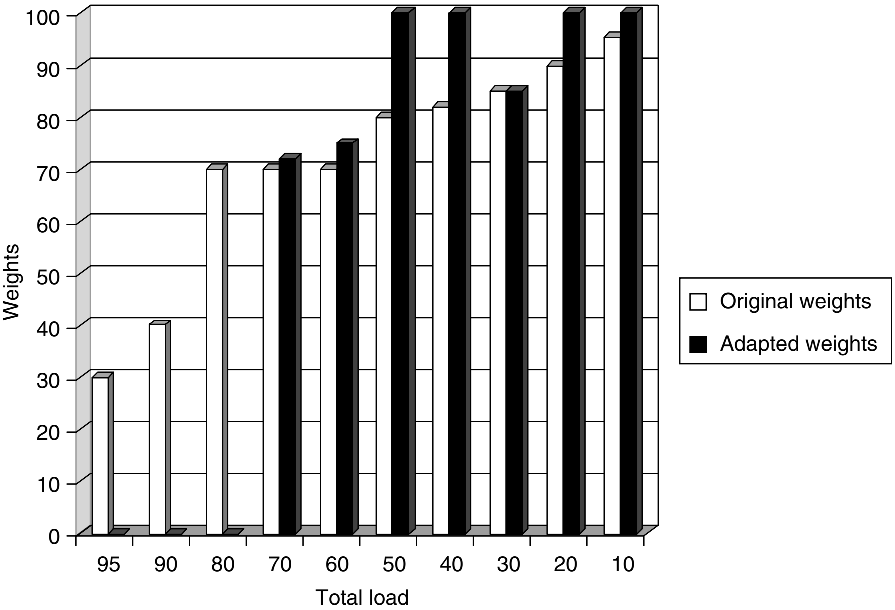

EXHIBIT 129.5 Adaptation credit assignment.

If the agent correctly updated the adaptation weights based on the feedback from the neighboring agent, then the next traffic load was evaluated correctly. The reason for a smaller list of feedback codes compared to adaptation weights and traffic data is because of the Java agent code baseline. For all traffic that generated a load higher than 95 on the current agent or if the neighboring agent was throttled (i.e., dropped from the simulation network to prevent node failures), the feedback codes were not utilized.

Examining Exhibit 129.5, the chart contains the original weights and the adapted weights. The Java agent code was processed through 100 iterations, and the graph in Exhibit 129.5 was generated. The original weight values were arbitrary initial values. Based on the feedback codes generated after every traffic load read, the adaptation weight file was updated. The weight value was increased by one if the response was positive and was reduced by one if the response was negative. Exhibit 129.5 shows the original and adapted weights and indicates that, if the neighbor load plus the traffic load were low, then the current agent would favor sending the data; however, if the neighbor load plus the traffic load was high, then the data was throttled. The test results suggest that adaptive agents would be successful in preventing cascading failures in a simulated network environment.

Exhibit 129.5 also shows the adjusted values necessary for each agent to make intelligent decisions for network traffic transmittal. The reinforcement learning process in each agent provides the ability for adaptation by providing a positive or negative feedback result. Adaptation is a significant characteristic of complex systems that are able to evolve and continue to exist. This test project utilized artificial intelligence techniques such as reinforcement learning and intelligent agents to deliver adaptation in a complex networking system in order to provide for continued network availability. This continued network availability offers optimum security for the confidentiality–integrity–availability security model.

PBX Firewalls: Closing the Back Door

William A. Yarberry, Jr.

130.1 Introduction

Given all the movement toward packet-based data communications, one would think that modems and dial-up communications would wither like the communist state. Clearly, that is not the case. There are many reasons. Sometimes, "rogue" employees want to communicate outside of corporate guidelines; servers, power reset devices, HVAC, fire alarms, certain medical equipment, and many other devices may still need to be accessed via dial-up. Some routers and DSU/CSUs are out-of-band addressable (i.e., maintenance via dial-up can be performed when the primary link is down). All these points of contact through the PSTN (public switched telephone network) represent an open target for war-dialing. The dialers have gotten sophisticated, using massive hacker dictionaries that often crack applications quickly. Modems are often left in auto-answer mode, so the war dialer is able to collect active numbers during the night. The hacker has his "cup of joe" and a "hit list" the next morning. The bottom line is that any organization without strong controls over dial-up lines and the voice network has a serious back-door exposure. Further compounding the remote access problem is unauthorized use of pc anywhere and similar products. Remote access products can be set up with little or no security. With thousands of employees, many of whom may want to access personal files on their workstation from home, it is likely that unauthorized modems/software will exist somewhere *inside* the network.

When presented with this vulnerability, management may consider a manual solution: Get rid of all but the most essential modems so the voice network carries virtually nothing but voice and fax traffic. The following are some of the reasons that make it difficult to pursue such a policy:

- Organizations that have been in a location for several years tend to build up an inventory of analog lines. The telecom director is usually loath to arbitrarily disconnect undocumented lines because they might be used for a legitimate business purpose or a person of "importance" might use it once every three months.

- Fax machines use analog lines. For expediency, these lines are sometimes used for modem connections. No one informs telecom that usage of the line has changed.
- Outbound fax/modems are commonly used. Sometimes, inbound dial-in is inadvertently enabled.
- The PBX has no way to look inside the channel to determine the type of traffic—voice, data, or fax.
- Analog lines are sometimes ordered directly from the local telephone company (without going through the telecom group). The lines, sometimes called "Centrex," go into the organization's demarc but do not pass through the PBX. Without strong controls over changes to the communications infrastructure, the telecom group may be unaware that a Centrex line has been installed.
- PBX and other equipment/software vendors often have a standard method of dialing into a maintenance port to troubleshoot, monitor, and upgrade systems. If the PBX is not secure, hackers can shut down the entire voice system. For example, each extension and line connected to the PBX has a class of service that determines its allowed function. A hacker could change all classes of service to outbound only so no calls could be received by the company.
- Analog jacks may be installed in conference rooms and other common areas. These jacks are for occasional use by contractors or other parties. When the need for the connection is over, the line is sometimes inadvertently left hot.

Projects to reclaim unused ports and lines are usually only partially effective. Determining who owns the line and what it is used for can easily consume a month or more of several technicians' time. One large financial services company in the Midwest hired two highly trained technicians to trace down and document every analog line in a multi-thousand employee campus. By the time the technicians reached the last building in their months-long project, new—and undocumented—lines had sprung up in the buildings already inventoried.

One solution to the analog line mess is to protect the firm's voice network with a PBX firewall. This device sits between the telephone demarc (the demarcation point between the local telephone company wiring and in-house wiring) and the PBXs. Housed in one or more pizza-sized boxes, the PBX firewall has enough firepower (proprietary algorithms, fast chips, large memory, and many gigs of storage) to look *inside* every channel carrying information (voice, fax, modem) into and out of the site. Before discussing the capabilities of the firewall, let's review the capabilities and limitations of the traditional large PBX.

130.2 Limitations of PBX Control and Reporting

Virtually all large-scale PBXs come equipped with the capability to report and control traffic to some degree. This capability is needed for capacity planning, day-to-day operations, and security (toll fraud prevention). Some voice network controls over unauthorized use of modems can be established with existing capabilities:

- Report origination and termination of calls. Using a call accounting package, calls can be summarized in various ways (by specific number, area code, country, etc.). Call details must be collected for this reporting to be available.
- Set the class of service on selected analog lines to outbound only.
- Block all calls to and from specific area codes (e.g., 900) or countries.
- Identify calls of long duration, such as those more than three hours.
- Identify calls under ten seconds, an indicator of possible war-dialing activity.

EXHIBIT 130.1 Smart card for two-factor authentication. (Courtesy of Aladdin, Arlington Heights, IL.)

Some other good practices that should be employed within the existing voice network include:

- Consolidate all dial-up lines to use a centrally controlled modem bank or RAS server.
- Enforce physical security (wiring closets, demarc, etc.).
- Assign dial-up lines to numbers that are outside the range of normal business activity for the location. For example, if the published business voice numbers range from 281-345-1000 to 281-345-2999, then analog circuits might be in a range such as 281-654-2500 to 281-654-3500.
- Disable banner information that provides a hacker with useful information.
- Perform a self-audit using war-dialing software. Independent consultants and audit staff are best used for this effort.
- Use dial-back systems such as CLI identification for a Shiva device.[1]
- Strengthen procedures for provisioning analog lines and charging for their use. Perform periodic inventories.
- Use two-factor authentication systems where practicals. Exhibit 130.1 shows Aladdin's eToken Pro smart card, which has on-board RSA 1024-bit key operations, enabling integration into publickey infrastructure (PKI) architectures.

130.3 PBX Firewall Capabilities

The PBX capabilities listed above are, to borrow a term from mathematics, necessary but not sufficient. What is needed is the ability to manage voice enterprise network security functions and set rules without going through the awkward security structures that make up the traditional PBX security system.[2] The PBX firewall, *when properly configured*, will plug many of the security gaps in the voice network. Although the following discussion of capabilities and related issues is based specifically on SecureLogix's TeleWall product (www.securelogix.com), the general principles will apply to any full-featured PBX firewall. Specific capabilities include:

- *Call type recognition*. The firewall has the capability to recognize the traffic, including voice, fax, modem, STU-III (Secure Telephone Unit, third generation), video, unanswered, and busy.
- *Rule-based security policy*. Policies can be constructed by building individual rules in a manner similar to industry-standard IP firewall rule creation. Policies are physically set using logical (GUI) commands across any combination of phone stations or groups.

[1] According to an Intel support Web site (http://support.intel.com/support/si/library/bi0706.htm),“ If the Shiva device is configured for general CLI Authentication (AuthFor DialbackOnly= False), and the remote client's phone number is not in an authorized list of numbers, the call is rejected. As the call never gets answered, unauthorized users are never presented with a username and password prompt”.

[2] Security for PBXs is often convoluted. Rules may be set in one table but overridden in another.

- *Rule-based call termination*. Rules can be configured to automatically terminate unauthorized calls without direct human intervention. For example, assume the internal number 281-345-1234 is assigned to a fax machine. An employee decides he needs a modem connection. Rather than going through procedures, he disconnects the fax line and uses it for his modem link. As soon as modem traffic is detected on the line, a rule is invoked that terminates the call—within a second or two.
- *Complex rule creation*. Rules should be flexible enough to fit business needs. For example, fax machines often have telephones that can be used to call the receiving party to ensure that the fax was received or to exchange some other brief information (and sometimes to help enter codes). The rules associated with that analog line could allow fax traffic for any reasonable duration, prohibit modem traffic altogether, and allow a voice call to last only five minutes.
- *Centralized administration*. The firewall should be capable of multiple-site links so rules can be administered across the enterprise.
- *Real-time alerts*. Rule violations can trigger a variety of messages, such as e-mail, pager, and SNMP security event notification. Assume, for example, that highly sensitive trade secrets are part of the organization's intellectual assets. Calls from anywhere in the enterprise to known competitors (at least their published telephone numbers) can be monitored and reported in a log or in real-time. More commonly, employees may occasionally dial up their personal ISP to get sports news, etc., during the day because sports and other non-work-related sites are blocked by the firm's IP firewall. Calls to local ISP access numbers can be blocked or at least flagged by the PBX firewall. This is more than an efficiency issue. A PC on the network that is dialed into an ISP links the outside world to the organization's IT resources directly, with no IP firewall protection.
- *Stateful call inspection*. Call content can be continuously monitored for call-type changes. Any change is immediately logged and the call is again compared to the security policy.
- *Dialback modem enforcement*. Security policies can be used to enforce dialback modem operation.
- *Consolidated reporting of policy violations*. By summarizing the output of multiple PBX firewalls, management can see any overall patterns of security violations, ranging from hacker attacks on specific sites to employee attempts to dial inappropriate, premium-900 numbers or country codes not relevant to the business.

Exhibit 130.2, adapted from a white paper by Gregory B. White, shows a communications environment with defenses against intruders from the Internet (data) and the public switched telephone network (voice).

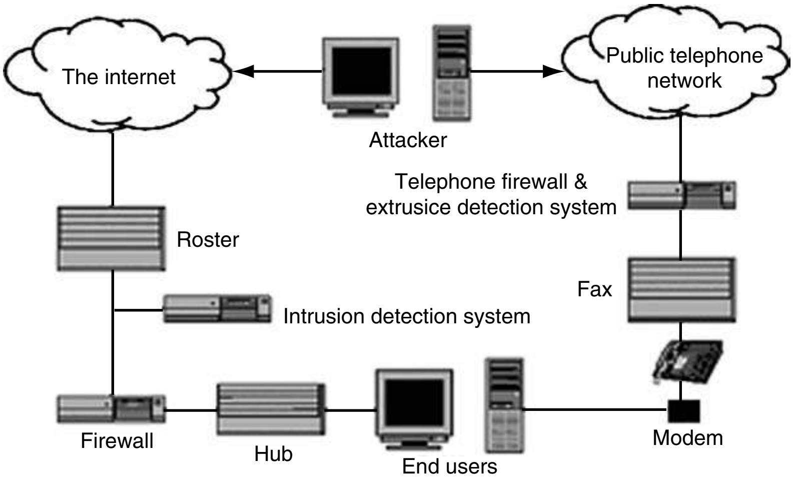

EXHIBIT 130.2 Increased security by combining IP and telephony firewalls.

130.3.1 Details of a PBX Firewall Implementation

The PBX firewall, located between the demarc and the PBX, can look at the traffic going through every trunk in the voice network. After installing a firewall, an organization could specify that any modem traffic other than what is authorized for specific lines (i.e., modem numbers) will be shut down. This eliminates the problem of unknown analog lines and unknown modem traffic. Initially, the organization would set up the logic rules in log or alert mode only and then lock down the network after the environment has been fully "discovered."

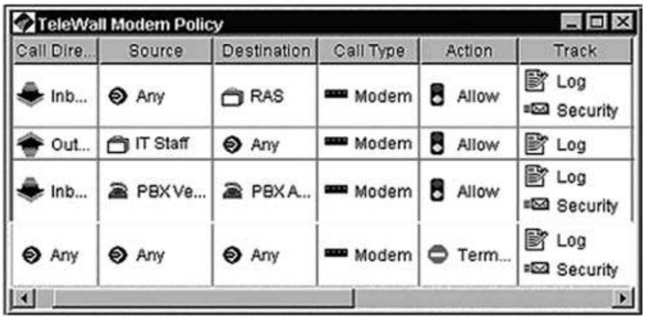
Exhibit 130.3 shows a policy screen that allows modem calls for the IT staff and recognized PBX vendors and employees dialing in through the authorized RAS server. If the call falls through these logic rules, it reaches the final "terminate call" action rule. Like the IP firewall, rules, groups, and actions must be set up for the enterprise based on business and security needs.

Because the PBX firewall has access to all the inbound and outbound traffic, including telephone numbers, type of traffic, duration, etc., it can create a plethora of reports showing both security and operationally related information. If it has a large storage capacity, trending reports can be generated. Some examples of possible reports include:

- Source, date, and duration of modem calls into maintenance ports on PBXs, routers, and other network equipment
- Non-fax calls on fax lines
- Number of unanswered calls sorted by phone station, department, office, or enterprise, which can help flag war dialing
- Percent of voice trunk infrastructure consumed by unauthorized modem calls to ISPs from inside the enterprise
- Call volume by source or destination numbers
- War-dialing attacks
- Utilization rates for remote access and fax resources
- Unused, orphaned phone lines showing no traffic activity
- Summary of calls terminated or flagged based on execution of particular rules; for example, the number of calls terminated due to unauthorized call type (e.g., modem or voice on a fax line) over several months can be listed

130.3.2 Privacy Considerations

In some military and other sensitive environments, secure communications are required. The PBX firewall can determine if STU-III encrypted conversations are in process. If communications between two



TeleWall Modem Policy

Call Dire...	Source	Destination	Call Type	Action	Track
Inb...	Any	RAS	Modem	Allow	Log Security

Any	Any	Any	Modem	Term...	Log Security

EXHIBIT 130.3 Example policy setting screen. (Courtesy of SecureLogix, San Antonio, TX.)

specific numbers are *supposed* to be always encrypted but are not, alerts can be sent or the calls can be terminated. Another potential privacy enhancement is the ability of two firewalls in separate locations to do end-to-end encryption.

For organizations requiring the highest levels of security, PBX firewalls may soon be able to perform word spotting. If, for example, the words “bomb” and “building” are used in a conversation, an alert could be sent to security. Obviously, there are many legal and ethical issues that must be resolved before such capabilities could be implemented, but with very fast chips and increasingly accurate voice recognition software such detection is possible.

Encrypted conversations have long been enabled by such devices as the telephone security device 3600, which use the STU-III government standard. The difficulty with this approach is that it does not scale. Any two users who want to encrypt information must have the same device and go through an encryption session at the beginning of the conversation. If many users need encryption, the solution becomes unwieldy and expensive because STU-III devices can cost several thousand dollars. With a PBX-to-PBX solution (i.e., both have PBX firewalls with encryption capabilities), every conversation from the users on one PBX to the other can be encrypted.

130.4 Operations

Capacity planning for the voice network is demanding. For the data network, packet congestion slows but does not stop traffic. In contrast, when the voice trunks get full, the user gets a busy signal. There is little forgiveness when the voice network does not work perfectly. Hence, telecom managers—the ones who stay employed—become conservative, tending to maintain excess capacity. There is some justification for this wariness because of the exponential increase in blockage when capacity has been reached.

PBX reports can provide indications of trunking blockage (percent busy) for local and long-distance trunks; however, some effort is required to monitor the trunks and communications links. Typically, line commands such as “list all trunks busy” are used on an *ad hoc* basis if problems arise. Some telecom groups use both call accounting packages and manual methods to identify trends and capacity bottlenecks. Also, unusual patterns of usage may indicate toll fraud or hacking.

Although there is overlap between the reporting offered by traditional call accounting/line commands on the PBX, the firewall provides a more convenient source of real-time and summarized information. Some functions include:

- *Real-time notification of availability.* Line errors, 100 percent busy trunks, frame slippage, D channel problems, and other potential disruptive events can be sent to pagers or to a console.
- *Monitoring of trunk spans over multiple locations.* If the PBX firewalls are linked via a management system, the entire telecommunications enterprise can be viewed from a central console. Security rules can be administered centrally as well.
- *History of usage.* Usage of all trunks can be recorded over time and plotted. This is a convenient method of identifying excess capacity.

The real-time capability of the firewall also provides some unique security capabilities. For example, in organizations where security requirements are high, calls can be monitored in real time and suspect calls can be manually terminated. Obviously, all the legal issues must be addressed for such a practice to be implemented.

130.5 Limitations of a PBX Firewall

The PBX firewall links to analog circuits, ISDN PRI circuits (the most common voice trunking for midsize to larger organizations), standard T1s, and Centrex lines from the local telephone company.

Some connection-oriented, data-link circuits such as Frame Relay and ATM are not addressed by the PBX firewall. Typically, data traffic (except for dial-up) is funneled through an IP firewall. Another limitation is direct wireless communications via cellular telephone, satellite, etc. While these are not typically hacker points of penetration, they should be considered in any comprehensive review of network security.

130.6 Summary

Psychological tests show that recent, high-profile events disproportionately influence our thinking relative to events over a longer period. Hence, well-publicized, data-related security problems overshadow exposures in the more mundane telecommunications infrastructure. “Black hat” hackers, by definition, do not care about the rules of engagement and will attack the weakest point—whether by the social engineering of a new employee or by bypassing the IP firewall via the telephone network. The PBX firewall, properly implemented with policy rules tailored to the organization, can block unauthorized access to the interior of the network.

131
Network Security Overview

Bonnie A. Goins

Christopher A. Pilewski

131.1 What Is Network Security?

Network security is multifaceted. “Networking” itself is about the provision of access to information assets and, as such, may or may not be secure. “Network security” can be thought of as the provision of consistent, appropriate access to information and the assurance that information confidentiality and integrity are maintained, also as appropriate. Contrary to what may seem intuitive, network security is not simply a technology solution. It involves the efforts of every level of an organization and the technologies and the processes that they use to design, build, administer, and operate a secure network.

131.2 Why Is Network Security Essential?

An organization must have provisions for network security to protect its assets. Appropriate network security identifies and protects against threats to people, processes, technologies, and facilities. It can minimize or mitigate exposures to the organization that could be exploited by a knowledgeable insider or a malicious outsider. It suggests appropriate safeguards designed to promote long-term, continuous function of the environment. For some organizations, the law mandates it.

131.3 Who Is Responsible for Network Security?

Every employee, in every position and at every rank, is responsible for network security within an organization. In some cases, such as in a regulated environment, business or trading partners are also responsible for adherence to security strategies in place at the organization. Security responsibilities also extend to casual or temporary employees, such as part-time workers, interns or consultants.

131.3.1 The Role of Senior Management

Senior management is responsible for any security violations that occur in the environment and, by extension, any consequences the organization suffers as a result. To repeat: *senior management is responsible for any security violations that occur in the environment*. For many senior executives, this is a new concept. After all, how could an executive presume to know whether or not appropriate security is in place?

It is senior management's responsibility to support, promote, and participate in the security process, from conception to implementation and maintenance. Senior management can facilitate this obligation through (1) active and continual participation in the security planning process; (2) communication of "the tone at the top" to all employees, vendors, and business and trading partners, indicating that security responsibilities rest organizationwide and that senior management will enforce this view unilaterally; (3) support of security professionals in the environment, through the provision of resources, training, and funding for security initiatives; and (4) the periodic review and approval of progress regarding security initiatives undertaken within the organization.

Many executives ask for methods to enhance their knowledge of the security space. Internal technology transfer, security awareness training, and self-study can all assist in expanding knowledge. The option also exists to contract with an appropriate consulting firm that specializes in executive strategy consulting in the security space.

Senior executives must also be prepared to communicate expectations for compliance to security responsibilities to the entire organizational community, through its approval of appropriate corporate security policies, security awareness training for employees, and appropriate support of its security professionals.

131.3.2 The Role of the User

It is important to reiterate that all users share in the responsibility for maintaining the security of the organization. Typically, user responsibilities are communicated through a corporate security policy and security awareness program or materials. Users are always responsible for protection of the security of their credentials for access (i.e., passwords, userIDs, tokens, etc.); maintenance of a clean workspace, to prevent casual removal of critical data or other resources from the desktop or workspace; protection of critical data and resources while they are in the user's possession (i.e., work taken offsite to complete, portable systems, such as laptops, etc.); vigilance in the environment, such as greeting strangers within their workspace and asking if they require help; reporting anything unusual in the environment, such as unexpected system performance; etc. Users may also have additional security responsibilities assigned to them.

Responsibilities must align with the user's ability to satisfy the requirement. For example, users responsible for shipping must not be held accountable to satisfy the responsibilities of a network administrator. Proper alignment of responsibilities to roles is essential for the organization to "function as advertised." An organization can facilitate this alignment by thoroughly and definitively documenting roles in the environment and outlining job function responsibilities for each. Job functions can then be aligned to security responsibilities. The personnel function also benefits from this elaboration and alignment.

131.3.3 The Role of the Security Professional

The responsibilities of a security professional vary among organizations. Perhaps this can best be explained by the notion that security professionals come from diverse backgrounds and skill sets. Security professionals may have legal, compliance, management or business, or technical backgrounds; likewise, professionals may have experience across industries ranging from education to government, financials to manufacturing, healthcare to pharmaceuticals, or retail to telecommunications. Positions held by security professionals include management, compliance officer, security officer, litigator, network administrator, systems analyst, etc.

One responsibility that most organizations agree upon is that the security professional, or team of professionals, is responsible for the periodic reporting to senior management on the current state of security within the organization, from both a business and technical perspective. To ensure this responsibility is carried out, the organization's current state of security must be assessed; in some cases, such as in a regulatory environment, additional audits are performed as well.

Given that security professionals come from myriad backgrounds and skill sets, many have never performed assessments. Some organizations choose to outsource this activity; others train to conduct this activity in-house, as appropriate.

131.4 Characteristics of a Secure Network

131.4.1 Confidentiality

A secure network must have mechanisms in place to guarantee that information is provided only to those with a "need-to-know" and to no one else.

131.4.2 Integrity

A secure network must have mechanisms in place to ensure that data in the environment is accurately maintained throughout its creation, transmission, and storage.

131.4.3 Availability

A secure network must have mechanisms in place to ensure that network resources are available to authorized users, as advertised.

131.4.4 Accountability

A secure network must have mechanisms in place to ensure that actions taken can be tied back to a unique user, system, or network.

131.4.5 Auditability

A secure network must have controls in place that can be inspected using an appropriate security or audit method.

The organization itself must determine the priority of importance for the security attributes listed above. In some organizations, multiple security attributes are considered at the same priority level when making decisions about resource allocation and function.

131.5 A Comprehensive Understanding of Network Architecture

To properly design and implement a secure architecture, a comprehensive understanding of the network architecture is also essential. In many modern institutions, the network may be compared to a production line, where information, messages, and documents for all vital business processes are stored, viewed, and acted upon. To protect the network and the assets available on it, a security professional must clearly understand the (1) hierarchical nature of the information assets that require protection; (2) structure of the network architecture itself; and (3) the network perimeter (i.e., the network's entry and exit points or portals, and the associated protection at these points).

A "secure network" is simply a network that, by its design and function, protects the information assets available on it from both internal and external threats.

131.5.1 Network Architectures

A security professional can use a variety of sources to gain an understanding of the network architecture. These include network diagrams, interviews, technical reports, or other exhibits. Each of these has its advantages and disadvantages.

Mapping and describing the network architecture can be a complicated endeavor. Network architectures can be described in a variety of terms. Many terms are, by their nature, relative and may have more than one meaning, depending upon the technology context in which they are used. Network professionals, when asked to describe their networks, will often begin by listing specific vendor-centric technologies in use at the site. This is not the most useful reference point for security professionals.

A reference point that nearly all institutions understand is the distinction between the LAN (local area network) and the WAN (wide area network). Although some might consider these terms outdated, they represent one of the few commonalities that nearly all network professionals understand consistently and agree with.

Both the LAN and the WAN can be accurately described using the following simple and empirical framework of three criteria: (1) locations, (2) links, and (3) topologies. Once the network architecture is clearly understood, the network perimeter can be investigated and properly mapped.

131.5.1.1 Wide Area Network (WAN)

Wide area networks (WANs) can be mapped by first identifying, through listing or drawing, the physical locations that belong to the institution. Each building name and address should be listed. This may entail only a single building or may be a list of hundreds. Each location should be indexed in a useful way, using a numerical identifier or an alphanumeric designation. Conspicuous hierarchies should be noted as well, such as corporate or regional headquarters' facilities and branch offices.

The second step in mapping the WAN is to identify the links between locations, again by listing or drawing and then indexing. The level of link detail required can vary by specific assessment needs but, at a minimum, each link should be specifically identified and indexed. Many institutions may have redundant links between locations in failover or load-balancing configurations. Other institutions may have "disaster wiring" or dedicated phone lines for network management purposes that are intended for use only during emergency situations. To accurately map the WAN, every physical link of all types must be identified and indexed. Additional link data, such as carriers, circuit types, IDs, and speeds, can be of use for other purposes.

The third step in mapping the WAN is to identify the topology or topologies of the WAN. The topology represents the relationship between locations and links. The topology can be very simple or very complex, depending upon the number of locations and links. An example of a simple topology would be a hub-and-spoke (or star) relationship between the headquarters of a regional business and individual branch offices. In this simple relationship, the headquarters represents a simple center of the network architecture. Other topologies may be much more intricate. A global organization can have independently operating national or regional centers, each with multiple satellite locations that connect through them. The regional centers of global organizations can connect only once to the global center. But more often, regional centers connect to more than one peer at a time in a partial mesh or full mesh topology. Accurately determining locations, links, and topologies will define the data security relationship(s) in the WAN.

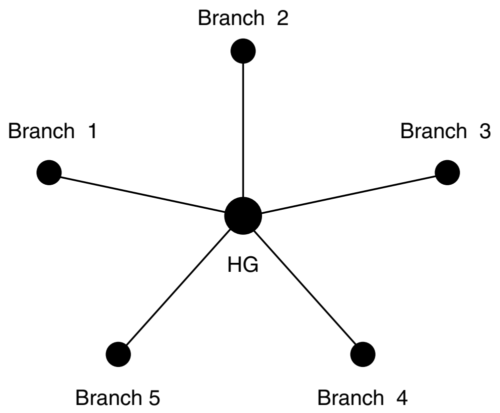

EXHIBIT 131.1 Star topology WAN.

Specific WAN topology examples illustrate the relationships between locations and links, and these are discussed below.

The hub-and-spoke, or "star" topology, WAN (see Exhibit 131.1) has a clear center, and has $(n-1)$ connections for the n nodes it contains. Network traffic is aggregated at the center. If any branch needs to send information to any other branch, the information must flow through the HQ (headquarters) node. This configuration allows the HQ node to provide centralized services to the branches and to control the flow of information through the network.

The partial mesh topology WAN (see Exhibit 131.2) is similar to the star topology. There is still a clear center, but additional connections have been added between the individual branches. There can be any number of connections beyond $n-1$ in a partial mesh. Unlike the star topology, branches can send and receive information to or from each other, without the information traversing the HQ center node. Many network designers use partial mesh topologies because they have desirable business continuity characteristics. In this partial mesh, any link (or any node) can be compromised and the others can continue to communicate. While these characteristics enable high availability, they complicate the security relationships between locations.

The full mesh topology WAN (see Exhibit 131.3) can be thought of as the full extension of the partial mesh. In terms of data flow, there may be no clear center. Each branch has a direct connection to every

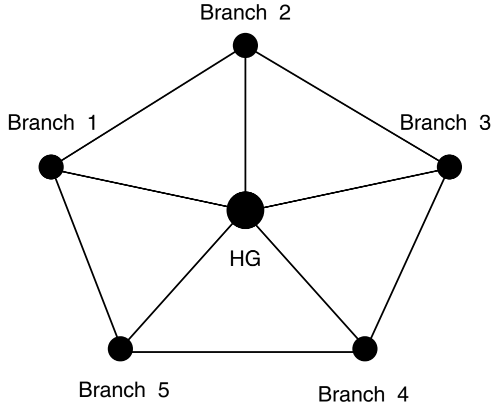

EXHIBIT 131.2 Partial mesh topology WAN.

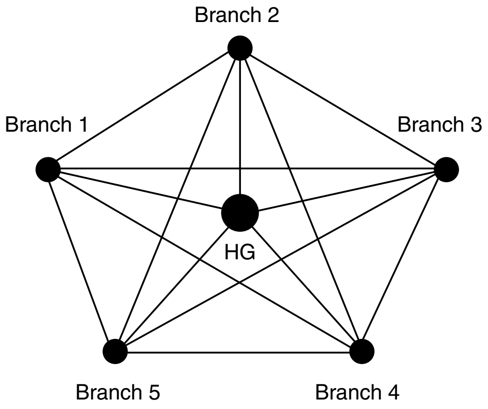

EXHIBIT 131.3 Full mesh topology WAN.

other branch. There are $n\times(n-1)$ connections in a full mesh. Full mesh topologies are rare in WANs because of the costs of maintaining a large number of links. They are most often found when both high availability and high performance are needed. In full mesh topology WANs, individual traffic flows, and the associated security relationships, may be difficult or impossible to trace if complex routing metrics are used in the design.

Specific technologies common to WANs include leased circuits, Frame Relay, SONET, and ATM. Technologies such as ISDN, SMDS, X.25, and others are less common, but are still seen. The particular technology in use on an individual link is potentially of some interest for security purposes, but far more important is the completeness and accuracy of the WAN mapping itself (locations, links, and topologies). These determine the desired, and potentially undesired, information flow characteristics that define security relationships.

131.5.1.2 Local Area Network (LAN)

Local area networks (LANs) can be mapped similarly to WANs by first identifying, either through listing or drawing, the physical locations. In the case of LANs, the physical locations to be identified are usually data centers, server rooms, wiring closets, or other areas within a building where network equipment and cabling reside. A typical building will have at least one room where individual networks aggregate and at least one wiring closet per floor. Large buildings may have more of both. As with WANs, each location should be indexed in a useful way, through a numerical identifier or an alphanumeric designation. Hierarchies should be noted, such as data center, major closet, minor closet, etc. Older facilities may present special challenges because network equipment and cabling may have been positioned in any location possible at the time the network was built. These may include individual offices, janitorial closets, or even above suspended ceiling tiles.

The second step in mapping the LAN is to identify the links between locations, again by listing or drawing and then indexing. At minimum, each link should be specifically identified and indexed. Just as when WANs are mapped, redundant links should be mapped between locations in failover or load-balancing configurations. Supplemental link data, such as media type, speeds, or protocols, may be of use for other purposes.

The third step in mapping the LAN is identifying the topology or topologies in use. The topology of LANs can initially appear to be very different from WANs, but similarities do exist. LANs are typically confined to a single building or to a campus. The LAN can be mapped by determining the physical locations where network cable segments aggregate. Typically, a single room houses the switching core for a designated building. The switching core may be comprised of a single network switch or of multiple switches connected by high-capacity links. The switching core connects to individual workgroup switches that, in turn, connect to individual computers, servers, or other network devices. Often, several workgroup or closet switches connect to the switching core of the LAN. There may be one workgroup switch per floor of the building or several, depending on the building's size. These connections are typically arranged in the same hub-and-spoke (or star) relationship that characterizes many WANs. But like WANs, multiple connections between switches may be present and may form a partial mesh or a full mesh.

Switched Ethernet of various speeds and on various physical media, such as unshielded twisted-pair cable or fiber optic cables, is the most common technology in use on a LAN. Other technologies, such as Token Ring or FDDI, are still in use. Again, the specific technical characteristics of a particular LAN may be of note, but the architecture itself is of primary importance.

131.5.1.3 Wireless LANs

Wireless LANs merit special consideration because the LAN itself is not contained within the physical premises, or even on physical media. Wireless LANs reside in specific radio frequencies that may permeate building materials. Depending upon the design purpose of an individual wireless LAN, this may be desirable or undesirable. A number of tools and techniques (beyond the scope of this chapter) exist to help a security professional detect and assess wireless LANs. A security professional must understand the relevance of the wireless LAN to the network architecture as a whole. Primary considerations include the existence and locations of wireless LANs and the termination points of individual wireless access points (WAPs). The termination points will determine the critical distinction between wireless LANs in use inside the network perimeter and wireless LANs in use outside the network perimeter.

Specific LAN topology examples illustrate the relationships between locations and links. There are similar relationships that exist in WANs but they involve different components and often appear very different on network diagrams.

The hub-and-spoke or "star" topology LAN (see Exhibit 131.4) has a clear center, and has $(n-1)$ connections for the n nodes it contains (as was shown in the WAN example of the same topology). Although this LAN topology is not illustrated with a clear center, the network traffic is aggregated at the core switch. If any workgroup switch needs to send information to any other workgroup switch, the information must flow through the core switch. Centralized services to all clients on workgroup switches can be positioned on the core switch.

The partial mesh topology LAN (see Exhibit 131.5) is similar to the star topology. There is still a clear center, but additional connections have been added between the individual workgroup switches. Network

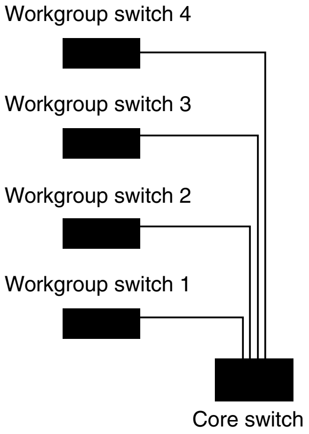

EXHIBIT 131.4 Star topology LAN.

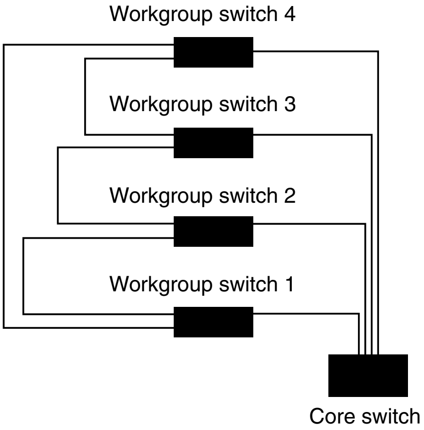

EXHIBIT 131.5 Partial mesh topology LAN.

switches often use special protocols that select the best path for data to take, when more than one path exists. Network switches use various versions of STP (Spanning Tree Protocol) on *bridged* links; or a variety of routing protocols can be used on *routed* links, including RIP or OSPF. Multiple routing protocols can be used concurrently on the same network switch. The design goal is often the same as those in partial mesh WANs—high availability.

Full mesh topology LANs, as depicted in Exhibit 131.6, are rarely found in practice. As in the WAN example, there are $n^*(n-1)$ connections in a full mesh. But because this topology facilitates both high availability and high performance, full mesh topologies are common in large network cores, such as those belonging to network providers.

131.5.1.4 The Network Perimeter

After mapping the LANs and WANs, the network perimeter can be defined and mapped. The network perimeter is the boundary where an organization's information leaves its immediate, direct control. As before, there may be a tendency to define the network perimeter in terms of technology products. Specific products are of interest, but the network perimeter should be defined by an organization's zone of authority. In more precise terms, the network perimeter should be thought of as the full set of entry points and exit points into and out of the network.

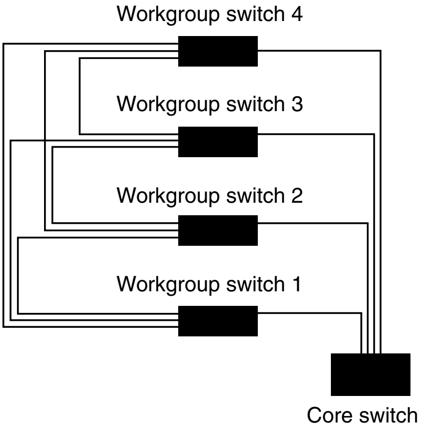

EXHIBIT 131.6 Full mesh topology LAN.

Defining the network perimeter this way will encompass many concepts familiar to security administrators, such as connections to Internet service providers (ISPs), but may also reveal aspects of the perimeter that are not routinely considered. Commonly understood network entry/exit points include ISP connections, remote access connections, virtual private networks (VPNs), and connections to business partners. Network entry and exit points that often go unexamined and unprotected include WAN and LAN components, such as links, server rooms, wiring closets, unrestricted network ports, and even computer workstations themselves.

Each entry and exit point should be documented and indexed, particularly the less obvious ones. After the network perimeter is properly assessed, appropriate safeguards can be evaluated for each entry and exit point. A common misconception in network security is that protecting against threats from the exterior is more important than protecting against threats from the interior. Both types must be addressed to make the network perimeter secure.

131.6 Where Does Network Security Start?

131.6.1 Identify Assets Requiring Protection

To apply security to any layer, the organization must determine the assets critical to its function. Arguably, all assets within the organization must be identified and categorized, to properly determine their criticality to the organization's function and to classify them accordingly. Classification of assets, particularly data and systems, instructs users on appropriate handling of the assets. This is essential if mistakes are to be avoided, such as the inappropriate dissemination of sensitive information. While all organizations consider their intellectual property as highly sensitive, regulated industries (e.g., healthcare and financials) also consider personally identifiable information of extreme importance and, therefore, sensitivity.

Organizations typically identify assets through the *process of business impact analysis* (BIA). Several methods exist to conduct a BIA; Disaster Recovery International (www.drii.org) presents a wealth of information to organizations engaged in this activity.

131.6.1.1 Identify Threats to Assets

To mount a successful defense of organizational assets, threats to those assets must be identified. Examples of threats typical to most environments include:

- *Malice*. People might be motivated to harm an organization's assets by harboring anger toward management, co-workers, or the organization itself. A common theme among these individuals is the intent to do harm. An example of a malicious act is a network administrator opening an organization up to attack after notification of termination.
- *Monetary gain*. Need or greed can also be a motivator for intrusion into a network. Many examples of the theft of intellectual or personal property, such as credit card numbers, are seen around the world.
- *Curiosity*. Human beings are curious by nature; many are equally clever. Curiosity can lead an individual to jeopardize assets, either knowingly or accidentally.
- *Accidents*. People make mistakes, despite best efforts. Accidents happen. Despite the fact that they are unintentional, accidents can cause harm to organizational assets and should be accounted for in security planning.
- *Natural disasters*. Weather-related and geographic emergencies must also be considered when planning for security. Data collected from the Federal Emergency Management Agency (FEMA) can assist the organization in assessing the threat from these disasters.

131.6.1.2 Identify Countermeasures ("Safeguards") to Threats

Once threats to the organization have been identified, it is important for the organization to take the next step and to design and implement appropriate countermeasures, which neutralize or minimize the threat. It is important to note that some threats pose more of a danger than others; additionally, some threats have a greater likelihood of occurring within, or to, the organization. To properly identify whether the threats are manifested as exposures in the organization, an assessment should be undertaken.

131.6.2 Assess the Environment

Assessment is typically done through "hunting" and "gathering." "Hunting" in this sense refers to the inspection of technology at its core ("intrusive assessment"). This is most often done through the use of software tools, both commercial-off-the-shelf (COTS) and open source. Security professionals who are experts in this area provide the most value for the organization through appropriate interpretation of information gathered both from tools and from research they have conducted in addition to the intrusive assessment. "Gathering" in this sense refers to the collection of data through documentation review, interviews, system demonstration, site visits, and other methods typically employed in nonintrusive assessments.

131.6.2.1 Nonintrusive Assessment Activities

Aspects of a security assessment that are evaluated through means other than direct manipulation and penetrative technology-based testing are considered "nonintrusive." Information is obtained through the review of previous assessments, existing policies and procedures, visits to the organization's sites, interviewing the organization's staff, and system demonstrations conducted by appropriate personnel. These assessment aspects are discussed in detail in Chapter 106: "Creating a Secure Architecture."

Nonintrusive assessment methods are very useful in gathering data surrounding people, processes, and facilities. Technology is also reviewed, although not at the granular level that can be attained through the use of software tools. An assessment method should be selected keeping the organization's business in mind. It is also highly advisable that a method recognized in the security space as a "best practice" be used. The National Security Agency (NSA), National Institute of Standards and Technology (NIST), and the International Organization for Standardization (ISO) all have security assessment methods that are easily adaptable to virtually any organization. All provide information that facilitates the building of a secure network environment.

131.6.2.2 Intrusive Assessment Activities

A number of activities might fall into the general description of intrusive assessment. These activities are loosely classified into two categories: (1) vulnerability scanning and (2) attack and penetration. The two can be employed individually, or attack and penetration can be employed as a complement to vulnerability scanning. Both activities help build a picture of an organization's network, servers, and workstations that is similar to the picture that an external attacker would develop.

131.6.2.3 Combining Assessment Activities to Promote a Holistic Approach to Security

As previously stated in this chapter, effective organizational security can only be achieved by examining all aspects of the organization: its people, its processes, its facilities, and its technologies. There is little wonder, then, that to meet the objective of inspecting the organization in total, multiple assessment approaches must be used. Intrusive or tool-based discovery methods will not adequately address more subjective elements of the environment, such as people or processes. Nonintrusive discovery methods will not be sufficient to inspect the recesses of network and technology function. It is clear that if these approaches are used together and information gathered is shared among the security professionals conducting the assessments, a more global view of the organization's function, and by extension exposures to that function, is obtained. Again, while it is important to note that no particular approach, be it joint as suggested here, will identify 100 percent of the exposures to an organization, a more thorough and unified evaluation moves the organization closer to an optimal view of its function and the threats to that function.

- *Remediation definition*. At a high level, remediation is defined as the phase where exposures to an organization are "fixed." These fixes are typically activities resulting in a deliverable, such as a policy, procedure, technical fix, or facility upgrade, that addresses the issue created by the exposure. Remediation and its characteristics are discussed in detail in Chapter 106: "Creating a Secure Architecture."
- *Examples of remediation activities*. Remediation steps occur after completion of the assessment phases. Remediation activities for an organization might include security policy and procedure development; secure architecture review, design, and implementation; security awareness training; ongoing executive-level security strategy consulting and program development; logging and monitoring; and other remediation activities.

131.7 Summary

Many factors combine to ensure appropriate network security within an organization. People, processes, data, technology, and facilities must be considered in planning, design, implementation, and remediation activities, in order to properly identify and minimize, or mitigate, the risks associated with each factor. Senior management must be clear in communicating its support of security initiatives to the entire organization. Additionally, security practitioners must be provided with the ability to succeed, through the provision of adequate resources, training, and budgetary support.

132

Putting Security in the Transport: TLS

Chris Hare

At the heart of most security managers' concerns is *transport layer security*. The transport is a concern because there is no way to effectively monitor all the devices on a network. And because network sniffers and other devices with promiscuous network interfaces are effectively invisible on the network, it is not possible to ensure that "no one is listening."

132.1 What is TLS?

Transport layer security (TLS) is intended to address this very problem. TLS provides both data confidentiality (privacy) and data integrity for a network session between two endpoints. To implement these protection features, TLS uses two protocols: the TLS Record Protocol and the TLS Handshake Protocol.

The TLS Record Protocol requires a reliable transport such as TCP and provides symmetric cryptography and integrity. This being said, it is also possible to use the TLS Record Protocol without encryption. Not using the encryption capabilities could be an option where privacy of the data is not a concern, but the integrity of the data is.

TLS was designed to provide a secure and extensible protocol that is capable of interoperating with any application or service. It was also intended to provide additional cryptographic algorithm support, which SSL did not have. The challenge of providing additional cryptographic algorithms was compounded by export controls on cryptographic technologies and requiring backward compatibility with browsers such as Netscape.

Secure Socket Layer (SSL) has typically been associated with World Wide Web transactions. It is possible to use TLS in this area; however, this is a highly technical discussion more appropriate for other audiences. Additionally, while TLS has been undergoing development, the Internet community has accepted SSL as a transport for VPN services, as an alternative to the seemingly more complex IPSec implementations.

In designing TLS, the architects had four major goals:

1. Provide secure communication between the two parties using cryptographic security features.
2. Allow independent programmers to exchange cryptographic parameters within knowledge of the programming language and code used on the remote end.
3. Provide a framework capable of supporting existing and new symmetric and asymmetric encryption services as they become available. This, in turn, eliminates the need for new code or protocols as advances are made.
4. Improve efficiency at the network by effectively managing the network connections.

132.2 Why Use TLS?

There are a variety of reasons for wanting to choose TLS over SSL when securing a protocol. SSL has been widely used and associated with HTTP traffic. While SSL and TLS both provide a generic security channel for the desired protocol, when security professionals hear “SSL,” they typically think that “HTTP” is the protocol being protected.

Netscape originally developed SSL, while TLS has taken a standards-oriented approach managed through the TLS Working Group of the Internet Engineering Task Force (IETF). Consequently, the implementation is not biased toward specific commercial implementations. Finally, there are a number of free and commercial implementations of TLS available.

However, be warned: developing a secure application using TLS or SSL is not simple and requires extensive technical knowledge of the TLS protocol and the protocol being protected. This knowledge promotes the development of an application capable of handling errors in a secure fashion and limits the attack possibilities against the application.

132.3 Protecting Data

Protecting data with TLS requires the negotiation of an encryption algorithm. TLS provides support for multiple algorithms, including:

- DES
- RC4
- RC2
- IDEA
- Triple DES (3DES)

Note that these are symmetric cryptographic algorithms. Symmetric algorithms are preferred due to the speed of the encryption and decryption process over asymmetric algorithms. The encryption key is unique and generated for each session. The seed or secret for generating the key is negotiated using an alternate protocol, such as the TLS Handshake Protocol.

132.4 Ensuring Data Integrity

Having an encrypted session may not be of much use without ensuring that the data was not modified and re-encrypted after the fact. Consequently, the TLS Record Protocol also provides an integrity checking function.

The integrity of the message is ensured using a keyed Message Authentication Code (MAC) using a secure hash function such as SHA or MD5.[1] These are message digest algorithms that are irreversible, making it extremely difficult, if not virtually impossible, to compute a message given the digest. Consequently, the use of message digests is an accepted method of verifying the integrity of the message. If a single character in the message is altered, it is virtually impossible to generate the same message digest.[2]

132.5 The TLS Protocols

As mentioned previously, there are two protocols in the TLS suite. Aside from the confidentiality and integrity functions of the TLS Record Protocol, this protocol also encapsulates other higher-level protocols. Of the protocols supported, the TLS Handshake Protocol is often used to provide the authentication and cryptographic negotiation.

The TLS Handshake Protocol provides two essential elements in establishing the session:

1. Authenticating at least one of the endpoints using asymmetric cryptography
2. Negotiation of a shared secret

The shared secret is used to generate the key for the symmetric cryptography used in the Record Protocol. However, of importance here is the high level of protection placed on the secret. During the negotiation, because the secret is protected by asymmetric cryptography, it is not possible for an eavesdropping attacker to recover the secret. Second, the manner in which the negotiation occurs means any attempt by an attacker to modify the communication will be detected. These features provide a high level of security and assurance of the privacy and data integrity of the connection.

Additionally, the Handshake Protocol also provides other sub-protocols to assist in the operation of the protected session. The entire protocol stack is presented in Exhibit 132.1. This chapter presents the protocol stack and operation of a TLS session.

132.5.1 Understanding the TLS Handshake Protocol

The TLS Handshake Protocol allows two peers to agree upon security parameters for the TLS Record layer, authenticate, initiate those negotiated security parameters, and report errors to each other.

During the session negotiation phase, the Handshake Protocol on each peer negotiates the security parameters in Exhibit 132.2.

Once the session is initiated, however, the application can request a change in the cryptographic elements of the connection. The change is handled through the “change cipher spec protocol,” which sends a message to the peer requesting a change to the cipher properties. The change itself is encrypted with the current cipher values to ensure the request and associated information cannot be deciphered if intercepted.

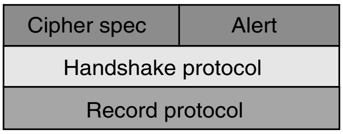

EXHIBIT 132.1 TLS Protocol stack.

[1] The operation of SHA and MD5 are not discussed in this chapter.

[2] This statement precludes issues such as the Birthday Paradox, illustrating the possibility that some two messages can generate the same message digest.

EXHIBIT 132.2 Security Parameters

Parameter	Description
Session identifier	This value is chosen by the server and is an arbitrary value to identify an active or resumable session state.
Peer certificate	This is the X509v3 [X509] certificate of the peer.
Compression method	The algorithm used to compress data prior to encryption.
Cipher spec	This identifies the bulk encryption algorithm, the MAC algorithm, and any other specific cryptographic attributes for both.
Master secret	This is a 48-byte secret shared between the client and server.
Is resumable	A flag indicating whether the session can be used to initiate new connections.

132.5.2 How the Protocol Works

For TLS to properly protect a session using cryptographic features, it must negotiate the cryptographic parameters. Exhibit 132.3 illustrates establishing the session.

Upon initiating a TLS connection, the two nodes must establish a "handshake" and negotiate the session parameters. These parameters include the cryptographic values, optional authentication, and generated shared secrets.

The process breaks down as follows:

1. Each node exchanges a "hello" message to communicate supported cryptographic algorithms, select one that is mutually acceptable, exchange random values used for session initialization, and finally to check to see if this is the resumption of a previous session.
2. Both nodes then exchange the needed cryptographic parameters to agree on a "pre-master" secret.
3. Both nodes exchange their certifications and appropriate cryptographic information to authenticate.
4. Both nodes use the pre-master secret from Step 2 to generate a master value, which is then exchanged.
5. Each node provides the agreed security parameters to the TLS record layer.
6. Verifies the other has calculated the same security parameters and the session was not tampered with by an attacker.

While TLS was designed to minimize the opportunity an attacker has to defeat the system, it may be possible according to RFC 2246 for an attacker to potentially get the two nodes to negotiate the lowest level of agreed encryption. Some methods are described later in this chapter.

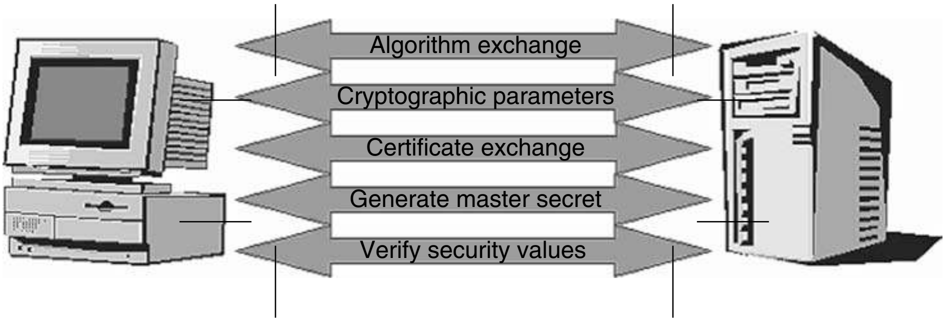

EXHIBIT 132.3 Handshake setup.

Regardless, the higher-level protocols should never assume the strongest protocol has been negotiated and should ensure whatever requirements for the specific connection have been met. For example, 40-bit encryption should never be used, unless the value of the information is sufficiently low as to be worth the effort.

132.5.3 Dissecting the Handshake Protocol

When the client contacts the server to establish a connection, the client sends a client hello message to the server. The server must respond with a server hello message or the connection fails. This is extremely important, as the hello messages provide the security capabilities of the two nodes.

Specifically, the hello message provides the following security capabilities to the other node:

- TLS protocol version
- Session ID
- Available cipher suite
- Compression method

As mentioned, both nodes compute a random value I that is also exchanged in the hello message.

Exchanging the keys can involve up to four discrete messages. The server first sends its certificate, provided the server is to be authenticated. If the certificate is only for signing, the server then sends its public key to the client. The server then sends a “server done” message, indicating that it is waiting for information from the client.

The server can send a request to the client for authentication, whereby the client sends its certificate, followed by the client’s public key and the “client done” message. The client done message is sent using the agreed-to algorithm, keys, and secrets. The server then responds with similar information and the change to the new agreed-to cipher is complete. This exchange is illustrated in Exhibit 132.4. At this point, the handshake between the two devices is complete and the session is ready to send application data in the encrypted session.

132.5.3.1 Resuming an Existing Session

When the client and server agree to either duplicate an existing session to continue a previous session, the handshake is marginally different. In this case, the client sends the “hello” message using the Session ID to be resumed. If the server has a match for that session ID and is willing to re-establish the session, it responds with a “hello” message using the same Session ID. Both the client and server then switch to the previously negotiated and agreed-to session parameters and transmit “done” messages to the other.

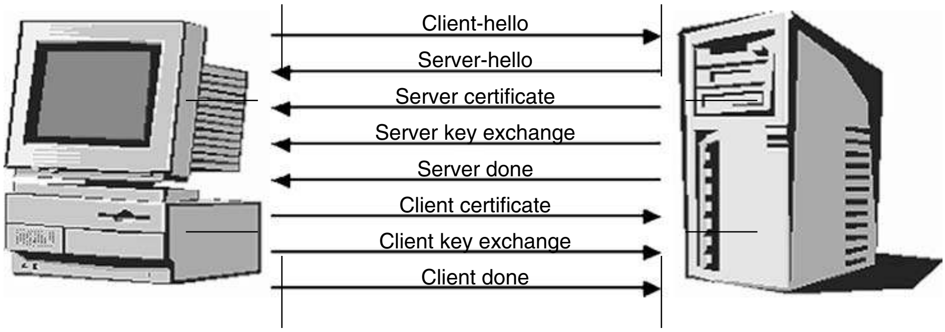

EXHIBIT 132.4 Handshake exchange.

EXHIBIT 132.5 Supported Certificate Types

Key Type	Description
RSA	This is the RSA public key, which must support use of the key for encryption.
RSA_EXPORT	This is an RSA public key with a length greater than 512 bits used only for signing. Alternatively, it is a key of 512 bits or less that is valid for either encryption or signing.
DHE_DSS	DSS public key.
DHE_DSS_EXPORT	DSS public key.
DHE_RSA	This is an RSA public key used for signing.
DHE_RSA_EXPORT	This is an RSA public key used for signing.
DH_DSS	This is a Diffie–Hellman key. The algorithm used to sign the certificate should be DSS.
DH_RSA	This is a Diffie–Hellman key. The algorithm used to sign the certificate should be RSA.

Note: Due to current restrictions documented in U.S. export laws, RSA values larger than 512 bits for key exchanges cannot be exported from the United States.

If the server does not have a match for the Session ID, or is not willing to establish a session based on the previous parameters, a full handshake must take place.

132.5.4 Certificates

The TLS Protocol is meant to be extensible and provide support in a wide variety of circumstances. Consequently, the certificate types[3] in Exhibit 132.5 are supported.

132.5.5 Inside the TLS Record Protocol

The Record Protocol is responsible for accepting cleartext messages, fragmenting them into chunks, compressing the data, applying a Message Authentication Code (MAC), encryption, and transmission of the result. Likewise, when an encrypted message is received, the protocol decrypts the data, verifies it using the MAC, decompresses and reassembles the data, which in turn is delivered to the higher-level clients. This process is illustrated in Exhibit 132.6.

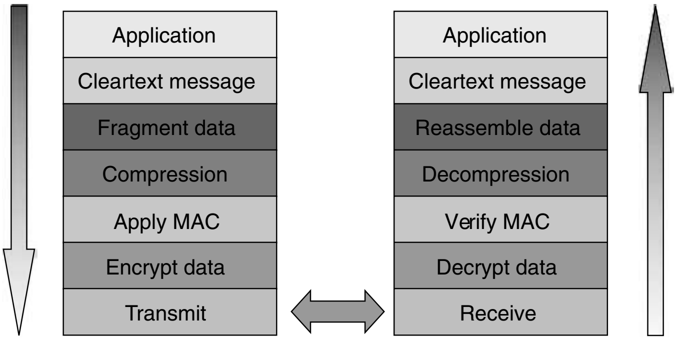

EXHIBIT 132.6 TLS data processing.

[3] All certificate profiles, and key and cryptographic formats are defined by the IETF PKIX working group.

EXHIBIT 132.7 TLS Record Protocol Parameters

Parameter	Description
Connection end	The value of this parameter determines if this is the sending or receiving end of the connection.
Bulk encryption algorithm	This is the negotiated algorithm for bulk encryption, including the key size, how much of the key is secret, block or stream cipher, cipher block size if appropriate, and whether this is an export cipher.
MAC algorithm	This is the Message Authentication Code algorithm and includes the size of the hash returned by the MAC algorithm.
Compression algorithm	This is the negotiated compression algorithm and includes all information required for compressing and decompressing the data.
Master secret	This is a 48-byte secret shared between the two peers.
Client random	This a 32-byte random value provided by the client.
Server random	This is a 32-byte random value provided by the server.

Achieving this process uses four record protocol clients:

1. Handshake protocol
2. Alert protocol
3. Change Cipher Spec protocol
4. Application Data protocol

The specific functions used to provide the Record Protocol services are controlled in the TLS connection state. The connection state specifies the:

- Compression algorithm
- Encryption algorithm
- MAC algorithm

Additionally, the appropriate parameters controlling the behaviors of the selected protocols are also known—specifically, the MAC keys, bulk encryption keys, and initialization vectors for both the read and write directions.

While the Record Protocol performs the specific functions noted here, the TLS Handshake Protocol performs the negotiation of the specific parameters. The parameters used in the TLS Record Protocol to protect the session are defined in Exhibit 132.7. These values are used for both sending and receiving data during the TLS session.

After the Handshake Protocol negotiates the security parameters, they are passed to the Record Protocol function to generate the appropriate keys. Once the keys are generated, the TLS Protocol tracks the state of the connection, ensuring proper operation and minimizing the risk of tampering during the session.

132.6 Handling Errors

The TLS Protocol carries data between a client and a server using an encrypted channel. This provides data confidentiality. Likewise, the protocol also ensures data integrity using a one-way hash, or Message Authentication Code (MAC) for each message. However, things sometimes go wrong; and when they do, the protocol must be able to inform the user and take appropriate action.

TLS Alert messages carry the severity of the message and a description of the alert. If the alert severity is fatal, the connection is terminated immediately. For other severity levels, the session may continue but the session ID is invalidated, which in turn prevents the failed session from being used to establish new sessions later.

The TLS protocol provides several alert types, including:

- Closure
- Error

Closure alerts are not errors, but rather a method for one side of the communication exchange to indicate the connection is being terminated. Error alerts indicate an error has occurred and what the error is.

When errors occur, the side detecting the error transmits an error message to the other side. If the error is fatal, then both sides immediately terminate the connection and invalidate all keys, session identifiers, and secrets. This prevents the reuse of information from the failed connection. Exhibit 132.8 lists the TLS error messages, their fatality status, and description.

Fatal error messages always result in the termination of the connection. However, when a non-fatal or warning message is received, continuing the connection is at the discretion of the receiving end. If the receiver decides to terminate the connection, a message to close the connection is transmitted and the connection is terminated.

132.7 Attacking TLS

The goal of TLS is to provide a secure channel for a higher-level protocol, as seen in Exhibit 132.9. Because the higher-level protocol is encapsulated within a secured transport, the vulnerabilities

EXHIBIT 132.8 TLS Error Messages

Error Message	Fatality	Description
unexpected_message	Fatal	The message received was unexpected or inappropriate.
bad_record_mac	Fatal	The received message has an incorrect MAC.
decryption_failed	Fatal	The decryption of the message failed.
record_overflow	Fatal	The received record exceeded the maximum allowable size.
decompression_failure	Fatal	The received data received invalid input.
handshake_failure	Fatal	The sender of this message was unable to negotiate an agreeable set of security parameters.
bad_certificate	Non-fatal	The supplied certificate was corrupt. It cannot be used for the connection.
unsupported_certificate	Non-fatal	The supplied certificate type is unsupported.
certificate_revoked	Non-fatal	The signer has revoked the supplied certificate.
certificate_expired	Non-fatal	The supplied certificate has expired.
certificate_unknown	Non-fatal	An error occurred when processing the certificate, rendering it unacceptable for the connection.
illegal_parameter	Fatal	A supplied parameter is illegal or out of range.
unknown_ca	Fatal	The Certificate Authority for the valid certificate is unknown.
access_denied	Fatal	The supplied certificate was valid, but access controls prevent accepting the connection.
decode_error	Fatal	The message could not be decoded.
decrypt_error	Non-fatal	The message could not be decrypted.
export_restriction	Fatal	The attempted negotiation violates export restrictions.
protocol_version	Fatal	The requested protocol version is valid, but not supported.
insufficient_security	Fatal	This occurs when the server requires a cipher more secure than those supported by the client.
internal_error	Fatal	An internal error unrelated to the protocol makes it impossible to continue the connection.
user_canceled	Warning	The connection is terminated for reasons other than a protocol failure.
no_renegotiation	Warning	The request for a renegotiation of security parameters is refused.

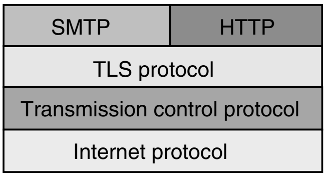

EXHIBIT 132.9 Encapsulating higher-level protocols.

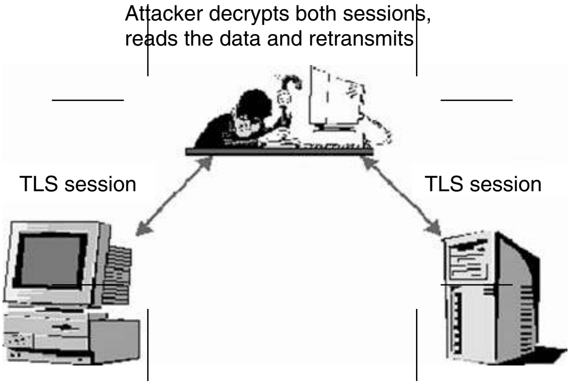

Attacker decrypts both sessions,
reads the data and retransmits
TLS session
TLS session

EXHIBIT 132.10 The man-in-the-middle attack.

associated with the higher-level protocol are not of particular importance. There are, however, documented attacks and attack methods that could be used against TLS.

One such attack is the man-in-the-middle attack, where the middle attacker attempts to have both the TLS client and server drop to the least-secure method supported by both. This is also known as a downgrade attack.

Exhibit 132.10 illustrates a man-in-the-middle attack. In this scenario, the attacker presents itself to the client as the TLS server, and to the real TLS server as the client. In this manner, the attacker can decrypt the data sent by both ends and store the data for later analysis.

An additional form of downgrade attack is to cause the client and server to switch to an insecure connection, such as an unauthenticated connection. The TLS Protocol should prevent this from happening, but the higher-level protocol should be aware of its security requirements and never transmit information over a connection that is less secure than desired.

A second attack is the *timing cryptanalysis attack*. This attack is not known to have been attempted against production systems and may not even be practical. With timing cryptanalysis, specific attention to the time taken for various cryptographic functions is required and used as the basis of the attack. Given sufficient samples and time, it may be possible to recover the entire key. This attack is not specific to TLS, but to public key cryptosystems in general. Paul Kocher discovered the timing cryptanalysis attack in 1996; the exact method of the attack is left for the reader to review.

A third attack is the *million-message attack*, which was discovered and documented by Daniel Bleichenbacher in 1998 to attack RSA data using PKCS#1. Here, the attacker sends chosen *ciphertext* messages to the server in an attempt to discover the *pre_master_secret* used in the protocol negotiation for a given session. Like the timing cryptanalysis attack, there is no evidence this attack has been used against production systems.

132.8 TLS Implementations

Several implementations of TLS commonly incorporate SSL as well. The available distributions include both commercial and open source implementations in the C, C++, and Java programming languages:

- Open source:
  — OpenSSL: http://www.openssl.org/
  — GNU TLS Library: http://www.gnu.org/software/gnutls/
  — PureTLS: http://www.rtfm.com/puretls
- Commercial:
  — SPYRUS: http://www.spyrus.com/content/products/SSLDeveloperToolkits_N7.asp
  — Certicom: http://www.certicom.com
  — Netscape Communications: http://www.netscape.com
  — RSA: http://www.rsasecurity.com
  — Baltimore: http://www.baltimore.com
  — Phaos Technology: http://www.phaos.com
  — Sun: http://www.javasoft.com

132.9 Summary

This chapter has presented what TLS is, how it works, and the common attack methods. While SSL continues to maintain momentum and popularity, support for TLS as the secured transport method is increasing dramatically. Like SSL, TLS provides a secured communications channel for a higher-layer protocol, with TLS providing protocol-independent implementations. SSL is typically associated with HTTP traffic, while TLS can support protocols aside from HTTP.

Web articles on implementing SMTP, FTP, and HTTP over TLS are available—just to name a few higher-level protocols. TLS implementations provide support for SSL clients as well, making the implementation backward compatible and standards based.

Finally, like SSL, TLS is prone to some attack methods. However, vigilance, attention to secure programming techniques, and configuration practices should alleviate most current attacks against this protocol suite.

WLAN Security Update

Franjo Majstor

133.1 Introduction and Scope

For the past few years, the explosion in deployment of wireless local area networks (WLANs) was delayed only due to concerns about their security exposures. Since introduction to the market in mid-1999, 802.11 WLAN technologies have gone through several revisions as 802.11b, 802.11a, and 802.11g, while the main headache to all of them was numerous vulnerabilities discovered in the 802.11 initial security mechanism known as Wire Equivalent Privacy (WEP). The Wi-Fi Alliance industry consortium since then has made several efforts to address the security issues as well as interoperability of the security solution; and as result of that effort, in mid-2003, the Wi-Fi Protected Access (WPA) specification was born to address major security issues within the WEP protocol. Despite all the headaches with the security exposures WLAN technologies have due to flexibility and easiness in their deployment, they have already penetrated the IT world in most enterprises as well as public areas, hotels, cafes, and airports. Hence, information security professionals must be aware of the issues with the old and current WLAN technology as well as technical solutions that already exist or are in the development pipeline to come to market soon. The aim of this chapter is to offer an overview of the 802.11 WLAN historical security facts and focus on a technical solution that lies ahead.

133.1.1 Demystifying the 802.11 Alphabet

WLAN technology gained its popularity after 1999 through the 802.11b standardization efforts of the IEEE and Wi-Fi Alliance, but 802.11b is definitely not a lone protocol within the 802.11 family. 802.11a and 802.11g followed quickly as speed enhancements, while others such as 802.11d, f, h, m, n, k, and i are addressing other issues in 802.11-based networks. For information security practitioners, it is important to understand the differences between them as well as to know the ones that have relevant security implications for wireless data communications. Short descriptions and meanings of 802.11 protocols are outlined in Exhibit 133.1, and more detailed descriptions on most of them can be obtained from the previous version of the *Information Security Management Handbook* as well as the IEEE web site under the 802.11 standards. It is also important to understand that although 802.11b, a, and g were developed at different times and describe different frequencies, numbers of channels, and speeds of communication, they initially all together suffered from the same security exposures.

133.2 Security Aspects of the 802.11 WLAN Technologies

133.2.1 Failures of the Past and the Road Map for the Future

Back in 1999 when the first of the 802.11 standards (802.11b) was ratified, the only security mechanism existing within it was Wired Equivalent Privacy (WEP). Not long after its development, WEP's cryptographic weaknesses began to be exposed. A series of independent studies from various academic and commercial institutions found that even with WEP enabled, third parties could breach WLAN security. A hacker with the proper equipment and tools can collect and analyze enough data to recover the shared encryption key. Although such security breaches might take days on a home or small business WLAN where traffic is light, it can be accomplished in a matter of hours on a busy corporate network. Despite its flaws, WEP provides some margin of security compared with no security at all and remains useful for the casual home user for purposes of deflecting would-be eavesdroppers. For large enterprise users, WEP native security can be strengthened by deploying it in conjunction with other security technologies, such as virtual private networks or 802.1x authentications with dynamic WEP keys. These appeared as proprietary vendor solutions in late 2000. As Wi-Fi users demanded a strong, interoperable, and immediate security enhancement native to Wi-Fi, the Wi-Fi Alliance defined Wi-Fi Protected Access (WPA) as a precursor to the 802.11i standard. In today's terminology, the first effort of the Wi-Fi Alliance was named WPAv1, while the full IEEE 802.11i security standard specification is getting referred as WPAv2. The timeline of this historical evolution, as well as the expected finalization from the current point in time of this not yet finished work, is illustrated in Exhibit 133.2.

n	High-speed

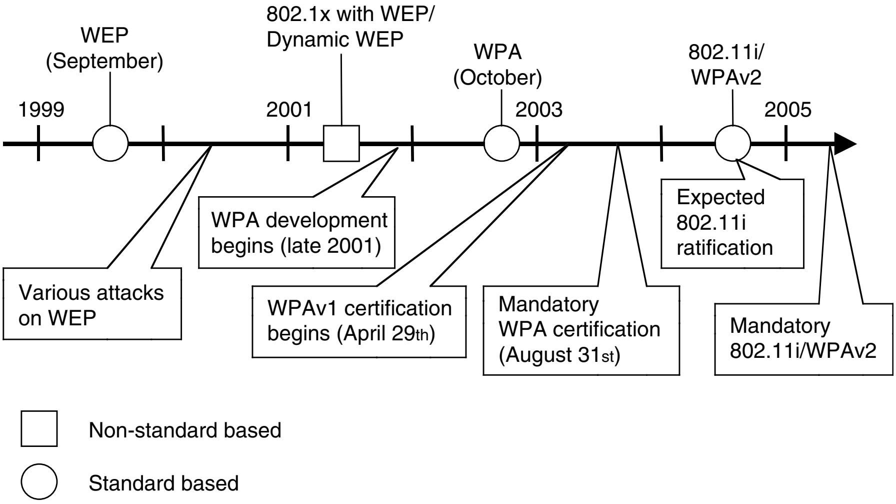

EXHIBIT 133.2 802.11 WLAN security technology evolution.

133.2.2 WLAN Security Threats

It is well known to information security professionals that a security threat analysis of any technology, and the WLAN technology is no exception, is done from the three main aspects: confidentiality, integrity, and availability of data. While the first two are addressed in detail, attacks on WLAN availability in the sense of jamming the radio space or a DoS attack on the WLAN Access Point are serious threats, yet are not easy to address by any of the security technologies or protocols discussed within this chapter.

On the other hand, WEP has tackled only the confidentiality of WLAN communication, and did not manage to solve the integrity part. Other major missing parts of WEP were the lack of a key management protocol and no user-level authentication, as well as cryptographic usage of RC-4 algorithm within WEP. Weaknesses of the WEP protocol and their influence on confidentiality, integrity, and authentication are outlined in Exhibit 133.3.

WLAN communication is in particular exposed to unintended parties not necessarily physically located within the network's physical boundaries and problems of WEP, even when it is deployed, have opened up WLANs to the possibility of passive eavesdropping that could be also augmented with active eavesdropping. Both passive and active eavesdropping attacks are exposing the problem of confidentiality of data sent over the WLAN network while the lack of a mutual authentication scheme is exposing WLAN traffic to a man-in-the-middle (MitM) attack. In the MitM attack, the attacker first breaks the connection between the target and the access point and then presents itself as an access point that allows the target to associate and authenticate with it. The target believes that it is interacting with the legitimate access point because the attacker has established a valid session with the destination access point. Once the MitM attack is successful and the target is communicating through the intermediary point, this attack can be used to bypass confidentiality and read the private data from a session or modify the packets, thus violating the integrity of a session.

EXHIBIT 133.3 WEP Security Issues

Authentication Problem	Confidentiality Problem	Integrity Problem
One-way authentication	No key management protocol	Bad choice of IV: CRC
No user-level authentication	Insufficient key length	Short IV space
Static and shared WEP key	Bad use of IV	

EXHIBIT 133.4 WPA versus WEP

Area	WEP Weakness	Attack/Problem	WPA	
Authentication	One-way authentication	MitM attack	802.1x/EAP	
	No user-level authentication	Theft of device		
	Bad authentication algorithm	Key recovery attack		
Key management	No key management (static and overhead)	Management overhead		
Encryption	RC4 key scheduling	Weak key attack	Per-packet key mixing function	TKIP
	Insufficient key length	Collision attack	Rapid re-keying	
	Bad use of IV	Replay attack	Extended IV with sequencing	
	Bad choice of ICV:CRC	Forgery attack	MIC called Michael	

To mitigate outlined threats, the Wi-Fi Alliance has defined the WPA specification that addresses the weakness of WEP, as illustrated in Exhibit 133.4.

133.3 Industry Initiatives

802.11 WLAN technology has its elements developed in several different standardization organizations. The IEEE is developing all the 802 standards, while the IETF is developing all the EAP methods. The Wi-Fi Alliance, as an industry consortium of the WLAN vendors, is on the third side putting together specifications, such as Wi-Fi Protected Access, for interoperability and compatibility testing among all WLAN products on the market.

133.3.1 Wi-Fi Protected Access

Wi-Fi Protected Access (WPA) is a specification of standards-based, interoperable security enhancements that strongly increase the level of data protection and access control for existing and future wireless LAN systems. WPA has in its specification addressed several goals, such as strong interoperable security as the replacement for WEP and software upgradeability of existing Wi-Fi certified products. It targets both home and large enterprise users, and a requirement for its development was to be available immediately. Because WPA is derived from IEEE 802.11i standardization efforts, it is also forward compatible with the upcoming standard. When properly installed, WPA provides wireless LAN users with a high level of assurance that their data will remain protected and that only authorized network users can access the network. The Wi-Fi Alliance started interoperability certification testing on WPA in February 2003 and mandates WPA certification from all vendors shipping WLAN products as of August 31, 2003.

To address the WEP problems, as already illustrated in Exhibit 133.4, WPA has improved data encryption and user authentication, together with a dynamic per-user, per-session key exchange mechanism. Enhanced data encryption is achieved through the Temporal Key Integrity Protocol (TKIP). TKIP provides important data encryption enhancements, including a per-packet key mixing function, a message integrity check (MIC) named Michael, and an extended initialization vector (IV) of 48 bits, together with sequencing rules. Through these enhancements, TKIP addresses all WEP encryption vulnerabilities known thus far. For the dynamic per-user, per-session key exchange, WPA relies on Extensible Authentication Protocol (EAP) methods and, depending on its use, WPA has several flavors: enterprise, home/SOHO, public, and mixed modes.

133.3.1.1 Wi-Fi Protected Access for the Enterprise

Wi-Fi Protected Access effectively addresses the WLAN security requirements for the enterprise and provides a strong encryption and authentication solution prior to the ratification of the IEEE 802.11i standard. In an enterprise scenario, WPA should be used in conjunction with an authentication server such as RADIUS to provide centralized access control and user-level authentication management. It includes enhanced data encryption through TKIP plus per-session, per-user key generation and management protocol via EAP methods.

133.3.1.2 Wi-Fi Protected Access for Home/SOHO

In a home or small office/home office (SOHO) environment where there are no central authentication servers or EAP frameworks, WPA runs in a special home mode. This mode, also called Pre-Shared Key (PSK), allows the use of manually entered keys or passwords and is designed to be easy to set up for the home user. All the home user needs to do is enter a password (also called a master key) in his access point or home wireless gateway and in each PC that is on the Wi-Fi wireless network. WPA takes over automatically from that point. First, the password allows only devices with a matching password to join the network, which keeps out eavesdroppers and other unauthorized users. Second, the password automatically kicks off the TKIP encryption process, which defeats known WEP encryption vulnerabilities. As for the WPA manual password security level, it is recommended to use a robust password or a passphrase greater than eight characters with alpha, numeric, and special characters, and no dictionary names.

133.3.1.3 Wi-Fi Protected Access for Public Access

The intrinsic encryption and authentication schemes defined in WPA may also prove useful for wireless Internet service providers (WISPs) offering Wi-Fi public access in “hot spots” where secure transmission and authentication are particularly important to users unknown to each other. The authentication capability defined in the specification enables a secure access control mechanism for the service providers and for mobile users not utilizing VPN connections.

133.3.1.4 Wi-Fi Protected Access in “Mixed Mode” Deployment

In a large network with many clients, a likely scenario is that access points will be upgraded before all the Wi-Fi clients. Some access points may operate in a “mixed mode,” which supports both clients running WPA and clients running original WEP security. While useful for transition, the net effect of supporting both types of client devices is that security will operate at the less secure level (i.e., WEP) common to all the devices. Therefore, the benefits of this mode are limited and meant to be used only during the transition period.

133.3.1.5 Wi-Fi Protected Access and IEEE 802.11i/WPAv2 Comparison

WPAv1 will be forward compatible with the IEEE 802.11i security specification currently still under development by the IEEE. WPAv1 is a subset of the current 802.11i draft, taking certain pieces of the 802.11i draft that are ready to go to market today, such as its implementation of 802.1x and TKIP. These features can also be enabled on most existing Wi-Fi certified products as a software upgrade. The main pieces of the 802.11i draft that are not included in WPAv1 are secure Independent Basic Service Set (IBSS), also known as ad hoc mode, secure fast handoff, secure de-authentication and disassociation, as well as enhanced encryption protocols for confidentiality and integrity such as Advance Encryption Standard in the Counter with CBC MAC Protocol (AES–CCMP) mode. These features are either not yet ready or will require hardware upgrades to implement. Publication of the IEEE 802.11i specification is expected by the end of 2004 and is already referred to as WPAv2. The comparison function table of WEP, WPAv1, and 802.11i/WPAv2 protocols is illustrated in Exhibit 133.5.

Similar to WPAv1, WPAv2-will have several flavors, such as WPAv2-Enterprise and WPAv2-Personal, as well as mixed mode WPAv2. WPAv2-Enterprise will be similar to WPAv1 and cover the full requirements for WPAv2, including support for 802.1x/EAP-based authentication and Pre-Shared Key (PSK).

EXHIBIT 133.5 Comparison of WEP, WPA, and 802.11i (WPAv2)

	Protocol		
Function	WEP	WPA	802.11i (WPAv2)
Cipher algorithm	RC4	RC4 with TKIP	AES (CCMP)
Encryption key size	40 bits 104 bits*	128 bits	128 bits
Authentication key size	—	64 bits	128 bits
IV size	24 bits	48 bits	48 bits
Per-packet key	Concatenated	Derived from mixing function	Not needed
Key uniqueness	Network	Packet, session, user	Packet, session
Data integrity	CRC-32	Michael	CCMP
Header integrity	—	Michael	CCMP
Replay protection	—	IV sequence	IV sequence
Key management	—	802.1x/EAP	802.1x/EAP

* Most of the WLAN vendors have implemented 104 bits as extensions to standard WEP.

WPAv2-Personal will require only the PSK method and not 802.1x/EAP-based authentication. In the mixed mode, WPAv2 will be backward compatible with WPAv1-certified products, which means that the WLAN access points should be able to be configured and to support WPAv1 and WPAv2 clients simultaneously.

133.4 802.1x and EAP Authentication Protocols Update

133.4.1 The Role of 802.1x

IEEE 802.1x is a specification for port-based authentication for wired networks. It has been extended for use in wireless networks. It provides user-based authentication, access control, and key transport. The 802.1x specification uses three types of entities: (1) the supplicant, which is the client; (2) the authenticator, which is the access point or the switch; and (3) the authentication server. The main role of the authenticator is to act as a logical gate to pass only authentication traffic through and block any data traffic until the authentication has successfully completed. Typically, authentication is done on the authentication server, which is, in most cases, the Remote Authentication Dial-In User Service (RADIUS) server. 802.1x is designed to be flexible and extensible so it relies on the Extensible Authentication Protocol (EAP) for authentication, which was originally designed for Point-to-Point Protocol (PPP) but was reused in 802.1x.

133.4.2 The Role of EAP

At the current point in time, there are several EAPs defined and implemented using the 802.1x framework available for deployment in both wired and wireless networks. The most commonly deployed EAPs include LEAP, PEAP, and EAP–TLS. In addition to these protocols, there are also some newer ones that try to address design shortcomings or the vulnerabilities present in the existing protocols.

133.4.3 xy-EAP: LEAP, MD5, TLS, TTLS, PEAP…

This section, after a quick introduction, focuses only on the delta from the chapter that can be found in the previous version of the *Information Security Management Handbook* (5th edition, Chapter 26). Details of all EAP methods can also be found on the IETF Web site.

The EAP protocol palette started with the development of the proprietary mechanisms such as LEAP in parallel with standard-defined EAP methods such as EAP–MD5 and EAP–TLS. By RFC 2284, the only mandatory EAP method is EAP–MD5; and although this is the easiest one to deploy, it is security-wise the least useful one. EAP–MD5 does not provide mutual authentication or dynamic key derivation. The EAP–TLS method is, from a security perspective, the most secure because it performs mutual authentication as well as dynamic key derivation via the use of public key cryptography with digital certificates for each communicating party. This makes it the most expensive one to deploy.

As a compromise between security and simplicity of deployment, several tunneling EAP methods such as EAP–TTLS and EAP–PEAP were developed. They all try to simplify the deployment by using a digital certificate for server authentication while using a password for user-side authentication, and protecting the user credentials exchange via a secure tunnel protected by the public key of the server.

Although at first sight tunneling EAP protocols seemed to be a viable solution for secure WLAN communication, analysis of the first generation of them gave the result that they are all vulnerable to a man-in-the-middle (MitM) attack.

133.4.4 Known "New" Vulnerabilities

133.4.4.1 Attack on the Tunneled Authentication Protocols

The two main problems with current tunneled authentication methods such as EAP–PEAP and EAP–TTLS, among the others, are that tunneling does not perform mutual authentication and that there is no evidence that tunnel endpoints and authentication endpoints are the same. This makes them vulnerable to MitM attacks, which are possible when one-way authenticated tunnels are used to protect communications of one or a sequence of authentication methods. Because the attacker has access to the keys derived from the tunnel, it can gain access to the network. The MitM attack is enabled whenever compound authentication techniques are used, allowing clients and servers to authenticate each other with one or more methods encapsulated within an independently authenticated tunnel. The simplest MitM attack occurs when the tunnel is authenticated only from the server to the client, and where tunneled authentication techniques are permitted both inside and outside a tunnel using the same credentials. The tunnel client, not having proved its identity, can act as a "man-in-the-middle," luring unsuspecting clients to authenticate to it, and using any authentication method suitable for use inside the tunnel. For the purposes of the MitM attack, it makes no difference whether or not the authentication method used inside the tunnel supports mutual authentication. The vulnerability exists as long as both sides of the tunnel are not required to demonstrate participation in the previous "tunnel authentication" as well as subsequent authentications, and as long as keys derived during the exchange are not dependent on material from all of the authentications.

Thus, it is the lack of client authentication within the initial security association, combined with key derivation based on a one-way tunnel authentication, and lack of "cryptographic binding" between the security association and the tunneled inner authentication method that enable the MitM vulnerability.

133.4.4.2 Attack on the LEAP

Now take a look at the one of the first EAP methods that made a compromise between deployment and security: Lightweight Extensible Authentication Protocol (LEAP) is a proprietary protocol developed by Cisco Systems. It has addressed both mutual authentication and dynamic key generation with simplicity of deployment all at once. It uses a simple username password mechanism for mutual authentication and, hence, is very simple to deploy. Based on the mutual challenges and responses, it generates a per-user, per-session unique key as is illustrated in Exhibit 133.6.

Compromise in simplicity of course has its price. Almost any password-based protection could be exposed to a dictionary attack. Considering that LEAP, due to its design, cannot provide support to OTP (One-Time Password) technology and considering that an average user typically does not invent, remember, or maintain strong passwords, it seems logical to think of LEAP key generation as vulnerable to a dictionary attack. With users using weak passwords and a knowledge of the LEAP key generation scheme, it is not that difficult to mount a dictionary attack on it. This was recognized at the very beginning, yet it became a serious threat once tools such as ASLEAP were publicly released on the Internet. The ASLEAP tool simply reads in an ASCII file of dictionary words and associated hashes

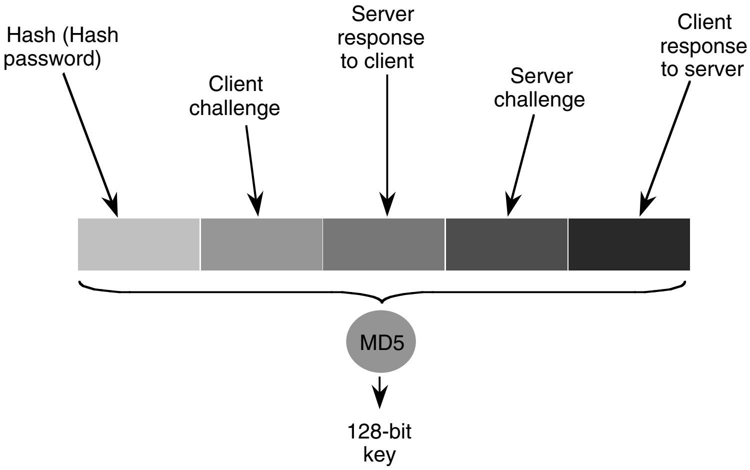

EXHIBIT 133.6 LEAP key generation.

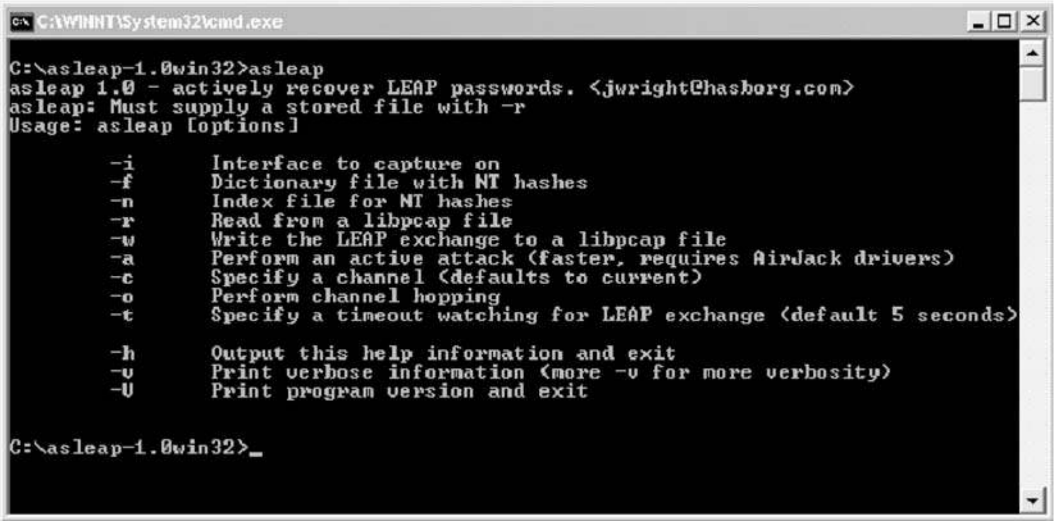
of those words and does brute-force LEAP challenge and response exchanges. Sample screen output from the tool is illustrated in Exhibit 133.7.

There are two follow-up protocols to solve the problems with MitM and dictionary attacks on current EAP methods that yet keep the promise of ease of deployment. These are the next generation of a PEAP: PEAPv2 and EAP–FAST.

133.4.5 PEAPv2

Protected EAP (PEAP) is an EAP authentication method that uses digital certificate authentication for the server side only; while for client-side authentication, PEAP can use any other authentication mechanism, such as certificates or simple username and password where username password exchange is done via a protected tunnel. Like multiple other first-generation tunneled authentication protocols that



```
C:\asleap-1.0win32>asleap
asleap 1.0 - actively recover LEAP passwords. <jwright@hasborg.com>
asleap: Must supply a stored file with -r
Usage: asleap [options]

        -i      Interface to capture on
        -f      Dictionary file with NT hashes
        -n      Index file for NT hashes
        -r      Read from a libpcap file
        -w      Write the LEAP exchange to a libpcap file
        -a      Perform an active attack (faster, requires AirJack drivers)
        -c      Specify a channel (defaults to current)
        -o      Perform channel hopping
        -t      Specify a timeout watching for LEAP exchange (default 5 seconds)

        -h      Output this help information and exit
        -v      Print verbose information (more -v for more verbosity)
        -V      Print program version and exit

C:\asleap-1.0win32>_
```

EXHIBIT 133.7 ASLEAP tool screen sample.

do not provide cryptographic binding between tunnel authentication and other EAP methods, PEAPv1 is also vulnerable to MitM attacks. This has been fixed in PEAPv2. PEAPv2, same as original PEAPv1, uses TLS to protect against rogue authenticators and against various attacks on the confidentiality and integrity of the inner EAP method exchange as well as providing EAP peer identity privacy. Other benefits of PEAPv2 include dictionary attack resistance and header protection via protected negotiation. PEAPv2 also provides fragmentation and reassembly, key establishment, and a sequencing of multiple EAP methods.

Because all sequence negotiations and exchanges are protected by the TLS channel, they are immune to snooping and MitM attacks with the use of cryptographic binding. To make sure that the same parties are involved in establishing the tunnel and EAP inner method, before engaging the next method to send more sensitive information, both the peer and server must use cryptographic binding between methods to check the tunnel integrity. PEAPv2 prevents a MitM attack using the keys generated by the inner EAP method in the cryptographic binding exchange in a protected termination section. A MitM attack is not prevented if the inner EAP method does not generate keys (e.g., in the case of EAP–MD5) or if the keys generated by the inner EAP method can be compromised.

Although PEAPv2 addresses MitM attacks and multiple other security issues, it still requires usage of public key cryptography, at least for server authentication as well as for tunnel protection. While public key cryptography does its function for protection, it also causes a slower exchange and requires a higher-performing CPU capability at the end node devices.

133.4.6 EAP–FAST

A protocol that avoids the use of public key cryptography can be more easily deployed on small, mobile, and skinny devices with low CPU power. Avoiding public key cryptography also makes roaming faster. Fast Authentication via Secure Tunneling (FAST) is the new IETF EAP method proposed to protect wireless LAN users from hacker dictionary or MitM attacks. EAP–FAST enables 802.11 users to run a secure network without the need for a strong password policy or certificates on either end of the client/server point connection. A simple feature and performance comparison of other tunneled authentication EAP protocols with EAP–FAST is illustrated in Exhibit 133.8.

TEAP–FAST is a client/server security architecture that encrypts EAP transactions within a TLS tunnel. While similar to PEAP in this respect, it differs significantly in the fact that EAP–FAST tunnel establishment is based on strong shared secrets that are unique to users. These secrets are called Protected Access Credentials (PACs). Because handshakes based on shared secrets are intrinsically faster than handshakes based on a PKI (public key infrastructure), EAP–FAST is significantly faster than solutions that provide protected EAP transactions based on PKI. EAP–FAST is also easy to deploy and allows smooth migration from LEAP due to the fact that it does not require digital certificates on the clients or on the server side.

133.4.6.1 How EAP–FAST Works

EAP–FAST is a two-phase mutual authentication tunneling protocol. Phase 1 uses a pre-shared secret named Protected Access Credential (PAC) to mutually authenticate client and server, and also to create the secure tunnel between them. PAC is associated with a specific Initiator ID (client) as well as with an Authority ID (server) and is used only during Phase 1 of the EAP–FAST authentication. As the Phase 2

EXHIBIT 133.8 Basic Comparison of EAP–TTLS, EAP–PEAP and EAP–FAST

	EAP Method		
Requirements	EAP-TTLS	EAP-PEAP	EAP-FAST
PKI infrastructure required	Yes	Yes	No
Suitable for skinny devices	No	No	Yes

exchange is protected by the Phase 1 mutually authenticated tunnel, it is sufficient for the inner EAP method to use a simple username and password authentication scheme. By deploying the tunnel endpoints' mutual authentication and acryptographically binding it to the following inner EAP method, EAP–FAST has successfully addressed the MitM attack, while secure tunnel protects the EAP exchange from a dictionary attack. Simplicity of deployment with EAP–FAST is achieved with both simple user authentication and a PAC. A PAC, although it looks like a certificate with fields such as Initiator ID and Authority ID, version, and expiration, completely removes the need for a PKI infrastructure and digital certificates. The PAC is the shared security credential generated by the server for the client and consists of the following three parts:

1. *PAC-Key:* a 32-byte key used by the client to establish the EAP–FAST Phase 1 tunnel. This key maps as the TLS pre-master-secret and is randomly generated by the server to produce a strong entropy key.
2. *PAC-Opaque:* a variable-length field sent to the server during EAP–FAST Phase 1 tunnel establishment. The PAC-Opaque can only be interpreted by the server to recover the required information for the server to validate the client's identity.
3. *PAC-Info:* a variable-length field used to provide the identity of an authority or PAC issuer and optionally the PAC-Key lifetime.

Details of the PAC are illustrated in Exhibit 133.9.

On the other hand, the PAC also needs provisioning. PAC provisioning to the client can be done manually out-of-band through some external application tool, or dynamically via the in-band PAC-Auto-Provisioning mechanism defined in the EAP–FAST protocol specification. Overall, the two major differences between EAP–FAST and any other PKI-based tunneled EAP method is that EAP–FAST has only one step provisioning of security credentials, and lower power consumption due to the fact that it does not require use of the PKI-based authentication, which makes it very attractive for deployment on low end devices as already illustrated in Exhibit 133.8.

133.4.7 EAP Methods Functionality Comparison

With the invention of new EAP methods as well as their scrutiny against new and old security vulnerabilities, the job of information security professionals with regard to WLAN technology and its security aspects did not get much easier. The choice of which EAP method to deploy is most of the time not based on its security, but rather on the risk acceptance and most of all on the functionality that can

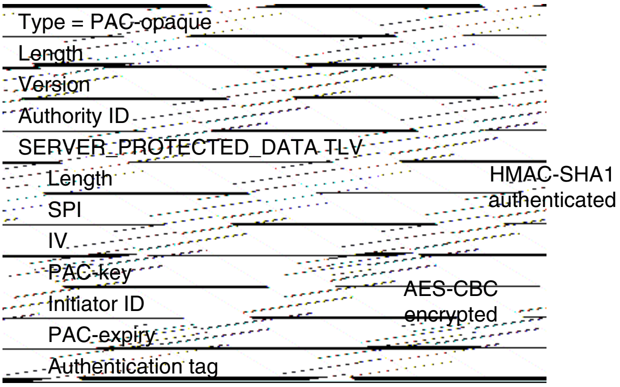


EXHIBIT 133.9 Protected access credential (PAC) details.

EXHIBIT 133.10 A Detailed Comparison of EAP Methods

Feature/Vulnerability	EAP Method				
	Cisco LEAP	EAP–FAST	Microsoft PEAP (MS–CHAPv2)	Cisco PEAP (EAP–GTC)	EAP–TLS
Single sign-on (MS AD)	Yes	Yes	Yes	No	Yes

Susceptible to MitM attacks	No	No	Yes	Yes	No
Deployment complexity	Low	Low	Medium	Medium	High

* The EAP–FAST protocol has capability to support OTP while Cisco Systems' initial implementation does not support it.

be achieved with it. Last but certainly not the least decision point is the availability of the specific products on the market that implement a certain EAP method. While the availability of products on the market will change over time, the information security professional should be aware of the security function brought by each of the EAP methods. A summarized view that compares features, security vulnerabilities, as well as deployment complexity of the latest EAP methods is given in Exhibit 133.10.

133.5 Interoperability

The main task of standards is to drive interoperability. However, interpretation of the standard specifications or, in particular, parts that are mandatory to implement versus optional ones are arguments why there is a need for interoperability testing and accreditation. The Wi-Fi Alliance has achieved significant results on the market with Wi-Fi technology interoperability testing and has successfully launched the Wi-Fi logos, which are illustrated in Exhibit 133.11.

It is now repeating the success with new WLAN security specifications by defining and mandating the WPAv1 (and soon WPAv2) as a part of the same accreditation. It is important, however, to understand that interoperability testing cannot possible test every single combination of features but rather is limited to a subset of the existing ones. An example of that is WPAv1, which mandates the

use of TKIP and Michael MIC while it leaves open which EAP methods to be used, so the interoperability testing is done only with the most pervasive methods such as EAP–TLS for enterprise mode or PSK for home use. The WPAv2 specification will include on top of that minimum the new AES crypto suite interoperability testing as well as backward compatibility modes. Some countries, on the other hand, due to economical or political reasons, have decided to take their own path in addressing WLAN security issues. On May 12, 2003, China issued two WLAN security standards that became compulsory on December 1, 2003. The information security portion of these standards specifies the WLAN Authentication and Privacy Infrastructure (WAPI), which appears to differ significantly and is incompatible with WPA and 802.11i. Many details required for implementation of the standard are not fully defined, including encryption, authentication, protocol interfaces, and cryptographic module APIs. Up to the current point in time, the Wi-Fi Alliance efforts to obtain the details of the WAPI specification have not been successful, which unfortunately makes WAPI specification-based products completely out of the interoperability scope of the Wi-Fi Alliance.

133.6 Future Directions

133.6.1 WLAN Mobility and Roaming

Although one could think of WLAN technology as mobile, actually it is not. A particular WLAN client associated to a particular WLAN Access Point (AP) is mobile only within the range of that particular AP. If it would require moving and associating to an AP from another vendor or different service provider, this would not be possible because the 802.11 specification does not stipulate any particular mechanism for roaming. Therefore, it is up to each vendor to define an algorithm for its WLAN clients of how to make roaming decisions. The basic act of roaming is making a decision to roam, followed by the act of locating a new AP to roam to. This scenario can involve reinitiating a search for an AP, in the same manner the client would when it is initialized, or another means, such as referencing a table built during the previous association. The timing of WLAN roams also varies according to vendor, but in most cases is less than one second, and in the best cases, less than 200 milliseconds.

133.6.2 Fast and Secure Roaming

The two main goals of roaming include being fast and being secure. While the speed of roaming is important for delay-sensitive applications such as Voice-over-IP, the security aspects of roaming are even more important. Speed and security are also technically opposite requirements most of the time. While we have seen that security solutions for the 802.11 WLAN technologies are rapidly progressing, combining them with roaming presents another challenge for a centralized key management structure, such as is illustrated in Exhibit 133.12.

The roaming mobile device, which has already associated and finished its secure association with AP1, and moving to an AP2 would need to restart all the security session negotiations, which is both a time-consuming and CPU-expensive task. This would not be necessary if there is a third party keeping all the necessary security information about the existing session of a particular mobile device with AP1.

Both topics—the roaming and the security of the roaming—are thus far only future standardization topics that depend only on the particular vendor implementations. Fast Secure Roaming is an example of the proprietary solution coming from Cisco Systems that follows the model of centralized key management. With Fast Secure Roaming, authenticated client devices can roam securely at layer two from one access point to another without any perceptible delay during re-association because the central Wireless Domain Services (WDS) device acts as the centralized key management server that keeps and distributes necessary security session information to all the APs involved in the roaming process. That releases the client from running the CPU-expensive security portion of the re-association process and saves the time necessary to gain speed in the overall secure roaming process.

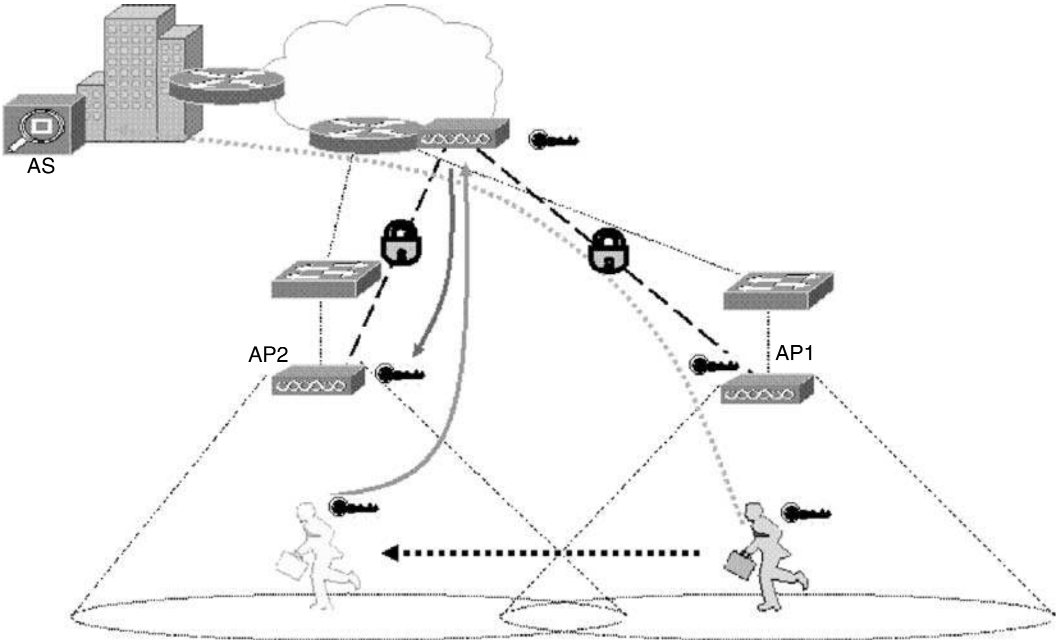

EXHIBIT 133.12 Roaming and security.

133.7 Securing WLAN with IPSec or SSL VPN

With all the security issues surrounding WLAN technology, relying on another technology such as the VPN to help solve security issues seems to be at first sight a viable solution—especially in the case of the growing interest in Web VPN-based technology that promises ease of use and no additional client installation. It is important, however, to understand that even VPN technology has its own limitations. In case of an IPSec, for example, it is not possible to transport multicast IP traffic, while in case of a Web VPN there is a limitation as to the number and type of supported applications. It is also important to understand that the integrity, authentication, and confidentiality functions in both VPN scenarios are done in software most of the time; this could be either a bottleneck or even not supported on low CPU handheld devices. Last but not least, while roaming with a Web-based VPN does not seem to be an issue, roaming with an IPSec-based VPN opens a can of worms with security issues and a special Mobile IP client stack underlying the IPSec client that requires the IP Home and Foreign Agent capable IP gateway devices. These are just some of the issues that must be considered before offloading the security role from WLAN technology to VPN technologies.

133.8 Summary

This chapter presented a brief historical overview of the 802.11 WLAN security issues with the sole purpose of helping the information security professional understand the current and future developments of security solutions within the 802.11 WLAN technology space. Despite that fact that WLAN technology had a few security "hiccups" at the beginning, it is rapidly spreading around and is already present in almost every modern network environment. Security solutions, such as WPAv1, are finding ground, new easy-to-deploy protocols such as EAP–FAST are already appearing on the horizon, and the future security specification WPAv2 is coming soon. In that entire matrix, it is not trivial to look for a proper solution without understanding the building blocks of the WLAN security technology and the threats on the WLAN protocols that do not address them properly. TKIP is on one side through WPAv1 addressing all known WEP vulnerabilities, while 802.1x and EAP methods are delivering promised user-level authentication together with a key exchange mechanism. Some of the EAP methods, such as LEAP, were already exposed to publicly available hacking tolls. Others, such as PEAP, which is vulnerable to the man-in-the-middle attack, got fixes with cryptographic binding of the tunnel and inner EAP authentication method on time and before the exploits were available. It is now on the shoulders of the information security professional to recognize the method, protocol, or solution as it is being implemented in a particular vendor solution and to do a proper risk analysis of the exposures versus ease of use before deploying it in any modern network environment.

133.9 Acronyms

AES: Advanced Encryption Standard
CBC: Cipher block chaining
CCMP: Counter with CBC MAC Protocol
CRC: Cyclic redundancy check
CSMA/CD: Carrier Sense Multiple Access Collision Detect
EAP: Extensible Authentication Protocol
EAP-FAST: Extensible Authentication—Fast Authentication via Secure Tunneling
GTC: Generic token card
IBSS: Independent Basic Service Set
IV: Initialization Vector
LEAP: Lightweight Extensible Authentication Protocol
MAC: Message Authentication Code
MD5: Message Digest 5
MIC: Message Integrity Check
MitM: Man-in-the-middle attack
MS-CHAPv2: Microsoft Challenge Handshake Authentication Protocol version 2
OTP: One-time password
PAC: Protected Access Credential
PEAP: Protected Extensible Authentication Protocol
PKI: Public key infrastructure
PPP: Point-to-Point Protocol
PSK: Pre-Shared Key
RADIUS: Remote Authentication Dial-In User Service
SSID: Service Set Identifier
SSL: Secure Sockets Layer
TLS: Transport Layer Security
TLV: Type length value
TTLS: Tunneled Transport Layer Security
VPN: Virtual private network
WAPI: WLAN Authentication and Privacy Infrastructure, Chinese specification
WEP: Wired Equivalent Privacy
WISP: Wireless Internet service provider
WLAN: Wireless local area network
WPA: Wi-Fi Protected Access

134 Understanding SSL

Chris Hare

Secure Socket Layer (SSL) is a common term in the language of the network. Users, administrators, and security professionals alike have come to learn the benefits of SSL. However, like so many technology elements, most do not understand how it works. This chapter examines what SSL is, how it works, and the role of certificates.

134.1 What Is SSL?

SSL is a method of authenticating both ends of a communication session and providing encryption services to prevent unauthorized access or modification of the data while in transit between the two endpoints. SSL is most commonly associated with protecting the data transferred in a Web browser session, although SSL is not limited to just a Web browser.

SSL is widely used in financial, healthcare, and electronic commerce applications. With the advent of SSL, users can now access banking records, make payments, and transfer funds through a financial institution's Web sites. Likewise, users can access healthcare information and even make online purchases from a favorite provider. All of this is possible without SSL; however, with the authentication and encryption capabilities, purchasers can provide their payment information immediately.

Aside from protecting Web-based transactions and other protocols, SSL is also being used to establish virtual private network (VPN) connections to a remote network.

Many network protocols in use today offer little or no protection of the data, allowing information to be transferred "in the clear." Consequently, confidentiality and integrity of the data processed in the protocol is a major concern for users and security professionals. Without additional protection, data protection is totally reliant upon the underlying network design, which itself is prone to problems.

The phenomenal growth of the Internet and its use for E-commerce, information sharing, government, and banking indicates more and more confidential information is being transferred over the Internet than ever before. SSL addresses the confidentiality issue by encrypting the data transmission between the client and server. Using encryption prevents eavesdropping of the communication. Additionally, the server is always authenticated to the client and the client may optionally authenticate to the server.

The intent of the SSL protocol was to provide higher-level protocols, such as Telnet, FTP, and HTTP, increased protection in the data stream. The protection is afforded by encapsulating the higher-level protocol in the SSL session. When establishing the connection between the client and the server, the SSL layer negotiates the encryption algorithm and session key, in addition to authenticating the server. The server authentication is performed before any data is transmitted, thereby maintaining the privacy of the session.

Developed by Netscape Communications Corporation, SSL was first proposed as an Internet Request for Comments Draft in 1994. Although never accepted as an Internet Standard by the IETF, SSL has been implemented in many commercial applications, and several open source implementations are available today.

134.2 Server Certificates

Enabling SSL requires that the application server be capable of accepting an SSL request and the existence of a server certificate. Without the server certificate, SSL is not available, even if the server is configured to offer it. The server certificate contains both public and private key components. The public certificate is provided to the client during the SSL handshake and the private component is kept on the server to verify requests and information encrypted with the server's public certificate.

The process of generating an SSL certificate is beyond the scope of the discussion. However, SSL certificates are available from a variety of certificate providers as well as OpenSSL implementations.

134.3 The SSL Handshake

There are two major phases in the SSL handshake. The first establishes the connection and authenticates the server, and the second authenticates the client. During phase 1, the client initiates the connection with the SSL server by sending a CLIENT-HELLO message.

134.3.1 The CLIENT-HELLO Message

The CLIENT-HELLO message contains a challenge from the client and the client's cipher specifications. If the client attempts to establish a connection with the SSL server using any message other than CLIENT-HELLO, it must be considered an error by the server, which in turn refuses the SSL connection request.

Within the CLIENT-HELLO message, the client specifies the following information:

- The client's SSL version
- The available cipher specifications

- A session ID if one is present
- A challenge, used for authentication

The session ID is a unique identifier indicating that the client has previously communicated with the server. If the session ID is still in the client's and the server's cache, there is no need to generate a new master key, because both ends still have a session ID from a previous connection. If the session ID is not found, then a new master key is required.

Once the client has sent the CLIENT-HELLO message to the server, the client suspends while awaiting the corresponding SERVER-HELLO message.

134.3.2 The SERVER-HELLO Message

When the server receives the CLIENT-HELLO message, it examines the provided data before responding. The server examines the parameters in the client's request, specifically to verify that it will support one of the ciphers and the client's SSL version. If the server cannot, it responds with an ERROR message to the client.

If the server can support the client's SSL version and one or more of the provided ciphers, it responds with a SERVER-HELLO message. The response includes the following information:

- The server's signed certificate
- A list of bulk ciphers and specifications
- A connection ID
- A response for the supplied SESSION ID if provided by the server

The server's signed certificate contains the server's public key, which will be used later during the connection phase if the client generates a new master key. The server provides:

- The bulk ciphers and specifications so both ends of the connection can agree upon the cipher to use in the communication
- The connection ID, which is a randomly generated value used by the client and server for a single connection

The server uses the provided SESSION ID to see if the session ID is found in the server's cache. If the session ID is not found, the server provides its certificate, and cipher specifications back to the client. The client then determines if a new master key is needed to continue the communications.

134.3.3 The CLIENT-MASTER-KEY Message

The client determines if a new master key is required, based on the response from the server for the provided session ID. The requirement for a new master key is based on the server responding positively to the provided SESSION ID, meaning that the data is in the server's cache. If the SESSION ID is not in the server's cache, then a new master key is required.

134.4 Generating a New Master Key

If a new master key is needed, the client generates the new master key using the data provided by the server in the SERVER-HELLO message and sends the new master key back to the server using a CLIENT-MASTER-KEY message. The CLIENT-MASTER-KEY message contains the following elements:

- The selected cipher chosen from the list provided by the server
- Any elements of the master key in cleartext

- An element of the master key encrypted using the server's public key
- Any data needed to initialize the key algorithm

The client uses the public key provided in the server's certificate to encrypt the new master key. After the server has received the new master key, it decrypts it using the private key corresponding to the server certificate. The master key consists of two components, one of which is transmitted to the server in the clear, and the other that is sent encrypted. The amount of master-key data sent in the clear depends on the encryption cipher in use, as explained in the section entitled "Determining the Encryption Cipher" later in this chapter.

134.4.1 Keys and More Keys

If no new master key is required, both ends of the connection generate new session keys using the existing master key, the challenge provided by the client, and the connection ID provided by the server.

The client and server use the master key to generate the session key pairs for this session. There are a total of four session keys generated, two for each end of the communication, as shown in Exhibit 134.1.

The draft Internet Request for Comments (RFC) for SSL represents the master key as a function between the server and client portions of the communications exchange. That is to say, the keys are generated using the following method:

```
CLIENT-READ-KEY=HASH(MASTER-KEY, "0," CHALLENGE, CONNECTION-ID)
SERVER-WRITE-KEY=HASH(MASTER-KEY, "0," CHALLENGE, CONNECTION-ID)
CLIENT-WRITE-KEY=HASH(MASTER-KEY, "1," CHALLENGE, CONNECTION-ID)
SERVER-READ-KEY=HASH(MASTER-KEY, "1," CHALLENGE, CONNECTION-ID)
```

The elements of the function are:

- The HASH is the cipher-specific function used to generate the keys.
- MASTER-KEY is the master key already exchanged between the client and server.
- CHALLENGE is the challenge data provided by the client in the CLIENT-HELLO message.
- CONNECTION-ID is the connection identifier provided by the server in the SERVER-HELLO message.

The "0" and "1" tell each side what key to generate. Notice the CLIENT-READ-KEY and the SERVER-WRITE-KEY both use the same "0" identifier. If they did not, the generated keys would not be related to each other and could not be used to encrypt and decrypt the data successfully. While the server is generating session keys, the client performs the same function, eliminating the need for key exchange across an untrusted network. The available ciphers are discussed later in the chapter.

134.4.2 The SERVER-VERIFY Message

Once the master key is decrypted, the server responds with a SERVER-VERIFY message. The SERVER-VERIFY response is sent after new session keys have been generated with an existing master key, or after

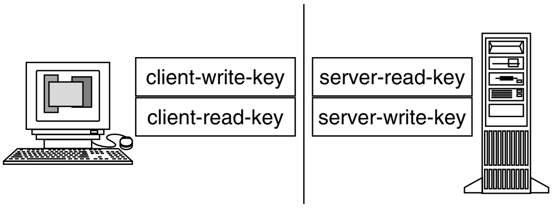

EXHIBIT 134.1 Two pairs of SSL keys are generated.

the client has sent a specific CLIENT-MASTER-KEY request. Consequently, not every SSL handshake requires an explicit CLIENT-MASTER-KEY message.

The SERVER-VERIFY message contains an encrypted version of the challenge originally sent by the client in the CLIENT-HELLO message. Only the authentic server has the private key matching the certificate, the authenticity of the server has been validated, and only the authentic server can encrypt the challenge properly using the session keys. Consequently, these two actions verify the authenticity of the server. The transaction to this point is illustrated in Exhibit 134.2.

If the client and the server cannot agree on the ciphers to use in the communication, the client returns an ERROR message to the server.

Once the keys have been generated and the server responds with the SERVER-VERIFY message, the server has been verified and phase 2 is started.

Phase 2 consists of authenticating the client, as the server is authenticated in phase 1. The server sends a message to the client requesting additional information and credentials. The client then transmits them to the server or, if it has none, responds with an ERROR response. The server can ignore the error and continue, or stop the connection, depending on how the implementation is configured.

134.4.3 The CLIENT-FINISHED and SERVER-FINISHED Messages

When the client has finished authenticating the server, it sends a CLIENT-FINISHED message with the connection ID encrypted using the client's write key (client-write-key). However, both ends of the connection must continue to listen for and acknowledge other messages until they have both sent and received a FINISHED message. Only then has the SSL handshake completed (see Exhibit 134.3).

In most cases, the SSL handshake is completed without any further effort, as rarely does the server authenticate the client. Client authentication is typically through client certificates, which are discussed later in the chapter.

134.5 Determining the Encryption Cipher

The encryption cipher is negotiated between the client and the server, based upon the cipher specifications provided in the CLIENT-HELLO and SERVER-HELLO messages. The available ciphers are:

- RC4 and MD5
- 40-bit RC4 and MD5

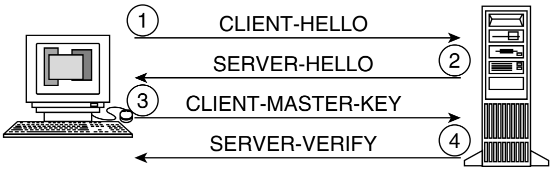

EXHIBIT 134.2 The SERVER-VERIFY message.

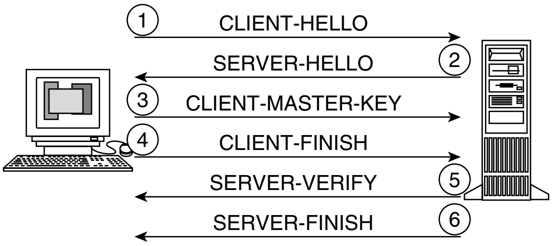

EXHIBIT 134.3 The full SSL handshake.

- RC2 with CBC and MD5
- 40-bit RC2 with CBC and MD5
- IDEA with CBC and MD5

The MD5 128-bit key is not used in the encryption. The actual encryption algorithm used in the SSL data transfer is RC2, RC4, or IDEA, with key sizes ranging from 40 to 128 bits. The actual length of the encryption key depends on the cipher negotiation. The use of cryptography and specific key lengths is often controlled by international legislation, affecting the available ciphers.

While this is not an exhaustive list and other encryption protocols may be supported, the available ciphers offer protection of the data. However, the 40-bit ciphers operate differently. When using the RC4 and RC2 ciphers, the entire session key is sent encrypted between the client and the server. However, in SSL Version 1, the 40-bit ciphers were limited to a maximum key length of 40 bits. Consequently, it is possible for the client and the server not to have a cipher they can agree upon, meaning they cannot communicate.

With SSL Version 2, the key became 128 bits regardless of implementation. However, with the EXPORT40 implementations, only 40 bits of the session key are encrypted—the other 88 bits are not.

A discussion of the encryption algorithms used is beyond the scope of this discussion; the reader is urged to review the appropriate cryptography references for information on ciphers.

134.6 Client Certificates

Unlike server certificates that are involved in phase 1 of the SSL handshake, client certificates are part of phase 2. The REQUEST-CERTIFICATE and CLIENT-CERTIFICATE messages are used during phase 2.

Client certificates must be generated or acquired and installed in the application. The process of certification acquisition and installation is outside the scope of this discussion.

134.6.1 The REQUEST-CERTIFICATE Message

The REQUEST-CERTIFICATE message is sent from the server to the client when the server has been configured to require this authentication element. The message contains:

- The desired authentication type
- A challenge

The desired authentication types are:

```
SSL_AT_MD5_WITH_RSA_ENCRYPTION
```

This message requires that the client responds with a CLIENT-CERTIFICATE message (see the following section) by constructing an MD5 message digest of the challenge and encrypting it with the client's private key. The server can then validate the authenticity when the CLIENT-CERTIFICATE message is received by performing the same MD5 digest functions, decrypting the data sent using the client's public key, and comparing it with its own MD5 digest. If the values match, the client has been authenticated.

134.6.2 The CLIENT-CERTIFICATE Message

The CLIENT-CERTIFICATE message, sent in response to a REQUEST-CERTIFICATE from the server, provides the information for the server to authenticate the client. The CLIENT-CERTIFICATE message contains the following information:

- The certificate type
- The certificate data
- The response data

However, if the client has no certificate installed, the client provides a NO-CERTIFICATE-ERROR to the server, generally meaning that the connection is refused. The certificate type used on the client side is generally an X.509 signed certificate provided by an external certificate authority.

When assembling the response to the server, the client creates a digital signature of the following elements:

- The CLIENT-READ-KEY
- The CLIENT-WRITE-KEY
- The challenge data from the REQUEST-CERTIFICATE message
- The server's signed certificate from the SERVER-HELLO message

The digital signature is encrypted with the client's private key and transmitted to the server. The server can then verify the data sent and accept the authenticity if the data is valid.

Other authentication types can be used between the client and the server and can be added by either defining a new authentication type or by changing the algorithm identifier used in the encryption engines.

134.7 Message Flow

To clarify the discussion to this point, the following examples illustrate the message flow between the client and the server—the handshake. As is evident from discussing the various messages in the protocol, there are several variations possible in establishing the connection between the client and the server.

134.7.1 Session Identifier Available

This is the simplest example of message flows in the SSL transaction. It occurs when the client and the server have the session in their cache (see Exhibit 134.4).

1. The client initiates the connection and sends the CLIENT-HELLO message, which includes the challenge, session identifier, and cipher specifications.
2. The server responds with a SERVER-HELLO message and provides the connection identifier and server hit flag.
3. The client sends the server a CLIENT-FINISH message with the connection identifier and the client-write-key. Remember that the connection identifier is encrypted with the client-write-key.
4. The server provides the original challenge from the client encrypted with the server-write-key in the SERVER-VERIFY message.

And finally, the server transmits the SERVER-FINISH message with the session identifier encrypted with the server write key.

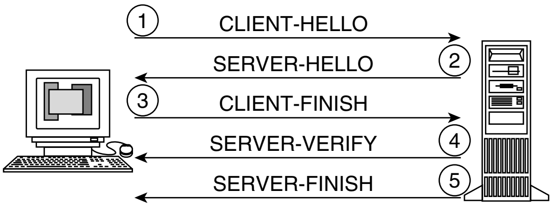

EXHIBIT 134.4 SSL session identifier available.

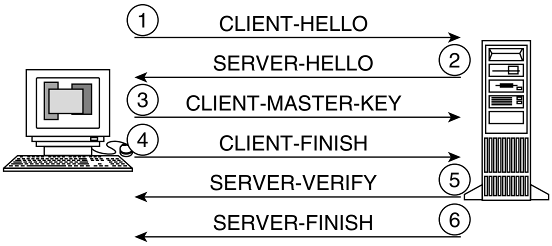

EXHIBIT 134.5 No session identifier.

134.7.2 No Session Identifier Available

This situation occurs when:

- The client has an identifier but the server does not.
- Neither the client nor the server has an identifier.

In this scenario (see Exhibit 134.5), the client connects and because there is no existing session identifier, the node must generate a new master key.

1. The client initiates the connection and sends the CLIENT-HELLO message, which includes the challenge and cipher specifications.
2. The server responds with a SERVER-HELLO message and provides the connection identifier, server certificate, and cipher specification.
3. The client selects the cipher, generates a new master key, and sends it to the server after encrypting it with the server's public key. This is the CLIENT-MASTER-KEY message.
4. The client sends the server a CLIENT-FINISH message with the connection identifier and the client-write-key. Remember that the connection identifier is encrypted with the client-write-key.
5. The server provides the original challenge from the client encrypted with the server-write-key in the SERVER-VERIFY message.

Finally, the server transmits the SERVER-FINISH message containing the new session identifier encrypted with the server-write-key.

134.7.3 The Entire Handshake Illustrated

This final example, shown in Exhibit 134.6, illustrates an SSL connection where the client must provide the new master key, new session keys are generated on both systems, and the server requests a client certificate.

1. The client initiates the connection and sends the CLIENT-HELLO message, which includes the challenge and cipher specifications.
2. The server responds with a SERVER-HELLO message and provides the connection identifier, server certificate, and cipher specification.
3. The client selects the cipher and generates a new master key, and sends it to the server after encrypting it with the server's public key. This is the CLIENT-MASTER-KEY message.
4. The client sends the server a CLIENT-FINISH message with the connection identifier and the client-write-key. Remember that the connection identifier is encrypted with the client-write-key.
5. The server provides the original challenge from the client encrypted with the server-write-key in the SERVER-VERIFY message.
6. The server sends the REQUEST-CERTIFICATE to the client, including the authentication type and challenge, encrypted with the server-write-key.
7. The client responds to the server, sending a CLIENT-CERTIFICATE message with the certificate type, the actual certificate, and the response to the challenge in the REQUEST-CERTIFICATE. All of the data is encrypted using the client-write-key.

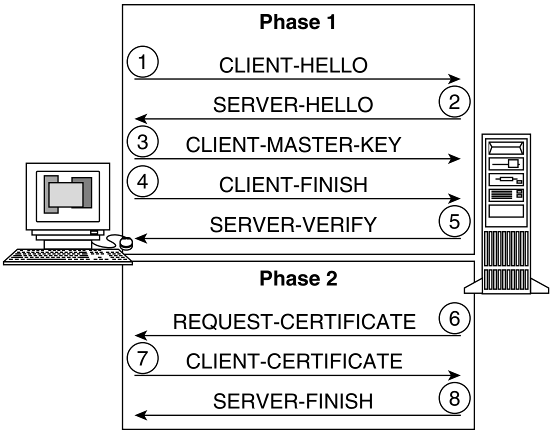

EXHIBIT 134.6 The complete SSL handshake.

Finally, the server transmits the SERVER-FINISH message containing the new session identifier encrypted with the server-write-key.

134.8 Is It All Encrypted?

The answer is no. Not all information during the handshake is actually sent encrypted, depending upon the phase of the handshake. Specifically, the following elements of the handshake are not encrypted:

- The CLIENT-HELLO message
- The SERVER-HELLO message
- The CLIENT-MASTER-KEY message
- The CLIENT-FINISHED
- SERVER-HELLO
- SERVER-FINISHED

Despite the messages that are not encrypted, sufficient information is sent in encrypted form so as to make it difficult to defeat. The encrypted messages include:

- SERVER-VERIFY
- CLIENT-CERTIFICATE
- REQUEST-CERTIFICATE

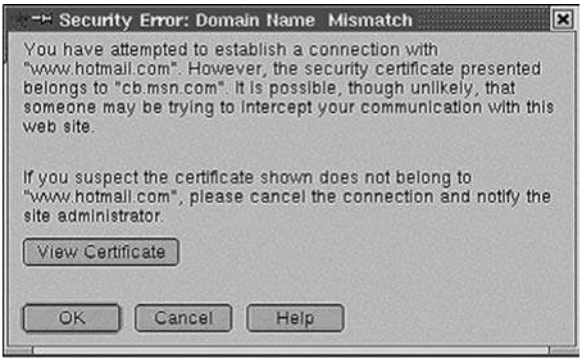
Depending on the situation, error messages can be encrypted or in cleartext, as described later in the chapter.

Once the session has been established, all further communications between the client and the server are encrypted.

134.9 Error Handling

Several errors can occur during the negotiations. These errors include:

- *NO-CIPHER-ERROR*. The client generates this error to the server indicating that there are no ciphers or key sizes supported by both ends of the connection. When this error occurs, the connection fails and cannot be recovered.

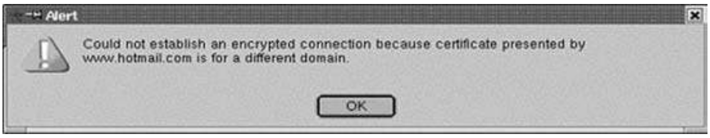


Security Error: Domain Name Mismatch

You have attempted to establish a connection with "www.hotmail.com". However, the security certificate presented belongs to "cb.msn.com". It is possible, though unlikely, that someone may be trying to intercept your communication with this web site.

If you suspect the certificate shown does not belong to "www.hotmail.com", please cancel the connection and notify the site administrator.

EXHIBIT 134.7 Domain name mismatch error.



Alert

Could not establish an encrypted connection because certificate presented by www.hotmail.com is for a different domain.

EXHIBIT 134.8 SSL connection is not established.

- *NO-CERTIFICATE-ERROR*. When the server requests a certificate from the client and there is no certificate available, the client returns this error message to the server. The server can choose to continue with the connection, depending on the local configuration.
- *BAD-CERTIFICATE-ERROR*. This error is generated when the certificate cannot be verified by the receiving party due to a bad digital signature or inappropriate information in the certificate. A common example of bad information in the certificate is when the host name in the certificate does not match the expected name. This error can be recovered and is not uncommon. Exhibit 134.7 illustrates the results when a Web client cannot verify a server certificate. The user is presented with a window similar to this, where he must choose to accept the certificate or not. Should the user choose not to accept the certificate, a window similar to that shown in Exhibit 134.8 would be shown to the user. The connection between the client and the server is not established.
- *UNSUPPORTED-CERTIFICATE-TYPE-ERROR*. Occasionally a server or client may receive a certificate that it does not have support for. This error is returned to the originating system.

134.10 After the Handshake

Once the handshake is complete, the client and the server exchange their messages using the services of the SSL transport. Because SSL allows higher-level protocols to protect their data while in transport, SSL has been used for a variety of purposes, including protecting HTTP-based traffic and SSL VPN sessions.

134.10.1 SSL and the Web

The most well-known use of SSL is the protection of HTTP (World Wide Web) data when traveling across an untrusted network or carrying sensitive information. For example, E-commerce, secure online ordering, and bill payments are all performed on the Web using SSL as the protection layer.

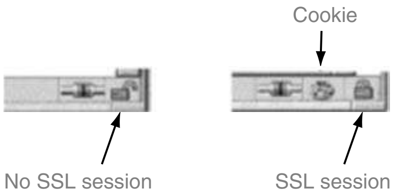


EXHIBIT 134.9 SSL on the Web.

The Web server must be capable of supporting SSL connections, and must have been properly configured with a server certificate, also known as a server-side certificate. The client specifies a Uniform Resource Locator (URL) with a https://prefix, indicating that the session is to be encapsulated within SSL.

The client contacts the Web server and the SSL handshake occurs. Once the SSL connection is established, the user sees a "key" or "lock" appear in the corner of their Web browser as seen in Exhibit 134.9.

Exhibit 134.9 illustrates a Web browser without an SSL connection, and the familiar lock indicating an SSL session has been established. Some Web servers will use SSL only for the specific transactions where protection is required, such as login forms, and credit card and E-commerce transactions.

134.10.2 SSL Tunnels

More recently, SSL has been used as the transport provider for virtual private networking. Commercial and open source software providers are including SSL VPN support in their products. One example is *stunnel*, an open source SSL VPN implementation for UNIX and Microsoft Windows-based systems.

SSL VPN solutions provide the same features as normal SSL applications, except the VPN implementation allows tunneling of non-SSL aware applications through the VPN to the target server or network. The VPN technology provides the encryption component, with no changes to the application required.

134.11 Attacking SSL

Like all network protocols and services, there are specific attacks that can be used against the SSL protocol or implementations of the protocol. Bear in mind that a weakness found in a specific implementation of the SSL protocol does not itself mean that SSL is flawed. What it means is that the implementation may be vulnerable to a specific attack or weakness, which does not inherently mean that all SSL implementations are vulnerable. For example, OpenSSL has been the subject of several attacks against its implementation of the protocol.

The attacks identified here do not constitute an all-inclusive list, but rather they represent some of the more commonly used attack methods that could be used to circumvent SSL.

134.11.1 Cipher Attacks

Because SSL uses several different technologies for the underlying encryption, attacks against the cryptographic engine or keys are inevitable. If a successful attack is found against any of the available cryptographic engines, SSL is no longer secure.

Consequently, any of the available methods of cryptographic analysis can be used. This includes recording a specific communications session and expending many CPU cycles to crack either the session or public key used.

Because many SSL sessions use 128-bit keys, the cost of launching an attack against a 128-bit key is still quite high. As new protocols and key lengths are supported within SSL, the work factor to defeat the cryptography increases.

134.11.2 Cleartext

Cleartext attacks are a fact of life with the SSL implementation. Because many messages in SSL are the same, such as HTTP GET commands, an attacker can build a dictionary where the entries are known values of specific words or phrases. The attacker then intercepts a session and compares the data in the session with the dictionary. Any match indicates the session key used and the entire data stream can be decrypted.

The work factor of the cleartext attack is quite high. For each bit added to the key, the dictionary size increases by a factor of two. This makes it virtually impossible to fabricate a dictionary with enough entries to defeat a 128-bit key using a cleartext attack methodology.

Given the high work factor associated with a cleartext attack, a brute-force attack, even with its high work factor, is considered the cheaper of the two. However, brute-force attacks also take an incredible amount of CPU horsepower and time. Even with today's high-speed computing equipment, the work factor associated with a brute-force attack against a 128-bit key is still considered an infinitely large problem.

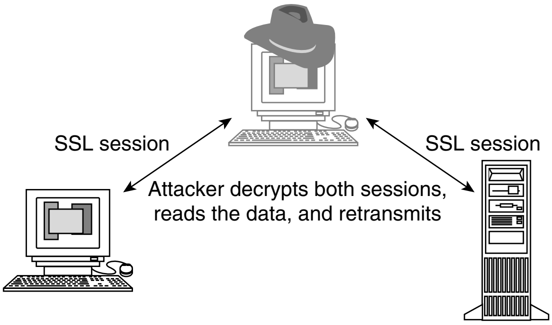
134.11.3 Replay

Replay attacks involve the attacker recording a communication between the client and the server and later connecting to the server and playing back the recorded messages. While a replay attack is easy to originate, SSL uses a connection ID that is valid only for that connection. Consequently, the attacker cannot successfully use the recorded connection information. Because SSL uses a 128-bit value for the connection ID, an attacker would have to record at least 2^64 sessions to have a 50 percent chance of getting a valid session ID.

134.11.4 Man in the Middle

The man-in-the-middle attack (Exhibit 134.10) works by having the bad guy sit between the client and the server, with the attacker pretending to be the real server. By fooling the client into thinking it has connected to the real server, the attacker can decrypt the messages sent by the client, collect the data, and then retransmit it to the real server through an SSL session between the attacker and the real server.

The use of server certificates makes the man-in-the-middle attack more difficult. If the certificate is forged to match the real server's identity, the signature verification will fail. However, the attacker could create his or her own valid certificate, although it would not match the real server's name. If the certificate



SSL session
SSL session
Attacker decrypts both sessions, reads the data, and retransmits

EXHIBIT 134.10 The man-in-the-middle attack.

matches the attacker but does not match the name, the user will see a window in his browser similar to Exhibit 134.7. If the user ignores the message, and many do, he will not be aware of the connection problem.

Consequently, organizations would do well to inform their users of the connection problems and issues associated with SSL and teach them to report problems when they are encountered. It is far better to report a configuration error than to realize later that the data was compromised.

134.12 The Cost of Encryption

Encryption of any form has a cost in performance—SSL included. If the SSL server experiences a high level of traffic, then the server itself may suffer performance degradation due to the load of performing the SSL encryption and decryption. This performance degradation can be addressed in a number of ways.

The first possibility is to redesign the application to limit the actual amount of data that is transferred via SSL. For example, a Web application may only require SSL on specific pages, and by switching SSL on and off when required, the server's performance can be increased. The danger in this approach is the possibility for data that should be protected to be missed. Only a thorough analysis of the application, data, and data flows can determine where the application must be SSL protected.

The second solution is to change the system or network architecture and implement SSL accelerator hardware to offload the primary CPU from the actual SSL operations. SSL accelerator hardware can be installed into the actual server hardware or implemented in the network to perform the SSL handshake and all the encryption/decryption operations. While this can be a more expensive approach, it does not require any re-design or thorough analysis of the application. Because SSL accelerators are often implemented in an application layer switch, other benefits can be achieved, including load balancing.

134.13 Policy

Any organization providing information to others on either a public or private network will need to consider the requirements for SSL. Many situations where it is necessary to encrypt data on the public network may apply to the private network as well. Consequently, organizations must consider their security policy and assist in determining when SSL is required.

For example, SSL should be used on the public network to protect every transaction containing any form of personal information about the user, financial data, or information that the organization does not want generally visible on the public network. Additionally, SSL should be used on the private network to protect employee data and any information potentially subject to privacy legislation.

Finally, any information exchange falling into the realm of HIPAA, Gramm–Leech–Bliley, or Sarbanes–Oxley within the United States should strongly consider the use of SSL due to its data integrity properties. However, the specific legislation for a country and an organization's data classification and security policies will assist in determining when and where SSL is required.

134.14 Summary

This chapter has presented how the Secure Socket Layer encryption facility works. Focused at the protocol level, the security professional should understand how SSL actually functions and the number of steps involved in achieving the SSL connection. SSL is used as the basis for protecting almost all encrypted Web traffic to prevent the loss of sensitive information in an untrusted network. It can easily be stated that Internet based E-commerce would not be where it is today without SSL.

SSL provides data confidentiality and integrity elements in the handshake to avoid successful attacks, although there is a certain degree of human intervention and understanding associated with doing the correct thing when problems occur. Additionally, once the SSL session is established, data is protected in the session from eavesdropping and it cannot be altered during transmit—alterations cause the decryption to fail at the receiving end, maintaining the integrity of the data.

Consequently, organizations should make use of SSL encryption whenever they work with data across an untrusted network such as the Internet and consider using it to protect sensitive data within their own network, as the same network threats apply.

Acknowledgments

The author thanks Mignona Cote, a trusted friend and colleague, for her support during the development of this chapter. Mignona continues to provide ideas and challenges in topic selection and application, always with an eye for practical application of the information gained. Her insight into system and application controls serves her and her team effectively on an ongoing basis.

Packet Sniffers and Network Monitors

James S. Tiller
Bryan D. Fish

Communications take place in forms that range from simple voice conversations to complicated manipulations of light. Each type of communication is based on two basic principles: wave theory and particle theory. In essence, communication can be established by the use of either, frequently in concert with a carrier or medium to provide transmission. An example is the human voice. The result of wave communications using the air as the signal-carrying medium is that two people can talk to each other. However, the atmosphere is a common medium, and anyone close enough to receive the same waves can intercept and surreptitiously listen to the discussion. For computer communications, the process is exponentially more complicated; the medium and type may change several times as the data is moved from one point to another. Nevertheless, computer communications are vulnerable in the same way that a conversation can be overheard. As communications are established, several vulnerabilities in the accessibility of the communication will exist in some form or another. The ability to intercept communications is governed by the type of communication and the medium that is employed. Given the proper time, resources, and environmental conditions, any communication—regardless of the type or medium employed—can be intercepted.

In the realm of computer communications, sniffers and network monitors are two tools that function by intercepting data for processing. Operated by a legitimate administrator, a network monitor can be extremely helpful in analyzing network activities. By analyzing various properties of the intercepted communications, an administrator can collect information used to diagnose or detect network performance issues. Such a tool can be used to isolate router problems, poorly configured network devices, system errors, and general network activity to assist in the determination of network design. In stark contrast, a sniffer can be a powerful tool to enable an attacker to obtain information from network communications. Passwords, e-mail, documents, procedures for performing functions, and application information are only a few examples of the information obtainable with a sniffer. The unauthorized use of a network sniffer, analyzer, or monitor represents a fundamental risk to the security of information.

This is a chapter in two parts. Part one introduces the concepts of data interception in the computer-networking environment. It provides a foundation for understanding and identifying those properties that make communications susceptible to interception. Part two addresses a means for evaluating the severity of such vulnerabilities. It goes on to discuss the process of communications interception with real-world examples. Primarily, this chapter addresses the incredible security implications and threats that surround the issues of data interception. Finally, it presents techniques for mitigating the risks associated with the various vulnerabilities of communications.

135.1 Functional Aspects of Sniffers

Network monitors and sniffers are equivalent in nature, and the terms are used interchangeably. In many circles, however, a network monitor is a device or system that collects statistics about the network. Although the content of the communication is available for interpretation, it is typically ignored in lieu of various measurements and statistics. These metrics are used to scrutinize the fundamental health of the network.

On the other hand, a sniffer is a system or device that collects data from various forms of communications with the simple goal of obtaining the data and traffic patterns, which can be used for dark purposes. To alleviate any interpretation issues, the term “sniffer” best fits the overall goal of explaining the security aspects of data interception.

The essence of a sniffer is quite simple; the variations of sniffers and their capabilities are determined by the network topology, media type, and access point. Sniffers simply collect data that is made available to them. If placed in the correct area of a network, they can collect very sensitive types of data. Their ability to collect data can vary, depending on the topology and the complexity of the implementation, and is ultimately governed by the communications medium.

For computer communications, a sniffer can exist on a crucial point of the network, such as a gateway, allowing it to collect information from several areas that use the gateway. Alternatively, a sniffer can be placed on a single system to collect specific information relative to that system only.

135.1.1 Topologies, Media, and Location

There are several forms of network topologies, and each can use different media for physical communication.

Asynchronous Transfer Mode (ATM), Ethernet, Token Ring, and X.25 are examples of common network topologies that are used to control the transmission of data. Each uses some form of data unit packaging that is referred to as a frame or cell, and represents a manageable portion of the communication.

Coax, fiber, twisted-pair wire, and microwave are a few examples of computer communications media that can provide the foundation for the specific topology to transmit data units.

The location of a sniffer is a defining factor in the amount and type of information collected. The importance of location is relative to the topology and media being used. The topology defines the logical organization of systems on a network and how data is negotiated between them. The medium being utilized can assist in determining the environment simply based on its location. A basic example of this logical deduction is a simple Ethernet network spread across multiple floors in a building with a connection to the Internet. Ethernet is the topology at each floor and typically uses CAT5 cabling. Fiber cables can be used to connect each floor, possibly using FDDI as the topology. Finally, connection to the Internet typically consists of a serial connection using a V.35 cable. Using this deduction, it is safe to say that a sniffer with serial capabilities (logically and physically) placed at the Internet router can collect every packet to and from the Internet. It is also feasible to collect all the data between the floors if access to the FDDI network is obtained.

It is necessary to understand the relationship of the topology to the location and the environment, which can be affected by the medium. The medium being used is relevant in various circumstances, but this is inherently related to the location. Exhibit 135.1 explains in graphical format the relationship between the location of the sniffer, the topology, and the medium being used.

There are three buckets on the left of a scale at varying distances from the axis point, or moment. Bucket A, the furthest from the axis point, represents the weight that the sniffer's *location* carries in the success of the attack and the complexity of implementing a sniffer into the environment. Bucket A, therefore, provides greater leverage in the calculation of success relative to the difficulty of integration. Nearly equally important is the ***topology***, represented by bucket B. Closer to the axis point, where the leverage is the least, is the ***medium*** represented by bucket C. Bucket C clearly has less impact on the calculation than the other two buckets.

Adding weight to a bucket is analogous to changing the value of the characteristic it represents. As the difficulty of the location, topology, or medium increases, more weight is added to the bucket. For example, medium bucket C may be empty if CAT5 is the available medium. The commonality of CAT5 and the ease of interacting with it without detection represents a level of simplicity. However, if a serial cable is intersected, the odds of detection are high and the availability of the medium in a large environment is limited; therefore, the bucket may be full. As the sophistication of each area is amplified, more weight is added to the corresponding bucket, increasing the complexity of the attack but enhancing the effectiveness of the assault.

This example attempts to convey the relationship between these key variables and the information collected by a sniffer. With further study, it is possible to move the buckets around on the bar to vary the impact each has on the scale.

135.1.2 How Sniffers Work

As one would imagine, there are virtually unlimited forms of sniffers, as each one must work in a different way to collect information from the target medium. For example, a sniffer designed for Ethernet would be nearly useless in collecting data from microwave towers.

However, the volume of security risks and vulnerabilities with common communications seems to focus on standard network topologies. Typically, Ethernet is the target topology for local area networks (LANs) and serial is the target topology for wide area networks (WANs).

135.1.2.1 Ethernet Networks

The most common among typical networks are Ethernet topologies and IEEE 802.3, both of which are based on the same principle of Carrier-Sensing Multiple Access with Collision Detection (CSMA/CD) technology. Of the forms of communication in use today, Ethernet is one of the most susceptible to security breaches by the use of a sniffer. This is true for two primary reasons: installation base and communication type.

CSMA/CD is analogous to a conference call with several participants. Each person has the opportunity to speak if no one else is talking and if the participant has something to say. In the event two or more people on the conference call start talking at the same time, there is a short time during which everyone is silent, waiting to see whether to continue. Once the pause is over and someone starts talking without interruption, everyone on the call can hear the speaker. To complete the analogy, the speaker is addressing only one individual in the group, and that individual is identified by name at the beginning of the sentence.

Computers operating in an Ethernet environment interact in very much the same way. When a system needs to transmit data, it waits for an opportunity when no other system is transmitting. In the event two systems inject data onto the network at the same time, the electrical signals collide on the wire. This collision forces both systems to wait for an undetermined amount of time before retransmitting. The segment in which a group of systems participates is sometimes referred to as a collision domain, because all of the systems on the segment see the collisions. Also, just as the telephone was a common medium for the conference call participants, the physical network is a shared medium. Therefore, any system on a shared network segment is privy to all of the communications on that particular segment.

As data traverses a network, all of the devices on the network can see the data and act on certain properties of that data to provide communication services. A sniffer can reside at key locations on that network and inspect the details of that same data stream.

Ethernet is based on a Media Access Control (MAC) address, typically 48 bits assigned to the network interface card (NIC). This address uniquely identifies a particular Ethernet interface. Every Ethernet data frame contains the destination station's MAC address. As data is sent across the network, it is seen by every station on that segment. When a station receives a frame, it checks to see whether the destination MAC address of that frame is its own. As detailed in Exhibit 135.2, if the destination MAC address defined in the frame is that of the system, the data is absorbed and processed. If not, the frame is ignored and dropped.

135.1.2.2 Promiscuous Mode

A typical sniffer operates in promiscuous mode. Promiscuous mode is a state in which the NIC accepts all frames, regardless of the destination MAC address of the frame. This is further detailed in Exhibit 135.3. The ability to support promiscuous mode is a prerequisite for an NIC to be used as a sniffer, as this allows it to capture and retain all of the frames that traverse the network.

For software-based sniffers, the installed NIC must support promiscuous mode to capture all of the data on the segment. If a software-based sniffer is installed and the NIC does not support promiscuous mode, the sniffer will collect only information sent directly to the system on which it is installed. This happens because the system's NIC only retains frames with its own MAC address.

For hardware-based sniffers—dedicated equipment whose sole purpose is to collect all data—the installed NIC must support promiscuous mode to be effective. The implementation of a hardware-based sniffer without the ability to operate in promiscuous mode would be nearly useless inasmuch as the device does not participate in normal network communications.

There is an aspect of Ethernet that addresses the situation in which a system does not know the destination MAC address, or needs to communicate with all the systems of the network. A broadcast occurs when a system simply injects a frame that every other system will process. An interesting aspect of broadcasts is that a sniffer can operate in nonpromiscuous mode and still receive broadcasts from other segments. Although this information is typically not sensitive, an attacker can use the information to learn additional information about the network.

135.1.2.3 Wide Area Networks

Wide area network communications typify the relationship between topology, transmission medium, and location as compared with the level of access. In a typical Ethernet environment, nearly any network jack in the corner of a room can provide adequate access to the network for the sniffer to do its job. However, in some infrastructures, location can be a crucial factor in determining the effectiveness of a sniffer.

For WAN communications, the topology is much simpler. As a focal point device, such as a router processes data, the information is placed into a new frame and forwarded to a corresponding endpoint. Because all traffic is multiplexed into a single data stream, the location of the device can provide amazing access to network activities. Exhibit 135.4 illustrates a common implementation of WAN connectivity. However, the location is sensitive and not easily accessed without authorization.

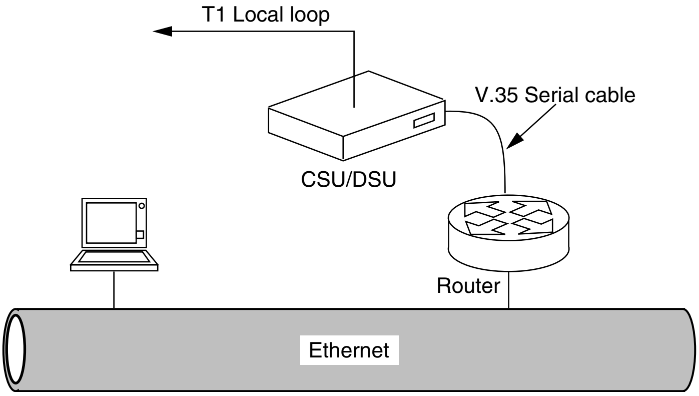

EXHIBIT 135.4 Common WAN connection.

One way the sniffer can gain access to the data stream is through a probe. A probe is an optional feature on some Channel Service Unit/Data Service Unit (CSU/DSU) devices; it is a device that provides connectivity between the customer premise equipment (CPE), such as a router, and the demarcation point of the serial line. As illustrated in Exhibit 135.5, a probe is implemented to capture all the frames that traverse the CSU/DSU.

Another way that the sniffer can gain access to the data stream is through a "Y" cable. A "Y" cable is connected between the CSU/DSU and the CPE. This is the most common location for a "Y" cable because of the complicated characteristics of the actual connection to the service provider's network, or local loop. Between the CSU/DSU and the CPE, a "Y" cable functions just like a normal cable. The third connector on the "Y" cable is free and can be attached to a sniffer. Once a "Y" cable is installed, each frame is electrically copied to the sniffer where it is absorbed and processed without disturbing the original data stream (see Exhibit 135.6). Unlike a probe, the sniffer installed with a "Y" cable must be configured for the topology being used. Serial communication can be provided by several framing formats, including Point-to-Point Protocol (PPP), High-Level Data Link Control (HDLC), and Frame Relay encapsulation. Once the sniffer is configured for the framing format of the topology—much as an Ethernet sniffer is configured for Ethernet frames—it can collect data from the communication stream.

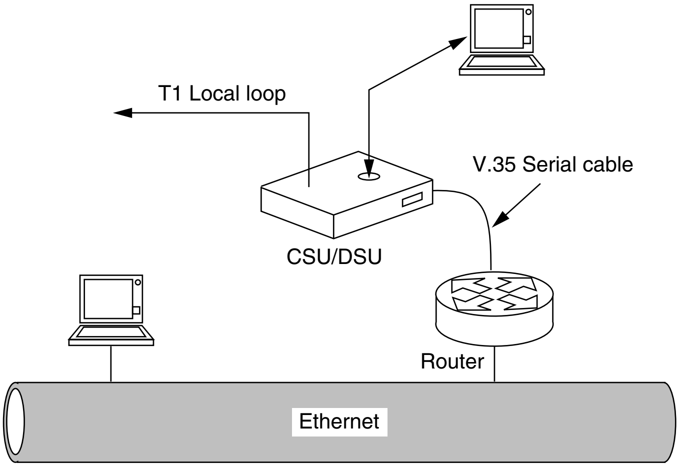

EXHIBIT 135.5 Sniffer probe used in a CSU/DSU.

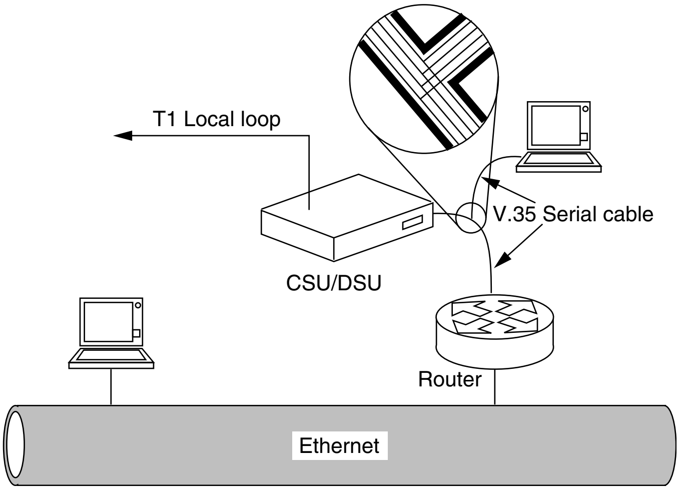

EXHIBIT 135.6 “Y” cable installation.

135.1.2.4 Other Communication Formats

Microwave communications are typically associated with line-of-sight implementations. Each endpoint has a clear, unobstructed focal path to the other. Microwave is a powerful carrier that can be precisely focused to reduce unauthorized interaction. However, as shown in Exhibit 135.7, the microwaves can wash around the receiving dish, or simply pass through the dish itself. In either event, a sniffer can be placed behind one of the endpoint microwave dishes to receive some of the signal. In some cases, all the of the signal is available but weak, but it can be amplified prior to processing.

Wireless communications devices, such as cellular phones or wireless home telephones, are extremely susceptible to interception. These devices must transmit their signal through the air to a receiving station. Even though the location of the receiving station is fixed, the wireless device itself is mobile. Thus, signal transmission cannot rely on a line of sight, because a direct signal such as this would have to traverse a variety of paths during the course of a transmission. So, to enable wireless devices to communicate with the receiving station, they must broadcast their signal across a wide enough space to ensure that the device on the other end will receive some of the signal. Because the signal travels across such a wide area, an eavesdropper would have little trouble placing a device in a location that would receive the signal.

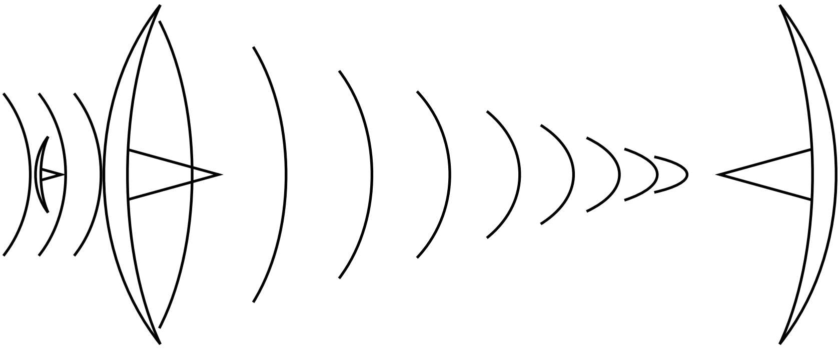

EXHIBIT 135.7 Microwave interception.

135.2 Security Considerations

Communication interception by unauthorized individuals represents the core concern for many aspects of information security. For information to remain private, the participants must be confident that the data is not being shared with others. However, this simple concept of communication protection is nearly impossible. All communications—especially those that utilize shared network links—have to be assumed to have a vulnerability to unauthorized interception and dissemination.

The availability of software-based sniffers is astounding. Combine the availability of free software with the fact that most modern NICs support promiscuous mode operations, and data interception becomes an expected occurrence rather than a novelty. Anyone with a PC, a connection to a network, and some basic, freely available software can wreak havoc on the security infrastructure.

The use of a sniffer as an attack tool is quite common, and the efforts of the attacker can be extremely fruitful. Even with limited access to remote networks that may receive only basic traffic and broadcasts, information about the infrastructure can be obtained to determine the next phase of the attack.

From an attacker's perspective, a sniffer serves one essential purpose: to eavesdrop on electronic conversations and gain access to information that would not otherwise be available. The attacker can use this electronic eavesdropper for a variety of attacks.

135.3 CIA

As elements of what is probably the most recognized acronym in the security industry, confidentiality, integrity, and availability (CIA) constitute the foundation of information security. Each one of these categories represents a vast collection of related information security concepts and practices.

Confidentiality corresponds to such concepts as privacy through the application of encryption in communications technology. Confidentiality typically involves ensuring that only authorized people have access to information. Integrity encompasses several aspects of data security that are to ensure that information has not had unauthorized modifications. The main objective of integrity is ensuring that data remains in the condition that was intended by the owner. In communications, the goal of integrity is to ensure that the data received has not been altered. The goal of availability is to ensure that information remains accessible to authorized users. Availability services do not attempt to distinguish between authorized and unauthorized users, but rely on other services to make that distinction. Availability services are designed to simply provide for the accessibility of the mechanisms and communication channels used to access information.

CIA embodies the core information security concepts that can be used to discuss the effectiveness of a sniffer. Sniffers can be used to attack these critical information properties directly, or to attack the mechanisms employed to guarantee these properties. An example of these mechanisms is authentication. Authentication is the process of verifying the identity of a user or resource so that a level of trust or access can be granted. Authentication also deals with verifying the source of a piece of information to establish the validity of that information. Authentication includes several processes and technologies to ultimately determine privileged access. Given the type of information exchange inherent in authentication, it has become a focal point for sniffer attacks. If an attacker obtains a password for a valid user name, other security controls may be rendered useless. This is also true for confidentiality and the application of encryption. If an attacker obtains the key being used to protect the data, it would be trivial to decrypt the data and obtain the information within.

Sniffer attacks expose any weakness in security technology and the application of that technology. As information is collected, various levels of vulnerabilities are exposed and acted upon to advance the attack. The goal of an attack may vary, but all of the core components of the security infrastructure must be functioning to reduce the risks.

This is highlighted by the interrelationship between the facets of CIA and the observation that, as one aspect fails, it may assist the attack in other areas. The goal of an attack may be attained if poor password protection is exploited or weak passwords are used that lead to the exposure of an encryption key. That key may have been used during a previous session that was collected by the sniffer. In that decrypted data may be instructions for a critical process that the attacker wishes to affect. The attacker can then utilize portions of data collected to reproduce the information, encrypt it, and retransmit it in a manner that produces the desired results.

Without adequate security, an attacker armed with a sniffer is limited only by his imagination. As security is added, the options available to the attacker are reduced but not eliminated. As more and more security is applied, the ingenuity and patience of the attacker is tested but not broken. The only real protection from a sniffer attack is not allowing one on the network.

135.3.1 Attack Methodologies

In various scenarios, a sniffer can be a formidable form of attack. If placed in the right location, a sniffer can be used to obtain proprietary information, or it can be used to gain information helpful in formulating a greater attack. In either case, information on a network can be used against the systems of that network.

There are many caveats regarding the level of success a sniffer can enjoy in a particular environment. Location is an obvious example. If the sniffer is placed in an area that is not privy to secret information, only limited data will be collected. Clearly, location and environment can have an impact on the type and amount of useful information captured. Therefore, attackers focus on specific concentrated areas of network activity in highly segmented networks.

135.3.1.1 Risks to Confidentiality

Confidentiality addresses issues of appropriate information disclosure. For information to remain confidential, systems and processes must ensure that unauthorized individuals are unable to access private information. The confidentiality implications introduced by a sniffer are clear. By surreptitiously absorbing conversations buried in network traffic, the attacker can obtain unauthorized information without employing conventional tactics. This contradicts the very definition of confidentiality.

Information security revolves around data and the protection of that data. Much of the information being shared, stored, or processed over computer networks is considered private by many of its owners. Confidentiality is fundamental to the majority of practicing information security professionals.

Encryption has been the obvious enabler for private exchanges, and its use dates back to Roman communications. Interestingly enough, computer communications are just now starting to implement encryption for confidentiality in communication domains that have traditionally been the most susceptible to sniffer attacks. Internal network communications, such as those within a LAN and WAN, do not utilize robust protection suites to ensure that data is not being shared with unauthorized individuals within the company. Terminal access emulation to a centralized AS/400 system is a prime example. Many companies have hundreds of employees accessing private data on centralized systems at banks, hospitals, insurance companies, financial firms, and government agencies. If the communication were to encroach onto an untrusted network, such as the Internet, encryption and data authentication techniques would not be questioned. Recently, the protection that has been normally afforded to external means of communication is being adopted for internal use because of the substantial risks that sniffers embody.

A properly placed sniffer would be privy to volumes of data, some of which may be open to direct interpretation. Internet services are commonly associated with the protection of basic private communications. However, at any point at which data is relayed from one system to another, its exposure must be questioned.

Ironically, the implementation of encryption can hinder the ultimate privacy. In a scenario in which poor communication encryption techniques are in use, the communication participants become overly trusting of the confidentiality of those communications. In reality, however, an attacker has leveraged a vulnerability in that weak encryption mechanism and is collecting raw data from the network.

This example conveys the importance of properly implemented confidentiality protection suites. Confidentiality must be supported by tested and verified communication techniques that have considered an attack from many directions. This results in standards, guidelines, and best practices for establishing a trusted session with a remote system such that the data is afforded confidentiality. IPSec, PGP, SSL, SSH, ISAKMP, PKI, and S/MIME are only a few of the technologies that exist to ensure confidentiality on some level—either directly or by collateral effect. A sniffer can be employed to inspect every aspect of a communication setup, processing, and completion, allowing attackers to operate on the collected data at their leisure offline. This aspect of an offline attack on confidentiality requires intensely robust communication standards to establish an encrypted session. If the standard or implementation is weak or harbors vulnerabilities, an attacker will defeat it.

135.3.1.2 Vulnerable Authentication Processes

Authentication deals with verification of the identity of a user, resource, or source of information and is a critical component in protecting the confidentiality, integrity, and availability of information. When one entity agrees to interact with another in electronic communications, there is an implicit trust that both parties will operate within the bounds of acceptable behavior. That trust is based on the fact that each entity believes that the other entity is, in fact, who it claims to be. Authentication mechanisms provide systems and users on a communication network with a reliable means for validating electronic claims of identity. Secure communications will not take place without proper authentication on the front end.

Trust is powerful in computer networking. If a user is trusted to perform a certain operation or process, she will be granted access to the system resources necessary to perform that function. Similarly, if a person is trusted in a communication session, the recipient of that person's messages will most likely believe what is being said. Trust, then, must be heavily guarded, and should not be granted without stringent proof of identity. Authentication mechanisms exist to provide that proof of identity.

Because authentication mechanisms govern trust, they are ripe targets for attack. If an attacker can defeat an authentication mechanism, he can virtually assume the identity of a trusted individual and immediately gain access to all of the resources and functions available to that individual. Even if the attacker gains access to a restricted user-level account, this is a huge first step that will likely lead to further penetration.

Sniffers provide an attacker with a means to defeat authentication mechanisms. The most straightforward example is a password sniffer. If authentication is based on a shared secret such as a password, then a candidate who demonstrates knowledge of that password will be authenticated and granted access to the system. This does a good job of guarding trust—until that shared secret is compromised. If an attacker learns the secret, he can present himself to the system for authentication and provide the correct password when prompted. This will earn him the trust of the system and access to the information resources inside.

Password sniffing is an obvious activity that can have an instant impact on security. Unless robust security measures are taken, passwords can be easily collected from a network. Most passwords are hashed or encrypted to protect them from sniffer-based attacks, but some services that are still heavily relied on do not protect the password. File Transfer Protocol (FTP), Telnet, and Hyper-Text Transfer Protocol (HTTP) are good examples of protocols that treat private information, such as usernames and passwords, as standard information and transmit them in the clear. This presents a significant threat to authentication processes on the network.

135.3.1.3 Communication Integrity

Integrity addresses inappropriate changes to the state of information. For the integrity of information to remain intact, systems and processes must ensure that an unauthorized individual cannot surreptitiously alter or delete that information. The implications of a sniffer on information integrity are not as clear-cut as those for confidentiality or authentication.

Sniffers are passive devices. However, by definition, an action is required to compromise the integrity of information. Sniffers and the information they procure are not always inherently valuable. The actions taken based on that information provide the real value either to an attacker or to an administrator. Sniffers, for example, can be used as part of a coordinated attack to capture and manipulate information and resubmit it, hence compromising its integrity. It is the sniffer's ability to capture the information in these coordinated attacks that allows the integrity of information to be attacked.

Session initiation provides an example. Essential information, such as protocol handshakes, format agreement, and authentication data, must be exchanged among the participants in order to establish the communication session. Although the attack is complicated, an attacker could use a sniffer to capture the initialization process, modify it, and use it later to falsify authentication. If the attacker is able to resend the personalized setup information to the original destination, the destination may believe that this is a legitimate session initialization request and allow the session to be established. In the event the captured data was from a privileged user, the copied credentials used for the attack could provide extensive access.

As with communications integrity, the threat of the sniffer from an availability standpoint is not direct. Because sniffers are passive devices, they typically do not insert even a single bit into the communication stream. Given this nature, a sniffer is poorly equipped to mount any form of denial-of-service (DoS) attack, the common name for attacks on resource availability. However, the sniffer can be used to provide important information to a would-be DoS attacker, such as addresses of key hosts and network services or the presence server software versions known to be vulnerable to DoS attacks. The attacker can use this information to mount a successful DoS attack against the resource, thus compromising its availability.

While the primary target of a sniffer attack will not be the availability of information resources, the results of the attack can provide information useful in subsequent attacks on resource availability.

135.3.1.4 Growth over Time

Information collected by the attacker may not be valuable in and of itself. Rather, that information can be used in a learning process, enabling the attacker to gain access to the information or systems that are the ultimate targets.

An attacker can use a sniffer to learn useful pieces of information about the network, such as addresses of interesting devices, services and applications running on the various systems, and types of system activity. Each of these examples and many others can be combined into a mass of information that allows the attacker to form a more complete picture of the target environment and that ultimately assists in finding other vulnerabilities. Even in a well-secured environment, the introduction of a sniffer can amount to death by a thousand cuts. Information gathering can be quite dangerous, as seemingly innocuous bits of data are collected over time. The skilled attacker can use these bits of data to mount an effective attack against the network.

135.3.2 Attack Types

There are several types of sniffer attacks. These attacks are distinguishable by the network they target. The following sub-sections describe the various types of attacks.

135.3.2.1 LAN Based

As discussed throughout this chapter, LAN-based attacks represent the most common and easiest to perform attacks, and can reveal an amazing amount of private information. The proliferation of LAN sniffer attacks has produced several unique tools that can be employed by an attacker to obtain very specific data that pertains to the target environment. As a result of the commonality of Ethernet, tools were quickly developed to provide information about the status of the network. As people became aware of their simplicity and availability and the relative inability to detect their presence, these tools became a desired form of attack.

There are nearly infinite ways to implement a sniffer on a LAN. The level and value of the data collected is directly related to the location of the sniffer, network infrastructure, and other system vulnerabilities. As an example, it is certainly feasible that the attacker can learn a password to gain access to network systems from sniffing on a remote segment. Some network devices are configured by HTTP access, which does not directly support the protection of private information. As an administrator accesses the device, the attacker can easily obtain the necessary information to modify the configuration at a later time to allow greater access in the future.

Given the availability of sniffing tools, the properties of Ethernet, and the amount of unprotected ports in an office, what may appear to be a dormant system could actually be collecting vital information. One common method of LAN-based sniffer attack is the use of an inconspicuous, seemingly harmless system. A laptop can easily fit under a desk, on a bookshelf, in a box, or in the open; anywhere that network access can be obtained is a valid location. An attacker can install the laptop after-hours and collect it the next evening. The batteries may be exhausted by the next evening, but the target time is early morning when everyone is logging in and performing a great deal of session establishment. The attacker is likely to obtain many passwords and other useful fragments of information during this time.

Another aspect of LAN attacks is that the system performing the collection does not have to participate as a member of the network. To further explain, if a network is running TCP/IP as the protocol, the sniffer system does not need an IP address. As a matter of fact, it is highly desirable by the attacker not to obtain an IP address or interact with other network systems. Because the sniffer is interested only in layer 2 activities (i.e., frames, cells, or the actual packages defined by the topology), any interaction with layer 3, or protocol layer, could alert systems and administrators to the existence of an unauthorized system. Clearly, the fact that sniffers can operate autonomously increases the respect for the security implications of such a device.

135.3.2.2 WAN Based

Unlike a sniffer on a LAN, WAN-based attacks can collect information as it is sent from one remote network to another. A common WAN topology is Frame Relay (FR) encapsulation. The ability of an attacker to access an FR cloud or group of configured circuits is limited, but the amount of information gained through such access is large.

There are three basic methods for obtaining data from a WAN, each growing in complexity but capable of collecting large amounts of private data. The first is access to the serial link between the router and the CSU/DSU, which was detailed earlier. Second, access to the carrier system would provide access not only to the target WAN but could conceivably allow the collection of data from other networks as well. This scenario is directly related to the security posture of the chosen carrier. It can be generally assumed that access to the carrier's system is limited and properly authenticated; however, it is not unheard of to find otherwise. The final form of access is to gather information from the digital line providing the Layer 1 connectivity. This can be accomplished, for example, with a fiber tap. The ability to access the provider's line is highly complicated and requires specialized tools in the proper location. This type of attack represents a typically accepted vulnerability, as the complexity of the attack reduces the risk associated with the threat. That is, if an attacker has the capability to intercept communications at this level, other means of access are more than likely available to the attacker.

135.3.2.3 Gateway Based

A gateway is a computer or device that provides access to other networks. It can be a simple router providing access to another local network, a firewall providing access to the Internet, or a switch providing virtual local area network (VLAN) segmentation to several networks. Nevertheless, a gateway is a focal point for network-to-network communications.

Installing a sniffer on a gateway allows the attacker to obtain information relative to internetworking activities, and in today's networked environments, many services are accessed on remote networks. By collecting data routed through a gateway, an attacker will obtain a great deal of data, with a high probability of finding valuable information within that data.

For example, Internet access is common and considered a necessity for doing business. E-mail is a fundamental aspect of Internet business activities. A sniffer installed on a gateway could simply collect all information associated with port 25 (SMTP). This would provide the attacker with volumes of surreptitiously gained e-mail information.

Another dangerous aspect of gateway-based attacks is simple neglect of the security of the gateway itself. A painful example is Internet router security. In the past few years, firewalls have become standard issue for Internet connectivity. However, in some implementations, the router that provides the connection to the Internet on the outside of the firewall is ignored. Granted, the internal network is afforded some degree of security from general attacks from the Internet, but the router can be compromised to gather information about the internal network indirectly. In some cases, this can be catastrophic. If a router is compromised, a privileged user's password could be obtained from the user's activities on the Internet. There is a strong possibility that this password is the same as that used for internal services, thus giving the attacker access to the inside network.

There are several scenarios of gateway-based sniffer attacks, each with varying degrees of impact. However, they all represent enormous potential to the attacker.

135.3.2.4 Server Based

Previously, the merits of traffic focal points as good sniffer locations were discussed. Given the type and amount of information that passes in and out of network servers, they become a focal point for sensitive information. Server-based sniffers take advantage of this observation, and target the information that flows in and out of the server. In this way, sniffers can provide ample amounts of information about the services being offered on the system and provide access to crucial information. The danger is that the attacker can isolate specific traffic that is relative to the particular system.

Common server-based sniffers operate much like normal sniffers in nonpromiscuous mode, capturing data from the NIC as information is passed into the operating system. An attacker can accomplish this type of sniffing with either of two basic methods: installing a sniffer, or using an existing one provided by the operating system.

It is well known that the majority of today's systems can be considered insecure, and most have various vulnerabilities for a number of reasons. Some of these vulnerabilities allow an attacker to obtain privileged access to the system. Having gained access, an attacker may choose to install a sniffer to gather more information as it is sent to the server. A good example is servers that frequently process requests to add users of various services. Free e-mail services are common on the Internet, and in the event that users' passwords are gathered when they enroll, their e-mail will be completely accessible by an attacker.

By employing the system's existing utilities, an attacker needs only the necessary permissions to operate the sniffer. An example is tcpdump, described in detail later, which can be used by one user to view the activities of other users on the system. Improperly configured UNIX systems are especially vulnerable to these utility attacks because of the inherent nature of the multi-user operating environment.

135.4 Sniffer Countermeasures

A sniffer can be a powerful tool for an attacker. However, there are techniques that reduce the effectiveness of these attacks and eliminate the greater part of the risk. Many of these techniques are commonplace and currently exist as standards, while others require more activity on the part of the user.

In general, sniffer countermeasures address two facets of the attacker's approach: the ability to actually capture traffic, and the ability to use that information for dark purposes. Many countermeasures address the first approach, and attempt to prevent the sniffer from seeing traffic at all. Other countermeasures take steps to ensure that data extracted by the sniffer will not yield any useful information to the attacker. The following sub-sections discuss examples of both of these types of countermeasures.

135.4.1 Security Policy

Security policy defines the overall security posture of a network. Security policy is typically used to state an organization's position on particular network security issues. These policy statements are backed up by specific standards and guidelines that provide details on how an organization is to achieve its stated posture. Every organization should have a security policy that addresses its overall approach to security.

A good security policy should address several areas that affect an attacker's ability to launch a sniffer-based attack.

Given physical access to the facility, it is easy to install a sniffer on most networks. Provisions in the security policy should limit the ability of an attacker to gain physical access to a facility. Denial of physical access to a network severely restricts an attacker's ability to install and operate a sniffer. Assuming an attacker does have physical access to a facility, provisions in the security policy should ensure that it is nontrivial to find an active but unused network port. A good security policy should also thoroughly address host security issues. Strong host security can prevent an attacker from installing sniffer software on a host already attached to the network. This closes down yet another avenue of approach for an attacker to install and operate a sniffer. Furthermore, policies that address the security of network devices help to deter gateway, LAN, and WAN attacks.

Policy should also clearly define the roles and responsibilities of the administrators who will have access to network sniffers. Because sniffing traffic for network analysis can easily lead to the compromise of confidential information, discretion should be exercised in granting access to sniffers and their output.

The following sections address point solutions that help to dilute the effectiveness of a sniffer-based attack. Security policy standards and guidelines should outline the specific use of these techniques.

135.4.2 Strong Authentication

It has been shown how password-based authentication can be exploited with the use of a sniffer. Stronger authentication schemes can be employed to render password-sniffing attacks useless. Password-sniffing attacks are successful, assuming that the attacker can use the sniffed password again to authenticate to a system. Strong authentication mechanisms ensure that the data seen on the network cannot be used again for later authentication. This defeats the password sniffer by rendering the data it captures useless.

Although certain strong authentication schemes can help to defeat password sniffers, they are not generally effective against all sniffer attacks. For example, an attacker sniffing the network to determine the version of Sendmail running on the mail server would not be deterred by a strong authentication scheme.

135.4.3 Encryption

Sniffer attacks are based on a fundamental security flaw in many types of electronic communications. The endpoints of a conversation may be extremely secure, but the communications channel itself is typically wide open, as many networks are not designed to protect information in transit. Encryption can be used to protect that information as it traverses various networks between the endpoints.

The process of encryption combines the original message, or plaintext, with a secret key to produce ciphertext. The definition of encryption provides that the ciphertext is not intelligible by an eavesdropper. Furthermore, without the secret key, it is not feasible for the eavesdropper to recover the plaintext from the ciphertext. These properties provide assurance that the ciphertext can be sent to the recipient without fear of compromise by an eavesdropper. Assuming the intended recipient also knows the secret key, she can decrypt the ciphertext to recover the plaintext and read the original message. Encryption is useful in protecting data in transit, because the ciphertext can be viewed by an eavesdropper, but is ultimately useless to an attacker.

Encryption protects the data in transit but does not restrict the attacker's ability to intercept the communication. Therefore, the cryptographic protocols and algorithms in use must themselves be resistant to attack. The encryption algorithm—the mathematical recipe for transforming plaintext into ciphertext—must be strong enough to prevent the attacker from decrypting the information without knowledge of the key. Weak encryption algorithms can be broken through a variety of cryptanalytic techniques. The cryptographic protocols—the rules that govern the use of cryptography in the communication process—must ensure that the attacker cannot deduce the encryption key from information made available during the conversation. Weak encryption provides no real security, only a false sense of confidence in the users of the system.

135.4.4 Switched Network Environments

Ethernet sniffers are by far the most commonly encountered sniffers in the wild. One of the reasons for this is that Ethernet is based on a shared segment. It is this shared-segment principle that allows a sniffer to be effective in an Ethernet environment; the sniffer can listen to all of the traffic within the collision domain.

Switches are used in many environments to control the flow of data through the network. This improves overall network performance through a virtual increase in bandwidth. Switches achieve this result by segmenting network traffic, which reduces the number of stations in an Ethernet collision domain. The fundamentals of Ethernet allow a sniffer to listen to traffic within a single collision domain. Therefore, by reducing the number of stations in a collision domain, switches also limit the amount of network traffic seen by the sniffer.

In most cases, servers reside on dedicated switched segments that are separate from the workstation switched networks. This will prevent a sniffer from seeing certain types of traffic. With the reduced cost of switches over the past few years, however, many organizations have implemented switches to provide a dedicated segment to each workstation. A sniffer in these totally switched environments can receive only broadcasts and information destined directly for it, missing out on all of the other network conversations taking place. Clearly, this is not a desirable situation for an attacker attempting to launch a sniffer-based attack.

Sniffers are usually deployed to improve network performance. The fact that sniffers heighten the security of the network is often a secondary consideration or may not have been considered at all. This is one of those rare cases in which the classic security/functionality paradox does not apply. In this case, an increase in functionality and performance on the network actually leads to improved security as a side effect.

135.4.5 Detecting Sniffers

The sniffer most commonly found in the wild is a software sniffer running on a workstation with a promiscuous Ethernet interface. Because sniffing is a passive activity, it is conceptually impossible for an administrator to directly detect such a sniffer on the network. It may be possible, however, to deduce the presence of a sniffer based on other information available within the environment. L0pht Heavy Industries has developed a tool that can deduce, with fairly high accuracy, when a machine on the network is operating its NIC in promiscuous mode. This tool is known as AntiSniff.

It is not generally possible to determine directly whether a machine is operating as a packet sniffer. AntiSniff uses deduction to form a conclusion about a particular machine and is quite accurate. Rather than querying directly to detect a sniffer, AntiSniff looks at various side effects exhibited by the operation of a sniffer. AntiSniff conducts three tests to gather information about the hosts on the network.

Most operating systems exhibit some unique quirks when operating an interface in promiscuous mode. For example, the TCP/IP stack in most early Linux kernels did not handle packets properly when operating in promiscuous mode. Under normal operation, the kernel behaves properly. When the stack receives a packet, it checks to see whether the destination MAC address is its own. If it is, the packet moves up to the next layer of the stack, which checks to see whether the destination IP address is its own. If it is, the packet is processed by the local system. However, in promiscuous mode, a small bug in the code produces abnormal results. In promiscuous mode, when the packet is received, the MAC address is ignored and the packet is handed up the stack. The stack verifies the destination IP address and reacts accordingly. If the address is its own, it processes the packet. If not, the stack drops the packet. Either way, the packet is copied to the sniffer software.

There is a flaw, however, in this logic. Suppose station A is suspected of operating in promiscuous mode. AntiSniff crafts a packet, a ping for example, with a destination of station B's MAC address, but with station A's IP address. When station B receives the packet, it will drop it because the destination IP address does not match. When station A receives the packet, it will accept it because it is in promiscuous mode, so it will grab the packet regardless of the destination MAC address. Then, the IP stack checks the destination IP address. Because it matches its own, station A's IP stack processes the packet and responds to the ping. In nonpromiscuous mode, station A would have dropped the packet, because the destination MAC address was not its own. The only way the packet would have made it up the stack for processing is if the interface happened to be in promiscuous mode. When AntiSniff receives the ping reply, it can deduce that station A is operating in promiscuous mode.

This quirk is specific to early Linux kernels, but other operating systems exhibit their own quirks. The first AntiSniff test exercises the conditions that uncover those quirks in the various operating systems, with the intent to gain some insight as to whether the machine is operating in promiscuous mode.

Many sniffer-based attacks will perform a reverse-DNS query on the IP addresses it sees, in an attempt to maximize the amount of information it gleans from the network. The second AntiSniff test baits the alleged sniffer with packets destined for a nonexistent IP address and waits to see whether the machine does a reverse-DNS lookup on that address. If it does, chances are that it is operating as a sniffer.

A typical machine will take a substantial performance hit when operating its NIC in promiscuous mode. The final AntiSniff test floods the network with packets in an attempt to degrade the performance of a promiscuous machine. During this window of time, AntiSniff attempts to locate machines suffering from a significant performance hit and deduces that they are likely running in promiscuous mode.

AntiSniff is a powerful tool because it gives the network administrator the ability to detect machines that are operating as sniffers. This enables the administrator to disable the sniffer capability and examine the hosts for further evidence of compromise by an attacker. AntiSniff is the first tool of its kind, one that can be a powerful countermeasure for the network administrator.

135.5 Tools of the Trade

Sniffers and their ability to intercept network traffic make for an interesting conceptual discussion. However, the concept is not useful in the trenches of the internetworking battlefield until it is realized as a working tool. The power of a sniffer, in fact, has been incarnated in various hardware- and software-based tools. These tools can be organized into two general categories: those that provide a useful service to a legitimate network administrator, and those that provide an attacker with an easily operated, highly specialized attack tool. It should be noted that an operational tool that sees the entirety of network traffic can just as easily be used for dark purposes. The following sub-sections describe several examples of both the operational tools and the specialized attack tools.

135.5.1 Operational Tools

Sniffer operational tools are quite useful to the network administrator. By capturing traffic directly from the network, the tool provides the administrator with data that can be analyzed to discern valuable information about the network. Network administrators use operational tools to sniff traffic and learn more about how the network is behaving. Typically, an administrator is not interested in the contents of the traffic, only in the characteristics of the traffic that relate to network operation.

There are three primary types of operational tools, or utilities, that can be used for network monitoring or unauthorized activities. On the lower end of the scale are raw packet collectors—simple utilities that obtain various specifics about the communication but do not typically absorb the user data. These tools allow the user to see the communication characteristics for analysis, rather than providing the exact packet contents. For example, the operator can view the manner in which systems are communicating and the services being used throughout the network. Raw packet collectors are useful for determining basic communication properties, allowing the observer to draw certain deductions about the communication.

The second, more common type of tool is the application sniffer. These are applications that can be loaded on a PC, providing several layers of information to the operator. Everything from frame information to user data is collected and presented in a clear manner that facilitates easy interpretation. Typically, extended tools are provided for analyzing the data to determine trends in the communication. The last type of tool is dedicated sniffer equipment. Highly flexible and powerful, such equipment can be attached to many types of networks to collect data. Each topology and associated protocol that is supported by the device is augmented with analyzing functionality that assists in determining the status of the network. These tools provide powerful access at the most fundamental levels of communication. This blurs the line between network administration and unauthorized access to network traffic. Sniffers should be treated as powerful tools with tremendous potential for harm and good. Access to network sniffers should be tightly controlled to prevent individuals from crossing over that line.

135.5.1.1 Raw Packet Collectors

There are several variations of raw packet collectors, most of which are associated with UNIX systems. One example is tcpdump, a utility built into most variations of UNIX. It essentially makes a copy of everything seen by the kernel's TCP/IP protocol stack. It performs a basic level of packet decode, and displays key values from the packets in a tabular format. Included in the display is information such as the packet's timestamp, source host and port, destination host and port, protocol type, and packet size.

Snoop, similar to tcpdump, is another of the more popular utilities used in UNIX. These utilities do not wrap a graphical interface around their functionality, nor do they provide extended analytical information as part of their native feature set. The format used to store data is quite basic, however, and can be exported into other applications for trend analysis.

These tools can be very dangerous because they are easily operated, widely available, and can be started and stopped automatically. As with most advanced systems, separate processes can be started and placed in the background; they remain undetected while they collect vital information and statistics.

135.5.1.2 Application Sniffers

There are several commercial-grade products that are available to provide collection, analysis, and trend computations along with unprecedented access to user data. The most common operate on Microsoft platforms because of the market share Microsoft currently enjoys. Many examples exist, but Etherpeek, Sniffer, and Microsoft's own, NetMon are very common. Be assured there are hundreds of others, and some are even proprietary to certain organizations.

Each supports customizable filters, allowing the user to be selective about the type of packets saved by the application. With filters enabled, the promiscuous interface continues to capture every packet it sees, but the sniffer itself retains only those packets that match the filters. This allows a user to be selective and retain only those packets that meet certain criteria. This can be very helpful, both in network troubleshooting and launching attacks, as it significantly reduces the size of the packet capture while isolating specific communications that have known weaknesses or information. If either an administrator or an attacker is looking for something particular, having a much smaller data set is clearly an advantage.

By default, many application products display a summary listing of the packets as they are captured and retained. Typically, more information is available through packet decode capabilities, which allow the user to drill down into individual packets to see the contents of various protocol fields. The legitimate network administrator will typically stop at the protocol level, as this usually provides sufficient information to perform network troubleshooting and analysis. Packet decodes, however, also contain the packet's data payload, providing access to the contents of the communications. Access to this information might provide the attacker with the information he is looking for.

In addition to the ability to display vital detailed information about captured packets, many packages perform a variety of statistical analyses across the entire capture. This can be a powerful tool for the attacker to identify core systems and determine application flow. An example is an attacker who has enough access to get a sniffer on the network but is unaware of the location or applications that will allow him to obtain the desired information. By capturing data and applying statistical analysis, application servers can be identified, and their use, by volume or time of day, can be compared with typical business practices. The next time the sniffer is enabled, it can be focused on what appears to have the desired data to assist in expanding the attack.

Microsoft's NetMon runs as a service and can be configured to answer to polls from a central Microsoft server running the network monitor administrator. This allows an administrator to strategically place sniffers throughout the network environment and have them all report packet captures back to a central server. Although it is a powerful feature for the network administrator, the ability to query a remote NetMon sniffer also presents security concerns. For example, if an attacker cannot gain physical access to the network he wishes to sniff but learns that NetMon is running, he may be able to attack the NetMon service itself, causing it to report its sniffer capture back to the attacker rather than to the legitimate administrative server. It is relatively simple to identify a machine running NetMon. An NBTSTAT –A/-a <IP/Name> command will provide a list of NetBIOS tags of the remote system. If a system tag of [BEh] is discovered, it indicates that the NetMon service is running on the remote system. Once this has been discovered, a sophisticated attacker can take advantage of the service and begin collecting information on a network that was previously inaccessible.

135.5.1.3 Dedicated Sniffer Equipment

Network General's Sniffer is the most recognized version of this type of tool; its existence is actually responsible for the term "sniffer." It is a portable device built to perform a single function: sniffing network traffic. Dedicated devices are quite powerful and have the ability to monitor larger traffic flows than could be accomplished with a PC-based sniffer. Additionally, dedicated devices have built-in interfaces for various media and topology types, making them flexible enough to be used in virtually any environment. This flexibility, while powerful, comes with a large price tag, so much so that dedicated equipment is not seen often in the wild.

Dedicated equipment supports advanced customizable filters, allowing the user to prune the traffic stream for particular types of packets. The sniffer is primarily geared toward capturing traffic, and allows the user to export the capture data to another machine for in-depth analysis.

135.5.2 Attack-Specific Tools

Staging a successful attack with an operational tool is often more an art than a science. Although there are many factors that determine the attacker's ability to capture network traffic, that is only half of the battle. The attacker must be able to find the proverbial needle in the haystack of packets provided by the sniffer. The attacker must understand internetworking protocols to decipher much of the information and must have a sound strategy for wading through the millions of packets that a sniffer might return.

Recent trends in computer hacking have seen the rise of scripted attacks and attacker toolkits. The Internet itself has facilitated the proliferation of hacking tools and techniques from the few to the many. Very few of the people who label themselves "hackers" actually understand the anatomy of the attacks they wage. Most simply download an exploit script, point it at a target, and pull the trigger. Simplifying the attack process into a suite of user-friendly software tools opens up the door to a whole new class of attacker.

Sniffer-based attacks have not escaped this trend. It can be argued that the information delivered by a sniffer does not provide any real value. It is what the attacker does with this information that ultimately determines the success of the sniffer-based attack. If this is true, then a sniffer in the hands of an unskilled attacker is probably of no use. Enter the attack-specific sniffer tool. Some of the talented few who understand how a sniffer's output can be used to launch attacks have bundled that knowledge and methodology into software packages.

These software packages are essentially all-in-one attack tools that leverage the information produced by a sniffer to automatically launch an attack. The following sub-sections present several examples of these attack-specific sniffer tools.

135.5.2.1 L0pht Crack Scanner

The L0pht Crack Scanner is produced by L0pht Heavy Industries, a talented group of programmers that specialize in security tools who operate on both sides of the network security battlefield. This tool is a password sniffer that exposes usernames and passwords in a Microsoft networking environment. L0pht Crack Scanner targets Microsoft's authentication processes, and uses mild algorithms to protect passwords from disclosure as they are sent across the network. This tool underscores the complementary role that a sniffer plays in many types of network attacks. The L0pht Crack Scanner combines a sniffer with a protocol vulnerability to attack the network, with drastic results.

The scanner capitalizes on several weaknesses in the authentication process to break the protection suites used, providing the attacker with usernames and passwords from the network. The individuals at L0pht have developed an algorithm to successfully perform cryptanalysis and recover the cleartext passwords associated with usernames.

The L0pht Crack Scanner uses a built-in sniffer to monitor the network, looking for authentication traffic. When the sniffer recognizes specific traffic, the packets are captured and the scanner applies L0pht's cryptanalysis routine and produces the password for the attacker.

135.5.2.2 PPTP Scanner

Microsoft's Point-to-Point Tunneling Protocol (PPTP) is a protocol designed to provide tunneled, encrypted communications. It has been proved that the encryption used in PPTP can be broken with simple cryptanalysis of the protocol. This cryptanalysis has been translated into a methodology for recovering traffic from a PPTP session.

PPTP Scanner combines a sniffer with a weakness in the design of PPTP, exposing and exercising a serious vulnerability. This vulnerability, when exercised, allows for the recovery of plaintext from an encrypted session.

PPTP Scanner is the incarnation of the PPTP cryptanalysis methodology. The Scanner uses built-in sniffer software to monitor network traffic, looking for a PPTP session. When PPTP traffic is recognized, the packets are captured and stored for analysis. The Scanner applies the cryptanalytic methodology, and recovers the plaintext traffic for the attacker.

Previously, we discussed the use of encryption to protect network traffic from sniffer-based attacks. The ease with which L0pht Crack Scanner and PPTP Scanner do their dirty work underscores an important point. Simply encrypting traffic before sending it across the network affords only limited protection. For this technique to provide any real security, the encryption algorithms and protocols chosen must be strong and resistant to attack.

135.5.2.3 Hunt

Hunt, an automated session hijack utility, is another example of a sniffer with a built-in attack capability. Hunt operates by examining network traffic flow for certain signatures—distinct traffic patterns that indicate a particular event or condition. When Hunt recognizes a signature for traffic it can work with, it springs into action. When Hunt goes active, it knocks one station offline, and assumes its identity in the ongoing TCP session. In this manner, Hunt hijacks the TCP session for itself, giving the operator access to an established connection that can be used to further explore the target system.

This capability can be quite useful to an attacker, especially if Hunt hijacks a privileged session. Consider the following example. If Hunt detects the traffic signature for a Telnet session that it can hijack, it will knock the originating station offline and resume the session itself. This gives the Hunt operator instant command-line access to the system. The attacker will be able to access the system as the original user, which could be anyone from a plain user to a system administrator.

135.6 Conclusion

Network sniffers exist primarily to assist network administrators in analyzing and troubleshooting their networks. These devices take advantage of certain characteristics of electronic communications to provide a window of observation into the network. This window provides the operator with a clear view into the details of network traffic flow.

In the hands of an attacker, a network sniffer can be used to learn many types of information. This information can range from basic operational characteristics of the network itself to highly sensitive information about the company or individuals who use the network. The amount and significance of the information learned through a sniffer-based attack are dependant on certain characteristics of the network and the attacker's ability to introduce a sniffer. The type of media employed, the topology of the network, and the location of the sniffer are key factors that combine to determine the amount and type of information seen by the sniffer.

Information security practitioners are committed to the pursuit of confidentiality, integrity, and availability of resources, as well as information in computing and electronic communications. Sniffers represent significant challenges in each of these arenas. As sniffer capabilities have progressed, so have the attacks that can be launched with a sniffer. The past few years have seen the evolution of easy-to-use sniffer tools that can be exercised by attackers of all skill levels to wage war against computing environments and electronic communications. As attackers have increased their capabilities, so have network administrators seeking to protect themselves against these attacks. The security community has responded with a myriad of techniques and technologies that can be employed to diminish the success of the sniffer-based attack.

As with most competitive environments, security professionals and system attackers continue to raise the bar for one another, constantly driving the other side to expand and improve its capabilities. This creates a seemingly endless chess match, in which both sides must constantly adjust their strategy to respond to the moves made by the other. As security professionals continue to improve the underlying security of computing and communications systems, attackers will respond by finding new ways to attack these systems. Similarly, as attackers continue to find new vulnerabilities in computer systems, networks, and communications protocols, the security community will respond with countermeasures to combat these risks.

136

Secured Connections to External Networks

Steven F. Blanding

A private network that carries sensitive data between local computers requires proper security measures to protect the privacy and integrity of the traffic. When such a network is connected to other networks, or when telephone access is allowed into that network, the remote terminals, phone lines, and other connections become extensions of that private network and must be secured accordingly. In addition, the private network must be secured from outside attacks that could cause loss of information, breakdowns in network integrity, or breaches in security.

Many organizations have connected or want to connect their private local area networks (LANs) to the Internet so that their users can have convenient access to Internet services. Because the Internet as a whole is not trustworthy, their private systems are vulnerable to misuse and attack. Firewalls are typically used as a safeguard to control access between a trusted network and a less trusted network. A firewall is not a single component; it is a strategy for protecting an organization's resources from the Internet. A firewall serves as the gatekeeper between the untrusted Internet and the more trusted internal networks. Some organizations are also in the process of connecting their private networks to other organizations' private networks. Firewall security capabilities should also be used to provide protection for these types of connections.

This chapter identifies areas of security that should be considered with connections to external networks. Security policies must be developed for user identification and authorization, software import controls, encryption, and system architecture, which include the use of Internet firewall security capabilities. Chapter sections discuss security policy statements that address connections to external networks including the Internet. Each section contains multiple sample policies for use at the different risk profiles. Some areas provide multiple examples at the same risk level to show the different presentation methods that might be used to get the message across.

The first section discusses the risks and assumptions that should be acknowledged before a security analysis can be performed.

136.1 Risks and Assumptions

An understanding of the risks and assumptions is required before defining security policies for external connections. It is beyond the scope of this chapter to quantify the probability of the risks; however, the risks should cover a broad, comprehensive area. The following are the risks and assumptions:

- The data being protected, while not classified, is highly sensitive and would do damage to the organization and its mission if disclosed or captured.
- The integrity of the internal network directly affects the ability of the organization to accomplish its mission.
- The internal network is physically secure; the people using the internal network are trustworthy.
- PCs on the internal network are considered to be unsecured. Reliance is placed on the physical security of the location to protect them.
- Whenever possible, employees who are connected from remote sites should be treated as members of the internal network and have access to as many services as possible without compromising internal security.
- The Internet is assumed to be unsecured; the people using the Internet are assumed to be untrustworthy.
- Employees are targets for spying; information they carry or communicate is vulnerable to capture.
- Passwords transmitted over outside connections are vulnerable to capture.
- Any data transmitted over outside connections are vulnerable to capture.
- There is no control over e-mail once it leaves the internal network; e-mail can be read, tampered with, and spoofed.
- Any direct connection between a PC on the internal network and one on the outside can possibly be compromised and used for intrusion.
- Software bugs exist and may provide intrusion points from the outside into the internal network.
- Password protection on PCs directly reachable from the outside can be compromised and used for intrusion.
- Security through obscurity is counter-productive. Easy-to-understand measures are more likely to be sound, and are easier to administer.

136.2 Security Policies

Security policies fall into two broad categories: technical policies to be carried out by hardware or software, and administrative policy to be carried out by people using and managing the system. The final section of this chapter discusses Internet firewall security policies in more detail.

136.2.1 Identification and Authentication

Identification and authentication are the processes of recognizing and verifying valid users or processes. Identification and authentication information is generally then used to determine what system resources a user or process will be allowed to access. The determination of who can access what should coincide with a data categorization effort.

The assumption is that there is connectivity to internal systems from external networks or the Internet. If there is no connectivity, there is no need for identification and authentication controls. Many organizations separate Internet-accessible systems from internal systems through the use of firewalls and routers.

Authentication over the Internet presents several problems. It is relatively easy to capture identification and authentication data (or any data) and replay it in order to impersonate a user. As with other remote identification and authorization controls, and often with internal authorization systems, there can be a high level of user dissatisfaction and uncertainty, which can make this data obtainable via social engineering. Having additional authorization controls for use of the Internet may also contribute to authorization data proliferation, which is difficult for users to manage. Another problem is the ability to hijack a user session after identification and authorization have been performed.

There are three major types of authentication available: static, robust, and continuous. Static authentication includes passwords and other techniques that can be compromised through replay attacks. They are often called reusable passwords. Robust authentication involves the use of cryptography or other techniques to create one-time passwords that are used to create sessions. These can be compromised by session hijacking. Continuous authentication prevents session hijacking.

136.2.1.1 Static Authentication

Static authentication only provides protection against attacks in which an impostor cannot see, insert, or alter the information passed between the claimant and the verifier during an authentication exchange and subsequent session. In these cases, an impostor can only attempt to assume a claimant's identity by initiating an access control session as any valid user might do and trying to guess a legitimate user's authentication data. Traditional password schemes provide this level of protection, and the strength of the authentication process is highly dependent on the difficulty of guessing password values and how well they are protected.

136.2.1.2 Robust Authentication

This class of authentication mechanism relies on dynamic authentication data that changes with each authenticated session between a claimant and verifier. An impostor who can see information passed between the claimant and verifier may attempt to record this information, initiate a separate access control session with the verifier, and replay the recorded authentication data in an attempt to assume the claimant's identity. This type of authentication protects against such attacks, because authentication data recorded during a previous session will not be valid for any subsequent sessions.

However, robust authentication does not provide protection against active attacks in which the impostor is able to alter the content or flow of information between the claimant and verifier after they have established a legitimate session. Since the verifier binds the claimant's identity to the logical communications channel for the duration of the session, the verifier believes that the claimant is the source of all data received through this channel.

Traditional fixed passwords would fail to provide robust authentication because the password of a valid user could be viewed and used to assume that user's identity later. However, one-time passwords and digital signatures can provide this level of protection.

136.2.1.3 Continuous Authentication

This type of authentication provides protection against impostors who can see, alter, and insert information passed between the claimant and verifier even after the claimant/verifier authentication is complete. These are typically referred to as active attacks, since they assume that the impostor can actively influence the connection between claimant and verifier. One way to provide this form of authentication is to apply a digital signature algorithm to every bit of data that is sent from the claimant to the verifier. There are other combinations of cryptography that can provide this form of authentication, but current strategies rely on applying some type of cryptography to every bit of data sent. Otherwise, any unprotected bit would be suspect.

136.2.1.4 Applying Identification and Authorization Policies

Although passwords are easily compromised, an organization may find that a threat is not likely, would be fairly easy to recover from, or would not affect critical systems (which may have separate protection mechanisms). In low-risk connections, only static authentication may be required for access to corporate systems from external networks or the Internet.

In medium-risk connections, Internet access to information and processing (low impact if modified, unavailable, or disclosed) would require a password, and access to all other resources would require robust authentication. Telnet access to corporate resources from the Internet would also require the use of robust authentication.

Internet access to all systems behind the firewall would require robust authentication. Access to information and processing (high impact if modified, unavailable, or disclosed) would require continuous authentication.

136.3 Password Management Policies

The following are general password policies applicable for Internet use. These are considered to be the minimum standards for security control.

- Passwords and user log-on IDs will be unique to each authorized user.
- Passwords will consist of a minimum of 6 alphanumeric characters (no common names or phrases). There should be computer-controlled lists of proscribed password rules and periodic testing (e.g., letter and number sequences, character repetition, initials, common words, and standard names) to identify any password weaknesses.
- Passwords will be kept private i.e., not shared, coded into programs, or written down.
- Passwords will be changed every 90 days (or less). Most operating systems can enforce password change with an automatic expiration and prevent repeated or reused passwords.
- User accounts will be frozen after 3 failed log-on attempts. All erroneous password entries will be recorded in an audit log for later inspection and action, as necessary.
- Sessions will be suspended after 15 minutes (or other specified period) of inactivity and require the password to be reentered.
- Successful log-ons should display the date and time of the last log-on and log-off.
- Log-on IDs and passwords should be suspended after a specified period of non-use.
- For high-risk systems, after excessive violations, the system should generate an alarm and be able to simulate a continuing session (with dummy data, etc.) for the failed user (to keep this user connected while personnel attempt to investigate the incoming connection).

136.3.1 Robust Authentication Policy

The decision to use robust authentication requires an understanding of the risks, the security gained, and the cost of user acceptance and administration. User acceptance will be dramatically improved if users are appropriately trained in robust authentication and how it is used.

There are many technologies available that provide robust authentication including dynamic password generators, cryptography-based challenge/ response tokens and software, and digital signatures and certificates. If digital signatures and certificates are used, another policy area is opened up: the security requirements for the certificates.

Users of robust authentication must receive training prior to use of the authentication mechanism. Employees are responsible for safe handling and storage of all company authentication devices. Authentication tokens should not be stored with a computer that will be used to access corporate systems. If an authentication device is lost or stolen, the loss must be immediately reported to security so that the device can be disabled.

136.3.2 Digital Signatures and Certificates

If identification and authorization makes use of digital signatures, then certificates are required. They can be issued by the organization or by a trusted third party. Commercial public key infrastructures (PKI) are emerging within the Internet community. Users can obtain certificates with various levels of assurance. For example, level 1 certificates verify electronic mail addresses. This is done through the use of a personal information number that a user would supply when asked to register. This level of certificate may also provide a name as well as an electronic mail address; however, it may or may not be a genuine name (i.e., it could be an alias). Level 2 certificates verify a user's name, address, social security number, and other information against a credit bureau database. Level 3 certificates are available to companies. This level of certificate provides photo identification (e.g., for their employees) to accompany the other items of information provided by a Level 2 certificate.

Once obtained, digital certificate information may be loaded into an electronic mail application or a web browser application to be activated and provided whenever a web site or another user requests it for the purposes of verifying the identity of the person with whom they are communicating. Trusted certificate authorities are required to administer such systems with strict controls, otherwise fraudulent certificates could easily be issued.

Many of the latest web servers and web browsers incorporate the use of digital certificates. Secure Socket Layer (SSL) is the technology used in most Web-based applications. SSL version 2.0 supports strong authentication of the Web server, while SSL 3.0 adds client-side authentication. Once both sides are authenticated, the session is encrypted, providing protection against both eavesdropping and session hijacking. The digital certificates used are based on the X.509 standard and describe who issued the certificate, the validity period, and other information.

Oddly enough, passwords still play an important role even when using digital certificates. Since digital certificates are stored on a computer, they can only be used to authenticate the computer, rather than the user, unless the user provides some other form of authentication to the computer. Passwords or "passphrases" are generally used; smart cards and other hardware tokens will be used in the future.

Any company's systems making limited distribution data available over the Internet should use digital certificates to validate the identity of both the user and the server. Only Company-approved certificate authorities should issue certificates. Certificates at the user end should be used in conjunction with standard technologies such as Secure Sockets Layer to provide continuous authentication to eliminate the risk of session hijacking. Access to digital certificates stored on personal computers should be protected by passwords or passphrases. All policies for password management must be followed and enforced.

136.4 Software Import Control

Data on computers is rarely static. Mail arrives and is read. New applications are loaded from floppy, CD-ROM, or across a network. Web-based interactive software downloads executables that run on a computer. Each modification runs the risk of introducing viruses, damaging the configuration of the computer, or violating software-licensing agreements. Organizations need to protect themselves with different levels of control depending on the vulnerability to these risks. Software Import Control provides an organization with several different security challenges:

- Virus and Trojan horse prevention, detection, and removal
- Controlling Interactive Software (Java, ActiveX)
- Software licensing

Each challenge can be categorized according to the following criteria:

- Control: who initiates the activity, and how easily can it be determined that software has been imported
- Threat type: executable program, macro, applet, violation of licensing agreement
- Cleansing action: scanning, refusal of service, control of permissions, auditing, deletion

When importing software onto a computer, one runs the risk of getting additional or different functionality than one bargained for. The importation may occur as a direct action, or as a hidden side effect, which is not readily visible. Examples of direct action include:

- File transfer—utilizing FTP to transfer a file to a computer
- Reading e-mail—causing a message which has been transferred to a computer to be read, or using a tool (e.g., Microsoft Word) to read an attachment
- Downloading software from a floppy disk or over the network can spawn indirect action. Some examples include (1) reading a Web page which downloads a Java applet to your computer and (2) executing an application such as Microsoft Word and opening a file infected with a Word Macro Virus.

136.4.1 Virus Prevention, Detection, and Removal

A virus is a self-replicating program spread from executables, boot records, and macros. Executable viruses modify a program to do something other than the original intent. After replicating itself into other programs, the virus may do little more than print an annoying message, or it could do something as damaging as deleting all of the data on a disk. There are different levels of sophistication in how hard a virus may be to detect.

The most common "carrier" of viruses has been the floppy disk, since "sneaker net" was the most common means of transferring software between computers. As telephone-based bulletin boards became popular, viruses travelled more frequently via modem. The Internet provides yet another channel for virus infections, one that can often bypass traditional virus controls.

For organizations that allow downloading of software over the Internet (which can be via Internet e-mail attachments) virus scanning at the firewall can be an appropriate choice—but it does not eliminate the need for client and server based virus scanning, as well. For several years to come, viruses imported on floppy disks or infected vendor media will continue to be a major threat.

Simple viruses can be easily recognized by scanning for a signature of byte strings near the entry point of a program, once the virus has been identified. Polymorphic viruses modify themselves as they propagate. Therefore, they have no signature and can only be found (safely) by executing the program in a virtual processor environment. Boot record viruses modify the boot record such that the virus is executed when the system is booted.

Applications that support macros are at risk for macro viruses. Macro viruses are commands that are embedded in data. Vendor applications, such as Microsoft Word, Microsoft Excel, or printing standards such as Postscript are common targets. When the application opens the data file the infected macro virus is instantiated.

The security service policy for viruses has three aspects:

- Prevention—policies which prevent the introduction of viruses into a computing environment,
- Detection—determination that an executable, boot record, or data file is contaminated with a virus, and
- Removal—deletion of the virus from the infected computing system may require reinstallation of the operating system from the ground up, deleting files, or deleting the virus from an infected file.

There are various factors that are important in determining the level of security concern for virus infection of a computer. Viruses are most prevalent on DOS, Windows (3.x, 95), and NT operating systems. However some UNIX viruses have been identified.

The frequency that new applications or files are loaded on to the computer is proportional to the susceptibility of that computer to viruses. Configuration changes resulting from exposure to the Internet, exposure to mail, or receipt of files from external sources are more at risk for contamination.

The greater the value of the computer or data on the computer, the greater the concern should be for ensuring that virus policy as well as implementation procedures are in place. The cost of removal of the virus from the computing environment must be considered within your organization as well as from customers you may have infected. Cost may not always be identified as monetary; company reputation and other considerations are just as important.

It is important to note that viruses are normally introduced into a system by a voluntary act of a user (e.g., installation of an application, executing a file, etc.). Prevention policies can therefore focus on limiting the introduction of potentially infected software and files to a system. In a high-risk environment, virus-scanning efforts should be focused on when new software or files are introduced to maximize protection.

136.4.2 Controlling Interactive Software

A programming environment evolving as a result of Internet technology is Interactive Software, as exemplified by Java and ActiveX. In an Interactive Software environment, a user accesses a server across a network. The server downloads an application (applet) onto the user's computer that is then executed. There have been various claims that when utilizing languages such as Java, it is impossible to introduce a virus because of restrictions within the scripting language for file system access and process control. However, security risks using Java and ActiveX have been documented.

Therefore, there are several assumptions of trust that a user must make before employing this technology:

- The server can be trusted to download trustworthy applets.
- The applet will execute in a limited environment restricting disk reads and writes to functions that do not have security.
- The applet can be scanned to determine if it is safe.
- Scripts are interpreted, not precompiled.

136.5 Firewall Policy

Firewalls are critical to the success of secured connections to external networks as well as the Internet. The main function of a firewall is to centralize access control. If outsiders or remote users can access the internal networks without going through the firewall, its effectiveness is diluted. For example, if a traveling manager has a modem connected to his office PC that he or she can dial into while traveling, and that PC is also on the protected internal network, an attacker who can dial into that PC has circumvented the controls imposed by the firewall. If a user has a dial-up Internet account with a commercial Internet Service Provider (ISP), and sometimes connects to the Internet from his office PC via modem, he is opening an unsecured connection to the Internet that circumvents the firewall.

Firewalls can also be used to secure segments of an organization's intranet, but this document will concentrate on the Internet aspects of firewall policy.

Firewalls provide several types of protection, to include:

- They can block unwanted traffic.
- They can direct incoming traffic to more trustworthy internal systems.
- They hide vulnerable systems, which can't easily be secured from the Internet.
- They can log traffic to and from the private network.
- They can hide information like system names, network topology, network device types, and internal user IDs from the Internet.
- They can provide more robust authentication than standard applications might be able to do.

Each of these functions is described in more detail below.

As with any safeguard, there are trade-offs between convenience and security. Transparency is the visibility of the firewall to both inside users and outsiders going through a firewall. A firewall is transparent to users if they do not notice or stop at the firewall in order to access a network. Firewalls are typically configured to be transparent to internal network users (while going outside the firewall); on the other hand, firewalls are configured to be non-transparent for outside network coming through the firewall. This generally provides the highest level of security without placing an undue burden on internal users.

136.5.1 Firewall Authentication

Router-based firewalls don't provide user authentication. Host-based firewalls can provide various kinds of authentication. *Username/password authentication* is the least secure, because the information can be sniffed or shoulder-surfed. *One-time passwords* use software or hardware tokens and generate a new password for each session. This means that old passwords cannot be reused if they are sniffed or otherwise borrowed or stolen. Finally, *Digital Certificates* use a certificate generated using public key encryption.

136.5.2 Routing versus Forwarding

A clearly defined policy should be written as to whether or not the firewall will act as a router or a forwarder of Internet packets. This is trivial in the case of a router that acts as a packet filtering gateway because the firewall (router in this case) has no option but to route packets. Applications gateway firewalls should generally not be configured to route any traffic between the external interface and the internal network interface, since this could bypass security controls. All external to internal connections should go through the application proxies.

136.5.2.1 Source Routing

Source routing is a routing mechanism whereby the path to a target machine is determined by the source, rather than by intermediate routers. Source routing is mostly used for debugging network problems but could also be used to attack a host. If an attacker has knowledge of some trust relationship between your hosts, source routing can be used to make it appear that the malicious packets are coming from a trusted host. Because of this security threat, a packet filtering router can easily be configured to reject packets containing source route option.

136.5.2.2 IP Spoofing

IP spoofing is when an attacker masquerades his machine as a host on the target's network (i.e., fooling a target machine that packets are coming from a trusted machine on the target's internal network). Policies regarding packet routing need to be clearly written so that they will be handled accordingly if there is a security problem. It is necessary that authentication based on source address be combined with other security schemes to protect against IP spoofing attacks.

136.5.3 Types of Firewalls

There are different implementations of firewalls, which can be arranged in different ways. These include packet filtering gateways, application gateways, and hybrid or complex gateways.

136.5.3.1 Packet Filtering Gateways

Packet filtering firewalls use routers with packet filtering rules to grant or deny access based on source address, destination address, and port. They offer minimum security but at a very low cost, and can be an appropriate choice for a low-risk environment. They are fast, flexible, and transparent. Filtering rules are not often easily maintained on a router, but there are tools available to simplify the tasks of creating and maintaining the rules.

Filtering gateways do have inherent risks, including:

- The source and destination addresses and ports contained in the IP packet header are the only information that is available to the router in making a decision whether or not to permit traffic access to an internal network.
- They don't protect against IP or DNS address spoofing.
- An attacker will have a direct access to any host on the internal network once access has been granted by the firewall.
- Strong user authentication isn't supported with packet filtering gateways.
- They provide little or no useful logging.

136.5.3.2 Application Gateways

An application gateway uses server programs called proxies that run on the firewall. These proxies take external requests, examine them, and forward legitimate requests to the internal host that provides the appropriate service. Application gateways can support functions such as user authentication and logging.

Because an application gateway is considered the most secure type of firewall, this configuration provides a number of advantages to the medium-high risk site:

- The firewall can be configured as the only host address that is visible to the outside network, requiring all connections to and from the internal network to go through the firewall.
- The use of proxies for different services prevents direct access to services on the internal network, protecting the enterprise against insecure or misconfigured internal hosts.
- Strong user authentication can be enforced with application gateways.
- Proxies can provide detailed logging at the application level. Application level firewalls shall be configured such that outbound network traffic appears as if the traffic had originated from the firewall (i.e., only the firewall is visible to outside networks). In this manner, direct access to network services on the internal network is not allowed. All incoming requests for different network services such as Telnet, FTP, HTTP, RLOGIN, etc., regardless of which host on the internal network will be the final destination, must go through the appropriate proxy on the firewall.

Applications gateways require a proxy for each service, such as FTP, HTTP, etc., to be supported through the firewall. When a service is required that is not supported by a proxy, an organization has three choices.

- Deny the service until the firewall vendor has developed a secure proxy. This is the preferred approach, as many newly introduced Internet services have unacceptable vulnerabilities.
- Develop a custom proxy—This is a fairly difficult task and should be undertaken only by very sophisticated technical organizations.

EXHIBIT 19.1 Firewall Security Risk

Firewall Architecture	High-Risk Environment (e.g., hospital)	Medium-Risk Environment (e.g., university)	Low-Risk Environment (e.g., florist shop)
Packet filtering	Unacceptable	Minimal security	Recommended
Application gateways	Effective option	Recommended	Acceptable
Hybrid gateways	Recommended	Effective option	Acceptable

- Pass the service through the firewall—Using what are typically called "plugs," most application gateway firewalls allow services to be passed directly through the firewall with only a minimum of packet filtering. This can limit some of the vulnerability but can result in compromising the security of systems behind the firewall.

136.5.3.3 Hybrid or Complex Gateways

Hybrid gateways combine two or more of the above firewall types and implement them in series rather than in parallel. If they are connected in series, then the overall security is enhanced; on the other hand, if they are connected in parallel, then the network security perimeter will be only as secure as the least secure of all methods used. In medium- to high-risk environments, a hybrid gateway may be the ideal firewall implementation.

Suggested ratings are identified in Exhibit 19.1 for various firewall types.

136.5.4 Firewall Architectures

Firewalls can be configured in a number of different architectures, providing various levels of security at different costs of installation and operation. Organizations should match their risk profile to the type of firewall architecture selected. The following describes typical firewall architectures and sample policy statements.

136.5.4.1 Multi-homed host

A multi-homed host is a host (a firewall in this case) that has more than one network interface, with each interface connected to logically and physically separate network segments. A dual-homed host (host with two interfaces) is the most common instance of a multi-homed host.

A dual-homed firewall is a firewall with two network interface cards (NICs) with each interface connected to different networks. For instance, one network interface is typically connected to the external or untrusted network, while the other interface is connected to the internal or trusted network. In this configuration, a key security tenet is not to allow traffic coming in from the untrusted network to be directly routed to the trusted network, that is, the firewall must always act as an intermediary. Routing by the firewall shall be disabled for a dual-homed firewall so that IP packets from one network are not directly routed from one network to the other.

136.5.4.2 Screened Host

A screened host firewall architecture uses a host (called a bastion host) to which all outside hosts connect, rather than allow direct connection to other, less secure internal hosts. To achieve this, a filtering router is configured so that all connections to the internal network from the outside network are directed towards the bastion host. If a packet filtering gateway is to be deployed, then a bastion host should be set up so that all connections from the outside network go through the bastion host to prevent direct Internet connection between the internal network and the outside world.

136.5.4.3 Screened Subnet

The screened subnet architecture is essentially the same as the screened host architecture, but adds an extra stratum of security by creating a network at which the bastion host resides (often call perimeter network) which is separated from the internal network. A screened subnet is deployed by adding a perimeter network in order to separate the internal network from the external. This assures that if there is a successful attack on the bastion host, the attacker is restricted to the perimeter network by the screening router that is connected between the internal and perimeter network.

136.5.5 Intranet

Although firewalls are usually placed between a network and the outside untrusted network, in large companies or organizations, firewalls are often used to create different subnets of the network, often called an intranet. Intranet firewalls are intended to isolate a particular subnet from the overall corporate network. The reason for the isolation of a network segment might be that certain employees can access subnets guarded by these firewalls only on a need-to-know basis. An example could be a firewall for the payroll or accounting department of an organization.

The decision to use an intranet firewall is generally based on the need to make certain information available to some but not all internal users, or to provide a high degree of accountability for the access and use of confidential or sensitive information.

For any systems hosting internal critical applications, or providing access to sensitive or confidential information, internal firewalls or filtering routers should be used to provide strong access control and support for auditing and logging. These controls should be used to segment the internal network to support the access policies developed by the designated owners of information.

136.5.6 Firewall Administration

A firewall, like any other network device, has to be managed by someone. Security policy should state who is responsible for managing the firewall.

Two firewall administrators (one primary and one secondary) shall be designated by the Chief Information Security Officer (or other manager) and shall be responsible for the upkeep of the firewall. The primary administrator shall make changes to the firewall, and the secondary shall only do so in the absence of the former so that there is no simultaneous or contradictory access to the firewall. Each firewall administrator shall provide their home phone number, pager number, cellular phone number, and other numbers or codes in which they can be contacted when support is required.

136.5.6.1 Qualification of the Firewall Administrator

Two experienced people are generally recommended for the day-to-day administration of the firewall. In this manner availability of the firewall administrative function is largely ensured. It should be required that on-call information about each firewall administrator be written down so that one may be contacted in the event of a problem.

Security of a site is crucial to the day-to-day business activity of an organization. It is therefore required that the administrator of the firewall have a sound understanding of network concepts and implementation. For instance, since most firewalls are TCP/IP based, a thorough understanding of this protocol is compulsory. An individual that is assigned the task of firewall administration must have good hands-on experience with networking concepts, design, and implementation so that the firewall is configured correctly and administered properly. Firewall administrators should receive periodic training on the firewalls in use and in network security principles and practices.

136.5.6.2 Remote Firewall Administration

Firewalls are the first line of defense visible to an attacker. By design, firewalls are generally difficult to attack directly, causing attackers to often target the administrative accounts on a firewall. The username/password of administrative accounts must be strongly protected.

The most secure method of protecting against this form of attack is to have strong physical security around the firewall host and to only allow firewall administration from an attached terminal. However, operational concerns often dictate that some form of remote access for firewall administration be supported. In no case should remote access to the firewall be supported over untrusted networks without some form of strong authentication. In addition, to prevent eavesdropping, session encryption should be used for remote firewall connections.

136.5.6.3 User Accounts

Firewalls should never be used as general purpose servers. The only user accounts on the firewall should be those of the firewall administrator and any backup administrators. In addition, only these administrators should have privileges for updating system executables or other system software. Only the firewall administrator and backup administrators will be given user accounts on the COMPANY firewall. Any modification of the firewall system software must be done by the firewall administrator or backup administrator and requires approval of the cognizant Manager.

Firewall Backup

To support recovery after failure or natural disaster, a firewall, like any other network host, has to have some policy defining system backup. Data files as well as system configuration files need to be components of a backup and recovery plan in case of firewall failure.

The firewall (system software, configuration data, database files, etc.) must be backed up daily, weekly, and monthly so that in case of system failure, data and configuration files can be recovered. Backup files should be stored securely on read-only media so that data in storage is not over-written inadvertently, and locked up so that the media is only accessible to the appropriate personnel.

Another backup alternative would be to have another firewall configured as one already deployed and kept safely in case there is a failure of the current one. This backup firewall would simply be turned on and used as the firewall while the previous one is undergoing a repair. At least one firewall should be configured and reserved (not-in-use) so that in case of a firewall failure, this backup firewall can be switched in to protect the network.

136.6 Other Firewall Policy Considerations

Firewall technology has only been around for the last five years. In the past two years, however, firewall products have diversified considerably and now offer a variety of technical security controls that can be used in ever more complex network connections.

This section discusses some of the firewall policy considerations in the areas of network trust relationships, virtual private networks, DNS and mail resolution, system integrity, documentation, physical firewall security, firewall incident handling, service restoration, upgrades, and audit trail logging.

136.6.1 Network Trust Relationships

Business networks frequently require connections to other business networks. Such connections can occur over leased lines, proprietary Wide area networks, value added networks (VANs), or public networks such as the Internet. For instance, many local governments use leased lines or dedicated circuits to connect regional offices across the state. Many businesses use commercial VANs to connect business units across the country or the world.

The various network segments involved may be under control of different organizations and may operate under a variety of security policies. By their very nature, when networks are connected the security of the resulting overall network drops to the level of the weakest network. When decisions are made for connecting networks, trust relationships must be defined to avoid reducing the effective security of all networks involved.

Trusted networks are defined as networks that share the same security policy or implement security controls and procedures that provide an agreed upon set of common security services. Untrusted networks are those that do not implement such a common set of security controls, or where the level of security is unknown or unpredictable. The most secure policy is to only allow connection to trusted networks, as defined by an appropriate level of management. However, business needs may force temporary connections with business partners or remote sites that involve the use of untrusted networks.

136.6.2 Virtual Private Networks (VPN)

Virtual private networks allow a trusted network to communicate with another trusted network over untrusted networks such as the Internet. Because some firewalls provide VPN capability, it is necessary to define policy for establishing VPNs. The following are recommended policy statements:

- Any connection between firewalls over public networks shall use encrypted virtual private networks to ensure the privacy and integrity of the data passing over the public network.
- All VPN connections must be approved and managed by the Network Services Manager.
- Appropriate means for distributing and maintaining encryption keys must be established prior to operational use of VPNs.

136.6.3 DNS and Mail Resolution

On the Internet, the Domain Name Service provides the mapping and translation of domain names to IP addresses, such as "mapping server1. acme.com to 123.45.67.8". Some firewalls can be configured to run as a primary, secondary, or caching DNS server.

Deciding how to manage DNS services is generally not a security decision. Many organizations use a third party, such as an Internet Service Provider, to manage their DNS. In this case, the firewall can be used as a DNS caching server, improving performance but not requiring your organization to maintain its own DNS database.

If the organization decides to manage its own DNS database, the firewall can (but doesn't have to) act as the DNS server. If the firewall is to be configured as a DNS server (primary, secondary, or caching), it is necessary that other security precautions be in place. One advantage of implementing the firewall as a DNS server is that it can be configured to hide the internal host information of a site. In other words, with the firewall acting as a DNS server, internal hosts get an unrestricted view of both internal and external DNS data. External hosts, on the other hand, do not have access to information about internal host machines. To the outside world all connections to any host in the internal network will appear to have originated from the firewall. With the host information hidden from the outside, an attacker will not know the host names and addresses of internal hosts that offer service to the Internet. A security policy for DNS hiding might state: If the firewall is to run as a DNS server, then the firewall must be configured to hide information about the network so that internal host data is not advertised to the outside world.

136.6.4 System Integrity

To prevent unauthorized modifications of the firewall configuration, some form of integrity assurance process should be used. Typically, checksums, cyclic redundancy checks, or cryptographic hashes are made from the run-time image and saved on protected media. Each time the firewall configuration has been modified by an authorized individual (usually the firewall administrator), it is necessary that the system integrity online database be updated and saved onto a file system on the network or removable media. If the system integrity check shows that the firewall configuration files have been modified, it will be known that the system has been compromised.

The firewall's system integrity database shall be updated each time the firewall's configuration is modified. System integrity files must be stored on read only media or off-line storage. System integrity shall be checked on a regular basis on the firewall in order for the administrator to generate a listing of all files that may have been modified, replaced, or deleted.

136.6.5 Documentation

It is important that the operational procedures for a firewall and its configurable parameters be well documented, updated, and kept in a safe and secure place. This assures that if a firewall administrator resigns or is otherwise unavailable, an experienced individual can read the documentation and rapidly pick up the administration of the firewall. In the event of a break-in such documentation also supports trying to recreate the events that caused the security incident.

136.6.6 Physical Firewall Security

Physical access to the firewall must be tightly controlled to preclude any authorized changes to the firewall configuration or operational status, and to eliminate any potential for monitoring firewall activity. In addition, precautions should be taken to assure that proper environment alarms and backup systems are available to assure the firewall remains online.

The firewall should be located in a controlled environment, with access limited to the Network Services Manager, the firewall administrator, and the backup firewall administrator. The room in which the firewall is to be physically located must be equipped with heat, air-conditioner, and smoke alarms to assure the proper working order of the room. The placement and recharge status of the fire extinguishers shall be checked on a regular basis. If uninterruptible power service is available to any Internet-connected systems, such service should be provided to the firewall as well.

136.6.7 Firewall Incident Handling

Incident reporting is the process whereby certain anomalies are reported or logged on the firewall. A policy is required to determine what type of report to log and what to do with the generated log report. This should be consistent with Incident Handling policies detailed previously. The following policies are appropriate to all risk environments.

- The firewall shall be configured to log all reports on daily, weekly, and monthly bases so that the network activity can be analyzed when needed.
- Firewall logs should be examined on a weekly basis to determine if attacks have been detected.
- The firewall administrator shall be notified at anytime of any security alarm by e-mail, pager, or other means so that he may immediately respond to such alarm.
- The firewall shall reject any kind of probing or scanning tool that is directed to it so that information being protected is not leaked out by the firewall. In a similar fashion, the firewall shall block all software types that are known to present security threats to a network (such as ActiveX and Java) to better tighten the security of the network.

136.6.8 Restoration of Services

Once an incident has been detected, the firewall may need to be brought down and reconfigured. If it is necessary to bring down the firewall, Internet service should be disabled or a secondary firewall should be made operational. Internal systems should not be connected to the Internet without a firewall. After being reconfigured, the firewall must be brought back into an operational and reliable state. Policies for restoring the firewall to a working state when a break-in occurs are needed.

In case of a firewall break-in, the firewall administrator(s) are responsible for reconfiguring the firewall to address any vulnerabilities that were exploited. The firewall shall be restored to the state it was before the break-in so that the network is not left wide open. While the restoration is going on, the backup firewall shall be deployed.

136.6.9 Upgrading the Firewall

It is often necessary that the firewall software and hardware components be upgraded with the necessary modules to assure optimal firewall performance. The firewall administrator should be aware of any hardware and software bugs, as well as firewall software upgrades that may be issued by the vendor. If an upgrade of any sort is necessary, certain precautions must be taken to continue to maintain a high level of operational security. Sample policies that should be written for upgrades may include the following:

- To optimize the performance of the firewall, all vendor recommendations for processor and memory capacities shall be followed.
- The firewall administrator must evaluate each new release of the firewall software to determine if an upgrade is required. All security patches recommended by the firewall vendor should be implemented in a timely manner.
- Hardware and software components shall be obtained from a list of vendor-recommended sources. Any firewall specific upgrades shall be obtained from the vendor. NFS shall not be used as a means of obtaining software components. The use of virus checked CD-ROM or FTP to a vendor's site is an appropriate method.
- The firewall administrator(s) shall monitor the vendor's firewall mailing list or maintain some other form of contact with the vendor to be aware of all required upgrades. Before an upgrade of any of the firewall components, the firewall administrator must verify with the vendor that an upgrade is required. After any upgrade the firewall shall be tested to verify proper operation prior to going operational.

Given the rapid introduction of new technologies and the tendency for organizations to continually introduce new services, firewall security policies should be reviewed on a regular basis. As network requirements change, so should security policy.

136.6.10 Logs and Audit Trails (Audit/Event Reporting and Summaries)

Most firewalls provide a wide range of capabilities for logging traffic and network events. Some security-relevant events that should be recorded on the firewall's audit trail logs are: hardware and disk media errors, login/logout activity, connect time, use of system administrator privileges, inbound and outbound e-mail traffic, TCP network connect attempts, inbound and outbound proxy traffic type.

136.7 Summary

Connections to external networks and to the Internet are rapidly becoming commonplace in today's business community. These connections must be effectively secured to protect internal trusted networks from misuse and attack. The security policies outlined above should provide an effective guideline for implementing the appropriate level of controls to protect internal networks from outside attack.

137
Security and Network Technologies

Chris Hare

While it is common for security people to examine issues regarding network connectivity, there can be some level of mysticism associated with the methods and technologies that are used to actually construct the network. This chapter addresses what a network is, and the different methods that can be used to build one. It also introduces issues surrounding the security of the network.

People send voice, video, audio, and data through networks. People use the Internet for bank transactions. People look up information in encyclopedias online. People keep in touch with friends and family using e-mail and video. As so much information is now conveyed in today's world through electronic means, it is essential that the security practitioner understands the basics of the network hardware used in today's computer networks.

137.1 What Is a Network?

A network is two or more devices connected together in such a way as to allow them to exchange information. When most people think of a network, they associate it with a computer network—ergo, the ability of two or more computers to share information among them. In fact, there are other forms of networks. Networks that carry voice, radio, or television signals. Even people establish networks of contacts—those people with whom they meet and interact.

In the context of this chapter, the definition is actually the first one: two or more devices that exchange information over some form of communication system.

137.2 Network Devices

Network devices are computer or topology-specific devices used to connect the various network segments together to allow for data communication between different systems. Such devices include repeaters, bridges, routers, and switches.

137.2.1 Hubs

Hubs are used to concentrate a series of computer connections into one location. They are used with twisted-pair wiring systems to interconnect the systems. Consider the traditional Ethernet network where each station is connected to a single network cable. The twisted-pair network is unlike this; it is physically a star network. Each cable from a station is electrically connected to the others through a hub.

Hubs can be passive or active. A passive hub simply splits the incoming signal among all of the ports in the device. Active hubs retransmit the received signal into the other access ports. Active hubs support remote monitoring and support, while passive hubs do not.

The term "hub" is often extended to bridges, repeaters, routers, switches, or any combination of these.

137.2.2 Repeaters

A repeater retransmits the signal on one network segment to another segment with the original signal strength. This allows for very long networks when the actual maximum distance associated with a particular medium is not. For example, the 10Base5 network standard allows for a maximum of four repeaters between two network stations. Because a coaxial segment can be up to 1500 meters, the use of the repeater significantly increases the length of the network.

137.2.3 Bridges

Bridges work by reading information in the physical data frames and determining if the traffic is for the network on the other side of the bridge. They are used in both Token Ring and Ethernet networks. Bridges filter the data they transmit from one network to another by only copying the frames that they should, based upon the destination address of the frame.

137.2.4 Routers

Routers are more sophisticated tools for routing data between networks. They use the information in the network protocol (e.g., IP) packet to determine where the packet is to be routed. They are capable of collecting and storing information on where to send packets, based on defined configurations or information that they receive through routing protocols. Many routers are only capable of two network connections, while larger-scale routers can handle hundreds of connections to different media types.

137.2.5 Switches

A switch is essentially a multi-port bridge, although the term is now becoming more confusing. Switches have traditionally allowed for the connection of multiple networks for a certain length of time, much like a rotary switch. Two, and only two, networks are connected together for the required time period. However, today's switches not only incorporate this functionality, but also include routing intelligence to enhance their capability.Network Types.

Networks can be large or small. Many computer hobbyists operate small, local area networks (LANs) within their own home. Small businesses also operate small LANs. Exactly when a LAN becomes something other than a LAN can be an issue for debate; however, a simpler explanation exists.

A LAN, as illustrated in Exhibit 137.1, connects two or more computers together, regardless of whether those computers are in the same room or on the same floor of a building. However, a LAN is no longer

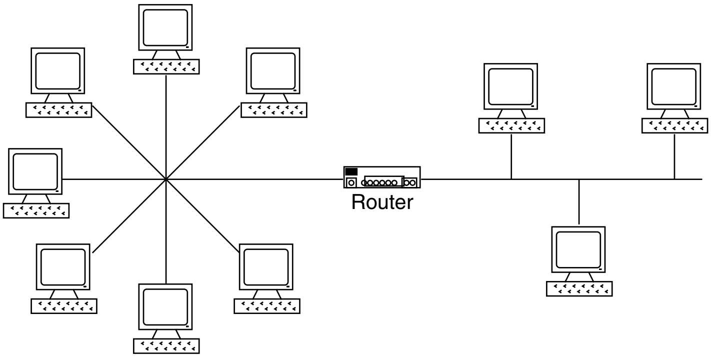

EXHIBIT 137.1 Sample local area network.

a LAN when it begins to expand into other areas of the local geography. For example, the organization that has two offices at opposite ends of a city and operates two LANs, one in each location. When they extend those two LANs to connect to each other, they have created a metropolitan area network (MAN); this is illustrated in Exhibit 137.2.

Note that a MAN is only applicable if two or more sites are within the same geographical location. For example, if the organization has two offices in New York City as illustrated in Exhibit 137.2, they operate a MAN. However, if one office is in New York and the other is in San Francisco (as shown in Exhibit 137.3), they no longer operate a MAN, but rather a WAN (i.e., wide area network).

These network layouts are combined to form inter-network organizations and establish a large collection of networks for information sharing. In fact, this is what the Internet is: a collection of local, metropolitan, and wide area networks connected together.

However, while networks offer a lot to the individual and the organization with regard to putting information into the hands of those who need it regardless of where they are, they offer some significant disadvantages.

It used to be that if people wanted to steal something, they had to break into a building, find the right desk or filing cabinet, and then physically remove something. Because information is now stored online, people have more information to lose, and more ways to lose it.

No longer do "burglars" need to break into the physical premises; they only have to find a way onto a network and achieve the same purpose. However, the properly designed and secured network offers more advantages to today's organizations than disadvantages.

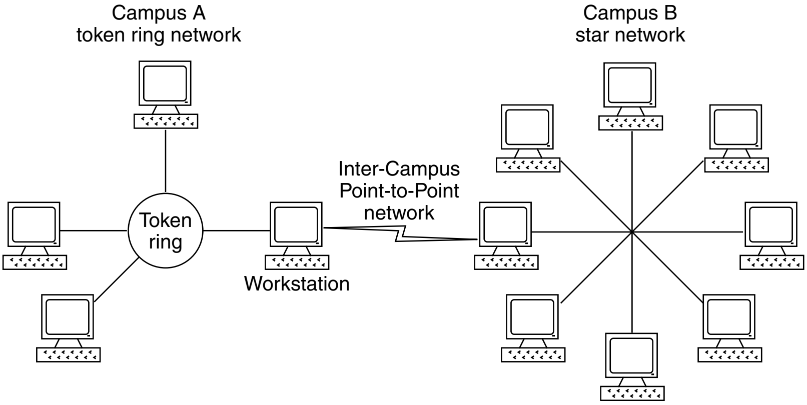

EXHIBIT 137.2 Sample metropolitan area network.

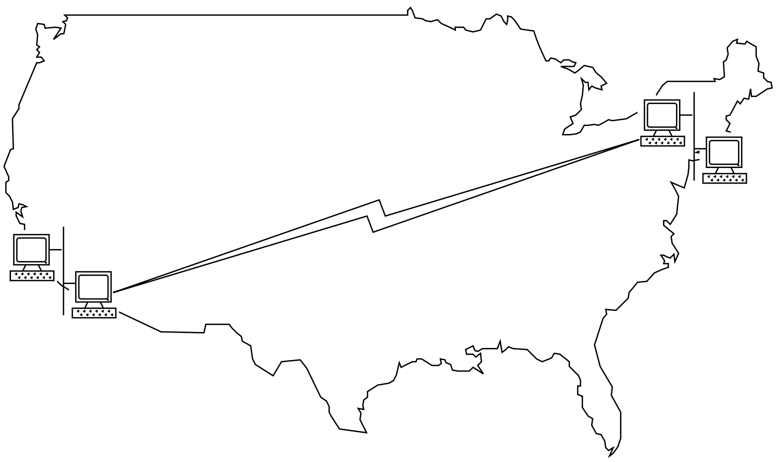

EXHIBIT 137.3 Sample wide area network.

However, a network must have a structure. That structure (or topology) can be as simple as a point-to-point connection, or as complicated as a multi-computer, multi-segment network. Network Topologies.

A network consists of segments. Each segment can have a specific number of computers, depending on the cable type used in the design. These networks can be assembled in different ways.

137.2.6 Point-to-Point

A point-to-point network consists of exactly two network devices, as seen in Exhibit 137.4. In this network layout, the two devices are typically connected via modems and a telephone line. Other physical media may be used, for example twisted pair, but the applications outside the phone line are quite specific. In this type of network, the attacks are based at either the two computers themselves, or at the physical level of the connection. Because the connection itself can be carried by an analog modem, it is possible to eavesdrop on the sound and create a data stream that another computer can understand.

137.2.7 Bus

The bus network (see Exhibit 137.5) is generally thought of when using either 10Base2 or 10Base5 coaxial cabling. This is because the electrical architecture of this cabling causes it to form a bus or electrical length. The computers are generally attached to the cable using a connector that is dependent on cable type.

Bus networks can have a computer or network sniffer added on to them without anyone's knowledge as long as the physical limitations of the cabling have not been exceeded. If there is a spare, unused connector, then it is not difficult to add a network sniffer to capture network traffic.

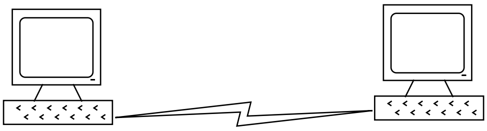

EXHIBIT 137.4 Point-to-Point network.

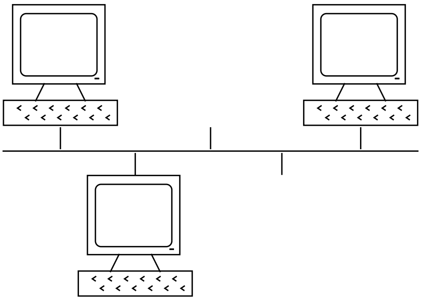

EXHIBIT 137.5 Sample bus network.

137.2.8 Daisy Chain

The daisy-chain network as seen in Exhibit 137.6 is used in the thin-client or 10Base2 coaxial network. When connecting stations in this environment, one can either create a point-to-point connection where systems are linked together using multiple dialup or point-to-point links, or connect station to station.

The illustration suggests that the middle station has two network cards. This is not the case, however; it was drawn in this exaggerated fashion to illustrate that the systems are *chained* together. In the case of the thin-client network, the connections are made using two pieces of cable and a T-connector, which is then attached directly to the workstation, as shown in Exhibit 137.7.

This example illustrates how systems are daisy-chained, and specifically how it is accomplished with the 10Base2 or thin-client network.

137.2.9 Star

Star networks (Exhibit 137.8) are generally seen in twisted-pair type environments, in which each computer has its own connection or segment between it and the concentrator device in the middle of the star. All the connections are terminated on the concentrator that electrically links the cables together to form the network. This concentrator is generally called a hub.

This network layout has the same issues as the bus. It is easy for someone to replace an authorized computer or add a sniffer at an endpoint of the star or at the concentrator in the middle.

137.2.10 Ring

The ring network (Exhibit 137.9) is most commonly seen in IBM Token Ring networks. In this network, a token is passed from computer to computer. No computer can broadcast a packet unless it has the token. In this way, the token is used to control when stations are allowed to transmit on the network.

However, while a Token Ring network is the most popular place to "see" a ring, a Token Ring network as illustrated in Exhibit 137.9 is electrically a star. A ring network is also achieved when each system only knows how to communicate with two other stations, but are linked together to form a ring, as illustrated in Exhibit 137.10. This means that it is dependent on those two other systems to know how to communicate with other systems that may be reachable.

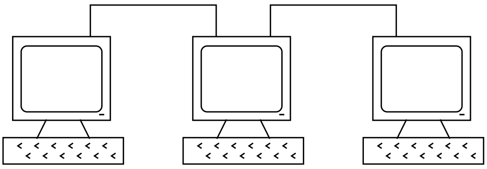

EXHIBIT 137.6 Sample daisy chain network.

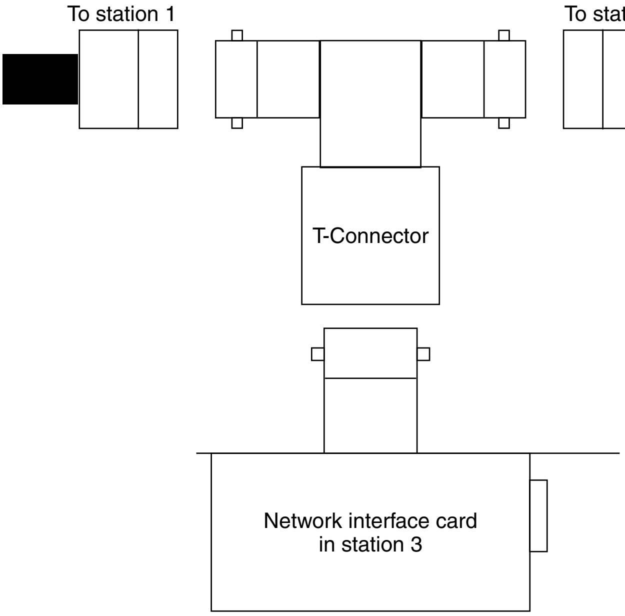

EXHIBIT 137.7 Thin-client connections.

137.2.11 Web

The Web network (Exhibit 137.11) is complex and difficult to maintain on a large scale. It requires that each and every system on the network knows how to contact any other system. The more systems in use, the larger and more difficult the configuration files. However, the Web network has several distinct advantages over any of the previous networks.

It is highly robust, in that multiple failures will still allow the computer to communicate with other systems. Using the example shown in Exhibit 137.11, a single system can experience up to four failures.

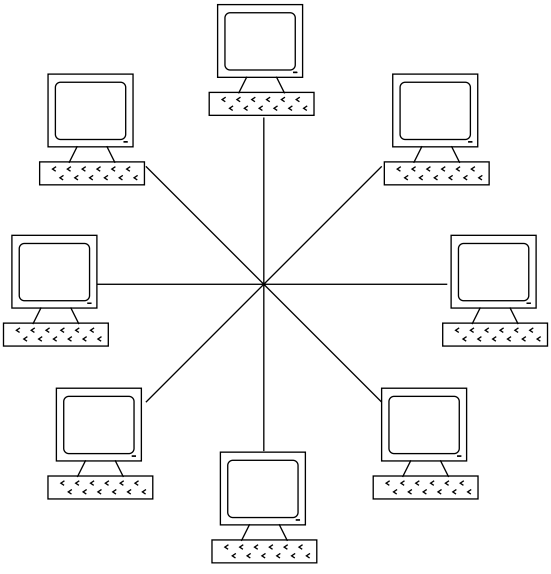

EXHIBIT 137.8 Sample star network.

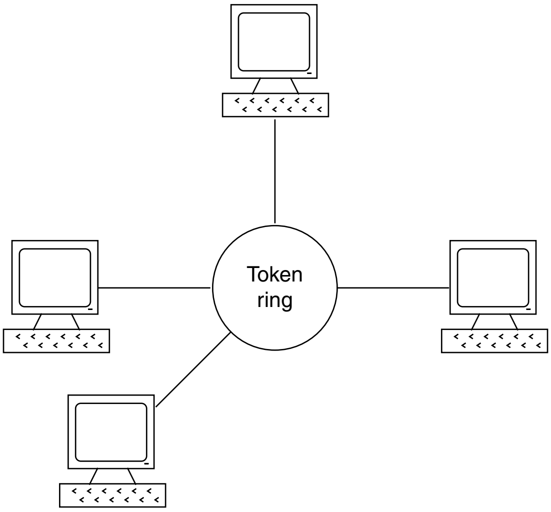

EXHIBIT 137.9 Token ring network.

Even at four failures, the system still maintains communication within the Web. The system must experience total communication loss or be removed from the network for data to not move between the systems.

This makes the Web network extremely resilient to network failures and allows data movement even in high failure conditions. Organizations will choose this network type for these features, despite the increased network cost in circuits and management.

Each of the networks described previously relies on specific network hardware and topologies to exchange information. To most people, the exact nature of the technology used and the operation is completely transparent; and for the most part, it is intended to be that way.

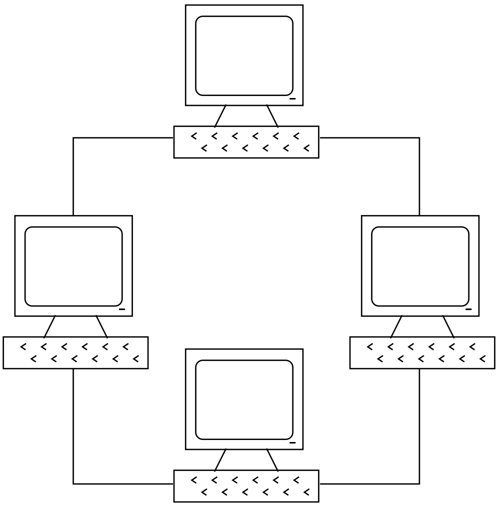

EXHIBIT 137.10 Ring network.

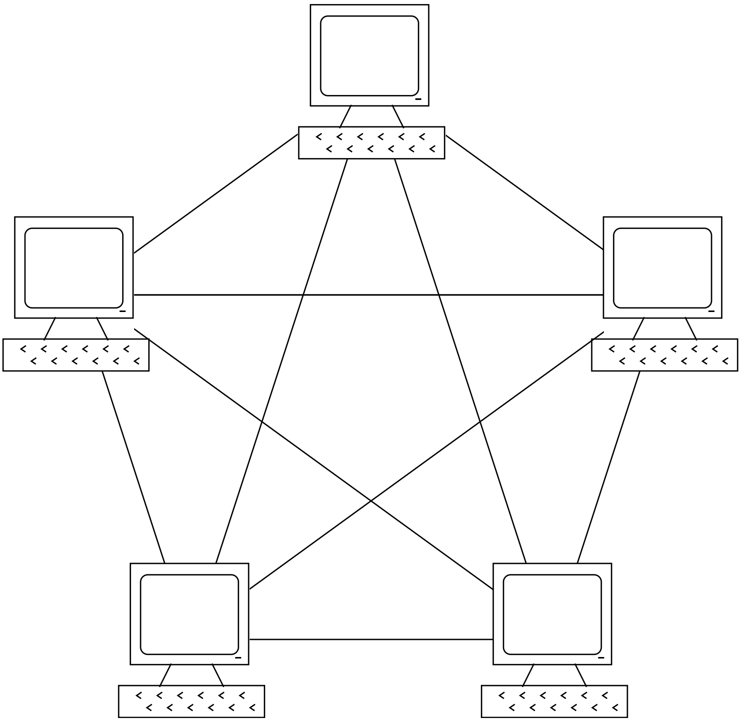

EXHIBIT 137.11 Web network.

137.3 Network Formats

Network devices must be connected using some form of physical medium. Most commonly, this is done through cabling. However, today's networks also include wireless, which can be extended to desktop computers, or to laptop or palmtop devices connected to a cellular phone. There are several different connection methods; however, the most popular today are Ethernet and Token Ring.

Serious discussions about both of these networks, their associated cabling, devices, and communications methods can easily fill large books. Consequently, this chapter only provides a brief discussion of the history and different media types available.

137.3.1 Ethernet

Ethernet is, without a doubt, the most widely used local area network (LAN) technology. While the original and most popular version of Ethernet supported a data transmission speed of 10 Mbps, newer versions have evolved, called Fast Ethernet and Gigabit Ethernet, that support speeds of 100 Mbps and 1000 Mbps.

Ethernet LANs are constructed using coaxial cable, special grades of twisted-pair wiring, or fiber-optic cable. Bus and star wiring configurations are the most popular by virtue of the connection methods to attach devices to the network. Ethernet devices compete for access to the network using a protocol called Carrier Sense Multiple Access with Collision Detection (CSMA/CD).

Bob Metcalfe and David Boggs of the Xerox Palo Alto Research Center (PARC) developed the first experimental Ethernet system in the early 1970s. It was used to connect the lab's Xerox Alto computers and laser printers at a (modest, but slow by today's standards) data transmission rate of 2.94 Mbps. This data rate was chosen because it was derived from the system clock of the Alto computer. The Ethernet technologies are all based on a 10 Mbps CSMA/CD protocol.

137.3.1.1 10Base5

This is often considered the grandfather of networking technology, as this is the original Ethernet system that supports a 10-Mbps transmission rate over "thick" (10 mm) coaxial cable. The "10Base5" identifier is shorthand for **10**-Mbps transmission rate, the baseband form of transmission, and the 500-meter maximum supported segment length. In a practical sense, this cable is no longer used in many situations. However, a brief description of its capabilities and uses is warranted.

In September 1980, Digital Equipment Corp., Intel, and Xerox released Version 1.0 of the first Ethernet specification, called the DIX standard (after the initials of the three companies). It defined the "thick" Ethernet system (10Base5), "thick" because of the thick coaxial cable used to connect devices on the network.

To identify where workstations can be attached, 10Base5 thick Ethernet coaxial cabling includes a mark every 2.5 meters to mark where the transceivers (multiple access units, or MAUs) can be attached. By placing the transceiver at multiples of 2.5 meters, signal reflections that may degrade the transmission quality are minimized.

10Base5 transceiver taps are attached through a clamp that makes physical and electrical contact with the cable that drills a hole in the cable to allow electrical contact to be made (see Exhibit 137.12). The transceivers are called non-intrusive taps because the connection can be made on an active network without disrupting traffic flow.

Stations attach to the transceiver through a transceiver cable, also called an attachment unit interface, or AUI. Typically, computer stations that attach to 10Base5 include an Ethernet network interface card (NIC) or adapter card with a 15-pin AUI connector. This is why many network cards even today still have a 15-pin AUI port.

A 10Base5 coaxial cable segment can be up to 500 meters in length, and up to 100 transceivers can be connected to a single segment at any multiple of 2.5 meters apart. A 10Base5 segment may consist of a single continuous section of cable or be assembled from multiple cable sections that are attached end to end.

10Base5 installations are very reliable when properly installed, and new stations are easily added by tapping into an existing cable segment. However, the cable itself is thick, heavy, and inflexible, making

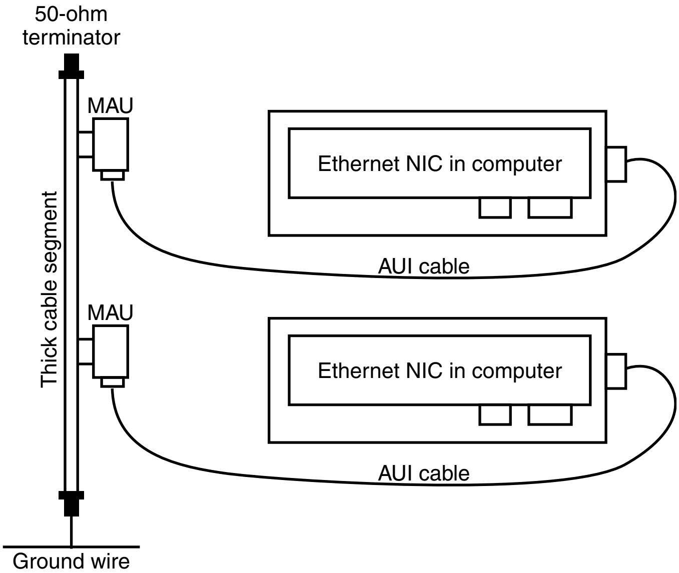

EXHIBIT 137.12 10Base5 station connections.

installation a challenge. In addition, the bus topology makes problem isolation difficult, and the coaxial cable does not support higher-speed networks that have since evolved.

137.3.1.2 10Base2

A second version of Ethernet called "thin" Ethernet, "cheapernet," or 10Base2 became available in 1985. It used a thinner, cheaper coaxial cable that simplified the cabling of the network. Although both the thick and thin systems provided a network with excellent performance, they utilized a bus topology that made implementing changes in the network difficult and also left much to be desired with regard to reliability. It was the first new variety of physical medium adopted after the original thick Ethernet standard.

While both the thin and thick versions of Ethernet have the same network properties, the thinner cable used by 10Base2 has the advantages of being cheaper, lighter, more flexible, and easier to install than the thick cable used by 10Base5. However, the thin cable has the disadvantage that its transmission characteristics are not as good. It supports only a 185-meter maximum segment length (versus 500 meters for 10Base5) and a maximum of 30 stations per cable segment (versus 100 for 10Base5).

Transceivers are connected to the cable segment through a BNC Tee connector and not through tapping as with 10Base5. As the name implies, the BNC Tee connector is shaped like the letter "T." Unlike 10Base5, where one can add a new station without affecting data transmission on the cable, one must "break" the network to install a new station with 10Base2, as illustrated in Exhibit 137.13. This method of adding or removing stations is due to the connectors used, as one must cut the cable and insert the BNC Tee connector to allow a new station to be connected. If care is not taken, it is possible to interrupt the flow of network traffic due to an improperly assembled connector.

The BNC Tee connector either plugs directly into the Ethernet network interface card (NIC) in the computer station or to an external thin Ethernet transceiver that is then attached to the NIC through a standard AUI cable. If stations are removed from the network, the BNC Tee connector is removed and replaced with a BNC Barrel connector that provides a straight-through connection.

The thin coaxial cable used in the 10Base2 installation is much easier to work with than the thick cable used in 10Base5, and the cost of implementing the network is lower due to the elimination of the external transceiver. However, the typical installation is based on the daisy-chain model illustrated in Exhibit 137.6 which results in lower reliability and increased difficulty in troubleshooting. Furthermore, in some office environments, daisy-chain segments can be difficult to deploy, and like 10Base5, thin-client networks do not support the higher network speeds.

137.3.1.3 10Base-T

Like 10Base2 and 10Base5 networks, 10Base-T also supports only a 10-Mbps transmission rate. Unlike those technologies, however, 10Base-T is based on voice-grade or Category 3 or better telephone wiring. This type of wiring is commonly known as twisted pair, of which one pair of wires is used for transmitting data, and another pair is used for receiving data. Both ends of the cable are terminated on an RJ-45 eight-position jack. The widespread use of twisted pair wiring has made 10Base-T the most popular version of Ethernet today.

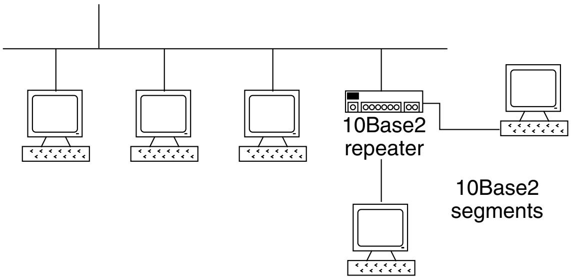

EXHIBIT 137.13 10Base2 network.

All 10Base-T connections are point-to-point. This implies that a 10Base-T cable can have a maximum of two Ethernet transceivers (or MAUs), with one at each end of the cable. One end of the cable is typically attached to a 10Base-T repeating hub. The other end is attached directly to a computer station's network interface card (NIC) or to an external 10Base-T transceiver. Today's NICs have the transceiver integrated into the card, meaning that the cable can now be plugged in directly, without the need for an external transceiver. If one is unfortunate enough to have an older card with an AUI port but no RJ-45 jack, the connection can be achieved through the use of an inexpensive external transceiver.

It is not a requirement that 10Base-T wiring be used only within a star configuration. This method is often used to connect two network devices together in a point-to-point link. In establishing this type of connection, a crossover cable must be used to link the receive and transmit pairs together to allow for data flow. In all other situations, a straight-through or normal cable is used.

The target segment length for 10Base-T with Category 3 wiring is 100 meters. Longer segments can be accommodated as long as signal quality specifications are met. Higher quality cabling such as Category 5 wiring may be able to achieve longer segment lengths, on the order of 150 meters, while still maintaining the signal quality required by the standard.

The point-to-point cable connections of 10Base-T result in a star topology for the network, as illustrated in Exhibit 137.14. In a star layout, the center of the star holds a hub with point-to-point links that appear to radiate out from the center like light from a star. The star topology simplifies maintenance, allows for faster troubleshooting, and isolates cable problems to a single link.

The independent transmit and receive paths of the 10Base-T media allow the full-duplex mode of operation to be optionally supported. To support full-duplex mode, both the NIC and the hub must be capable of, and be configured for, full-duplex operation.

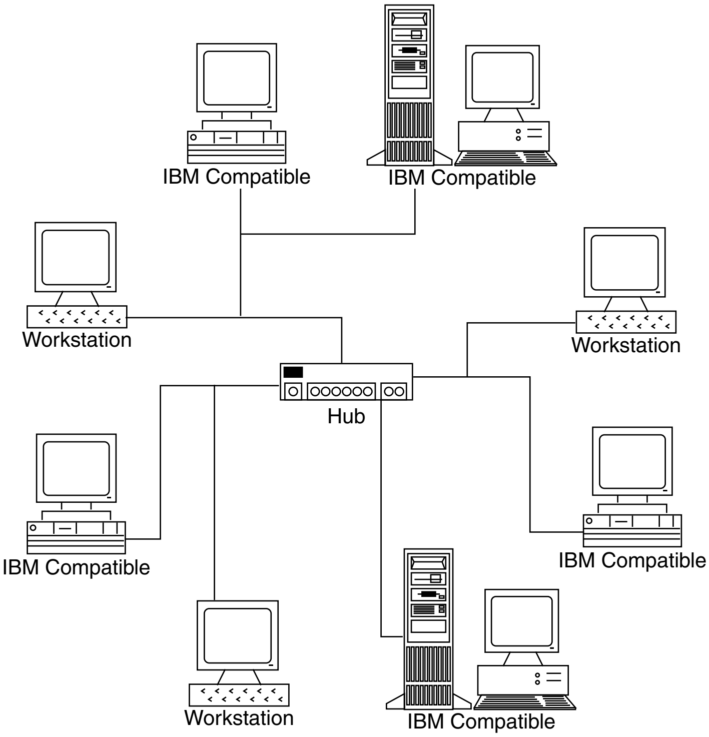

EXHIBIT 137.14 10Base-T star network.

137.3.1.4 10Broad36

10Broad36 is not widely used in a LAN environment. However, because it can be used in a MAN or WAN situation, it is briefly discussed. 10Broad36 supports a 10-Mbps transmission rate over a broadband cable system. The "36" in the name refers to the 3600-meter total span supported between any two stations, and this type of network is based on the same inexpensive coaxial cable used in cable TV (CATV) transmission systems.

Baseband network technology uses the entire bandwidth of the transmission medium to transmit a single electrical signal. The signal is placed on the medium by the transmitter with no modulation. This makes baseband technology cheaper to produce and maintain and is the technology of choice for all of the Ethernet systems discussed, except for 10Broad36.

Broadband has sufficient bandwidth to carry multiple signals across the medium. These signals can be voice, video, and data. The transmission medium is split into multiple channels, with a guard channel separating each channel. The guard channels are empty frequency space that separates the different channels to prevent interference.

Broadband cable has the advantage of being able to support transmission of signals over longer distances than the baseband coaxial cable used with 10Base5 and 10Base2. Single 10Broad36 segments can be as long as 1800 meters. 10Broad36 supports attachment of stations through transceivers that are physically and electrically attached to the broadband cable. Computers attach to the transceivers through an AUI cable as in 10Base5 installations.

When introduced, 10Broad36 offered the advantage of supporting much longer segment lengths than 10Base5 and 10Base2. But this advantage was diminished with introduction of the fiber-based services. Like 10Base2 and 10Base5, 10Broad36 is not capable of the higher network speeds, nor does it support the full-duplex mode of operation.

137.3.2 Fiber-Optic Inter-repeater Link

The fiber-optic inter-repeater link (FOIRL) was developed to provide a 10-Mbps point-to-point link over two fiber-optic cables. As defined in the standard, FOIRL is restricted to links between two repeaters. However, vendors have adapted the technology to also support long-distance links between a computer and a repeater.

137.3.2.1 10Base-FL

Like the Ethernet networks discussed thus far, the 10Base-FL (fiber link) supports a 10-Mbps transmission rate. It uses two fiber-optic cables to provide full-duplex transmit and receive capabilities. All 10Base-FL segments are point-to-point with one transceiver on each end of the segment. This means that it would most commonly be used to connect two router or network devices together. A computer typically attaches through an external 10Base-FL transceiver.

10Base-FL is widely used in providing network connectivity between buildings. Its ability to support longer segment lengths, and its immunity to electrical hazards such as lightning strikes and ground currents, make it ideal to prevent network damage in those situations. Fiber is also immune to the electrical noise caused by generators and other electrical equipment.

137.3.2.2 10Base-FB

Unlike 10Base-FL, which is generally used to link a router to a computer, 10Base-FB (fiber backbone) supports a 10-Mbps transmission rate over a special synchronous signaling link that is optimized for interconnecting repeaters.

While 10Base-FL can be used to link a computer to a repeater, 10Base-FB is restricted to use as a point-to-point link between repeaters. The repeaters used to terminate both ends of the 10Base-FB connection must specifically support this medium due to the unique signaling properties and method used. Consequently, one cannot terminate a 10Base-FB link on a 10Base-FL repeater; the 10Base-FL repeater does not support the 10Base-FB signaling.

137.3.2.3 10Base-FP

The 10Base-FP (fiber passive) network supports a 10-Mbps transmission rate over a fiber-optic passive star system. However, it cannot support full-duplex operations. The 10Base-FP star is a passive device, meaning that it requires no power directly, and is useful for locations where there is no direct power source available. The star unit itself can provide connectivity for up to 33 workstations. The star acts as a passive hub that receives optical signals from special 10Base-FP transceivers (and passively distributes the signal uniformly to all the other 10Base-FP transceivers connected to the star, including the one from which the transmission originated).

137.3.3 100Base-T

The 100Base-T identifier does not refer to a network type itself, but to a series of network types, including 100Base-TX, 100Base-FX, 100Base-T4, and 100Base-T2. These are collectively referred to as Fast Ethernet.

The 100Base-T systems generally support speeds of 10 or 100 Mbps using a process called auto-negotiation. This process allows the connected device to determine at what speed it will operate. Connections to the 100Base-T network is done through an NIC that has a built-in media-independent interface (MII), or by using an external MII much like the MAU used in the previously described networks.

137.3.3.1 100Base-TX

100Base-TX supports a 100-Mbps transmission rate over two pairs of twisted-pair cabling, using one pair of wires for transmitting data and the other pair for receiving data. The two pairs of wires are bundled into a single cable that often includes two additional pairs of wires. If present, the two additional pairs of wires must remain unused because 100Base-TX is not designed to tolerate the “crosstalk” that can occur when the cable is shared with other signals. Each end of the cable is terminated with an eight-position RJ-45 connector, or jack.

100Base-TX supports transmission over up to 100 meters of 100-ohm Category 5 unshielded twisted pair (UTP) cabling. Category 5 cabling is a higher grade wiring than the Category 3 cabling used with 10Base-T. It is rated for transmission at frequencies up to 100 MHz. The different categories of twisted pair cabling are discussed in Exhibit 137.15.

All 100Base-TX segments are point-to-point with one transceiver at each end of the cable. Most 100Base-TX connections link a computer station to a repeating hub. 100Base-TX repeating hubs typically have the transceiver function integrated internally; thus, the Category 5 cable plugs directly into an RJ-45 connector on the hub. Computer stations attach through an NIC. The transceiver function can be integrated into the NIC, allowing the Category 5 twisted-pair cable to be plugged directly into an RJ-45 connector on the NIC. Alternatively, an MII can be used to connect the cabling to the computer.

137.3.3.2 100Base-FX

100Base-FX supports a 100-Mbps transmission rate over two fiber-optic cables and supports both half- and full-duplex operation. It is essentially a fiber-based version of 100Base-TX. All of the twisted pair components are replaced with fiber components.

137.3.3.3 100Base-T4

100Base-T4 supports a 100-Mbps transmission rate over four pairs of Category 3 or better twisted-pair cabling. It allows 100-Mbps Ethernet to be carried over inexpensive Category 3 cabling, as opposed to the Category 5 cabling required by 100Base-TX.

Of the four pairs of wire used by 100Base-T4, one pair is dedicated to transmit data, one pair is dedicated to receive data, and two bi-directional pairs are used to either transmit or receive data. This

EXHIBIT 137.15 Twisted Pair Category Ratings

The following is a summary of the UTP cable categories:

Category 1 & Category 2: Not suitable for use with Ethernet.

Category 3: Unshielded twisted pair with 100-ohm impedance and electrical characteristics supporting transmission at frequencies up to 16 MHz. Defined by the TIA/EIA 568-A specification. May be used with 10Base-T, 100Base-T4, and 100Base-T2.

Category 4: Unshielded twisted pair with 100-ohm impedance and electrical characteristics supporting transmission at frequencies up to 20 MHz. Defined by the TIA/EIA 568-A specification. May be used with 10Base-T, 100Base-T4, and 100Base-T2.

Category 5: Unshielded twisted pair with 100 ohm impedance and electrical characteristics supporting transmission at frequencies up to 100 MHz. Defined by the TIA/EIA 568-A specification. May be used with 10Base-T, 100Base-T4, 100Base-T2, and 100Base-TX. May support 1000Base-T, but cable should be tested to make sure it meets 100Base-T specifications.

Category 5e: Category 5e (or "Enhanced Cat 5") is a new standard that will specify transmission performance that exceeds Cat 5. Like Cat 5, it consists of unshielded twisted pair with 100-ohm impedance and electrical characteristics supporting transmission at frequencies up to 100 MHz. However, it has improved specifications for NEXT (Near End Cross Talk), PSELFEXT (Power Sum Equal Level Far End Cross Talk), and Attenuation. To be defined in an update to the TIA/EIA 568-A standard. Targeted for 1000Base-T, but also supports 10Base-T, 100Base-T4, 100Base-T2, and 100Base-TX.

Category 6: Category 6 is a proposed standard that aims to support transmission at frequencies up to 250 MHz over 100-ohm twisted pair.

Category 7: Category 7 is a proposed standard that aims to support transmission at frequencies up to 600 MHz over 100-ohm twisted pair.

scheme ensures that one dedicated pair is always available to allow collisions to be detected on the link, while the three remaining pairs are available to carry the data transfer.

100Base-T4 does not support the full-duplex mode of operation because it cannot support simultaneous transmit and receive at 100 Mbps.

137.3.4 1000Base-X

The identifier "1000Base-X" refers to the standards that make up Gigabit networking. These include 1000Base-LX, 1000Base-SX, 1000Base-CX, and 1000Base-T. These technologies all use a Gigabit Media-Independent Interface (GMII) that attaches the Media Access Control and Physical Layer functions of a Gigabit Ethernet device. GMII is analogous to the Attachment Unit Interface (AUI) in 10-Mbps Ethernet, and the Media-Independent Interface (MII) in 100-Mbps Ethernet. However, unlike AUI and MII, no connector is defined for GMII to allow a transceiver to be attached externally via a cable. All functions are built directly into the Gigabit Ethernet device, and the GMII mentioned previously exists only as an internal component.

137.3.4.1 1000Base-LX

This cabling format uses long-wavelength lasers to transmit data over fiber-optic cable. Both single-mode and multi-mode optical fibers (explained later) are supported. Long-wavelength lasers are more expensive than short-wavelength lasers but have the advantage of being able to drive longer distances.

137.3.4.2 1000Base-SX

This cabling format uses short-wavelength lasers to transmit data over fiber-optic cable. Only multi-mode optical fiber is supported. Short-wavelength lasers have the advantage of being less expensive than long-wavelength lasers.

137.3.4.3 1000Base-CX

This cabling format uses specially shielded balanced copper jumper cables, also called "twinax" or "short haul copper." Segment lengths are limited to only 25 meters, which restricts 1000Base-CX to connecting equipment in small areas such as wiring closets.

137.3.4.4 1000Base-T

This format supports Gigabit Ethernet over 100 meters of Category 5 balanced copper cabling. It employs full-duplex transmission over four pairs of Category 5 cabling. The aggregate data rate of 1000 Mbps is achieved by transmission at a data rate of 250 Mbps over each wire pair.

137.3.5 Token Ring

Token Ring is the second most widely used local area network (LAN) technology after Ethernet. Stations on a Token Ring LAN are organized in a ring topology, with data being transmitted sequentially from one ring station to the next. Circulating a token initializes the ring. To transmit data on the ring, a station must capture the token. When a station transmits information, the token is replaced with a frame that carries the information to the stations. The frame circulates the ring and can be copied by one or more destination stations. When the frame returns to the transmitting station, it is removed from the ring and a new token is transmitted.

IBM initially defined Token Ring at its research facility in Zurich, Switzerland, in the early 1980s. IBM pursued standardization of Token Ring and subsequently introduced its first Token Ring product, an adapter for the original IBM personal computer, in 1985. The initial Token Ring products operated at 4 Mbps. IBM collaborated with Texas Instruments to develop a chipset that would allow non-IBM companies to develop their own Token Ring-compatible devices. In 1989, IBM improved the speed of Token Ring by a factor of four when it introduced the first 16-Mbps Token Ring products.

In 1997, Dedicated Token Ring (DTR) was introduced that provided dedicated, or full-duplex operation. Dedicated Token Ring bypasses the normal token passing protocol to allow two stations to communicate over a point-to-point link. This doubles the transfer rate by allowing each station to concurrently transmit and receive separate data streams. This provides an overall data transfer rate of 32 Mbps. In 1998, a new 100 Mbps Token Ring product was developed that provided dedicated operation at this extended speed.

137.3.5.1 The Ring

The ring in a Token Ring network consists of the transmission medium or cabling and the ring station. While most people consider that Token Ring is a ring network-based topology, it is not. Token Ring uses a star-wired ring topology as illustrated in Exhibit 137.9.

Each station must have a Token Ring adapter card and connects to the concentrator using a lobe cable. Concentrators can be connected to other concentrators through a patch or trunk cable using the ring-in and ring-out ports on the concentrator. The concentrator itself is commonly known as a Multi-Station Access Unit (MSAU).

Each station in the ring receives its data from one neighbor, the nearest upstream neighbor, and then transmits the data to a downstream neighbor. This means that data in the Token Ring network moves sequentially from one station to another, while checking the data for errors. The station that is the intended recipient of the data copies the information as it passes. When the information reaches the originating station again, it is stripped, or removed from the ring.

A station gains the right to transmit data, commonly referred to as frames, onto the network when it detects the token passing it. The token is itself a frame that contains a unique signaling sequence that circulates on the network following each frame transfer.

Upon detecting a valid token, any station can itself modify the data contained in the token. The token data includes:

- Control and status fields
- Address fields
- Routing information fields
- Information field
- Checksum

After completing the transmission of its data, the station transmits a new token, thus allowing other stations on the ring to gain access to the ring and transmitting data of their own.

Like some Ethernet-type networks, Token Ring networks have an insertion and bypass mechanism that allows stations to enter and leave the network. When the station is in bypass mode, the lobe cable is "wrapped" back to the station, allowing it to perform diagnostic and self-tests on a single node network. In this mode, the station cannot participate in the ring to which it is connected. When the concentrators receive a "phantom drive" signal, it is inserted into the ring.

Token Ring operates at either 4 or 16 Mbps and is known as Classic Token Ring. There are Token Ring implementations that operate at higher speeds, known as Dedicated Token Ring. Today's Token Ring adapters include circuitry to allow them to detect and adjust to the current ring speed when inserting into the network.

137.4 Cabling Types

This section introduces several of the more commonly used cable types and their uses (see also Exhibit 137.16).

137.4.1 Twisted-Pair

Twisted-pair cabling is so named because pairs of wires are twisted around each other. Each pair of wires consists of two insulated copper wires that are twisted together. By twisting the wire pairs together, it is possible to reduce crosstalk and decrease noise on the circuit.

137.4.1.1 Unshielded Twisted-Pair Cabling (UTP)

Unshielded twisted pair cabling is in popular use today. This cable, also known as UTP, contains no shielding, and like all twisted-pair formats is graded based upon "category" level. This category level determines what the acceptable cable limits are and the implementations in which it is used.

UTP is a 100-ohm cable, with multiple pairs, but most commonly contains four pairs of wires enclosed in a common sheath. 10Base-T, 100Base-TX, and 100Base-T2 use only two of the twisted-pairs, while 100Base-T4 and 1000Base-T require all four twisted-pairs.

137.4.1.2 Screened Twisted-Pair (ScTP)

Screened twisted pair (ScTP) is four-pair 100-ohm UTP, with a single foil or braided screen surrounding all four pairs. This foil or braided screen minimizes EMI radiation and susceptibility to outside noise. This type of cable is also known as foil twisted pair (FTP), or screened UTP (sUTP). Technically, screened twisted pair is the same as unshielded twisted pair with the foil shielding. It is used in Ethernet applications in the same manner as the equivalent category of UTP cabling.

137.4.1.3 Shielded Twisted-Pair Cabling (STP)

This form of cable is technically a form of shielded twisted-pair and is the term most commonly used to describe the cabling used in Token Ring networks. Each twisted-pair is individually wrapped in a foil shield and enclosed in an overall out-braided wire shield. This level of shielding both minimizes EMI radiation and crosstalk. While this cable is not generally used with Ethernet, it can be adapted for such use with the use of "baluns" or impedance-matching transformers.

137.4.2 Optical Fiber

Unlike other cable systems in which the data is transmitted using an electrical signal, optical fiber uses light. This system converts the electrical signals into light, which is transmitted through a thin glass fiber, where the receiving station converts it back into electrical signals. It is used as the transmission medium for the FOIRL, 10Base-FL, 10Base-FB, 10Base-FP, 100Base-FX, 1000Base-LX, and 1000Base-SX communications standards.

EXHIBIT 137.16 Cable Types and Properties

Standard Rate	Data Nodes per Segment	Topology	Medium	Maximum Cable Segment Length (meters)	Half-duplex	Full-duplex
10Base5	10 Mbps	100	Bus	Single 50-ohm coaxial cable (thick Ethernet) (10-mm thick)	500	n/a
10Base2	10 Mbps	30	Bus	Single 50-ohm RG 58 coaxial cable (thin Ethernet) (5-mm thick)	185	n/a
10Broad36	10 Mbps	2	Bus	Single 75-ohm CATV broadband cable	1800	n/a
FOIRL	10 Mbps	2	Star	Two optical fibers	1000	>1000
1Base5	1 Mbps		Star	Two pairs of twisted telephone cable	250	n/a
10Base-T	10 Mbps	2	Star	Two pairs of 100-ohm Category 3 or better UTP cable	100	100
10Base-FL	10 Mbps	2	Star	Two optical fibers	2000	>2000
10Base-FB	10 Mbps	2	Star	Two optical fibers	2000	n/a
10Base-FP	10 Mbps	2	Star	Two optical fibers	1000	n/a
100Base-TX	100 Mbps	2	Star	Two pairs of 100-ohm Category 5 UTP cable	100	100
100Base-FX	100 Mbps	2	Star	Two optical fibers	412	2000
100Base-T4	100 Mbps	2	Star	Four pairs of 100-ohm Category 3 or better UTP cable	100	n/a
100Base-T2	100 Mbps	2	Star	Two pairs of 100-ohm Category 3 or better UTP cable	100	100
1000Base-LX	1 Gbps	2	Star	Long-wavelength laser		
1000Base-SX	1 Gbps	2	Star	Short-wavelength laser		
1000Base-CX	1 Gbps	2	Star	Specialty shielded balanced copper jumper cable assemblies (twinax or short haul copper)	25	25
1000Base-T	1 Gbps	2	Star	Four pairs of 100-ohm Category 5 or better cable	100	100

Fiber-optic cabling is manufactured in three concentric layers. The central-most layer (or core) is the region where light is actually transmitted through the fiber. The "cladding" forms the second or middle layer. This layer has a lower refraction index, meaning that light does not travel through it as well as in the core. This serves to keep the light signal confined to the core. The outer layer serves to provide a "buffer" and protection for the inner two layers.

There are two primary types of fiber-optic cable: multi-mode fiber and single-mode fiber.

137.4.2.1 Multi-Mode Fiber (MMF)

Multi-mode fiber (MMF) allows many different modes or light paths to flow through the fiber-optic path. The MMF core is relatively large, which allows for good transmission from inexpensive LED light sources.

MMF has two types: graded or stepped. Graded index fiber has a lower refraction index toward the outside of the core and progressively increases toward the center of the core. This index reduces signal dispersion in the fiber. Stepped index fiber has a uniform refraction index in the core, with a sharp decrease in the index of refraction at the core/cladding interface. Stepped index multi-mode fibers generally have lower bandwidths than graded index multi-mode fibers.

The primary advantage of multi-mode fiber over twisted-pair cabling is that it supports longer segment lengths. From a security perspective, it is much more difficult to obtain access to the information carried on the fiber than on twisted-pair cabling.

137.4.2.2 Single-Mode Fiber (SMF)

Single-mode fiber (SMF) has a small core diameter that supports only a single mode of light. This eliminates dispersion, which is the major factor in limiting bandwidth. However, the small core of a single-mode fiber makes coupling light into the fiber more difficult, and thus the use of expensive lasers as light sources is required. Laser sources are used to attain high bandwidth in SMF because LEDs emit a large range of frequencies, and thus dispersion becomes a significant problem. This makes use of SMFs in networks more expensive to implement and maintain.

SMF is capable of supporting much longer segment lengths than MMF. Segment lengths of 5000 meters and beyond are supported at all Ethernet data rates through 1 Gbps. However, SMF has the disadvantage of being significantly more expensive to deploy than MMF.

137.4.2.3 Token Ring

As mentioned, Token Ring systems were originally implemented using shielded twisted-pair cabling. It was later adapted to use the conventional unshielded twisted-pair wiring. Token Ring uses two pairs of wires to connect each workstation to the concentrator. One pair of wires is used for transmitting data and the other for receiving data.

Shielded twisted-pair cabling contains two wire pairs for the Token Ring network connection and may include additional pairs for carrying telephone transmission. This allows a Token Ring environment to use the same cabling to carry both voice and data. UTP cabling typically includes four wire pairs, of which only two are used for Token Ring.

Token Ring installations generally use a nine-pin D-shell connector as the media interface. With the adaptation of unshielded twisted-pair cabling, it is now possible to use either the D-shell or the more predominant RJ-45 data jack. Modern Token Ring cards have support for both interfaces.

Older Token Ring cards that do not have the RJ-45 jack can still be connected to the unshielded twisted-pair network through the use of an impedance matching transformer, or balun. This transformer converts from the 100-ohm impedance of the cable to the 150-ohm impedance that the card is expecting.

137.5 Cabling Vulnerabilities

There are only a few direct vulnerabilities to cabling, because this is primarily a physical medium and, as a result, direct interference or damage to the cabling is required. However, with the advent of wireless communications, it has become possible for data on the network to be eavesdropped without anyone's knowledge.

137.5.1 Interference

Interference occurs when a device is placed intentionally or unintentionally in a location to disrupt or interfere with the flow of electrical signals across the cable. Data flows along the cable using electrical properties and can be altered by magnetic or other electrical fields. This can result in total signal loss or in the modification of data on the cable. The modification of the data generally results in data loss.

Interference can be caused by machinery, microwave devices, and even by fluorescent light fixtures. To address situations such as these, alternate cabling routing systems (including conduit) have been deployed and specific installations arranged to accommodate the location of the cabling. Additionally, cabling has been developed that reduces the risk of such signal loss by including a shield or metal covering to protect the cabling. Because fiber-optic cable uses light to transmit the signals, it does not suffer from this problem.

137.5.2 Cable Cutting

This is likely the cause of more network outages than any other. In this case, the signal path is broken as a result of physically cutting the cable. This can happen when the equipment is moved or when digging in the vicinity of the cable cuts through it. Communications companies that offer public switched services generally address this by installing network-redundant circuits when the cable is first installed. Additionally, they design their network to include fault tolerance to reduce the chance of total communications loss.

Generally, the LAN manager does not have the same concerns. His concerns focus on the protection of the desktop computers from viruses and from being handled incorrectly resulting in lost information. The LAN managers must remember that the office environment is also subject to cable cuts from accidental damage and from service or construction personnel. Failure to have a contingency and recovery plan could jeopardize their position.

137.5.3 Cable Damage

Damage to cables can result from normal wear and tear. The act of attaching a cable over time damages the connectors on the cable plug and the jack. The cable itself can also become damaged due to excessive bending or stretching. This can cause intermittent communications in the network, leading to unreliable communications.

Cable damage can be reduced through proper installation techniques and by regularly performing checks on exposed cabling to validate proper operation to specifications.

137.5.4 Eavesdropping

Eavesdropping occurs when a device is placed near the cabling to intercept the electronic signals and then reconvert them into similar signals on an external transmission medium. This provides unauthorized users with the ability to see the information without the original sender and receiver being aware of the interception. This can be easily accomplished with Ethernet and serial cables, but it is much more difficult with fiber-optic cables because the cable fibers must be exposed. Damage to the outer sheath of the fiber cables modifies their properties, producing noticeable signal loss.

137.5.5 Physical Attack

Most network devices are susceptible to attack from the physical side. This is why any serious network designer will take appropriate care in protecting the physical security of the devices using wiring closets, cable conduits, and other physical protection devices. It is understood that with physical access, the attacker can do almost anything. However, in most cases, the attacker does not have the luxury of time. If attackers need time to launch their attack and gain access, then they will use a logical or network-based approach.

137.5.6 Logical Attack

Many of these network elements are accessible via the network. Consequently, all of these devices must be appropriately configured to deny unauthorized access. Additional preventive, detective, and reactive controls must be installed to identify intrusions or attacks against these devices and report them to the appropriate monitoring agency within the organization.

137.6 Summary

In conclusion, there is much about today's networking environments for the information security specialist to understand. However, being successful in assisting the network engineers in designing a secure solution does not mean understanding all of the components of the stack, or of the physical transport method involved. It does, however, require knowledge of what they are talking about and the differences in how the network is built with the different media options and what the inherent risks are.

However, despite the different network media and topologies available, there is a significant level of commonality between them as far as risks go. If one is not building network-level protection into the network design (i.e., network-level encryption), then it needs to be included somewhere else in the security infrastructure.

The network designer and the security professional must have a strong relationship to ensure that the concerns for data protection and integrity are maintained throughout the network.

138

Wired and Wireless Physical Layer Security Issues

James Trulove

Network security considerations normally concentrate on the higher layers of the OSI seven-layer model. However, significant issues exist in protecting physical security of the network, in addition to the routine protection of data message content that crosses the Internet. Even inside the firewall, an enterprise network may be vulnerable to unauthorized access.

Conventional wired networks are subject to being tapped by a variety of means, whether copper or fiber connections are used. In addition, methods of network snooping exist that make such eavesdropping minimally invasive, but no less significant. Wireless networking has additional characteristics that also decrease physical network security. As new technologies emerge, the potential for loss of company information through lax physical security must be carefully evaluated and steps taken to mitigate the risk.

In addition to automated security measures, such as intrusion detection and direct wiring monitoring, careful network management procedures can enhance physical security. Proper network design is critical to maintaining the desired level of security. In addition to the measures used on wired networks, wireless networks should be protected with encryption.

138.1 Wired Network Topology Basics

Everyone involved with local area networking has a basic understanding of network wiring and cabling. Modern LANs are almost exclusively Ethernet hub-and-spoke topologies (also called star topologies). Individual cable runs are made from centralized active hubs to each workstation, network printer, server, or router. At today's level of technology, these active hubs may perform additional functions, including switching, VLAN (virtual LAN) filtering, and simple layer 3 routing. In some cases, relatively innocuous decisions in configuring and interconnecting these devices can make a world of difference in a network's physical security.

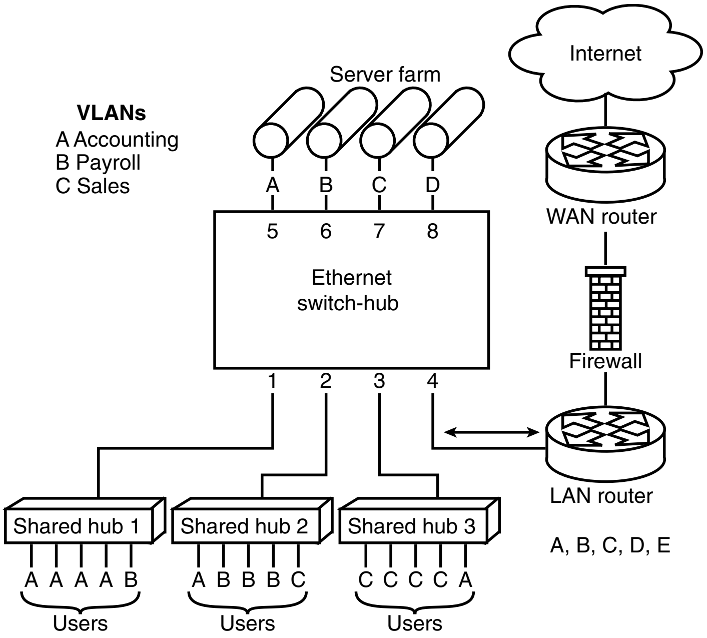

EXHIBIT 138.1 Topology of a network with shared, switched, and routed connections.

An illustration of network topology elements is shown in Exhibit 138.1. The exhibit shows the typical user-to-hub and hub-to-hub connections, as well as the presence of switching hubs in the core of the network. Three VLANs are shown that can theoretically separate users in different departments. The general purpose of a VLAN is to isolate groups of users so they cannot access certain applications or see each other's data. VLANs are inherently difficult to diagram and consequently introduce a somewhat unwelcome complexity in dealing with physical layer security. Typically, a stand-alone router is used to interconnect data paths between the VLANs and to connect to the outside world, including the Internet, through a firewall. A so-called layer 3 switch could actually perform the non-WAN functions of this router, but some sort of WAN router would still be needed to make off-site data connections, such as to the Internet.

This chapter discusses the physical layer security issues of each component in this network design as well as the physical security of the actual interconnecting wiring links between the devices.

138.2 Shared Hubs

The original concept of the Ethernet network topology was that of a shared coaxial media with periodic taps for the connection of workstations. Each length of this media was called a segment and was potentially interconnected to other segments with a repeater or a bridge. Stations on a segment listened for absence of signal before beginning a transmission and then monitored the media for indication of a collision (two stations transmitting at about the same time). This single segment (or group of segments linked by repeaters) is considered a collision domain, as a collision anywhere in the domain affects the entire domain. Unfortunately, virtually any defect in the main coax or in any of the connecting transceivers, cables, connectors, or network interface cards (NICs) would disrupt the entire segment.

One way to minimize the effects of a single defect failure is to increase the number of repeaters or bridges. The shared hub can decrease the network failures that are a result of physical cable faults. In the coaxial-Ethernet world, these shared hubs were called multiport repeaters, which closely described their function. Additional link protection was provided by the evolution to twisted-pair Ethernet, commonly known as 10BaseT. This link topology recognizes defective connections and dutifully isolates the offending link from the rest of the hub, which consequently protects the rest of the collision domain. The same type of shared network environment is available to 10BaseF; 100BaseT, FX, and SX (Fast Ethernet); and 1000BaseT, TX, FX, SX (Gigabit Ethernet).

Shared hubs, unfortunately, are essentially a party line for data exchange. Privacy is assured only by the courtesy and cooperation of the other stations in the shared network. Data packets are sent out on the shared network with a destination and source address, and the protocol custom dictates that each workstation node "listens" only to those packets that have its supposedly unique address as the destination. Conversely, a courteous workstation would listen exclusively to traffic addressed to itself and would submit a data packet only to the shared network with its own uniquely assigned address as the source address. Right!?

In practice, it is possible to connect sophisticated network monitoring devices, generically called network sniffers to any shared network and see each and every packet transmitted. These monitoring devices are very expensive (U.S.$10,000 to $25,000) and high-performance, specialized test equipment, which would theoretically limit intrusion into networks. However, much lower-performance, less-sophisticated packet-snooping software is readily available and can run on any workstation (including PDAs). This greatly complicates the physical security problem, as any connected network device, whether authorized or not, can snoop virtually all of the traffic on a shared LAN.

In addition to the brute-force sniffing devices, a workstation may simply attempt to access network resources for which it has no inherent authorization. For example, in many types of network operating system (NOS) environments, one may easily access network resources that are available to any authorized user. Microsoft's security shortcomings are well documented, from password profiles to NetBIOS and from active control structures to the infamous e-mail and browser problems. A number of programs are available to assist the casual intruder in unauthorized information mining.

In a shared hub environment, physical layer security must be concerned with limiting physical access to workstations that are connected to network resources. For the most part, these workstation considerations are limited to the use of boot-up, screen saver, and log-in passwords; the physical securing of computer equipment; and the physical media security described later. Most computer boot routines, network logins, and screen savers provide a method of limiting access and protecting the workstation when not in use. These password schemes should be individualized and changed often.

Procedures for adding workstations to the network and for interconnecting hubs to other network devices should be well documented and their implementation limited to staff members with appropriate authorization. Adds, moves, and changes should also be well documented. In addition, the physical network connections and wiring should be periodically audited by an outside organization to ensure the integrity of the network. This audit can be supplemented by network tools and scripts that self-police workstations to determine that all of the connected devices are known, authorized, and free of inappropriate software that might be used to intrude within the network.

138.3 Switched Hubs Extend Physical Security

The basic security fault of a shared network is the fact that all packets that traverse the network are accessible to all workstations within the collision domain. In practice, this may include hundreds of workstations. A simple change to a specialized type of hub, called a switched hub, can provide an additional measure of security, in addition to effectively multiplying data throughput of the hub.

A switched hub is an OSI layer 2 device, which inspects the destination media access layer (MAC) address of a packet and selectively repeats the packet only to the appropriate switch port segment on which that MAC address device resides. In other words, if a packet comes in from any port, destined for a known MAC address X_1 on port 3, that packet would be switched directly to port 3, and would not appear on any other outbound port. This is illustrated in Exhibit 138.2. The switch essentially is a multiport layer 2 bridge that learns the relative locations of all MAC addresses of devices that are attached and

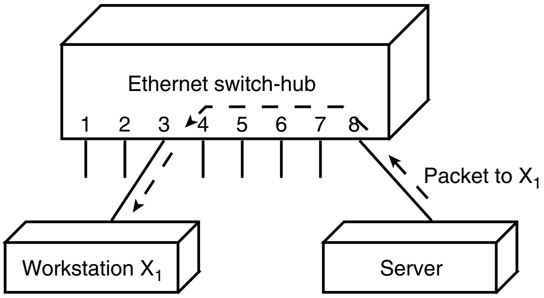

EXHIBIT 138.2 Switched Ethernet hub operation.

forms a temporary path to the appropriate destination port (based on the destination MAC address) for each packet that is processed. This processing is normally accomplished at "wire speed." Simultaneous connection paths may be present between sets of ports, thus increasing the effective throughput beyond the shared hub.

Switched hubs are often used as simple physical security devices, because they isolate the ports that are not involved in a packet transmission. This type of security is good if the entire network uses switched connections. However, switched hubs are still more expensive than shared hubs, and many networks are implemented using the switch-to-shared hub topology illustrated in Exhibit 138.1. While this may still provide a measure of isolation between groups of users and between certain network resources, it certainly allows any user on a shared hub to view all the packets to any other user on that hub.

Legitimate testing and monitoring on a switched hub is much more difficult than on a shared hub. A sniffing device connected to port 7 (Exhibit 138.2), for example, could not see the packet sent from port 8 to port 3! The sniffer would have its own MAC address, which the switch would recognize, and none of the packets between these two other nodes would be sent. To alleviate this problem somewhat, a feature called port mirroring is available on some switches. Port mirroring can enable a user to temporarily create a shared-style listening port on the switch that duplicates all the traffic on a selected port. Alternatively, one could temporarily insert a shared hub on port 3 or port 8 to see each port's respective traffic. An inadvertent mirror to a port that is part of a shared-hub network can pose a security risk to the network. This is particularly serious if the mirrored port happens to be used for a server or a router connection, because these devices see data from many users.

To minimize the security risk in a switched network, it is advisable to use port mirroring only as a temporary troubleshooting technique and regularly monitor the operation of switched hubs to disable any port mirroring. In mixed shared/switched networks, layer 2 VLANs may offer some relief (the cautions of the next section notwithstanding). It may also be possible to physically restrict users to hubs that are exclusively used by the same department, thus minimizing anyone's ability to snoop on other departments' data. This assumes that each department-level shared hub has an uplink to a switched hub, perhaps with VLAN segregation.

In addition, administrators should tightly manage the passwords and access to the switch management interface. One of the most insidious breaches in network security is the failure to modify default passwords and to systematically update control passwords on a regular basis.

138.4 VLANS Offer Deceptive Security

One of the most often used network capabilities for enhancing security is the virtual LAN (VLAN) architecture. VLANs can be implemented at either layer 2 or layer 3.

A layer 2 VLAN consists of a list of MAC addresses that are allowed to exchange data and is rather difficult to administer. An alternative style of layer 1/layer 2 VLAN assigns physical ports of the switch to

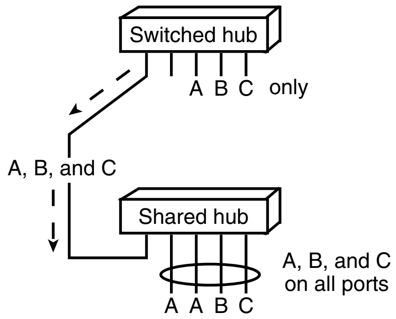

EXHIBIT 138.3 VLANs A, B, and C behavior across both switched and shared Ethernet hubs.

different VLANs. The only caveat here is that all of the devices connected to a particular switch port are restricted to that VLAN. Thus, all of the users of shared hub 1 (Exhibit 138.1) would be assigned to switch hub port 1's VLAN. This may be an advantage in many network designs and can actually enhance security.

Here is the deception for layer 2. A layer 2 VLAN fails to isolate packets from all of the other users in either a hierarchical (stacked) switch network or in a hybrid shared/switched network. In the hybrid network, all VLANs may exist on any shared hub, as shown in Exhibit 138.3. Therefore, any user on shared hub 2 can snoop on any traffic on that hub, regardless of VLAN. In a port-based layer 2 VLAN, the administrator must be certain that all users that are connected to each port of the VLAN are entitled to see any of the data that passes to or from that port. Sadly, the only way to do that is to connect every user to his own switch port, which takes away the convenience of the VLAN and additionally adds layers of complexity to setup. A MAC-based VLAN can still allow others to snoop packets on shared hubs or on mirrored switch hubs.

A layer 3 VLAN is really a higher-level protocol subnet. In addition to the MAC address, packets that bear Internet Protocol (IP) data possess a source and destination address. A subset of IP addresses, called a subnet, consists of a contiguous range of addresses. Typically, IP devices recognize subnets through a base address and a subnet mask that "sizes" the address range of the subnet. The IP protocol stack screens out all data interchanges that do not bear addresses within the same subnet. A layer 3 router allows connection between subnets. Technically, then, two devices must have IP addresses in the same subnet to "talk," or they must connect through a router (or series of routers) that recognizes both subnets.

The problem is that IP data packets of different subnets may coexist within any collision domain—that is, on the same shared hub or switched link. The TCP/IP protocol stack simply ignores any packet that is not addressed to the local device. As long as everybody is a good neighbor, packets go only where they are intended. Right?

In reality, any sniffer or snooping program on any workstation can see all data traffic that is present within its collision domain, regardless of IP address. The same was true of non-IP traffic, as was established previously. This means that protecting data transmission by putting devices in different subnets is a joke, unless care is taken to limit physical access to the resources so that no unauthorized station can snoop the traffic.

138.5 VLAN/Subnets Plus Switching

A significant measure of security can be provided within a totally switched network with VLANs and subnets. In fact, this is exactly the scheme that is used in many core networks to restrict traffic and resources to specific, protected paths. For the case of direct access to a data connection, physical security of the site is the only area of risk. As long as the physical connections are limited to authorized devices, port mirroring is off, and no remote snooping (often called Trojan horse) programs are running surreptitiously and firewalling measures are effective, then the protected network will be reasonably secure, from the physical layer standpoint.

Reducing the risk of unauthorized access is very dependent on physical security. Wiring physical security is another issue that is quite important, as is shown in the following section.

138.6 Wiring Physical Security

Physical wiring security has essentially three aspects: authorized connections, incidental signal radiation, and physical integrity of connections. The first requirement is to inspect existing cabling and verify that every connection to the network goes to a known location. Organized, systematic marking of every station cable, patch cord, patch panel, and hub is a must to ensure that all connections to the network are known and authorized.

Where does every cable go? Is that connection actually needed? When moves are made, are the old data connections disabled? Nothing could be worse than having extra data jacks in unoccupied locations that are still connected to the network. The EIA/TIA 569 A *Commercial Building Standard for Telecommunications Pathways and Spaces and* EIA/TIA 606 *The Administration Standard for the Telecommunications Infrastructure of Commercial Buildings* give extensive guidelines for locating, sizing, and marking network wiring and spaces.

In addition, the cable performance measurements that are recommended by ANSI/TIA/EIA-568-B *Commercial Building Telecommunications Cabling Standard* should be kept on file and periodically repeated. The reason is simple. Most of the techniques that could be used to tap into a data path will drastically change the performance graph of a cable run. For example, an innocuous shared hub could be inserted into a cable path, perhaps hidden in a wall or ceiling, to listen in to a data link. However, this action would change the reported cable length, as well as other parameters reported by a cable scanner.

Network cabling consists of two types: four-pair copper cables and one-pair fiber-optic cables. Both are subject to clandestine monitoring. Copper cabling presents the greater risk, as no physical connection may be required. As is well known, high-speed data networking sends electrical signals along two or more twisted pairs of insulated copper wire. A 10BaseT Ethernet connection has a fundamental at 10 MHz and signal components above that. A 100BaseT Fast Ethernet connection uses an encoding technique to keep most of the signal component frequencies below 100 MHz. Both generate electromagnetic fields, although most of the field stays between the two conductors of the wire pair. However, a certain amount of energy is actually radiated into the space surrounding the cable.

The major regulatory concern with this type of cabling is that this radiated signal should be small so it does not interfere with conventional radio reception. However, that does not mean that it cannot be received! In fact, one can pick up the electromagnetic signals from Category 3 cabling anywhere in proximity to the cable. Category 5 and above cabling is better only by degree. Otherwise, the cable acts like an electronic leaky hose, spewing tiny amounts of signal all along its length.

A sensor can be placed anywhere along the cable run to pick up the data signal. In practice, it is (fortunately) a little more difficult than this, simply because this would be a very sophisticated technique and because access, power, and an appropriate listening point would also be required. In addition, bidirectional (full-duplex) transmission masks the data in both directions, as do multiple cables. This probably presents less of a threat to the average data network than direct physical connection, but the possibility should not be ignored.

Fiber cable tapping is a much subtler problem. Unlike that on its copper equivalent, the signal is in the form of light and is carried within a glass fiber. However, there are means to tap into the signal if one has access to the bare fiber or to interconnect points. It is true that most of the light passes longitudinally down the glass fiber. However, a tiny amount may be available through the sidewall of the fiber, if one has the means to detect it. Presumably, this light leakage would be more evident in a multi-mode fiber, where the light is not restricted to so narrow a core as with single-mode fiber. In addition, anyone with access to one of the many interconnection points of a fiber run could tap the link and monitor the data.

Fiber-optic cable runs consist of patch and horizontal fiber cable pairs that are connectorized at the patch panel and at each leg of the horizontal run. Each connectorized cable segment is interconnected to the next leg by a passive coupler (also called an adapter). For example, a typical fiber link is run through the wall to the workstation outlet. The two fibers are usually terminated in an ordinary fiber connector, such as an SC or one of the new small-form factor connectors. The pair of connectors is then inserted into the inside portion of the fiber adapter in the wall plate, and the plate is attached to the outlet box. A user cable or patch cord is then plugged into the outside portion of the same fiber adapter to connect the equipment. If some person were to have access to removing the outlet plate, it would take a few seconds to insert a device to tap into the fiber line, since it is conveniently connectorized with a standard connector, such as the SC connector.

Modern progress has lessened this potential risk somewhat, as some of the new small-form factor connector systems use an incompatible type of fiber termination in the wall plate. However, this could certainly be overcome with a little ingenuity.

Most of the techniques that involve a direct connection or tap into a network cable require that the cable’s connection be temporarily interrupted. Cable-monitoring equipment is available that can detect any momentary break in a cable, to make the reconnection of a cable through an unauthorized hub, or to make a new connection into the network. This full-time cable-monitoring equipment can report and log all occurrences, so that an administrator can be alerted to any unusual activities on the cabling system.

Security breaches happen and, indeed, should be anticipated. An intrusion detection system should be employed inside the firewall to guard against external and internal security problems. It may be the most effective means of detecting unauthorized access to an internal network. An intrusion detection capability can include physical layer alarms and reporting, in addition to the monitoring of higher layers of protocol.

138.7 Wireless Physical Layer Security

Wireless networking devices, by their very nature, purposely send radio signals out into the surrounding area. Of course, it is assumed that only the authorized device receives the wireless signal, but it is impossible to limit potential eavesdropping. Network addressing and wireless network “naming” cannot really help, although they are effective in keeping the casual user out of a wireless network.

The only technique that can ensure that someone cannot easily monitor wireless data transmissions is data encryption. Many of the wireless LAN devices on the market now offer Wired Equivalent Privacy (WEP) as a standard feature. This is a 64-bit encryption standard that uses manual key exchange to privatize the signal between a wireless network interface card (WNIC) and an access point bridge (which connects to the wired network). As the name implies, this is not expected to be a high level of security; it is expected only to give one approximately the same level of privacy that would exist if the connection were made over a LAN cable.

Some WNICs use a longer encryption algorithm, such as 128-bit encryption, that may provide an additional measure of security. However, there is an administration issue with these encryption systems, and keys must be scrupulously maintained to ensure integrity of the presumed level of privacy.

Wireless WAN connections, such as the popular cellular-radio systems, present another potential security problem. At the present time, few of these systems use any effective encryption whatsoever and thus are accessible to anyone with enough reception and decoding equipment. Strong-encryption levels of SSL should certainly be used with any private or proprietary communications over these systems.

138.8 Conclusion

A complete program of network security should include considerations for the physical layer of the network. Proper network design is essential in creating a strong basis for physical security. The network practices should include the use of switching hubs and careful planning of data paths to avoid unnecessary exposure of sensitive data. The network manager should ensure that accurate network cabling system records are maintained and updated constantly to document authorized access and to reflect all moves and adds. Active network and cable monitoring may be installed to enhance security. Network cable should be periodically inspected to ensure integrity and authorization of all connections. Links should be rescanned periodically and discrepancies investigated. Wireless LAN connections should be encrypted at least to WEP standards, and strong encryption should be considered. Finally, the information security officer should consider the value of periodic security audits at all layers to cross-check the internal security monitoring efforts.

139
Network Router Security

Steven F. Blanding

Routers are a critical component in the operation of a data communications network. This chapter describes network router capabilities and the security features available to manage the network. Routers are used in local area networks, wide area networks, and for external connections, either to service providers or to the Internet.

139.1 Router Hardware and Software Components

Routers contain a core set of hardware and software components, although the router itself provides different capabilities and has different interfaces. The core hardware components include the central processing unit (CPU), random access memory (RAM), nonvolatile RAM, read-only memory (ROM), flash memory, and input/output (I/O) ports. These are outlined in Exhibit 139.1. While these components may be configured differently, depending on the type of router, they remain critical to the proper overall operation of the device and support for the router's security features.

- *Central processing unit.* Typically known as a critical component in PCs and larger computer systems, the CPU is also a critical component found in network routers. The CPU, or microprocessor, is directly related to the processing power of the router, executing instructions that make up the router's operating system (OS). User commands entered via the console or Telnet connection are also handled by the CPU.
- *Random access memory.* RAM is used within the router to perform a number of different functions. RAM is also used to perform packet buffering, provide memory for the router's configuration file (when the device is operational), hold routing tables, and provide an area for the queuing of packets when they cannot be directly output due to traffic congestion at the

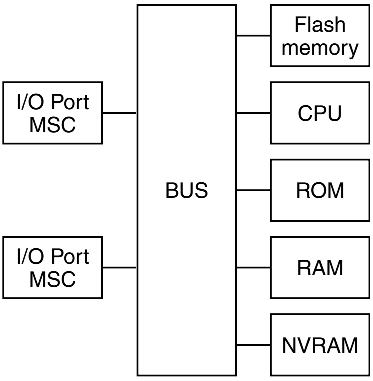

EXHIBIT 139.1 Basic router hardware components.

common interface. During operation, RAM provides space for caching Address Resolution Protocol (ARP) information that enhances the transmission capability of local area networks connected to the router.

- *Nonvolatile RAM*. When the router is powered off, the contents of RAM are cleared. Nonvolatile RAM (NVRAM) retains its contents when the router is powered off. Recovery from power failures is performed much more quickly where a copy of the router's configuration file is stored in NVRAM. As a result, the need to maintain a separate hard disk or floppy device to store the configuration file is eliminated. The wear-and-tear or moving components such as hard drives is the primary source of router hardware failures. As a result, the absence of these moving components provides for a much longer life span.
- *Read-only memory*. Code contained on read-only memory (ROM) chips on the system board in routers performs power-on diagnostics. This function is similar to the power-on self-test that PCs perform. In network routers, OS software is also loaded by a bootstrap program in ROM. Software upgrades are performed by removing and replacing ROM chips on some types of routers, while others may use different techniques to store and manage the operating system.
- *Flash memory*. An erasable and reprogrammable type of ROM is referred to as flash memory. The router's microcode and an image of the OS can be held in flash memory on most routers. The cost of flash memory can easily be absorbed through savings achieved on chip upgrades over time because it can be updated without having to remove and replace chips. Depending on the memory capacity, more than one OS image can be stored in flash memory. A router's flash memory can also be used to Trival File Transfer Protocol (TFTP) an OS image to another router.
- *Input/output ports*. The connection through which packets enter and exit a router is the I/O port. Media-specific converters, which provide the physical interface to specific types of media, are connected to each I/O port. The types of media include Ethernet LAN, Token Ring LAN, RS-232, and V.35 WAN. As data packets pass through the ports and converters, each packet must be processed by the CPU to consult the routing table and determine where to send the packet. This process is called process switching mode. Layer 2 headers are removed as the packet is moved into RAM as data is received from the LAN. The packet's output port and manner of encapsulation are determined by this process.

A variation of process switching mode is called fast switching, in which the router maintains a memory cache containing information about destination IP addresses and next-hop interfaces. In fast switching, the router builds the cache by saving information previously obtained from the routing table. In this scheme, the first packet to a specific destination causes the CPU to consult the routing table. After information is obtained regarding the next-hop interface for that particular destination and that information is inserted into the fast switching cache, the routing table is no longer consulted for new packets sent to this destination. As a result, a substantial reduction in the load on the router's CPU occurs and the router's capacity to switch packets takes place at a much faster rate. Some of the higher-end router models are special hardware features that allow for advanced variations of fast switching. Regardless of the type of router, cache is used to capture and store the destination address to interface mapping. Some advanced-feature routers also capture the source IP address and the upper layer TCP ports. This type of switching mode is called netflow switching.

139.1.1 Initializing Routers

The router executes a series of predefined operations when the device is powered on. Depending on the previous configuration of the router, additional operations can be performed. These operations contribute to the stability of the router, and are necessary to its proper and secure performance.

The first function performed by the router is a series of diagnostic tests called power-on tests or POST. These tests validate the operation of the router's processor, memory, and interface circuitry. This function, as well as all of the other major functions performed during power-on time, is illustrated in Exhibit 139.2.

According to the flowchart, upon completion of the POST process, the bootstrap loader is to initialize the operating system (OS) into main memory. The first step in this process is to determine the location of

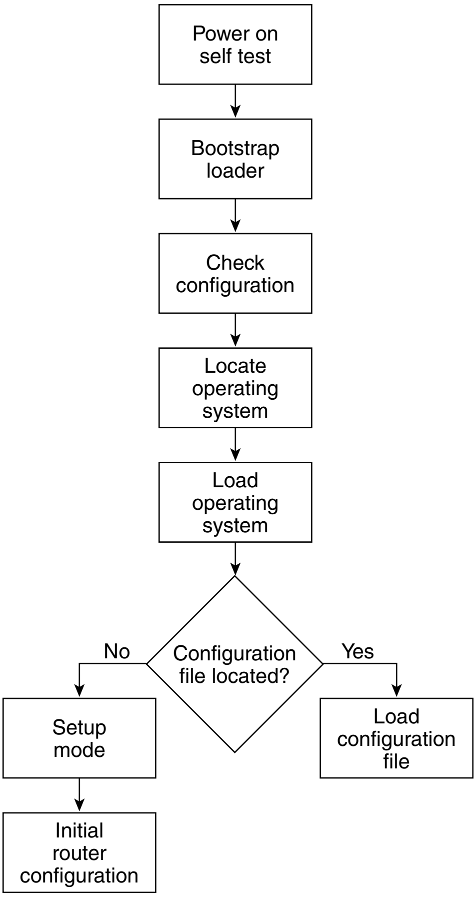

EXHIBIT 139.2 Router initialization.

the OS image by checking the router's configuration register. The image could be located in either ROM, flash memory, or possibly on the network. The register settings not only indicate the location of the OS, but they also define other key functions, including whether the console terminal displays diagnostic messages and how the router reacts to the entry to the entry of a break key on the console keyboard. Typically, the configuration register is a 16-bit value with the last four bits indicating the boot field. The location of the router's configuration file is identified by the boot field. The router will search the configuration file for boot commands if the boot register is set to 2, which is the most common setting. The router will load the OS image from flash memory if this setting is not found. The router will send a TFTP request to the broadcast address requesting an OS image if no image exists in flash memory. The image will then be loaded from the TFTP server.

The bootstrap loader loads the OS image into the router's RAM once the configuration register process is complete. With the OS image now loaded, NVRAM is examined by the bootstrap loader to determine if a previous version of the configuration file had been saved. This file is then loaded into RAM and executed, at which point the router becomes operational. If the file is not stored in NVRAM, a Setup dialog is established by the operating system. The Setup dialog is a predefined sequence of questions posed to the console operator that must be completed to establish the configuration information that is then stored in NVRAM.

During subsequent initialization procedures, this version of the configuration file will be copied from NVRAM and loaded into RAM. To bypass the contents of the configuration file during password recovery of the router, the configuration register can be instructed to ignore the contents of NVRAM.

139.1.2 Operating System Image

As mentioned, the bootstrap loader locates the OS image based on the setting of the configuration register. The OS image consists of several routines that perform the following functions:

- Executing user commands
- Supporting different network functions
- Updating routing tables
- Supporting data transfer through the router, including managing buffer space

The OS image is stored in low-address memory.

139.1.3 Configuration File

The role of the configuration file was discussed briefly in the router initialization process. The router administrator is responsible for establishing this file, which contains information interpreted by the OS. The configuration file is a key software component responsible for performing different functions built into the OS. One of the most important functions is the definition of access lists and how they are applied by the OS to different interfaces. This is a critical security control function that establishes the degree of control concerning packet flow through the router. In other words, the OS interprets and executes the access control list statements stored in the configuration file to establish security control. The configuration file is stored in the upper-address memory of the NVRAM when the console operator saves it. The OS then accesses it, which is stored in the lower-address memory of NVRAM.

139.2 Controlling Router Data Flow

Understanding how the router controls data flow is key to the overall operation of this network device. The information stored in the configuration file determines how the data will flow through the router.

To begin, the types of frames to be processed are determined at the media interface—either Ethernet, Token Ring, FDDI, etc.—by previously entered configuration commands. These commands consist of one or more operating rates and other parameters that fully define the interface. The router verifies the frame format of arriving data and develops frames for output after it knows the type of interface it must support. The frames for output could be formed via that interface or through a different interface. An important control feature provided by the router is its ability to use an appropriate cyclic redundancy check (CRC). The CRC feature checks data integrity on received frames because the interface is known to the router. The appropriate CRC is also computed and appended to frames placed onto media by the router.

The method by which routing table entries occur is controlled by configuration commands within NVRAM. These entries include static routing, traffic prioritization routing, address association, and packet destination interface routing. When static routing is configured, the router does not exchange routing table entries with other routers. Prioritization routing allows data to flow into one or more priority queues where higher-priority packets pass ahead of lower-priority packets. The area within memory that stores associations between IP addresses and their corresponding MAC layer 2 addresses is represented by ARP cache. The destination interfaces through which the packet will be routed are also defined by entries in the routing table.

As data flows into a router, several decision operations take place. For example, if the data packet destination is a LAN and address resolution is required, the router will use the ARP cache to determine the MAC delivery address and outgoing frame definition. The router will form and issue an ARP packet to determine the necessary layer 2 address if the appropriate address is not in cache. The packet is ready for delivery to an outgoing interface port once the destination address and method of encapsulation are determined. Depending on priority definitions, the packet could be placed into a priority queue prior to delivery into the transmit buffer.

139.3 Configuring Routers

Before addressing the security management areas associated with routers, the router configuration process must first be understood. This process includes a basic understanding of setup considerations, the Command Interpreter, the user mode of operation, the privileged mode of operation, and various types of configuration commands. Once these areas are understood, the access security list and the password control functions of security management are described.

139.3.1 Router Setup Facility

The router setup facility is used to assign the name to the router and to assign both a direct connect and virtual terminal password. The operator is prompted to accept the configuration once the setup is complete. During the setup configuration process, the operator must be prepared to enter several specific parameters for each protocol and interface. In preparation, the operator must be familiar with the types of interfaces installed and the list of protocols that can be used.

The router setup command can be used to not only review previously established configuration entries, but also to modify them. For example, the operator could modify the enable password using the enable command. The enable password must be specified by the operator upon entering the enable command on the router console port. This command allows access to privileged execute commands that alter a router’s operating environment. Another password, called the enable secret password, can also be used to provide access security. This password serves the same purpose as the enable password; however, the enable secret password is encrypted in the configuration file. As a result, only the encrypted version of the enable secret password is available when the configuration is displayed on the console. Therefore, the enable secret password cannot be disclosed by obtaining a copy of the router configuration. To encrypt the enable password—as well as the virtual terminal, auxiliary, and console ports—the service password-encryption command can be used. This encryption technique is not very powerful and can be easily compromised through commonly available password-cracking software. As a result, the enable secret password should be used to provide adequate security to the configuration file.

139.3.2 Command Interpreter

The command interpreter is used by the router to interpret router commands entered by the operator. The interpreter checks the command syntax and executes the operation requested. To obtain access to the command interpreter, the operator must log on to the router using the correct password, which was established during the setup process. There are two separate command interpreter levels or access levels available to the operator. These are referred to as user and privileged commands, each of which is equipped with a separate password.

- *User mode of operation*. The user mode of operation is obtained by simply logging into the router. This level of access allows the operator to perform such functions as displaying open connections, changing the terminal parameters, establishing a logical connection name, and connecting to another host. These are all considered noncritical functions.
- *Privileged mode of operation*. The privileged commands are used to execute sensitive, critical operations. For example, the privileged command interpreter allows the operator to lock the terminal, turn privileged commands off or on, and enter configuration information. Exhibit 139.3 contains a list of some of the privileged mode commands. All commands available to the user mode are also available to the privileged mode. User mode commands are not included in the list.

The privileged mode of operation must be used to configure the router. A password is not required the first time one enters this mode. The enable-password command would then be used to assign a password for subsequent access to privileged mode.

139.3.3 Configuration Commands

Configuration commands are used to configure the router. These commands are grouped into four general categories: global, interface, line, and router subcommands. Exhibit 139.4 contains a list of router configuration commands.

Global configuration commands define systemwide parameters, to include access lists. Interface commands define the characteristics of a LAN or WAN interface and are preceded by an interface command. These commands are used to assign a network to a particular port and configure specific parameters required for the interface. Line commands are used to modify the operation of a serial terminal line. Finally, router subcommands are used to configure IP routing protocol parameters and follow the use of the router command.

139.3.4 Router Access Control

As mentioned previously, access control to the router and to the use of privileged commands is established through the use of passwords. These commands are included in Exhibit 139.5.

EXHIBIT 139.3 Prigileged Mode Commands

Command	Function
Clear	Reset functions
Configure	Enter configuration mode
Connect	Open a terminal connection
Disable	Turn off privileged commands
Erase	Erase flash or configuration memory
Lock	Lock the terminal
Reload	Halt and perform cold restart
Setup	Run the SETUP command facility
Telnet	Open a telnet session
Tunnel	Open a tunnel connection
Write	Write running configuration to memory

EXHIBIT 139.4 Router Configuration Commands

Command	Use
Write terminal	Display the current configuration in RAM
Write network	Share the current configuration in RAM with a network server via TFTP
Write erase	Erase the contents of NVRAM
Configure network	Load a previously created configuration from a network server
Configure memory	Load a previously created configuration from NVRAM
Configure terminal	Configure router manually from the console

EXHIBIT 139.5 Router Access Control Commands

Command	Function
Enable password	Privileged EXE mode access is established with this password
Enable secret	Enable secret access using MD5 encryption is established with this password
Line console 0	Console terminal access is established with this password
Line vty 0 4	Telnet connection access is established with this password
Service password encryption	When using the Display command, this command protects the display of the password

139.4 Router Access Lists

The use of router access lists plays a key role in the administration of access security control. One of the most critical security features of routers is the capability to control the flow of data packets within the network. This feature is called packet filtering, which allows for the control of data flow in the network based on source and destination IP addresses and the type of application used. This filtering is performed through the use of access lists.

An ordered list of statements permitting or denying data packets to flow through a router based on matching criteria contained in the packet is defined as an access list. Two important aspects of access lists are the sequence or order of access list statements and the use of an implicit deny statement at the end of the access list. Statements must be entered in the correct sequence in the access list for the filtering to operate correctly. Also, explicit permit statements must be used to ensure that data is not rejected by the implicit deny statement. A packet that is not explicitly permitted will be rejected by the implicit "deny all" statement at the end of the access list.

Routers can be programmed to perform packet filtering to address many different kinds of security issues. For example, packet filtering can be used to prevent Telnet session packets from entering the network originating from specified address ranges. The criteria used to permit or deny packets depend on the information contained within the packet's layer 3 or layer 4 header. While access lists cannot use information above layer 4 to filter packets, context-based access control (CBAC) can be used. CBAC provides for filtering capability at the application layer.

139.4.1 Administrative Domains

An administrative domain is a general grouping of network devices such as workstations, servers, network links, and routers that are maintained by a single administrative group. Routers are used as a boundary between administrative domains. Each administrative domain typically has its own security policy and, as a result, there is limited access between data networks in separate domains. Most organizations would typically need only one administrative domain; however, separate domains can be created if different security policies are required.

While routers are used as boundaries between domains, they also serve to connect separate administrative domains. Routers can be used to connect two or more administrative domains of corporate networks or to connect the corporate administrative domain to the Internet. Because all data packets must flow through the router and because routers must be used to connect separate geographic sites, packet-filtering functionality can be provided by the router without the need for additional equipment or software. All of the functionality for establishing an adequate security policy with sophisticated complex security can be provided by network routers.

The operating system used by Cisco Corporation to create security policies as well as all other router functions is called the internetwork operating system (IOS). The commands entered by the console operator interface with the IOS. These commands are used by the IOS to manage the router's configuration, to control system hardware such as memory and interfaces, and to execute system tasks such as moving packets and building dynamic information like routing and ARP tables. In addition, the IOS has many of the same features as other operating systems such as Windows, Linux, and UNIX.

Access lists also provide functions other than packet filtering. These functions include router access control, router update filtering, packet queuing, and dial-on-demand control. Access lists are used to control access to the router through mechanisms such as SNMP and Telnet. Access lists can also be used to prevent a network from being known to routing protocols through router update filtering. Classes of packets can be given priority over other classes of packets by using access lists to specify these packet types to different outgoing queues. Finally, access lists can be used to trigger a dial connection to occur by defining packets to permit this function.

139.4.2 Packet Filtering

As described previously, a primary function performed by access lists is packet filtering. Filtering is an important function in securing many networks. Many devices can be used to implement packet filters. Packet filtering is also a common feature within firewalls where network security exists to control access between internal trusted systems and external, untrusted systems. The specification of which packets are permitted access through a router and which packets are denied access through a router, as determined by the information contained within the packet, is called a packet filter.

Packet filters allow administrators to specify certain criteria that a packet must meet in order to be permitted through a router. If the designated criteria are not met, the packet is denied. If the packet is not explicitly denied or permitted, then the packet will be denied by default. This is called an implicit deny, which is a common and important security feature used in the industry today. As mentioned, the implicit deny, although it operates by default, can be overridden by explicit permits. Other security features available through packet filtering are subject to limitations. These limitations include stateless packet inspection, information examination limitations, and IP address spoofing.

139.4.3 Stateless Packet Inspection

Access control lists cannot determine if a packet is part of a TCP/UDP conversation because each packet is examined as if it is a stand-alone entity. No mechanism exists to determine that an inbound TCP packet with the ACK bit set is actually part of an existing conversation. This is called stateless packet filtering (e.g., the router does not maintain information on the status or state of existing conversations). Stateless packet inspection is performed by non-context-based access control lists.

State tables are used to record the source and destination addresses and ports from which the router places the entries. While incoming packets are checked to ensure they are part of the existing session, the traditional access list is not capable of detecting whether a packet is actually part of an existing upper-layer conversation. Access lists can be used to examine individual packets to determine if it is part of an existing conversation, but only through the use of an established keyword. This check, however, is limited to TCP conversations because UDP is a connectionless protocol and no flags exist in the protocol header to indicate an existing connection. Furthermore, in TCP conversations, this control can easily be compromised through spoofing.

139.4.4 Information Examination Limits

Traditional access lists have a limited capability to examine packet information above the IP layer, no way of examining information above layer 4, and are incapable of securely handling layer 4 information. Extended access lists can examine a limited amount of information in layer 4 headers. There are, however, enhancements that exist in more recent access list technology; these are described later in this chapter.

139.4.5 IP Address Spoofing

IP address spoofing is a common network attack technique used by computer hackers to disrupt network systems. Address filtering is used to combat IP address spoofing, which is the impersonation of a network address so that the packets sent from the impersonator's PC appear to have originated from a trusted PC. For the spoof to work successfully, the impersonator's PC instead of the legitimate PC whose network address the impersonator is impersonating. To achieve this, the impersonator would need to guess the initial sequence number sent in reply to the SYN request from the attacker's PC during the initial TCP three-way handshake. The destination PC, upon receiving a SYN request, returns a SYN-ACK response to the legitimate owner of the spoofed IP address. As a result, the impersonator never receives the response, therefore necessitating guessing the initial sequence number contained in the SYN-ACK packet so that the ACK sent from the attacker's PC would contain the correct information to complete the handshake. At this point, the attacker or hacker has successfully gained entry into the network.

Attackers need not gain entry into a network to cause damage. For example, an attacker could send malicious packets to a host system for purposes of disrupting the host's capability to function. This type of attack is commonly known as a denial-of-service attack. The attacker only needs to spoof the originating address, never needing to actually complete the connection with the attacked host.

139.4.6 Standard Access Lists

Standard access lists are very limited functionally because they allow filtering only by source IP address. Typically, this does not provide the level of granularity needed to provide adequate security. They are defined within a range of 1 to 99; however, named access lists can also be used to define the list. By using names in the access list, the administrator avoids the need to recreate the entire access list after specific entries in the list are deleted.

In standard access lists, each entry in the list is read sequentially from beginning to end as each packet is processed. Any remaining access list statements are ignored once an entry or statement is reached in the list that applies to that packet. As a result, the sequence or order of the access list statements is critical to the intended processing/routing of a packet. If no match is made between the access list statement and the packet, the packet continues to be examined by subsequent statements until the end of the list is reached and it becomes subject to the implicit "deny all" feature. The implicit deny all can be overridden by an explicit permit all statement at the end of the list, allowing any packet that has not been previously explicitly denied to be passed through the router. This is not a recommended or sound security practice. The best practice is to use explicit permit statements in the access list for those packets that are allowed and utilize the implied deny all to deny all other packets. This is a much safer practice simply because of the length and complexity of standard access lists.

Standard access lists are best used where there is a requirement to limit virtual terminal access, limit Simple Network Management Protocol (SNMP) access, and filter network ranges. Virtual terminal access is the ability to Telnet into a router from an external device. To limit remote access to routers within the network, an extended access list could be applied to every interface. To avoid this, a standard access list can be applied to restrict remote access from only a single device (inbound). In addition, once remote access is gained, all outbound access can be restricted by applying a standard access list to the outbound interface.

Standard access lists are also used to limit SNMP access. SNMP is used in a data network to manage network devices such as servers and routers. SNMP is used by network administrators and requires the use of a password or authentication scheme called a community string. Standard access lists are used to limit the IP addresses that allow SNMP access through routers, reducing the exposure of this powerful capability.

Standard access lists are also used to filter network ranges, especially where redistribution routes exist between different routing protocols. Filtering prevents routing redistribution from an initial protocol into a second protocol and then back to the initial protocol. That is, the standard access list is used to specify the routes that are allowed to be distributed into each protocol.

139.4.7 Extended IP Access Lists

As indicated by their name, extended access lists are more powerful than standard access lists, providing much greater functionality and flexibility. Both standard and extended access lists filter by source address; however, extended lists also filter by destination address and upper layer protocol information. Extended access lists allow for filtering by type of service field and by IP precedence. Another feature of extended access lists is logging. Access list matches can be logged through the use of the LOG keyword placed at the end of an access list entry. This feature is optional and, when invoked, sends log entries to a database facility enabled by the router.

When establishing a security policy on the network using router access lists, a couple of key points must be noted. With regard to the placement of the access list relative to the interface, the standard access list should be placed as close to the destination as possible and the extended access list should be placed as close to the source as possible. Because standard access lists use only the source address to determine whether a packet is to be permitted or denied, placement of this list too close to the source would result in blocking packets that were intended to be included. As a result, extended access lists would be more appropriately placed close to the source because these lists typically use both source and destination IP addresses.

A strong security policy should also include a strategy to combat spoofing. Adding “anti-spoofing” access list entries to the inbound access list would help support this effort. The anti-spoofing entries are used to block IP packets that have a source address of an external network or a source address that is invalid. Examples of invalid addresses include loopback addresses, multicast addresses, and unregistered addresses. Spoofing is a very popular technique used by hackers. The use of these invalid address types allows hackers to engage in attacks without being traced. Security administrators are unable to trace packets back to the originating source when these illegitimate addresses are used.

139.4.8 Dynamic Access Lists

Dynamic access lists provide the capacity to create dynamic openings in an access list through a user authentication process. These list entries can be inserted in all of the access list types presented thus far—traditional, standard, and extended access lists. Dynamic entries are created in the inbound access lists after a user has been authenticated and the router closes the Telnet session to the router invoked by the user. This dynamic entry then is used to permit packets originating from the IP address of the user’s workstation. The dynamic entry will remain until the idle timeout is reached or the maximum timeout period expires. Both of these features, however, are optional, and if not utilized, will cause the dynamic entries to remain active until the next router reload process occurs. Timeout parameters, however, are recommended as an important security measure.

Use of dynamic access lists must be carefully planned because of other security limitations. Only one set of access is available when using dynamic access—different levels of access cannot be provided. In addition, when establishing the session, logon information is passed without encryption, allowing hackers access to this information through sniffer software.

139.5 Conclusion

Network router security is a critical component of an organization's overall security program. Router security is a complex and fast-growing technology that requires the constant attention of security professionals. This chapter has examined the important aspects of basic router security features and how they must be enabled to protect organizations from unauthorized attacks. Future security improvements are inevitable as the threat and sophistication of attacks increase over time.

140
What's Not So Simple about SNMP?

Chris Hare

The Simple Network Management Protocol, or SNMP, is a defined Internet, standard from the Internet, Engineering Task Force, as documented in Request for Comment (RFC) 1157. This chapter discusses what SNMP is, how it is used, and the challenges facing network management and security professionals regarding its use.

While several SNMP applications are mentioned in this chapter, no support or recommendation of these applications is made or implied. As with any application, the enterprise must select its SNMP application based upon its individual requirements.

140.1 SNMP Defined

SNMP is used to monitor network and computer devices around the globe. Simply stated, network managers use SNMP to communicate management information, both status and configuration, between the network management station and the SNMP agents in the network devices.

The protocol is aptly named because, despite the intricacies of a network, SNMP itself is very simple. Before examining the architecture, a review of the terminology used is required.

- *Network element*: any device connected to the network, including hosts, gateways, servers, terminal servers, firewalls, routers, switches and active hubs.

- *Network management station (or management station)*: a computing platform with SNMP management software to monitor and control the network elements; examples of common management stations are HP Open view and CA Unicenter.
- *SNMP agent*: a software management agent responsible for performing the network management functions received from the management station.
- *SNMP request*: a message sent from the management station to the SNMP agent on the network device.
- *SNMP trap receiver*: the software on the management station that receives event notification messages from the SNMP agent on the network device.
- *Management information base*: a standard method identifying the elements in the SNMP database.

A network configured to SNMP for the management of network devices consists of at least one SNMP agent and one management station. The management station is used to configure the network elements and receive SNMP traps from those elements.

Through SNMP, the network manager can monitor the status of the various network elements, make appropriate configuration changes, and respond to alerts received from the network elements (see Exhibit 140.1). As networks increase in size and complexity, a centralized method of monitoring and management is essential. Multiple management stations may exist and be used to compartmentalize the network structure or to regionalize operations of the network.

SNMP can retrieve the configuration information for a given network element in addition to device errors or alerts. Error conditions will vary from one SNMP agent to another but would include network interface failures, system failures, disk space warnings, etc. When the device issues an alert to the management station, network management personnel can investigate to resolve the problem. Access to systems is controlled through knowledge of a community string, which can be compared to a password. Community strings are discussed in more detail later in the chapter, but by themselves should not be considered a form of authentication.

From time to time it is necessary for the management station to send configuration requests to the device. If the correct community string is provided, the device configuration is changed appropriately. Even this simple explanation evidences the value gained from SNMP. An organization can monitor the status of all its equipment and perform remote troubleshooting and configuration management.

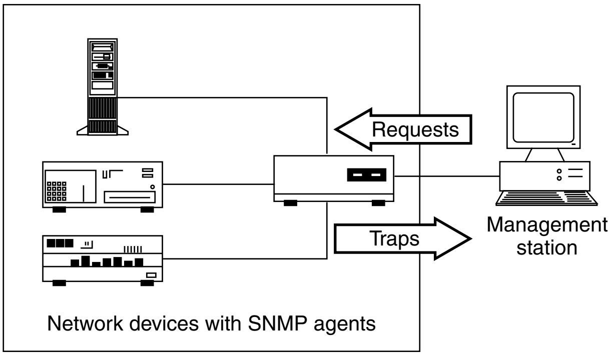

EXHIBIT 140.1 The SNMP network manager.

140.2 The Management Information Base (MIB)

The MIB defines the scope of information available for retrieval or configuration on the network element. There is a standard MIB all devices should support. The manufacturer of the device can also define custom extensions to the device to support additional configuration parameters. The definition of MIB extensions must follow a defined convention for the management stations to understand and interpret the MIB correctly.

The MIB is expressed using the ASN.1 language; and, while important to be aware of, it is not a major concern unless you are specifically designing new elements for the MIB. All MIB objects are defined explicitly in the Internet, standard MIB or through a defined naming convention. Using the defined naming convention limits the ability of product vendors to create individual instances of an MIB element for a particular network device. This is important, given the wide number of SNMP capable devices and the relatively small range of monitoring station equipment.

An understanding of the MIB beyond this point is only necessary for network designers who must concern themselves with the actual MIB structure and representations. Suffice it to say that for this discussion, the MIB components are represented using English identifiers.

140.3 SNMP Operations

All SNMP agents must support both inspection and alteration of the MIB variables. These operations are referred to as SNMP *get* (retrieval and inspection) and SNMP *set* (alteration). The developers of SNMP established only these two operations to minimize the number of essential management functions to support and to avoid the introduction of other imperative management commands. Most network protocols have evolved to support a vast array of potential commands, which must be available in both the client and the server. The File Transfer Protocol (FTP) is a good example of a simple command set that has evolved to include more than 74 commands.

The SNMP management philosophy uses the management station to poll the network elements for appropriate information. SNMP uses *traps* to send messages from the agent running on the monitored system to the monitoring station, which are then used to control the polling. Limiting the number of messages between the agent and the monitoring station achieves the goal of simplicity and minimizes the amount of traffic associated with the network management functions.

As mentioned, limiting the number of commands makes implementing the protocol easier: it is not necessary to develop an interface to the operating system, causing a system reboot, or to change the value of variables to force a reboot after a defined time period has elapsed.

The interaction between the SNMP agent and management station occurs through the exchange of protocol messages. Each message has been designed to fit within a single User Datagram Protocol (UDP) packet, thereby minimizing the impact of the management structure on the network.

140.4 Administrative Relationships

The management of network elements requires an SNMP agent on the element itself and on a management station. The grouping of SNMP agents to a management station is called a *community*. The community string is the identifier used to distinguish among communities in the same network. The SNMP RFC specifies an authentic message as one in which the correct community string is provided to the network device from the management station. The authentication scheme consists of the community string and a set of rules to determine if the message is in fact authentic. Finally, the SNMP authentication service describes a function identifying an authentic SNMP message according to the established authentication schemes.

Administrative relationships called communities pair a monitored device with the management station. Through this scheme, administrative relationships can be separated among devices. The agent and management station defined within a community establish the SNMP access policy. Management stations can communicate directly with the agent or, in the event of network design, an SNMP proxy agent. The proxy agent relays communications between the monitored device and the management station.

The use of proxy agents allows communication with all network elements, including modems, multiplexors, and other devices that support different management frameworks. Additional benefits from the proxy agent design include shielding network elements from access policies, which might be complex.

The community string establishes the access policy community to use, and it can be compared to passwords. The community string establishes the password to access the agent in either read-only mode, commonly referred to as the public community, or the read-write mode, known as the private community.

140.5 SNMP Requests

There are two access modes within SNMP: *read-only* and *read-write*. The command used, the variable, and the community string determine the access mode. Corresponding with the access mode are two community strings, one for each access mode. Access to the variable and the associated action is controlled by:

- If the variable is defined with an access type of *none*, the variable is not available under any circumstances.
- If the variable is defined with an access type of *read-write* or *read-only*, the variable is accessible for the appropriate *get*, *set*, or *trap* commands.
- If the variable does not have an access type defined, it is available for *get* and *trap* operations.

However, these rules only establish what actions can be performed on the MIB variable. The actual communication between the SNMP agent and the monitoring station follows a defined protocol for message exchange. Each message includes the:

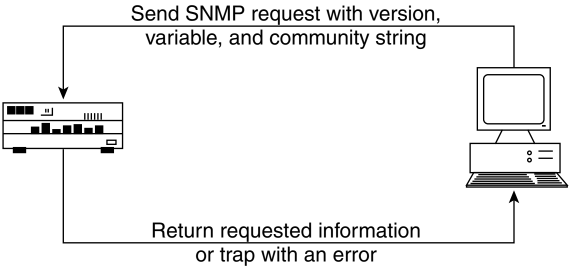
- SNMP version identifier
- Community string
- Protocol data unit (PDU)

The SNMP version identifier establishes the version of SNMP in use—Version 1, 2, or 3. As mentioned previously, the community string determines which community is accessed, either public or private. The PDU contains the actual SNMP trap or request. With the exception of traps, which are reported on UDP port 162, all SNMP requests are received on UDP port 161. RFC 1157 specifies that protocol implementations need not accept messages more than 484 bytes in length, although in practice a longer message length is typically supported.

There are five PDUs supported within SNMP:

1. GetRequest-PDU
2. GetNextRequest-PDU
3. GetResponse-PDU
4. SetRequest-PDU
5. Trap-PDU

When transmitting a valid SNMP request, the PDU must be constructed using the implemented function, the MIB variable in ASN.1 notation. The ASN.1 notation, the source and destination IP addresses, and UDP ports are included along with the community string. Once processed, the resulting request is sent to the receiving system.



Send SNMP request with version,
variable, and community string
Return requested information
or trap with an error

EXHIBIT 140.2 The SNMP transmission process.

As shown in Exhibit 140.2, the receiving system accepts the request and assembles an ASN.1 object. The message is discarded if the decoding fails. If implemented correctly, this discard function should cause the receiving system to ignore malformed SNMP requests. Similarly, the SNMP version is checked; and if there is a mismatch, the packet is also dropped. The request is then authenticated using the community string. If the authentication fails, a trap may be generated indicating an authentication failure, and the packet is dropped.

If the message is accepted, the object is again parsed to assemble the actual request. If the parse fails, the message is dropped. If the parse is successful, the appropriate SNMP profile is selected using the named community, and the message is processed. Any resulting data is returned to the source address of the request.

140.6 The Protocol Data Unit

As mentioned, there are five protocol data units supported. Each is used to implement a specific request within the SNMP agent and management station. Each will be briefly examined to review purpose and functionality.

The *GetRequest* PDU requests information to be retrieved from the remote device. The management station uses the *GetRequest* PDU to make queries of the various network elements. If the MIB variable specified is matched exactly in the network element MIB, the value is returned using the *GetResponse* PDU. We can see the direct results of the *GetRequest* and *GetResponse* messages using the *snmpwalk* command commonly found on Linux systems:

```
[chare@linux chare]$ for host in 1 2 3 4 5
> do
> snmpwalk 192.168.0.$host public system.sysDescr.0
> done
system.sysDescr.0 = Instant Internet, version 7.11.2
Timeout: No Response from 192.168.0.2
system.sysDescr.0= Linux linux 2.4.9--31 #1 Tue Feb 26 07:11:02 EST 2002
   i686
Timeout: No Response from 192.168.0.4
Timeout: No Response from 192.168.0.5
[chare@linux chare]$
```

Despite the existence of a device at all five IP addresses in the above range, only two are configured to provide a response; or perhaps the SNMP community string provided was incorrect.

Note that, on those systems where *snmpwalk* is not installed, the command is available in the net-ucb-cnmp source code available from many network repositories.

The *GetResponse* PDU is the protocol type containing the response to the request issued by the management station. Each *GetRequest* PDU results in a response using *GetResponse*, regardless of the validity of the request.

The *GetNextResponse* PDU is identical in form to the *GetResponse* PDU, except it is used to get additional information from a previous request. Alternatively, table traversals through the MIB are typically done using the *GetNextResponse* PDU. For example, using the *snmpwalk* command, we can traverse the entire table using the command:

```
# snmpwalk localhost public
system.sysDescr.0= Linux linux 2.4.9--31 #1 Tue Feb 26 07:11:02 EST 2002
   i686
system.sysObjectID.0= OID: enterprises.ucdavis.ucdSnmpAgent.linux
system.sysUpTime.0= Timeticks: (4092830521) 473 days, 16:58:25.21
system.sysContact.0= root@localhost
system.sysName.0= linux
system.sysLocation.0= Unknown
system.sysORLastChange.0= Timeticks: (4) 0:00:00.04
…
<end of snmpwalk output>
```

In our example, no specific MIB variable is requested, which causes all MIB variables and their associated values to be printed. This generates a large amount of output from *snmpwalk*. Each variable is retrieved until there is no additional information to be received.

Aside from the requests to retrieve information, the management station also can set selected variables to new values. This is done using the *SetRequest* PDU. When receiving the *SetRequest* PDU, the receiving station has several valid responses:

- If the named variable cannot be changed, the receiving station returns a *GetResponse* PDU with an error code.
- If the value does not match the named variable type, the receiving station returns a *GetResponse* PDU with a bad value indication.
- If the request exceeds a local size limitation, the receiving station responds with a *GetResponse* PDU with an indication of too big.
- If the named variable cannot be altered and is not covered by the preceding rules, a general error message is returned by the receiving station using the *GetResponse* PDU.

If there are no errors in the request, the receiving station updates the value for the named variable. The typical read-write community is called *private*, and the correct community string must be provided for this access. If the value is changed, the receiving station returns a *GetResponse* PDU with a "No error" indication.

As discussed later in this chapter, if the SNMP read-write community string is the default or set to another well-known value, any user can change MIB parameters and thereby affect the operation of the system.

140.7 SNMP Traps

SNMP traps are used to send an event back to the monitoring station. The trap is transmitted at the request of the agent and sent to the device specified in the SNMP configuration files. While the use of traps is universal across SNMP implementations, the means by which the SNMP agent determines where to send the trap differs among SNMP agent implementations.

There are several traps available to send to the monitoring station:

- coldStart
- warmStart
- linkDown
- linkUp
- authenticationFailure
- egpNeighborLoss
- enterpriseSpecific

Traps are sent using the PDU, similar to the other message types, previously discussed.

The *coldStart* trap is sent when the system is initialized from a powered-off state and the agent is reinitializing. This trap indicates to the monitoring station that the SNMP implementation may have been or may be altered. The *warmStart* trap is sent when the system restarts, causing the agent to reinitialize. In a *warmStart* trap event, neither the SNMP agent's implementation nor its configuration is altered.

Most network management personnel are familiar with the *linkDown* and *linkUp* traps. The *linkDown* trap is generated when a link on the SNMP agent recognizes a failure of one or more of the network links in the SNMP agent's configuration. Similarly, when a communication link is restored, the *linkUp* trap is sent to the monitoring station. In both cases, the trap indicates the network link where the failure or restoration has occurred.

Exhibit 140.3 shows a device, in this case a router, with multiple network interfaces, as seen in a Network Management Station. The failure of the red interface (shown here in black) caused the router to send a *linkDown* trap to the management station, resulting in the change in color for the object. The green objects (shown in white) represent currently operational interfaces.

The *authenticationFailure* trap is generated when the SNMP agent receives a message with the incorrect community string, meaning the attempt to access the SNMP community has failed. When the SNMP agent communicates in an Exterior Gateway Protocol (EGP) relationship, and the peer is no longer reachable, an *egpNeighborLoss* trap is generated to the management station. This trap means routing information available from the EGP peer is no longer available, which may affect other network connectivity.

Finally, the *enterpriseSpecific* trap is generated when the SNMP agent recognizes an *enterpriseSpecific* trap has occurred. This is implementation dependent and includes the specific trap information in the message sent back to the monitoring station.

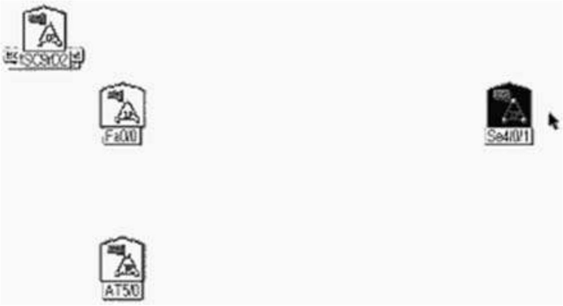


EXHIBIT 140.3 Router with multiple network interfaces.

140.8 SNMP Security Issues

The preceding brief introduction to SNMP should raise a few issues for the security professional. As mentioned, the default SNMP community strings are public for read-only access and private for read-write. Most system and network administrators do not change these values. Consequently, any user, authorized or not, can obtain information through SNMP about the device and potentially change or reset values. For example, if the read-write community string is the default, any user can change the device's IP address and take it off the network.

This can have significant consequences, most notably surrounding the availability of the device. It is not typically possible to access enterprise information or system passwords or to gain command line or terminal access using SNMP. Consequently, any changes could result in the monitoring station identifying the device as unavailable, forcing corrective action to restore service.

However, the common SNMP security issues include:

- Well-known default community strings
- Ability to change the configuration information on the system where the SNMP agent is running
- Multiple management stations managing the same device
- Denial-of-service attacks

Many security and network professionals are undoubtedly familiar with the Computer Emergency Response Team (CERT) Advisory, CA-2002-03 published in February 2002. While this is of particular interest to the network and security communities today, it should not overshadow the other issues mentioned above because many of the issues in CA-2002-03 are possible due to the other security issues.

140.8.1 Well-Known Community Strings

As mentioned previously, there are two SNMP access policies, read-only and read-write, using the default community strings of public and private, respectively. Many organizations do not change the default community strings. Failing to change the default values means it is possible for an unauthorized person to change the configuration parameters associated with the device.

Consequently, SNMP community strings should be treated as passwords. The better the quality of the password, the less likely an unauthorized person could guess the community string and change the configuration.

140.8.2 Ability to Change SNMP Configuration

On many systems, users who have administrative privileges can change the configuration of their system, even if they have no authority to do so. This ability to change the local SNMP agent configuration can affect the operation of the system, cause network management problems, or affect the operation of the device.

Consequently, SNMP configuration files should be controlled and, if possible, centrally managed to identify and correct configuration changes. This can be done in a variety of ways, including tools such as *tripwire.*

140.8.3 Multiple Management Stations

While this is not a security problem per se, multiple management stations polling the same device can cause problems ranging from poor performance, to differing SNMP configuration information, to the apparent loss of service.

If your network is large enough to require multiple management stations, separate communities should be established to prevent these events from taking place. Remember, there is no constraint on the number of SNMP communities that can be used in the network; it is only the network engineer who imposes the limits.

140.8.4 Denial-of-Service Attacks

Denial of service is defined as the loss of service availability either through authorized or unauthorized configuration changes. It is important to be clear about authorized and unauthorized changes. The system or application administrator who makes a configuration change as part of his job and causes a loss of service has the same impact as the attacker who executes a program to cause the loss of service remotely.

A key problem with SNMP is the ability to change the configuration of the system causing the service outage, or to change the SNMP configuration and imitate a denial of service as reported by the monitoring station. In either situation, someone has to review and possibly correct the configuration problem, regardless of the cause. This has a cost to the company, even if an authorized person made the change.

140.8.5 The Impact of CERT CA-2002-03

Most equipment manufacturers, enterprises, and individuals felt the impact of the CERT Advisory, issued by the Carnegie Mellon Software Engineering Institute (CM-SEI) Computer Emergency Response Team Coordination Center (CERT-CC). The Advisory, was issued after the Oulu University Secure Programming Group conducted a very thorough analysis of the message-handling capabilities of SNMP Version 1. While the Advisory, is specifically for SNMP Version 1, most SNMP implementations use the same program code for decoding the PDU, potentially affecting all SNMP versions.

The primary issues noted in the Advisory, as it affects SNMP involve the potential for unauthorized privileged access, denial-of-service attacks, or other unstable behavior. Specifically, the work performed by Oulu University found problems with decoding trap messages received by the SNMP management station or requests received by the SNMP agent on the network device.

It was also identified that some of the vulnerabilities found in the SNMP implementation did not require the correct community string. Consequently, vendors have been issuing patches for their SNMP implementations; but more importantly, enterprises have been testing for vulnerabilities within their networks.

The vulnerabilities in code, which has been in use for decades, will cost developers millions of dollars for new development activities to remove the vulnerabilities, verify them, and release patches. The users of those products will also spend millions of dollars on patching and implementing other controls to limit the potential exposures.

Many of the recommendations provided by CERT for addressing the problem are solutions for the common security problems when using SNMP. The recommendations provided by CERT can be considered common sense, because SNMP should be treated as a network service:

- *Disable SNMP.* If the device in question is not monitored using SNMP, it is likely safe to disable the service. Remember, if you are monitoring the device and disable SNMP in error, your management station will report the device as down.
- *Implement perimeter network filtering.* Most enterprises should filter inbound SNMP requests from external networks to prevent unauthorized individuals or organizations from retrieving SNMP information about your network devices. Sufficient information exists in the SNMP data to provide a good view of how to attack your enterprise. Secondly, outbound filtering should be applied to prevent SNMP requests from leaving your network and being directed to another enterprise. The obvious exceptions here are if you are monitoring another network outside yours, or if an external organization is providing SNMP-based monitoring systems for your network.

- *Implement authorized SNMP host filtering*. Not every user who wants to should be able to issue SNMP queries to the network devices. Consequently, filters can be installed in the network devices such as routers and switches to limit the source and destination addresses for SNMP requests. Additionally, the SNMP configuration of the agent should include the appropriate details to limit the authorized SNMP management and trap stations.
- *Change default community strings*. A major problem in most enterprises, the default community strings of public and private should be changed to a complex string; and knowledge of that string should be limited to as few people as possible.
- *Create a separate management network*. This can be a long, involved, and expensive process that many enterprises do not undertake. A separate management network keeps connectivity to the network devices even when there is a failure on the network portion. However, it requires a completely separate infrastructure, making it expensive to implement and difficult to retrofit. If you are building a new network, or have an existing network with critical operational requirements, a separate management network is highly advisable.

The recommendations identified here should be implemented by many enterprises, even if all their network devices have the latest patches implemented. Implementing these techniques for other network protocols and services in addition to SNMP can greatly reduce the risk of unauthorized network access and data loss.

140.9 Summary

The goal of SNMP is to provide a simple yet powerful mechanism to change the configuration and monitor the state and availability of the systems and network devices. However, the nature of SNMP, as with other network protocols, also exposes it to attack and improper use by network managers, system administrators, and security personnel.

Understanding the basics of SNMP and the major security issues affecting its use as discussed here helps the security manager communicate concerns about network design and implementation with the network manager or network engineer.

Acknowledgments

The author thanks Cathy Buchanan of Nortel Network's Internet, Engineering team for her editorial and technical clarifications.

And thanks to Mignona Cote, my friend and colleague, for her continued support and ideas. Her assistance continues to expand my vision and provides challenges on a daily basis.

Network and Telecommunications Media: Security from the Ground Up

Samuel W. Chun

141.1 Introduction

One of the most challenging aspects of understanding telecommunications and network security is the overwhelming number of resources that are required to maintain it. Making telecommunications and networking "work" involves millions of miles of cabling, thousands of communications devices, and an uncounted number of people all working together to deliver information among devices. Whether the information is a word-processing document, an e-mail message, an Internet phone call, or an ATM transaction, it starts from a device and traverses media that are largely unknown to most people. The focus of this chapter is on those media that carry the information. From the thousands of miles of optical cable that run deep beneath the oceans to connect continents, to the inexpensive "patch" cables that are sold in hardware stores, to home users, each has an important role to play and each has an implication in securing a network environment from one end to the other.

A later chapter introduces the Open System Interconnect (OSI) model to present a conceptual view of how computers communicate with each other over a network. Although the OSI model is only a framework, it is the accepted architectural reference model for all computer communications. The OSI model layers network communications in a logical hierarchical format that is easy to understand and apply. At the lowest layer, the physical layer, data is converted into patterns of electrical voltage changes and transferred in the appropriate medium—cabling. Without this fundamental function taking place at the lowest and earliest layer, network and telecommunication traffic would not be possible. It is a wonder why, then, the cabling and transport medium is one of the least emphasized aspects of network security. Its function is vital, and vulnerabilities and weaknesses of a given network's cabling infrastructure can potentially impact all aspects of the Availability, Integrity, and Confidentiality triad.

141.2 Cabling Issues

Before discussing the various types of wiring and transport media, it is important to review some of the more important issues involving cabling that also impact security. Some of the issues are a result of the nature of the materials used in manufacturing, while others deal with the matter in which they are produced. All of these factors should be considered when deploying a new cable infrastructure and certainly when evaluating the security posture of a given network at its lowest component level.

141.2.1 Maximum Transmission Speed

Depending on the wiring and network equipment that is used, a wide array of transmission speeds can be accomplished in a network. From the 16 Mbps that can be supported on Category 4 unshielded twisted pair (UTP) cabling, to the 10 Gbps that can be run on single mode fiber (SMF), the nature of the wiring can determine the maximum transmission speed a network can support. When a service or application's transmission requirements exceed the supported limit, system availability or data integrity issues may occur. A typical example of this is the potential for synchronization problems or dropped video frames in video conferencing and its high bandwidth requirements. Wiring infrastructure based on 2-Mbps thinnet coaxial cable will not support it, while fiber and Category 5 UTP with its support for 100-Mbps transmission speeds will.

141.2.2 Susceptibility to Interference

Different media types have varying levels of susceptibility to ambient environmental interference. Consequently, different types of wiring are generally, but not always, implemented for specific situations. For example, optical fiber cables, which transmit light waves, are used as the *de facto* standard in connecting buildings or geographical regions, due their to immunity from interference caused by electricity, light, heat, and moisture. Copper cable-based wiring, on the other hand, is vulnerable to a variety of environmental factors because its function is based on electrical conduction over a strand (or multiple strands) of wire.

There are three specific interference issues that are important to consider when selecting an appropriate wiring medium: attenuation, crosstalk, and noise.

141.2.2.1 Attenuation

Attenuation is the degradation of any signal resulting from travel over long distances. It is often referred to as signal "loss," and occurs as signal power, measured as voltage for traditional copper cabling and light intensity for fiber, degrades over distance due to resistance in the medium. Regardless of medium or signal, attenuation is the measure of signal loss per distance unit.

Attenuation in networking is generally measured in decibels of signal loss per foot, kilometer, or mile. Attenuation is a bigger problem for higher frequency signals. For example, a wireless Gigabit Ethernet connection transmitting at 38 GHz will experience more attenuation than one running at 18 GHz over the same distance. Consequently, there are specific cable length standards for different networking speeds, media, and technologies. Generally, less attenuation means greater distances and clearer signals between network devices and components. When any cabling is installed for a network, regardless of the type, it should be thoroughly tested for the effects of attenuation.

141.2.2.2 Crosstalk

The phenomenon of hearing other voice conversations during a telephone conversation is a classic example of crosstalk. Crosstalk, as the name implies, is the interference caused by one channel during transmission to another nearby channel. Crosstalk in a network medium could result in packet collisions and retransmissions that can impact performance and reliability. Reducing crosstalk results in better cable efficiency. A common method for reducing crosstalk is to sheathe the metal wire with insulating materials. For example, shielded twisted pair (STP) cables are less likely than UTP cables to experience crosstalk.

141.2.2.3 Noise

The broadest definition of noise is the negative effect of environmental conditions on a transport medium's signal. Noise can result from numerous causes, including heat or cold, weather, light, electricity, and ionizing radiation. From common sources such as electrical appliances, fluorescent lights, or x-ray machines, to powerful environmental events such as rain or fog, numerous conditions can influence a given network transmission medium's ability to send a signal effectively. One of the best examples of environmental noise influencing network availability is the effect of inclement weather on microwave-based WAN connections. Unlike the postal service, wireless networks can be brought to a standstill by rain, sleet, or snow.

141.2.3 Maximum Distance

Distance plays a big role in the network media selection. The distance that the cable will need to "run" before it is attached to another device can amplify attenuation, noise, and crosstalk. There are standards that specify how long different types of cables can be specifically run before a repeater is necessary to boost the signal. The maximum distance between repeaters can vary with some media that can only span hundreds of meters, while some, such as microwave, can span miles. The maximum required distances between physical connections can dictate the type of media that needs to be used.

141.2.4 Susceptibility to Intrusion

One of the factors to consider when selecting a medium for a network is its susceptibility to intrusion. Some transmission media are more of a target for eavesdropping than others, just by the nature of the material used for manufacturing. Others are, by design or as a side effect, more difficult to "tap." For example, unshielded twisted-pair cables are easy to tap into and also emanate electrical current. Conversely, optical fiber does not emanate at all and is almost impossible to tap. If confidentiality is a big factor in a network, then it will help determine which media can be used best in that particular environment.

141.2.5 Manageability, Construction, and Cost

Overall cost often plays a major role in choosing network media. Many factors influence the cost of media: the type of materials used, quality of construction, and ease of handling all play roles in the overall cost of ownership of a particular networking media deployment. In addition, there are also indirect costs that should be considered. For example, when optical fiber is used as the networking transmission medium, there are greater costs associated from a networking equipment standpoint than an otherwise identical network made of copper cabling. Fiber network cards, switch and router modules, and media testing equipment tend to be much more expensive than their copper counterparts. All these cost factors—both direct and indirect—should be considered during the evaluation process.

141.3 Coaxial Copper Cable

141.3.1 Background and Common Uses

Coaxial copper cable, invented prior to World War II, is perhaps the oldest wire-based communications medium. Before the advent and explosive growth of UTP cabling, coaxial cabling was commonly used for radio antennae, cable TVs, and LAN applications. The cable is referred to as "coaxial" because it contains a thick, conductive metal wire at the center that is surrounded by meshed or braided metal shield along the same parallel axis. The thick wire in the center of the cable is generally separated from the metal shield by PVC insulation. The meshed metal shield that surrounds the core copper wire insulates the cable from interference such as crosstalk and noise. Compared to UTP, coaxial cable can transmit signals greater distances and at a higher bandwidth. Due to these factors, "coax" was commonly deployed in a variety of different applications. By the mid to late 1980s, coax cable was found almost everywhere—in homes as wiring for cable TVs and radios, as LAN cabling for business and government (especially school systems), and by telephone companies to connect their poles. However, during the 1990s, the inexpensive UTP gained favor in almost all LAN-based installations. Today, coaxial cabling is rarely seen in LAN applications; however, it continues to be popular as a medium for high-speed broadband communications such as cable TVs.

141.3.2 Categories and Standards

There are two main types of coaxial cabling. The 75-ohm cable is the most familiar to the average person because it is commonly used in homes to connect AM/FM radios to antennae and TV sets to cable boxes. The 75-ohm coaxial cable is unique in that, in addition to analog signals, it can also transmit high-speed digital signals. Consequently, it is commonly used in digital multimedia transmissions (e.g., digital cable TVs) and broadband Internet connections (mainly cable modems) in many people's homes.

The 50-ohm coaxial copper cable is the other type of coaxial cabling. It is most commonly used for LAN purposes. There are also two types of 50-ohm coaxial cables used in networking.

141.3.2.1 Thin Coax, Also Known as "Thinnet" or 10Base2 Specification

RG58 is a 52-ohm, low-impedance copper coaxial cable that can carry a 10-Mb Ethernet signal for approximately 200 meters (specifically, 185 meters) before requiring a repeater. Thin coax was typically deployed in a bus topology fashion in many networks, especially in educational environments. Thinnet "daisy chains" were known as "cheapernets" due to their low cost and low reliability. Thinnet Ethernet and AppleTalk networks were popular network configurations during the 1980s. However, Thinnet quickly lost favor to the inexpensive, reliable star topology of hub-based UTP networks during the 1990s.

141.3.2.2 Thick Coax, Also Known as "Thicknet" or 10Base5 Specification

Thicknet can carry a 10-Mb Ethernet signal for 500 meters. The rigid RG8 and RG11 cables, as the name implies, are thicker than Thinnet due to its larger core and extra layers of insulation. Thicknet was commonly used to connect bus-based networks across long distances (due to its thick insulation) and had the unique ability to allow for a connection to be added while signals were being transmitted—"vampire taps."

141.3.3 Strengths and Capabilities

Compared to UTP, coaxial cables can transmit signals at higher bandwidths and over longer distances without requiring the signal to be boosted by a repeater. The wire braid shielding, the insulation, and thick plastic jacket protect the cable from electromagnetic interference (EMI) and environmental effects such as heat and moisture. In addition, the insulation makes electronic eavesdropping more difficult because electric emanations are also minimized.

141.3.4 Vulnerabilities and Weaknesses

The two drawbacks to using coaxial cabling for networking are its difficulty in installation and its cost. The elements that make coax so effective—the insulation and thick core—also make it difficult to deploy and relatively expensive compared to UTP. In addition, the widespread proliferation of network hubs and switches have negated the distance advantages of coax cables. Manufacturers of networking equipment have wholeheartedly supported the widespread deployment of UTP by making coaxial cable-based networking equipment difficult to find and procure. Currently, it is nearly impossible to find networking infrastructure equipment such as switches, hubs, or even network cards that are based on a coaxial cable connection.

141.3.5 Future Growth

The use of coaxial cables for general-purpose networking is likely to become an anomaly within the next five to ten years. The latest standards and products for high-speed networking are increasingly focusing on fiber- and UTP-based networks. Most large organizations have already migrated away from coax, and, as time progresses, the likelihood of encountering 10Base2 or 10Base5 networks will become increasingly slim. However, the tried-and-true 75-ohm "home" coaxial cables that can transmit both analog and digital signals will continue to play a strong role in delivering high-speed data to peoples' homes. The use of 75-ohm copper cable in cable boxes, and increasingly with cable modems, ensures that the coaxial copper cable medium will continue to play a role, even if only a small one, in the future of networking.

141.4 Unshielded Twisted Pair (UTP) Cable

141.4.1 Background and Common Uses

Unshielded twist pair (UTP) cable is the most commonly installed networking medium. It supports very high bandwidths, is inexpensive, flexible, easy to manage, and can be used in a variety of networking topologies. 10 Mbps Ethernet, 100 Mbps Fast Ethernet, 4/16 Mbps Token Ring, 100 Mb FDDI over copper, and 1000 Mbps Gigabit Ethernet can all be run over UTP cabling. UTP cable and its properties are well known and are utilized in almost all network environments.

141.4.2 Categories and Standards

As the name implies, UTP cables have four pairs of conductive wires inside the protective jacket, tightly twisted in pairs. UTP cables do not have any shielding other than the insulation of the copper wires and the outer plastic jacket. The most important properties of UTP cabling are derived from the characteristic twisting of the pairs of cables. These twists of the conductive material help to eliminate interference and minimize attenuation. The tighter the twisting per inch, the higher the supported maximum bandwidth and the greater the cost per foot. Because there are different levels of twisting, conductive material, and insulation, the Electronic Industry Association/Telecommunications Industry Association, also known as EIA/TIA, has established EIA/TIA 568 Commercial Building Wire Standard for UTP cabling and rated the categories of wire:

- Category 1:
  — Maximum rated speed: generally less than 1 Mbps (1 MHz)
  — Pairs and twists per foot: generally two pairs; may or may not be twisted
  — Common use: analog phone lines and ISDN; not used for data
- Category 2:
  — Maximum rated speed: 4 Mbps (10 MHz)
  — Pairs and twists per foot: four pairs; generally two or three twists per foot
  — Common use: analog phone lines, T-1 lines, ISDN, IBM Token Ring, ARCNET
- Category 3:
  — Maximum rated speed: 10 Mbps (16 MHz)
  — Pairs and twists per foot: four pairs; three twists per foot
  — Common use: 10Baset-T, 4-Mbps Token Ring
- Category 4:
  — Maximum rated speed: 20 Mbps (20 MHz)
  — Pairs and twists per foot: four pairs; five or six twists per foot
  — Common use: 10Base-T, 100Base-T4, 100VG-AnyLAN, 16-Mbps Token Ring
- Category 5:
  — Maximum rated speed: 100 Mbps (100 MHz)
  — Pairs and twists per foot: four pairs, 36–48 twists per foot
  — Common use: 100Base-T4, 100Base-TX, FDDI, and 155-Mbps ATM
- Category 5e:
  — Maximum rated speed: 1 Gbps (350 MHz)
  — Pairs and twists per foot: four pairs; 36–48 twists per foot
  — Common use: 100Base-T4, 100Base-TX, 1000Base-TX, 155-Mbps ATM
- Proposed Category 6:
  — Maximum rated speed: 300 Mbps (Unknown; vendors manufacturing 400 MHz)
  — Pairs and twists per foot: four pairs; twists per foot not specified
  — Common use: anticipated to be used in high-speed environments, especially 1000-Base-TX and ATM
- Proposed Category 7:
  — Maximum rated speed: 600 Mbps (600 Mz)
  — Pairs and twists per foot: four pairs; twists per foot not specified
  — Common use: anticipated to be used in high-speed environments. Cat 7/Class F is anticipated to have a completely different plug/interface design.

141.4.3 Strengths and Capabilities

UTP cabling in all of its different flavors has become ubiquitous in networking. It is difficult to find a networking environment where UTP, especially Category 5 UTP cabling and “patch” cables, is not used. It is relatively inexpensive per foot, easy to install and terminate, and has broad support from networking equipment vendors. Because it is able to support multiple networking topologies, protocols, and speeds, it has rapidly replaced most cabling, other than high-speed fiber, for network use.

141.4.4 Vulnerabilities and Weaknesses

UTP cabling's drawbacks are based on its lack of shielding. It is flimsy and easy to cut and damage, and susceptible to interference and attenuation due to its lack of shielding and use of copper as a conductor. Because data transmission is based on electrical conduction (without shielding), it radiates energy that potentially can be intercepted by intruders. The easy manageability of UTP cabling also allows it to be easily tapped into. Consequently, highly secure environments are more likely to use optical fiber for their media needs.

141.4.5 Future Growth

UTP cabling, without a doubt, will continue to play a major role in networking. Its flexibility in its ability to support different protocols and speeds allows its use in a variety of environments. In addition, its low cost is a big plus in selecting media. Although the latest bandwidth and speed advancements are always introduced through fiber, there is always an initiative that quickly follows to support it on copper—and mainly UTP copper cabling. This was the case when Fast Ethernet was devised and was certainly the case recently when Gigabit Ethernet was introduced. Although Gigabit Ethernet was supported on fiber first, the development of CAT 5E and 6 cables quickly followed, with networking companies offering to switch modules and NIC cards very quickly. This trend is likely to continue with further advances in networking with CAT 6 and CAT 7 cables offering even higher maximum transmissions speeds to feed the growing appetite for data transmission bandwidth.

141.5 Shielded Twisted-Pair (STP) Cable

141.5.1 Background and Common Uses

Shielded twisted-pair (STP) cabling was initially developed by IBM for its Token Ring networks during the 1980s. The original Type 1 STP cable was a bulky, shielded cable with two pairs of conductive wire that was commonly deployed with Token Ring networks. The Token Ring STP combination offered a 16-Mbps deterministic network topology that was ideal for networks that needed the extra bandwidth, because Ethernet 10Base2 and 10Base5 coaxial were the only competitors during the early years. With the development of inexpensive UTP and the ever-increasing bandwidth that it supports, Type 1 STP with its one topology and one-speed support has been deemed almost obsolete in networking.

A new type of STP, which is basically a Category 5 UTP cable wrapped in shielding, has recently been introduced and holds some promise for specific network environments.

141.5.2 Categories and Standards

The original Type 1 STP cable was distinctive in its presentation. It was thick due to the braided shielding that surrounds both pairs of 150-ohm conductive copper core. Its end connectors were large (compared to modern-day RJ-45 caps of UTP) square blocks that plugged into network devices called multi-station access units (MAUs). Many engineers with Token Ring/Type 1 cable experience will recall the familiar "clicks" that preceded a network connection on the MAUs. Type 1 cables were rated up to 16 Mbps and were eventually replaced by Category 3, 4, and 5 cables for Token Ring.

The newer STP cable is similar to Category 5 UTP cable in that it has four pairs of tightly wound copper wire. However, a thin layer of aluminum foil shielding surrounds all four pairs of the cable in lieu of the heavy braided layers of Type 1. There is also metal in the plugs themselves to allow grounding and additional shielding. The new STP is referred to as screened twisted pair (ScTP) or foil twisted pair (FTP) and is more flexible, lightweight, and easier to deploy than Type 1. Currently, there are no standards for this new type of STP cabling, but most vendors follow the EIA/TIA 568 UTP Category 5 standard that allows for 100-Mbps transmissions.

141.5.3 Strengths and Capabilities

The strength of STP cable is in its shielding and insulation. The braided aluminum/copper mesh that surrounds the twisted pairs allows the cable to resist noise and electromagnetic interference (EMI). Although the old Type 1 cables are no longer being actively deployed, the new STP cables are being manufactured and marketed for high-interference environments. The newer STP cables offer some of the advantages of UTP cabling—high-bandwidth, multi-topology support, and lower cost—and have the added benefit of resistance to EMI. Environments such as medical facilities, airports, and manufacturing plants can derive benefits from using ScTP/FTP.

141.5.4 Vulnerabilities and Weaknesses

The weaknesses of the Type 1 STP medium are well documented. Type 1 is bulky, difficult to deploy, slow, and only supports one network topology. It is not surprising that Type 1 STP cables have been almost forgotten for general-purpose networking. Although the new ScTP and FTP cables show great promise, they still have some of the limitations based on the disadvantages of metal shielding. All STP cabling systems require careful emphasis on grounding because an STP cable that has not been grounded on both ends offers little resistance against EMI. In addition, unlike UTP, the cables must be deployed with great care so that none of the shielding elements, such as the connectors or the cable itself, are damaged. For STP cables to work, both grounding and shielding integrity must be maintained during installation, or the benefits of using shielded cables are lost.

141.5.5 Future Growth

The future of STP media is uncertain. The Type 1 cabling so common during the 1980s has been all but abandoned during the “Fast Ethernet” rush of the 1990s. The new lightweight, flexible STP cables, drawing on the strength of the characteristics of UTP cabling, have yet to be deployed in mass due to their narrow marketing focus and high overall cost. However, renewed focus in the United States and abroad on ensuring that cabling, regardless of type, be electromagnetically compatible (EMC) with its environment holds some promise for the growth of STP.

141.6 Optical Fiber Cable

141.6.1 Background and Common Uses

At the time of writing this chapter (March 2003), Stanford University’s Linear Accelerator Center set a new speed record for transmitting data on the Internet, by sending 6.7 gigabytes of data across 6800 miles in less than 60 seconds. That technological marvel is equivalent to sending all of the data on the two-DVD set of “Gone with the Wind” from New York City, in the United States, to Tokyo, Japan, in about the time it takes to read this paragraph. This amazing accomplishment is part of the continuing evolution of the networking technologies that are being used by millions of people every day. The common network component that has fueled this growth in data transmission speed and volume on the Internet has been the increased reliance on hair-thin strands of silica glass—better known optical fiber cable.

The idea of transmitting data with light dates back to the 1800s with Alexander Graham Bell having the first recorded patent of a light-data transmitting device—his Photophone—in 1890. However, real advances in transmitting light through strands of glass fiber did not occur until after World War II. The advent of semiconductor diode lasers that can be used at room temperature and advances in the manufacturing processes of optical fiber cables in the early 1980s set the stage for the first large-scale commercial use of optical fiber cables by AT&T. By the mid to late 1980s, fiber was being laid across oceans, with the first being the English Channel; and by the 1990s, fiber-optic cables were beginning to be widely used in local area network environments, primarily as backbones for office networks.

Today, with the exponential advances in network speeds, optical fiber is the *de facto* standard for connecting wide area and local area networks. Two general types of fiber cable—single mode (SMF) and multimode (MMF)—are commonly used to connect cities, buildings, floors, departments, and even homes. Fiber-optic cable's inherent resistance to attenuation (allowing for long distances and speeds), noise, and EMI make it a perfect choice for transmitting data.

141.6.2 Categories and Standards

Optical fiber refers to the medium that allows for the transmission of information via light. Fiber cable consists of a very clear, thin filament of glass or plastic that is surrounded by a refractive sheath called "cladding." The core, or axial, part of fiber-optic cable is the intended area for transmission, while the cladding is intended to "bounce" errant light beams back into the center. The core has a refractive index approximately 0.5 percent higher than that of the surrounding cladding so that errant light rays transmitted at shallow angles to the cladding are reflected back into the center core. This transmitting "center," made of a thin strand of glass, generally needs to be protected because, unlike copper metal wire, it is brittle and fragile. Often, the cladded core is coated with plastic, and Kevlar fibers are embedded around the outside to give it strength. The outer insulation is generally made of PVC or Teflon.

There are three specific types of fiber cables, and each has its specific uses.

141.6.2.1 Step-Index Multimode Fiber

Step-index multimode fiber has a relatively thick center core and is almost never used for networking. It has a thick, 100-micron core surrounded by cladding that allows light rays to reflect randomly, which results in the light rays arriving at different times at the receiver, resulting in what is known as modal dispersion. Consequently, information can only be transmitted over limited distances. Step-index multimode fiber is most often used in medical instruments.

141.6.2.2 Graded-Index Multimode Fiber or Multimode Fiber (MMF)

Graded-index multimode fiber, or MMF, is likely the most well-known fiber medium to most network administrators and engineers. MMF cables are commonly used in local network backbones to connect floors and departments between networking components such as switches and hubs. The graded-index MMF has the characteristic of the refractive index between the cladding and core changing gradually. Consequently, multiple light rays that traverse the core do not "bounce" off the cladding in a random manner. Rather, the light refracts off the core in a helical fashion, allowing for most of the beams to arrive at the receiver at about the same time. The end result is that the light rays arrive less dispersed. MMF fiber, although designed to minimize modal dispersion, is still best suited for shorter distances compared to single-mode fiber, which can transmit data for miles. Although MMF fiber is limited as to the distances over which it can be used, it is still able to transmit far greater distances than traditional copper wires. Consequently, it is widely used and widely supported by networking equipment companies to connect network backbones in traditionally UTP-cabling-based environments.

141.6.2.3 Single-Mode Fiber (SMF)

Single-mode fiber (SMF) has the narrowest core of all fiber cables. The extremely thin core, generally less than 10 microns in diameter, is designed to transmit light parallel to the axis of the core in a monomode fashion, attempting to eliminate modal dispersion. This single-beam mode of transmission permits data transmission over far greater distances. SMF is generally used to connect distant points and therefore is commonly used by telecommunications companies. In addition, SMF is increasingly being used by cable television companies to deliver digital cable as well as broadband data connections to homes. However, SMF use in LAN applications is generally not common due to its high cost and the limited support for SMF components in network equipment intended for LANs.

141.6.3 Strengths and Capabilities

Optical fiber media have distinct advantages due to their use of light instead of electrical impulses through a metal conductor. Light, and consequently fiber-based media, is highly resistant to attenuation, noise, and EMI. Consequently, fiber-based connections can traverse distances much farther and transmit more data than wire-based media. Fiber is perfect for high-bandwidth applications such as multimedia and video conferencing. In addition, because no electrical charges travel across it, it does not emanate any data, thereby providing security that no other media can offer. Its fragility also offers protection from intruders in that it is very difficult to tap into fiber-based networks without detection. It is commonly accepted that fiber-based networks run farther, faster, and more securely than any other available medium.

141.6.4 Vulnerabilities and Weaknesses

Unfortunately, fiber has some drawbacks that prevent it from being used in almost all situations. Because fiber is made of glass or plastic, it is more difficult to manufacture and work with than copper. It is not malleable, is difficult to terminate and install, and can be more easily damaged than wire-based media. In LAN-based environments, it is common for administrators and engineers to “crimp” or custom-create cable lengths in data centers and server rooms for use with UTP cabling. This is almost never the case with fiber, which is generally purchased in specific lengths.

In summary, although fiber has some distinct advantages, it has a very high cost of ownership. It is expensive to purchase, install, and maintain a fiber-based infrastructure. Even the network components that support fiber, such as router and switch modules, fiber-based NIC cards, etc., are much more expensive and rare than their UTP-based counterparts. Although prices for all types of PC and networking equipment have decreased dramatically in the past seven or eight years, the difference in support costs between fiber and copper media is not expected change in the future.

141.6.5 Future Growth

Most networking experts agree that Internet traffic has, on average, doubled each year since the mid-1980s. With the increased availability of high-speed network connections in people’s homes and the increases in application demand for bandwidth, it is difficult to imagine being able to support these ever-increasing needs without the availability of fiber-optic media. Although fiber and its infrastructure are expensive, it will without a doubt, remain a critical component of network technologies with its seemingly endless potential for increased speeds and bandwidths. Millions of miles of optical fiber are being laid throughout the world each year by governments and private companies, and this trend can be expected to continue to grow as the world’s needs for higher bandwidths increase each year.

141.7 Wireless Media

141.7.1 Background and Common Uses

When most people think of wireless technologies, they often seem to forget that wireless was developed more than a century ago by Guglielmo Marconi. Before the advent of “Wi-Fi” (Wireless Fidelity) networking, satellites, and cell phones, the good old-fashioned radio had been sending information through the wireless medium for decades. Recently, wireless has been introduced in almost every home with remote control TVs, garage door openers, and now even wireless appliances and PCs. The extension of attempting to use wireless technology into the area of PC and network computing was an easy one with obvious benefits. The topic of wireless technologies is broad and is rich with information; this section focuses on an overview of three specific, commonly available and well-known wireless network technologies.

First, wireless local area networks (WLANs), based on the IEEE 802.11 standard and now available in many offices, homes, coffee shops and restaurants will be reviewed. Then we discuss the extension of wireless LANs into metropolitan areas (WMANs) will be discussed, followed by a brief introduction to the new wireless arena intended to cover an extremely small area known as the personal area network (WPANs).

141.7.2 Categories and Standards

141.7.2.1 Wireless Local Area Network

The IEEE 802.11 standard, also known as "Wi-Fi," is specifically geared for wireless LANs. Almost all wireless LANs are based on 802.11 and are being increasingly installed in offices, homes, airports, and even in fast-food restaurants. All "Wi-Fi" networks have transmitting antennae known as access points that PCs connect to. The access point is generally connected to a traditional wired network LAN that allows access to the Internet via an ISP or to local resources such as file servers and printers. The laptops and PCs that connect to the access point must also have a "Wi-Fi" antenna. Although the specific components of all 802.11 wireless networks are the same, there are three different standards of 802.11 that are commonly seen. Each has its different strengths and uses.

141.7.2.2 IEEE 802.11a

The 802.11a-based WLANs transmit data at the unlicensed frequency of 5 GHz. This high-frequency WLAN allows a maximum speed of 54 Mbps with fairly good encryption of the data transmitted. It also is able to handle more concurrent users and connections than 802.11b. Unfortunately, 802.11a has a limited effective range and is generally used in line-of-sight situations. It is ideal for office environments with cubicles and conference rooms where the access points are mounted in the ceiling. It is also more expensive to deploy than 802.11b; consequently, 802.11a WLANs do not have a large install base.

141.7.2.3 IEEE 802.11b

The 802.11b WLANs use the unlicensed 2.4-GHz frequency range (which is currently used by common appliances such as cordless phones) and has an effective range of up to 100 yards. It was the first low-cost wireless LAN technology made available and has a comparatively large install base. The 802.11b-based networks generally transmit at speeds of 11 Mbps, but some network vendors use data compression algorithms to be able to offer maximum transmission speeds of 22 Mbps. The 802.11b standard allows for much greater distances than 802.11a (approximately 100 yards) and is cheaper to deploy. Consequently, it has a large install base in public and home use.

141.7.2.4 IEEE 802.11g

This new proposed standard works in the same 2.4-GHz frequency band as 802.11b but offers a maximum speed of 54 Gbps. Because it works in the same frequency range as 802.11b, it is able to support existing 802.11b installations, which is a big plus. Vendors have already released networking devices based on the proposed 802.11g standard, and its performance capabilities are promising. In addition, 802.11g network devices are even less expensive than 802.11b devices. With the promise of better performance for less cost, 802.11g will likely replace 802.11b, and possibly even 802.11a.

141.7.2.5 Wireless Metropolitan Area Network (WMAN)

"Wi-Fi" networks in actual use are confined to a relatively small area of approximately 300 feet. However, there are obvious advantages to being free from having to rely on fiber- or metal-based media that frequently make up for the limitations of short available "Wi-Fi" ranges. The IEEE 802 committee set up the 802.16 working group in 1999 to develop a standard for wireless metropolitan broadband access. There were three working groups of 802.16: 802.16.1 through 802.16.3. The 802.16.1 has shown the most potential and interest because it focuses on a readily available frequency range. The 802.16.1 WMAN infrastructure relies on a core network provider, such as the telephone company, offering wireless services to subscribers who will access the core network through their fixed antennae. In effect, subscribers in homes and offices will access the core switching center through base stations and repeaters. The connections will be provided through dynamic wireless channels ranging from 2 Mbps to 155 Mbps via an 802.16.1-based frequency range of 10 GHz to 66 GHz.

141.7.2.6 Wireless Personal Area Network (WPAN)

The personal area network (PAN) is a low-power, short-range, wireless two-way connection that connects personal devices such as PDAs, cell phones, camcorders, PC peripherals, and home appliances. The Bluetooth specification with its associated technology is the front-runner in providing personal wireless connectivity to users. It uses the unlicensed 2.4-GHz frequency with signal hopping to provide an interference-resistant connection for up to seven concurrent devices. Typically, a small Bluetooth network will be set up with a common authentication scheme and encryption so that other Bluetooth networks will not be able to connect automatically.

The Bluetooth standard has been around for many years. The Bluetooth Special Interest Group (SIG), a consortium of vendors that intends to develop and promote Bluetooth products, agreed on the third and current iteration Version 1.1 in 1999. Since that time, a host of new products has been introduced and new ones are planned—from PC peripherals to microwave ovens, cell phones, and even washers and dryers—all based on the Bluetooth PAN standard.

141.7.3 Strengths and Capabilities

Wireless networking has the obvious advantage of freeing one from the need to run cabling. The medium through which the communication travels is publicly available and free. Wireless networks allow for truly mobile computing, with the greatest benefit for roving laptop users. Wireless "hotspots" are springing up in many places, allowing Internet access for a growing number of users. Coupled with VPN technologies and wireless networking, users can extend the "office" environment beyond home networks and corporate offices.

141.7.4 Vulnerabilities and Weaknesses

The freedom of mobility that wireless networks provide their users also has its limitations. Wireless networking has not been widely deployed due to several issues. Wireless networks are slower than traditional cabled systems, are more expensive to deploy, and are susceptible to interference from environmental conditions such as weather and EMI.

However, the most important vulnerability that inhibits wireless networking from becoming more widely used is its lack of security. Because wireless uses a public medium in which data is transmitted, it is susceptible to "snooping" and eavesdropping. In the most widespread LAN application of wireless (i.e., 802.11b), networks are generally secured using LAN authentication by means of the wireless adapter's hardware MAC address. This is not really secure because MAC addresses can easily be falsified. Other techniques of encrypting the data using shared keys on the access point and receiver are available but not practical in large enterprise organizations due to difficulty in managing large numbers of keys. Even protocols intended to assist with wireless key management, such as Wired Equivalent Privacy (WEP), are cumbersome because key distribution and updates must be done in a secure medium outside of 802.11. In addition, although WEP encrypts the data that is being transmitted through the airwaves (via the RC4 algorithm), it is not completely secure. WEP can be easily cracked by anyone who has extensive knowledge of network sniffers.

141.7.5 Future Growth

It is clear that wireless networking holds a promising future for specific applications. The proliferation of 802.11b/802.11g-based "hot spots" grants greater freedom to casual users who need access to the Internet from a variety of locations. In addition, the relative ease of deploying wireless in home environments, as opposed to wiring cable, provides a niche market for networking companies. For enterprise-level environments, wireless networking will likely only play a small role due to its limitation in performance, lack of security, and high administration costs. However, for specific users and needs, such as areas in which wiring is difficult or impossible, conference room applications, mobile users, and roving service staff, there may be a natural fit for wireless.

141.8 Broadband: Digital Subscriber Line and Cable Modem

141.8.1 Digital Subscriber Line (DSL)

Digital Subscriber Line (DSL) is a broadband-based technology that uses existing telephone copper cabling to deliver high-speed Internet service to its subscribers. It largely depends on telephone companies, because it uses an upgraded telephone infrastructure. DSL signals are transmitted via special equipment over the existing phone lines and use frequencies that are higher than those of traditional voice traffic. A DSL filter, often referred to as a DSL modem, is used to segregate voice and data traffic on the recipient side.

DSL connections are always on, available 24 hours per day, regardless of the voice-phone traffic. It can theoretically provide up to 52-Mbps transmission under ideal conditions. It is inexpensive, and is becoming increasingly available in metropolitan areas. There are different types of DSL: the type depends on the carrier and what type is available in which area (see Exhibit 141.1).

DSL, however, does have its limitations. DSL technology relies on the carrier having the upgraded equipment, generally referred to as a Digital Subscriber Line Access Multiplexer (DSLAM) available in the area. The subscriber must be within a certain distance of the DSLAM and performance is impacted based on that distance. The further the subscriber is from the CO (central office) with the DSLAM, the less bandwidth it is able to achieve. In addition, other subtle factors, such as quality of the phone cables used in an installation, can impact DSL performance. Even with these limitations, it is being widely accepted by remote and home users due to its low price and performance, which easily exceed that of dialup and ISDN connections.

141.8.2 Cable Modems

Cable television companies have been installing optical fiber cables for years to deliver digital-quality cable TV channels to their subscribers. The cabling infrastructure that cable companies have installed, mainly optical fiber to buildings and 75-ohm coaxial once inside, is increasingly being used to offer high-speed digital network service to the Internet. Similar to DSL, a specific cable modem is required to receive high-speed access through the same medium that cable television is received. It is capable of delivering approximately 50 Mbps, but its speeds are generally less because segments are shared among subscribers. Consequently, bandwidth can change over time for a particular subscriber because performance is based on aggregate segment usage.

There have been several different iterations of cable modem service. Initially, cable modems used various proprietary protocols so that a cable TV provider could only use a specific cable modem for service. Within the past three years, there has been a movement toward standardization so that various

EXHIBIT 141.1 Types of DSL

Type	Max. Downstream Speed	Max. Upstream Speed	Max. Distance Central Office to Subscriber	Copper Pairs Used
Asymmetric (ADSL)	1.5–9 Mbps	16–640 Kbps	18,000 feet	1
Single-line (SDSL)	1.544 Mbps	1.544 Mbps	10,000 feet	1
High-rate (HDSL)	1.544 Mbps	1.544 Mbps	12,000 feet	2
Very-high-rate (VDSL)	13–52 Mbps	1.5–2.3 Mbps	4,500 feet	2

cable modems can be used regardless of the provider. So far, no formal body has established any specific standard, but, in general, three standards are used:

1. Digital Video Broadcasting (DVB)/Digital Audio-Video Council (DAVIC), also known as DVB-RCC: not very common, but still used in Europe.
2. *MCN/DOCSIS:* a predominately U.S. standard that almost all U.S. cable modems are based on.
3. *EuroDOCSIS:* a European standard based on DOCSIS.

In addition, the IEEE is attempting to develop its own standard, referred to as 802.14.

Cable modems have become popular because they are always on, readily available, inexpensive, and provide high bandwidth to most users. Unfortunately, cable modems are considered notoriously insecure because traffic within a cable modem segment is generally not filtered. Once a cable modem is installed, a packet sniffer can easily capture traffic that is being broadcast by other users in the segment.

141.8.3 Strengths and Capabilities of Broadband

Cable modem and DSL service rely on vastly different technologies to deliver the same type of service—high-speed Internet. Both are relatively inexpensive, not much more than analog dialup, and require minimal equipment for start-up. They both deliver speeds that far exceed traditional access methods, such as analog dialup and ISDN. They are also simple to use and do not require any connection procedures. Users generally leave them on continuously because they do not interfere with other services, whether TV, voice, or fax. These capabilities have encouraged both cable modem and DSL service to become ever more widespread in use. With advances in VPN technologies, they are commonly being used from homes not only to the Internet, but to offices as well. The availability of inexpensive, high-speed service that can be used for personal and work functions has been an invaluable advancement for remote offices and telecommuters.

141.8.4 Vulnerabilities and Risks

Unfortunately, having high-speed Internet access that is continuously available poses risks. Cable and DSL modems are usually never turned off, and systems run without pause. In addition, residential DSL and cable modem consumers are less likely to be aware of the capabilities of and the need for a firewall. These users who are always on the Internet without protection are precisely the targets that hackers are looking for. They can scan ports, stage distributed denial-of-service (DDoS) attacks, and upload worms, viruses, and Trojan horses at any time and at very high speeds. Many residential broadband customers have become unwitting accomplices to DDoS attacks against innocent targets, due to ignorance or a lack of vigilance.

A potential vulnerability that one needs to be particularly mindful of is the use of DSL and cable modems with VPN connections into enterprise environments. The benefit of having high-speed, secure access from home into the office network is a wonderful productivity tool. However, having fast access to your corporate network through the Internet poses a risk to the corporate network. Imagine a scenario in which a hacker uploads a virus, a worm, or a Trojan horse to a PC with a cable modem that also has established a VPN tunnel to a corporate network. The “pathogen” is free to travel through the VPN tunnel into the corporate network and attack it from the inside. This particular type of risk is magnified in environments that allow VPNs to perform “split-tunneling.” Split-tunnels allow traffic that is intended for the private protected network to travel through the tunnel AND traffic that is intended elsewhere to flow outside the tunnel. This means that users with split-tunnels are free to surf the Internet (i.e., download viruses and worms through their own broadband connection) while simultaneously sending traffic into the tunnel destined for the private protected network.

141.8.5 Risk Mitigation Strategies

DSL and cable modem technologies have real tangible benefits for their users at relatively low cost. These services are fast, always available, and getting easier to deploy. However, users should exercise good

Internet computing habits to minimize some of the risks that have been described. There are numerous personal firewalls available that will limit hackers' ability to scan and access the vulnerable hosts. In addition, home and small office networks should use the stateful inspection firewalls that are becoming more widely available. Good computing habits, such as having updated anti-virus software and clearing caches and cookies, help to minimize the risks of having a connection that is always available on the Internet.

In using broadband technology to access corporate networks through VPN tunnels, it is especially important to have personal firewalls installed with appropriate policies. In addition, split-tunneling should be disabled on the VPNs so that all access to the Internet is done through the corporate network and its firewalls. This may seem like a lot of work for administrators, but compared to the risks to the overall network, it is definitely worth doing.

The good news is that recent advances in client VPN software have integrated many of these functions into the client itself, so that the management of personal firewall policies and anti-virus updates is easier. For example, numerous vendors allow for control of personal firewall policies from the central VPN endpoint (firewall or VPN appliance) through the VPN client.

141.8.6 Future Growth

One of the great success stories in networking has been the widespread proliferation of broadband in the past five years. From a relatively modest start, high-speed Internet broadband connection has become readily available in most metropolitan areas. The In-Stat Group, a digital communications market research company, estimates that U.S. broadband subscribers will surpass 39 million customers by 2005. That is roughly 13 percent of the U.S. population. The same group performed a survey in 2001 and found that 50 percent of then-current broadband users did not use any form of intrusion detection protection. This means that if current trends continue, by 2005 the possibility exists that there will be more than 20 million unprotected broadband subscribers. Broadband usage will undoubtedly grow, along with its risks. Both casual subscribers and security professionals should exercise care and diligence in protecting themselves and others from the risks that follow exposure to the Internet via cable modems and DSL "always-on" connections.

141.9 Summary

Securing an enterprise network goes beyond configuring firewalls, servers, PCs, and networking equipment. It involves the combined evaluation of all the components of the network infrastructure, including people, processes, and equipment. The focus of this particular chapter has been on the foundation of network communications—the physical transmission media. Whether the requirements call for an optical fiber-based backbone or a high-speed wireless local area network, the relative strengths and weaknesses, with particular emphasis on security, should be thoroughly reviewed before making a selection. An informed decision on the cabling infrastructure ensures that the foundation of that network is built securely from the ground up.

142

Security and the Physical Network Layer

Matthew J. Decker

Networks have become ubiquitous both at home and in the office, and various types of media have been deployed to carry networking traffic. Much of the Internet is now carried over a fiber-optic backbone, and most businesses use fiber-optic cables to provide high-speed connectivity on their corporate campuses. Cable providers bring high-speed networking to many homes and businesses via coaxial cable. Local exchange carriers (LECs) and competitive local exchange carriers (CLECs) bring high-speed networking to many homes and businesses via twisted-pair cables, and numerous buildings are wired with twisted-pair cables to support high-speed networking to user desktops. Wireless networks have been deployed to provide network connectivity without the need for users to connect to any cables at all, although antennas and pigtail cables (coaxial cables) can be used to great advantage in maximizing the value of a wireless environment. These information highways and back roads lie within the physical layer of the seven-layer OSI (Open Systems Interconnection) model. The physical layer of the OSI model comprises the cables, standards, and devices over which data-link (layer 2 of the OSI model) encapsulation is performed.

This chapter serves as an introduction to common physical media used for modern networks, including fiber optics, twisted-pair, coaxial cables, and antennas. The reader will develop an understanding of each type of physical media, learn how an attacker might gain access to information by attacking at the physical layer, and learn how to apply sound industry practices to protect the network physical layer.

142.1 Fiber-Optic Cables

Much of the Internet is now carried over a fiber-optic backbone, and many businesses use fiber-optic cables to provide high-speed connectivity on their corporate campuses. Although they come bundled in a multitude of ways, there are essentially two types of fiber-optic cables on the market. These commonly used types of fiber-optic cables are known as “multimode” and “single mode.”

Multimode fiber gets its name from the fact that light can take multiple “modes” or paths down the fiber. This is possible because the core, at the center of the fiber, is wide enough to allow light signals to zigzag their way down the fiber. Single-mode fiber, on the other hand, has a very narrow core, only 8 to 10 micrometers (μm) in diameter. This is wide enough for light traveling down the fiber to take only one path. It is the difference in size of the cores of these fiber types that gives each its unique characteristics.

Multimode fibers come in various sizes. The two most common sizes are 50 and 62.5-micrometer cores. The core is the center portion of the cable designed to carry the transmission signal (light). Cladding comprises the outer coating that surrounds the core and keeps light from escaping the fiber. Exhibit 142.1 provides a visual reference showing the core and cladding, and will assist in explaining key differences and similarities between single and multimode fiber.

Cladding is the material surrounding the fiber core. Both single and multimode fiber-optic cables that are typically used for networking applications have the same outside diameter (125 micrometers). The core is doped with a substance that alters the refractive index of the glass, making it higher than the cladding. This is desirable because light bends toward the perpendicular when passing from a material of high refractive index to a lower one, thus tending to keep the light from ever passing from the core into the cladding.

To clarify this point, we consider a simple test using air, water, and a flashlight. If you are in the air and shoot a flashlight into a pool at an angle, the portion of the beam that enters the water bends toward the perpendicular—toward the bottom of the pool. If you are in the water and shoot a flashlight out of the pool at an angle, the portion of the beam that enters the air bends away from the perpendicular—tending more to be parallel with the surface of the water. This is because the refractive index of water is greater than that of air. As you move the flashlight progressively more parallel to the surface of the water, less and less light escapes into the air until you reach a point at which no light escapes into the air at all. This is the principle of total internal reflection, and is the result that fiber-optic cable designers endeavor to achieve. Further, this explains why tight turns in optical fiber runs are not desirable. Bending a fiber-optic cable too tightly can change the angle at which light strikes the cladding, and thus permit some of the signal to escape from the fiber core. This is called "micro-bending" the fiber.

Another important term in the world of fiber-optic cabling is "graded index." Most multimode fiber is "graded-index" fiber, meaning that the refractive index decreases progressively from the center of the core out toward the cladding. This causes light in the core to continuously bend toward the center of the core as it progresses down the fiber. The diagram is oversimplified, in that it shows three modes of light traveling in straight lines, one traveling directly down the center of the core and two bouncing off the cladding, as they progress down the core of the fiber. With a graded-index fiber, this light beam travels in

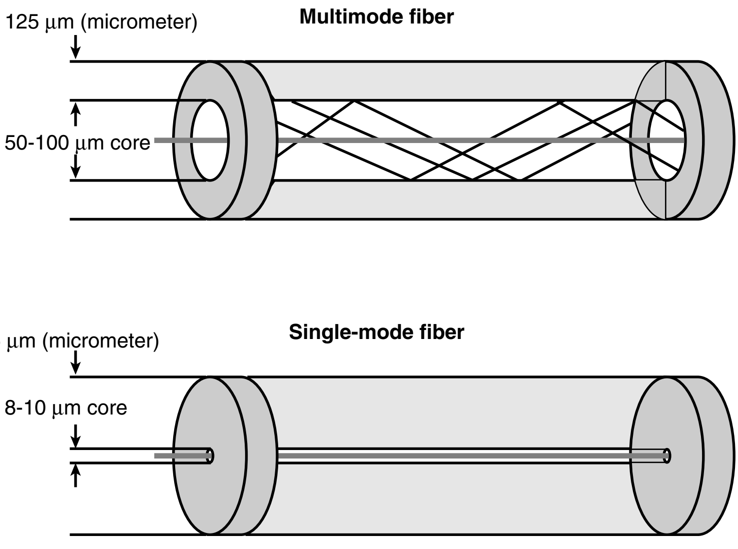

EXHIBIT 142.1 Core and cladding.

a more helical fashion down the fiber, always tending toward the center of the core as it progresses down the fiber. Further, because light traveling through a medium with a higher refractive index travels slower, the effects of "modal distortion" are significantly diminished in a graded index fiber.

There are a number of causes of signal loss in fiber-optic cables, but the two that best exemplify the differences between fiber types are "modal distortion" and "chromatic dispersion." Modal distortion is the spreading of the transmitted signal over time due to the fact that multiple modes of a signal arrive at the destination at different times. One signal takes many different paths, and each path is a different length, so the information arrives over a very short period of time rather than at a distinct point in time. The reason single-mode fiber is best for long distances is primarily because modal distortion is a factor in multimode fiber only. Single-mode fiber is most susceptible to losses due to chromatic dispersion. Light traveling through a vacuum travels at a constant speed, regardless of the wavelength. This is not so for materials like glass and plastic from which fiber-optic cables are made. "Chromatic dispersion" is signal degradation caused by the various wave components of the signal having different propagation velocities within the physical medium.

It is another type of loss that concerns us most from a security perspective. We previously introduced "micro-bending," which causes light to escape from the core into the cladding by simply bending the cable on a tight radius. This phenomenon gives us the most common means to tap a fiber-optic cable without having to perform a cable splice. By micro-bending a cable and placing an optical receiver against the cladding to collect the escaping light, the fiber can effectively be tapped, and the information traversing the cable can be captured. There are troubleshooting devices on the market that use the micro-bending technique to capture light from fiber-optic cables, and they take only seconds to install. These commonly available devices are only intended to identify whether or not a cable is active and do not actually process the data signal. Using this technique with more sophisticated equipment, a fiber-optic cable is easily tapped, although devices to do so are not readily available on the open market due to the lack of a commercial need for such a capability.

The brute-force means of tapping a fiber-optic cable involves cutting the cable and introducing a splice. This method brings the fiber-optic cable down for the minute or so required to introduce the splice, and introduces a 3-dB loss if half the light is transmitted into each half of the splice. If the target is monitoring their optical signal strengths, then this sudden added loss is easily detected, especially if found to have been introduced after a brief outage. Splices are also easily detected through use of an optical time domain reflectometer (OTDR), which is a tool that measures loss on a fiber-optic cable, and indicates the distance to points of significant signal loss.

142.2 Twisted-Pair Cables

Twisted-pair (TP) cabling is commonly used to carry network traffic within business complexes, and to bring high-speed Internet to homes and businesses through Digital Subscriber Line (DSL) services. DSL typically uses TP wiring to transport DSL signals from your home or business to your local telephone company's central office, where they terminate at a (Digital Subscriber Line Access Multiplexer DSLAM). DSLAMs translate these DSL signals into a format that is compatible with standard network equipment, such as switches and routers. CAT 3 or CAT 5 cabling, which we describe in some detail shortly, is typically used for these connections.

Twisted-pair cable is manufactured to comply with carefully crafted standards to support modern networks. A single cable is comprised of four wire pairs bundled together and bound by a protective sheath. The two types of TP cabling are identified as shielded twisted pair (STP) and unshielded twisted pair (UTP). STP cables have a conductive shield surrounding the wire bundle, which reduces (electromagnetic interference/radio frequency interference) EMI/RFI in order to:

- Limit the effects of the signal traversing the cable upon the local RF environment
- Limit the effects of a noisy RF environment upon the signal traversing the cable

UTP cables have no such shield, but the data-carrying performance characteristics of the medium are the same. Shielding a TP cable is not needed as a security measure to prevent eavesdropping, and proper installation of STP cable is a much more painstaking operation than that of UTP. It is recommended to avoid the use of STP except in environments where it is required for operational purposes, such as RF noisy industrial environments. An attacker can tap a shielded cable in the same manner as an unshielded cable, and no attacker will be found sitting in the parking lot across the street capturing your data from RF signals emanating from your unshielded cables. Fortunately, this is not where we find the interesting differences in performance characteristics among TP cables. For TP, we must dive into the various categories of cables prescribed in the prevailing standards. Exhibit 142.2 highlights the prevailing categories, standards, and bandwidth limitations for the TP cables commonly used in networking.

Note that each of these standards uses four wire pairs to carry signals. Each wire pair is twisted a certain number of times per foot of cable. These twists are not arbitrary, and, in general, the more twists per foot, the greater the bandwidth capacity of the cable. CAT 3 cables typically have about 3–4 twists per foot, while CAT 5e cables have about 36–48 twists per foot, but this varies depending on other factors, such as the distance between the wire conductors. These twists work their magic by serving two distinct purposes: (1) they reduce EMI and crosstalk between adjacent wire pairs, and (2) they play a key role in creating the proper inductance/capacitance relationship to sustain a given impedance (typically 100 ohms) for each wire pair. EMI and crosstalk are reduced because the signal from each wire of the pair cancels the electromagnetic radiation from the other. Maintaining the proper impedance for the cable minimizes signal loss and maximizes the distance over which high data rates can be sustained over the cable.

Like fiber-optic cable, TP can be tapped without cutting or splicing the wires. The protective sheath must be cut to gain access to the four wire pairs, and the pairs must be separated by half an inch or so to achieve access to eight distinct wires. They must be separated to eliminate the EMI-canceling property of the closely bound and twisted arrangement. Only one wire from each pair need be tapped, but access to all four pairs may or may not need to be achieved, depending on the standard and configuration being used (e.g., 10Base-T, 100Base-TX, 100Base-T4, 1000Base-T, half-duplex, full-duplex, etc.). All four wires may or may not be in use, and they may be used for transmit or receive, depending on the standard in use. The attacker can now pull information from the targeted lines by inducing the electromagnetic signal of each onto his own cable set, and feeding it to his equipment for analysis. A more invasive technique for

EXHIBIT 142.2 Categories, Standards, and Bandwidth Limitations for TP Cables

Category Designation	Bandwidth	Description
CAT 3	Bandwidth up to 16 MHz per wire pair (four-pair wire)	Performs to Category 3 of ANSI/TIA/EIA-568-B.1 & B.2, and ISO/IEC 11801 Class C standards. CAT 3 is standard telephone cable.
CAT 5e	Bandwidth up to 100 MHz per wire pair (four-pair wire)	Performs to Category 5e of ANSI/TIA/EIA-568-B.1 & B.2, and ISO/IEC 11801 Class D standards. 1000Base-T (IEEE 802.3a,b) supports 1000 Mbps operation over a maximum 100-meter-long Category 5e cable. Encoding is used to remain within the 100-MHz bandwidth limitation and achieve 1000-Mbps operation.
CAT 6	Bandwidth up to 250 MHz per wire pair (four-pair wire)	Performs to Category 6 requirements developed by TIA under the ANSI/TIA/EIA-568B-2.1, and ISO/IEC 11801Class E standards. The TIA/EIA 568B.2-1 standard was published in its final form in June 2002. 1000Base-TX (ANSI/TIA/EIA-854) supports 1000-Mbps operation over a maximum 100-meter-long Category 6 twisted-pair cable.
CAT 7	Bandwidth up to 600 MHz per wire pair (four-pair wire)	Performs to Category 7 of ISO/IEC 11801 Class E standard. At the time of this writing, TIA does not intend to adopt the ISO/IEC 11801 Class E standard.

tapping a network is to cut the line, install connectors, and plug them into a hub, but such techniques are much easier for the targeted entity to detect.

The greatest security threat posed at the physical layer, however, is at accessible physical devices such as hubs and repeaters. A hub permits an attacker to simply plug into the device and gain direct access to the network. This permits an attacker to not only "sniff" all the information traversing a network cable, but also all the information traversing the device. Further, the attacker can initiate network traffic from a device much more easily than from a tapped cable. Further, if the hub is in an out-of-the-way place, the attacker can take an added step and install a wireless access point to provide continued remote access to the network from a nearby location.

142.3 Coaxial Cables

Cable providers bring high-speed Internet services to many homes and businesses via coaxial cable. These broadband cable modem services typically offer customers the ability to upload and download data at contracted rates. The maximum rate limits are set by the service provider and are programmed into the users' cable modems.

Coaxial cables are comprised of a center conductor surrounded by a dielectric nonconductor material, which in turn is surrounded by an outer conductor. The whole thing is wrapped in a protective sheath to form a finished coaxial cable. The center conductor is typically used to carry the transmission signal, while the outer conductor usually functions as the signal ground.

Coaxial cable is no longer widely used to employ LANs, but the coaxial cable used for networking is typically the 50-ohm impedance variety, versus the 75-ohm variety used for CATV. A brief description of what these numbers mean is in order. Earlier, in the TP discussion, I mentioned that maintaining the proper impedance for the cable minimizes signal loss, and maximizes the distance over which high data rates can be sustained over the cable. This statement also holds true for coaxial cables.

So what does it mean that I have a 50-ohm cable? If you were to use an ohmmeter to measure the resistance across the center conductor and outer shield of a nonterminated coax cable, you would quickly learn that you do not receive a reading of 50 ohms. In fact, the reading approaches infinity. Now, if you were to transmit a signal down this nonterminated coax cable, you would find that nearly 100 percent (the remainder is absorbed by the line or radiated into the atmosphere) of the signal is reflected back to the source, because there is no load at the other end to absorb the signal. This reflected signal represents a "standing wave" on your coax line that is not desirable, as it is effectively noise on your line. If you terminate the cable with a resistor connected between the center and outer conductor, and repeat the testing process, you will find that the reflected wave is significantly reduced as the value of the chosen resistor approaches 50 ohms. Finally, you will learn that terminating the cable with a 50-ohm resistor eliminates the reflected wave, and thus provides the most efficient transmission characteristics for this cable.

This introduces the concept of impedance matching, and all coaxial cables are manufactured to an impedance specification (e.g., 50 ohms). In the real world, impedance matching can be good, but not perfect, and the way this is measured is through a metric called a voltage standing wave ratio (VSWR). A perfectly balanced transmission system with no "standing wave" on the transmission medium has a VSWR of 1:1 (one-to-one). This applies to our example of the 50-ohm coax line terminated with a 50-ohm resistor. In a worst-case scenario, such as the nonterminated test we performed, the VSWR is $1{:}\infty$ (infinity). It should be clear at this point that a lower VSWR is better. Modern communication systems and components provide VSWRs below 1:2, which is typically represented by dropping the "1:" ratio designation, and simply identifying "VSWR $<$ 2." Failing to match the impedances of your transmission system components, including the cables, can have a dramatic impact on the rated bandwidth-carrying capacity of the system.

Do coaxial cables present a significant RFI problem, such that one needs to worry about attackers accessing the information traversing the line even if they are unable to physically tap the line? If all cables are properly terminated, the answer is no. The outer conductor completely surrounds the center conductor and provides effective RFI shielding and noise immunity. Cables that are connected to equipment on one end, and nonterminated on the other, however, can act as antennas, thus creating an RFI problem. As with all physical media, coaxial cables are susceptible to a physical tap if an attacker gains working access to the cable.

142.4 Antennas

We live in a digital world, but the laws of physics are not giving up any ground in the radio frequency (RF) analog arena. Coaxial cables are used to carry signals to and from antennas. Short coax cables, designed to permit the quick connect and disconnect of antenna components using various connector types, are commonly referred to as "pigtails." The concepts of impedance matching and VSWR, discussed earlier, are important concepts in selecting antennas, and are now assumed to be understood by the reader. Antennas are becoming increasingly important physical devices through which we achieve Internet, wide area network (WAN), and local area network (LAN) connectivity. In the networking arena, we use them for satellite communications, wireless access points, and point-to-point links between facilities. They offer the distinct advantage of establishing network connections while disposing of the need for cabling the gap between the antennas. Of course, from an attacker standpoint, these links dispense with the need to tap a physical cable to gain access to the transmission medium.

An antenna is a physical device designed to transfer electrical energy on a wire into electromagnetic energy for transmission via RF waves, and vice versa. It is tuned to a specific set of frequencies to maximize this transfer of energy. Further, an efficient antenna is impedance-matched to become part of an overall system that maintains a low VSWR. The characteristics of antennas we concern ourselves with in this chapter are gain, beam width, impedance, and VSWR. As we already have an understanding of the last two, let's look at the first two.

Gain is typically measured in terms of decibels referenced to an isotropic radiator (dBi). Isotropic means radiating in all directions, including up, down, and all around; thus, an antenna achieves gain by narrowing its focus to a limited area rather than wasting resources where no signal exists for reception, or is needed for transmission. It is important to note that dBis are measured on a logarithmic scale; thus, 10 dBi represents an increase of signal strength by 10 times, 20 dBi by 100 times, 30 dBi by 1000 times, etc. Every increase of 3 dBi is a doubling of gain; thus, 3 dBi represents an increase of signal strength by 2 times, 6 dBi by 4 times, 9 dBi by 8 times, 12 dBi by 16 times, etc.

Beam width is measured in degrees. An omni-directional antenna exhibits equal gain over a full circle, and thus has a beam width of 360 degrees. Directional antennas focus their gain on a smaller area, defined by beam width; thus, an antenna with a beam width of 90 degrees exhibits its quoted gain over an area shaped like a quarter piece of pie. Such an antenna would be a good choice for a wireless network antenna intended to serve one floor of a square building, if placed in one of the four corners and aimed at the opposing corner. Satellite antennas on Earth have narrow beam widths, as any portion of a transmitted signal that does not impact the satellite's antenna is wasted, and only a small percentage of the signal transmitted from the satellite actually reaches it. The satellite's own antenna, however, has a beam width tuned to ensure coverage of a prescribed area (e.g., all of Brazil).

By far, the most common use of antennas in current networks is for use with wireless access points (WAPs). The most common standards in use for WAPs are 802.11a, 802.11b, and 802.11g. The 802.11b and g wireless radios provide data rates up to 11 Mbps and 54 Mbps, respectively, and operate over a 2.4-GHz carrier wave (2.4 to 2.483 GHz) to transmit and receive data. These two standards use antennas with identical specifications because they share a common frequency band.

IEEE 802.11a is a physical layer standard (IEEE Std. 802.11a, 1999) that supports data rates ranging from 6 to 54 Mbps, and operates in the 5-GHz UNII band in the United States. The 5-GHz UNII band is segmented into three ranges, with the lower band ranging from 5.15 to 5.25 GHz, the middle from 5.25 to 5.35 GHz, and the upper from 5.725 to 5.825 GHz. Be careful using 802.11a devices in Europe, as these frequency ranges are not permitted for public use in many European countries. Due to the vast separation in frequencies, antennas intended for use with 802.11a are not compatible with those for 802.11b and g.

The greatest security concern for wireless networks is the fact that attackers have access to your transmitted signal. Do not assume that just because your wireless network manual told you that you would not be able to reliably connect beyond 500 feet, that an attacker cannot pick up the signal from much greater distances. The standard antennas that ship with most WAPs are omni-directional, and typically have a gain of about 1 or 2 dBi. Wireless access cards installed in user computers typically have internal antennas with similar characteristics. Given these numbers, 500 feet is generous, and the data rate will often suffer. A knowledgeable attacker is not going to rely on the default hardware to connect to your WAP. A common suite of attacker hardware includes a 5-dBi (or greater) omni-directional antenna and a 14-dBi (or greater) directional antenna with a narrow beam width (20 to 50 degrees), used in conjunction with a high-power (100 mW or more) wireless access card with dual external antenna inputs. This suite of physical layer tools permits both antennas to be connected to the wireless access card simultaneously, and the entire package fits neatly into a laptop carrying case. Using this hardware, the attacker is able to easily find the WAP using the omni-directional antenna, pinpoint the location of the WAP and receive a stronger signal (by about 10 times) with the directional antenna, and gain full duplex access to the WAP from much greater distances than can be achieved with default hardware. Note that an attacker will not likely use the same antenna to seek out 802.11a networks as 802.11b and g networks because the target frequencies are so far apart. Additional hardware is required to attack both standards.

Protecting against unauthorized access to WAPs requires that they be treated just like public access points, such as Internet connections. Connections through WAPs should be authenticated, filtered, and monitored in accordance with the organization's remote access policy, or wireless access policy, as applicable.

142.5 Protected Distribution Systems

We have discussed various types of physical media used to carry network traffic. We have made clear that a knowledgeable attacker with physical access to the transmission media can tap the cable to gain access to the data traversing that media, with the exception of antenna systems, which only require that an attacker achieve relatively close proximity. We are now prepared to address the protection of these physical layer assets. When it is impractical to use strong encryption to protect the confidentiality and integrity of data traversing a physical link, the techniques incorporated by protected distribution systems (PDSs) may be warranted. A PDS is a wireline or fiber-optic telecommunication system that includes terminals and adequate acoustical, electrical, electromagnetic, and physical safeguards to permit its use for the unencrypted transmission of classified information [see NIS]. The physical security objective of a PDS is to deter unauthorized personnel from gaining access to the PDS without such access being discovered. There are two categories of PDS: (1) hardened distribution systems, and (2) simple distribution systems. Hardened distribution systems afford a high level of physical security by employing one of three types of carriers:

1. A hardened carrier, which includes specifications for burying cable runs and sealing protective conduits
2. An alarmed carrier, which includes specifications for the use of alarm systems to detect PDS tampering
3. A continuously viewed carrier, which mandates that carriers be maintained under continuous observation

Simple distribution systems afford a reduced level of security, can be implemented without the need for special alarms and devices, and are practical for many organizations. Some of the techniques, such as locking manhole covers and installing data cables in some type of carrier (or conduit), are sound practices. These are policy issues that promote the fundamental objective of protecting networks at the physical layer, are effective at protecting unauthorized access to critical data infrastructure, and should be considered for implementation to the extent that they are cost-effective for an organization.

142.6 Strong Security Follows Good Policy
