The change in electric field at the junction calls for a change in the *transition region width*, W, since it is necessary that a proper number of positive and negative charges (in the form of uncompensated donor and acceptor ions) be exposed for a given value of the $\mathscr{E}$ field. Thus, we expect the width, W, to decrease under forward bias (smaller $\mathscr{E}$, fewer uncompensated charges) and to increase under reverse bias.

The *diffusion current* is composed of majority-carrier electrons on the n side surmounting the potential-energy barrier to diffuse the p side, and holes surmounting their barrier from p to n. With forward bias, the barrier is lowered from V_o to $V_o - V_f$, and many more electrons in the n-side conduction band have sufficient energy to diffuse from n to p over the smaller barrier. Therefore, the electron diffusion current can be quite large with forward bias. Similarly, more holes can diffuse from p to n under forward bias because of the lowered barrier. For reverse bias, the barrier becomes so large ($V_o + V_r$) that virtually no electrons in the n-side conduction band or holes in the p-side valence

band have enough energy to surmount it. Therefore, the diffusion current is usually negligible for reverse bias.

The *drift current* is relatively insensitive to the height of the potential barrier. The reason for this is that the drift current is limited *not* by *how fast* carriers are swept down the barrier, *but* rather *how often*. For example, minority-carrier electrons on the p side which wander into the transition region will be swept down the barrier by the $\mathscr{E}$ field, giving rise to the electron component of drift current. However, this current is small not because of the size of the barrier, but because there are very few minority electrons in the p side to participate. Every p-side electron that diffuses to the transition region will be swept down the potential energy hill, whether the hill is large or small. Similar comments apply regarding the drift of minority holes from the n side to the p side of the junction. To a good approximation, therefore, the electron and hole drift currents at the junction are independent of the applied voltage.

The supply of minority carriers on each side of the junction required to participate in the drift component of current is generated by thermal excitation of electron-hole-pairs (EHPs). For example, an EHP created near the junction on the p side provides a minority electron in the p material. If the EHP is generated within a diffusion length L_n of the transition region, this electron can diffuse to the junction and be swept down the barrier to the n side. The resulting current is commonly called the *generation current* since its magnitude depends entirely upon the rate of generation of EHP. This generation current can be greatly increased by optical excitation of EHPs near the junction (the pn junction *photodiode*).

The *total current* crossing the junction is composed of the sum of the diffusion and drift components. The electron and hole diffusion currents are both directed from p to n (although the particle flow directions are opposite to each other), and the drift currents are from n to p. The *net* current crossing the junction is zero at equilibrium, since the drift and diffusion components cancel for each type of carrier. Under reverse bias, both diffusion components are negligible because of the large barrier at the junction, and the only current is the relatively small (and essentially voltage-independent) generation current from n to p.

We expect from Fig. 4 that injection of excess holes from p to n will produce a *distribution* of excess holes in the n material. As the holes diffuse deeper into the n region, they recombine with electrons, and the resulting excess hole distribution is obtained as a solution of the diffusion equation, Eq. 16B. If the n region is long compared with the hole diffusion length, L_p, the solution is exponential, as in Fig. 4. Similarly, the injected electrons in the p material diffuse and recombine, giving an exponential distribution of excess electrons. These excess carrier distributions must be accounted for in switching a pn junction from forward bias to reverse bias.

By evaluating the diffusion currents of electrons and holes across the junction, it can be shown that the current-voltage characteristic of the diode is given by

$$I = qA[(D_p/L_p)p_n + (D_n/L_n)n_p](e^{qV/kT} - 1) \quad \text{(Eq. 21)}$$

Equation 21 is called the *diode equation*, which describes the total current through the diode for either forward or reverse bias. We can calculate the current with reverse bias (commonly called the reverse saturation current) by letting $V = -V_r$

$$I = qA[(D_p/L_p)p_n + (D_n/L_n)n_p](e^{-qV_r/kT} - 1) \quad \text{(Eq. 22)}$$

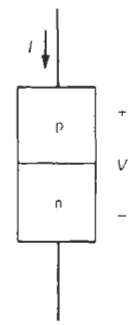
If V_r is larger than a few kT/q, the total current is just the reverse saturation current

$$I = -qA[(D_p/L_p)p_n + (D_n/L_n)n_p] \quad \text{(Eq. 23)}$$

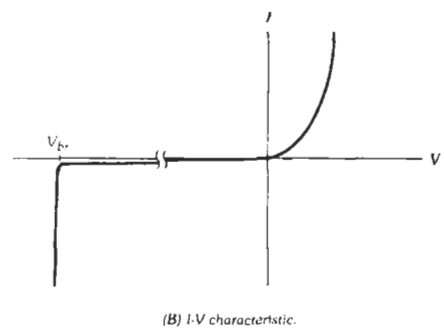
The *I-V* characteristic for the pn junction is shown in Fig. 6. It exhibits conduction for forward bias (V positive), negligible current for moderate reverse bias, and avalanche breakdown at a large reverse bias (V_{br}).

Reverse Breakdown

The small reverse saturation current typical of reverse bias in a junction is valid until a critical reverse bias is reached, for which *reverse breakdown* occurs (Fig. 6). At this critical voltage (V_{br}), the reverse current through the diode increases sharply, and relatively large currents can flow with little further increase in voltage. The



(A) Definitions of directions.



(B) I-V characteristic.

Fig. 6. Current and voltage in a pn junction.

existence of a critical breakdown voltage introduces almost a right-angle appearance to the reverse characdiodes.

There is nothing inherently destructive about reverse breakdown. If the current is limited to a reasonable value by the external circuit, the pn junction can be operated safely in the reverse-breakdown condition. Useful devices called *breakdown diodes* are designed to operate in the reverse-breakdown regime of their characteristics.

Reverse breakdown can occur by two mechanisms, each of which requires a critical electric field in the junction transition region. The first mechanism, called the *zener effect,* is operative at low voltages (up to a few volts reverse bias). If the breakdown occurs at higher voltages (from a few volts to hundreds of volts), the mechanism is *avalanche breakdown.*

Zener breakdown occurs in heavily doped junctions in which the transition from the p side to the n side is very abrupt. Under these conditions, the potential barrier separating carriers on the two sides of the junction is very narrow, and a quantum-mechanical process called *tunneling* can take place. In effect, electrons from the p-side valence band are able to tunnel across the barrier into the empty states in the n-side conduction band when a small reverse bias is applied. The result is a strong current from n to p in the diode, causing zener breakdown. We shall discuss tunneling again in relation to tunnel diodes in a later section.

For diodes with lighter doping or with a graded junction, the avalanche mechanism is the operative breakdown process. In this effect, the electric field in the transition region becomes strong enough under reverse bias to accelerate carriers to quite high kinetic energy. For example, if a minority hole is generated thermally on the n side and wanders into the transition region, it is swept by the junction field to the p side. If the field is high enough, the hole can collide with the lattice with sufficient energy to create an electron-hole pair. As a result, the newly created hole is swept to the p side and the electron is swept to the n side. With one carrier entering the transition region, we in effect have three carriers leaving. This *carrier multiplication* adds to the reverse current. Furthermore, if on the average each carrier (including carriers created by ionizing collisions) can create one EHP during its transit across the transition region, a runaway (avalanche) process develops. Avalanche breakdown usually occurs at a sharply defined breakdown voltage which corresponds to the establishment of a critical field in the transition region. This critical field is that necessary to cause a series of ionizing collisions by carriers in transit across the transition region.

Capacitance and Transient Behavior

Since many pn-junction devices are used in ac circuits or for switching applications, it is important to consider their time-dependent properties. The transient behavior of a junction is influenced strongly by the presence of stored charge. For example, the charge (Q) due to excess minority carriers in a forward-biased junction must be changed as the current varies. Since this charge cannot be altered instantaneously, current and voltage may vary in a complex fashion for the transient case.

The problem of stored charge is particularly important in applications that call for switching a diode from forward conduction to the reverse-biased state. In this case, the distribution of excess minority carriers is swept across the junction, giving rise to a brief pulse of reverse current after the applied voltage has been switched negative (Fig. 7). The time this reverse current ($-I_r$) lasts is called the *storage delay time,* t_{sd}. This time is proportional to the minority-carrier lifetime, τ, in the region where the charge is stored. After the charge distribution has properly rearranged to that expected for a reverse-biased junction, the small reverse saturation current is reached. However, the relatively large reverse current during switching must be accounted for in circuit designs. Special switching devices can be constructed which store very little charge in forward bias, and therefore are able to switch from the forward to the reverse state with a minimum of time delay or reverse current.

When ac signals are applied to a junction, the necessity for buildup and depletion of stored charge causes the voltage to lag behind the current. The resulting capacitance is an important junction property. For a reverse-biased junction, the capacitance is due to the changing charge in the depletion region (Fig. 5). As the reverse bias increases, W must increase to accommodate the increased charge on each side of the junction. We calculate the junction capacitance, C_j, from the rate of change of charge within W as the voltage is varied. The result is equivalent to the usual parallel-plate capacitor formula

$$C_j = \epsilon A/W \qquad \text{(Eq. 24)}$$

where,

W is the depletion width,
ϵ is the permittivity of the semiconductor.

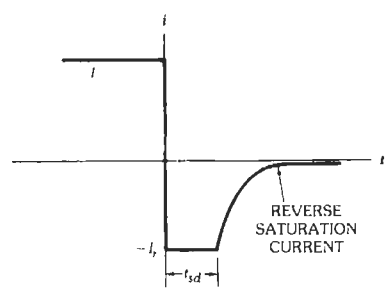


Fig. 7. Reverse recovery transient for a diode switched from forward conduction (I) to reverse bias.

Since W depends on the reverse bias, C_j is a *voltage-variable capacitance*. This property can be used in tuning circuits, as discussed below.

For forward bias, ac variations impressed on a steady forward current I (dc) call for variations in stored charge of the minority carrier distribution (Fig. 4). A forward-biased pn diode in which hole injection dominates responds to ac signals with an equivalent RC time constant τ_p required for redistribution of the charge due to holes stored in the n region. The current in a forward-biased junction ($V >> kT/q$) is

$$I = I_s\, e^{qV/kT} \qquad \text{(Eq. 25)}$$

where I_s is the magnitude of the saturation current, described in Eq. 23.

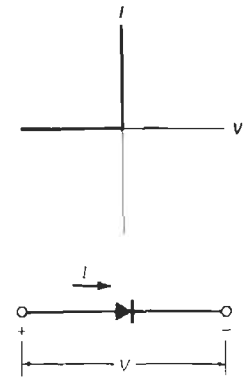
If we take the derivative with respect to V, we find the ac conductance to be

$$G_{ac} = (q/kT)\, I_s\, e^{qV/kT} = (q/kT)\, I \qquad \text{(Eq. 26)}$$

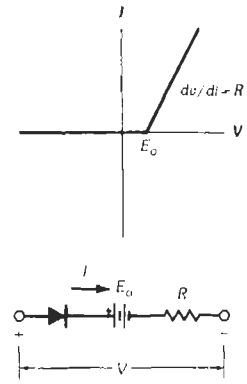
Thus charge-storage capacitance $C_s = \tau_p G$ is

$$C_s = (q\, \tau_p/kT)\, I \qquad \text{(Eq. 27)}$$

In summary, the reverse-bias junction capacitance, C_j, varies with the reverse bias voltage, V_r, and the forward bias capacitance, C_s, varies with the forward bias current, I. The storage delay time is an important limitation in switching circuits, and the forward-bias capacitance is important in high-frequency ac circuits. In either case, the effects of charge storage can be minimized by reducing the carrier lifetime in the minority-carrier storage region. One approach used in silicon devices involves doping the junction with gold, which introduces a high density of recombination centers, thereby reducing carrier lifetime.



(A) Behavior of an ideal diode.



(B) Piecewise linear model of pn junction.

Fig. 8. Semiconductor diode.

DIODES AND RECTIFIERS

The most obvious property of a pn junction is its *unilateral* nature; that is, to a good approximation it conducts current in only one direction. We can think of an *ideal diode* as a short circuit when forward biased and an open circuit when reverse biased (Fig. 8A). The pn junction diode does not quite fit this description, but the I-V characteristics of many junctions can be approximated by the ideal diode in series with other circuit elements to form an equivalent circuit. For example, most forward-biased diodes exhibit an *offset voltage*, E_o, which can be approximated in a circuit model by a battery in series with the ideal diode (Fig. 8B). The series battery in the model keeps the ideal diode turned off for applied voltages less than E_o. In some cases, the approximation to the actual diode characteristic is improved by adding a series resistor, R. The values of E_o and R depend on the particular diode, and can be obtained from the actual I-V characteristic of the device. The circuit approximations illustrated in Fig. 8B are called *piecewise-linear equivalents*, since the approximate characteristics are linear over specific ranges of voltage and current.

An ideal diode can be placed in series with an ac voltage source to provide *rectification* of the signal. Since current can flow only in the forward direction through the diode, only the positive half-cycles of an input sine wave are passed to the load. During the negative half-cycles, the diode is nonconducting, and the resulting voltage across a load resistor is zero. The output voltage is a *half-rectified sine wave*. The rectified signal has an average value, and therefore contains a dc component. By appropriate filtering, this dc level can be extracted from the rectified signal.

The unilateral nature of diodes is useful for many other circuit applications that require *waveshaping*. This involves alteration of ac signals by passing only certain portions of the signal while blocking other portions.

Other properties of pn junctions can be exploited for electronic-device applications. For example, the *breakdown diode* (sometimes called *zener diode*) makes use of the abrupt reverse breakdown shown in Fig. 6. The breakdown voltage is strongly dependent on doping, and junctions can be made with accurately chosen values of V_{br}. Breakdown diodes can be used as *voltage*

regulators in circuits with varying inputs. Such a device can also be used as a *reference diode;* since the breakdown voltage of a particular diode is known, the voltage across it during breakdown can be used as a reference in circuits that require a known value of voltage.

The junction capacitance described by Eq. 24 can be put to use in a device called a *varactor*. Since C_j is inversely proportional to the depletion width, W, and W varies with the reverse bias, V_r, the junction is a *voltage-variable capacitor*. For an abrupt junction, C_j is proportional to $V_r^{-1/2}$. Thus it is possible to vary C_j by choosing values of the applied bias. A set of varactors can be used, for example, to replace variable-plate capacitors in the tuning section of a radio receiver. By proper adjustment of doping profiles in the junction, the voltage dependence of C_j can be tailored for the specific application.

In abrupt pn junctions that are very heavily doped on both sides, current can be carried by the quantum-mechanical process called tunneling. In reverse bias, a tunnel diode passes current at very small voltage, and the same occurs for a fraction of a volt of forward bias (Fig. 9). However, at a critical forward voltage (V_p), the tunneling decreases, and eventually the usual forward diode current dominates. As Fig. 9 indicates, a range of the *I-V* characteristic exists in which the tunneling current decreases with increasing voltage, giving rise to a *negative resistance* region. Such a negative resistance can be used in various switching, oscillation, amplification, and other circuit functions.

When light shines on a pn junction, electron-hole pairs are generated by optical excitation. The collection of these optically generated charge carriers across the junction results in a net excess current from n to p (i.e., *I-V* curve A in Fig. 10 is moved down to curve B). The shift of the *I-V* curve is proportional to the optical generation rate of excess electrons and holes, and therefore to the intensity of the light. In the third quadrant (III), the junction can be used as a *photodiode*, in which the reverse current at a fixed reverse bias voltage is proportional to the intensity of the light. When the junction operates in the fourth quadrant of the *I-V* curve (IV), power is delivered from the junction to the external load. (Notice that at IV, the diode current is negative while the junction voltage is positive. Thus, the current in this case flows from minus to plus relative to the voltage, as in a battery.) In this case, the pn junction can be used as a *solar cell* (or *photovoltaic junction*). Such solar cells are widely used as power sources for satellites and in certain terrestrial applications.

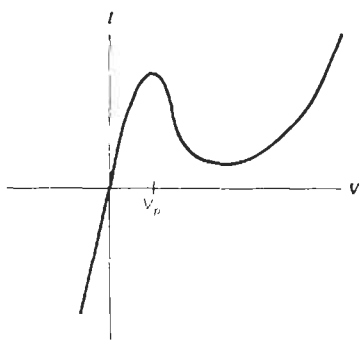


Fig. 9. *I-V* characteristic for a tunnel diode.

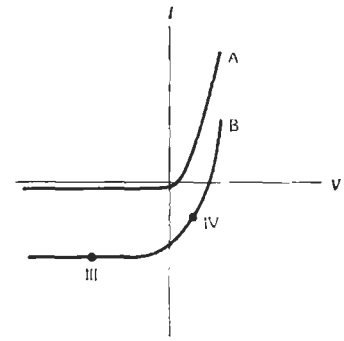

Fig. 10. *I-V* characteristics for a photodiode in the dark (A) and with light applied (B).

In many compound semiconductors (e.g., GaAs, InP, and alloys such as InGaAsP), electrons and holes recombine with each other at a forward-biased pn junction, giving off light. The wavelength of the resulting light depends on the material used, generally ranging from the infrared (e.g., GaAs) to the green (GaP). By proper choice of materials, *light-emitting diodes* (LEDs) can be made that cover a wide range of wavelengths. Such LEDs are useful as visible indicator lamps and in alphanumeric displays. In addition, infrared LEDs can be used in optical communication systems in which light signals are sent over optical fibers and are detected at the other end with a photodiode. Such optoelectronic systems can be made very efficient if the compound semiconductor diode is made in the form of a laser and the photodetector operates in the reverse-bias avalanche condition. For further discussion, see Chapters 21 and 22.

TRANSISTORS

The basic building block of modern electronics is the transistor. This device, which has replaced the vacuum tube in all but a few special applications, is used in most circuits requiring amplification or switching. Complex integrated circuits are also based on the transistor. This section deals with the operation of three transistor types—the junction field-effect transistor, the MOS field-effect transistor, and the bipolar junction transistor. We concentrate here on the internal operation of these devices, reserving treatments of their circuit operation for later chapters. Transistor fabrication methods are discussed in Chapter 20.

As an amplifying device, the transistor converts weak time-varying signals into strong signals. As a switching element, it can be changed from a conducting state to a

nonconducting state quickly with the application of very little control power. In the field-effect transistor, current through two terminals is varied by voltage applied to a third terminal. In the bipolar transistor, the current through two terminals is controlled by a small current applied to a third terminal.

Junction Field-Effect Transistors

In Fig. 5, the width of the depletion region (W) under reverse bias is controlled by the voltage applied to the junction. This property is the basis for the operation of the *junction field-effect transistor (JFET)*. In a JFET, the voltage-variable depletion-region width of a junction is used to control the effective cross-sectional area of a conducting *channel*. In the device of Fig. 11, current I_D flows through an n-type channel between two p regions. A reverse bias between these p regions and the channel causes the depletion regions to intrude into the n material, and therefore the effective width of the channel can be restricted. Since the resistivity of the channel region is fixed by its doping, the channel resistance varies with changes in the effective cross-sectional area.

In Fig. 11, electrons in the n-type channel drift from right to left, opposite to the current. The end of the channel from which electrons flow is called the *source*, and the end toward which they flow is called the *drain*. The p regions are called *gates*. If the channel were p-type, holes would flow from source to drain, in the same direction as the current, and the gate regions would be n. Voltage V_{GS} refers to the potential from each gate region, G, to the source, S. Since the conductivity of the heavily doped gate regions is high, we can assume that the potential is uniform throughout each gate. In the lightly doped channel material, however, the potential varies with position (Fig. 11B). For low values of current, we can consider the channel to be a distributed resistor, and assume that voltage V_{xS} varies linearly from V_{DS} at the drain end to zero at the source end of the channel.

In Fig. 12, assume the gates are short-circuited to the source ($V_{GS} = 0$), such that the potential at $x = L$ is the same as the potential everywhere in the gate regions. For very small currents, the widths of the depletion regions are close to the equilibrium values (Fig. 11A). As current I_D is increased, however, it becomes important that V_{xS} is large near the drain end and small near the source end of the channel. Since the reverse bias across each point in the gate-to-channel junction ($-V_{Gx}$) is simply V_{xS} when V_{GS} is zero, we can estimate the shape of the depletion regions as in Fig. 12A. The reverse bias is relatively large near the drain ($-V_{GD} = V_{DS}$) and decreases toward zero near the source. As a result, the depletion region intrudes into the channel near the drain, and the effective channel area is constricted. Since the resistance of the constricted channel is higher, the I-V plot for the channel begins to depart from the straight line that was valid at low current

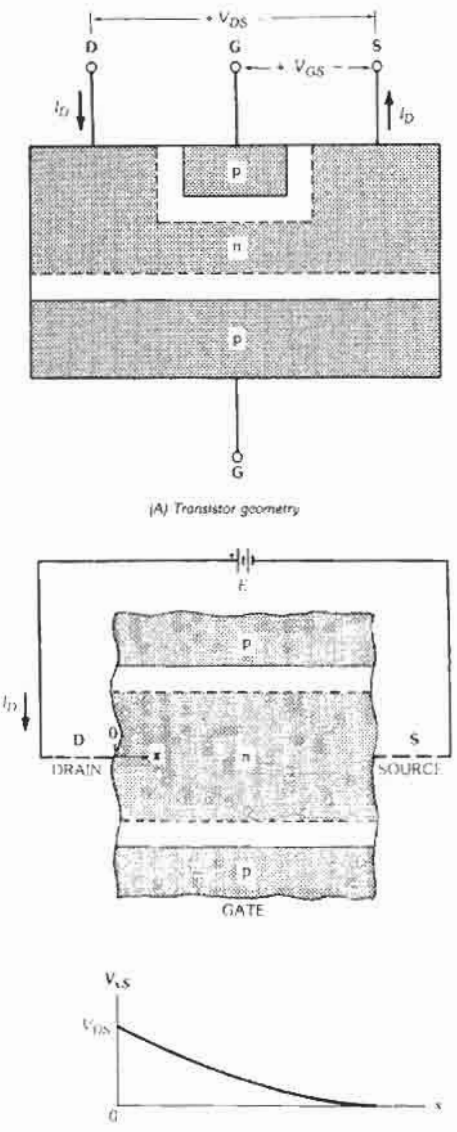

Fig. 11. Simplified cross-sectional view of a junction FET.

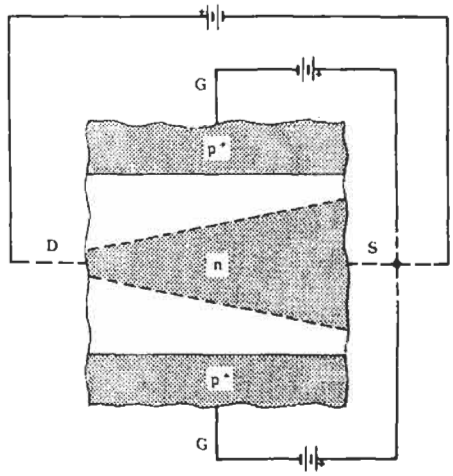
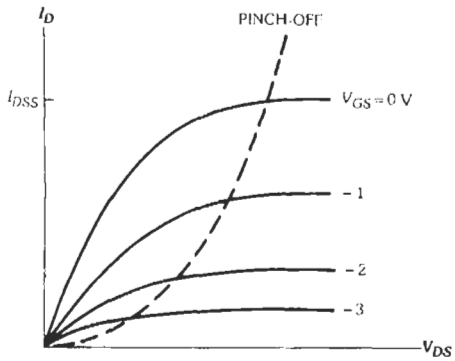
levels. As V_{DS} is increased, there must be some bias voltage at which the depletion regions meet near the drain and essentially *pinch off* the channel. When this happens, current I_D cannot increase significantly with further increase in V_{DS}. For higher voltages, the current is *saturated* approximately at its value at pinch-off.

The effect of a negative gate bias, $-V_{GS}$, is to increase the resistance of the channel and induce pinch-off at a lower value of current (Fig. 12B). Since the depletion regions are larger with V_{GS} negative, the slopes of the I_D-versus-V_{DS} curves below pinch-off become smaller. As current I_D increases, the pinch-off condition is reached at a lower drain-to-source voltage,



(A) Variation of depletion-region widths.



(B) Family of current-voltage curves for the channel as V_{GS} is varied.

Fig. 12. Effects of negative gate bias in the JFET.

and the saturation current is lower than for the case of zero gate bias. As V_{GS} is varied, a family of curves is obtained for the *I-V* characteristic of the channel, as in Fig. 12B. By varying the gate bias, we can obtain amplification of an ac signal or switch the device from its off ($I_D = 0$) to its on condition. Since the input control voltage, V_{GS}, appears across the reverse-biased gate junctions, the input impedance of the device is relatively high.

The JFET is generally used in the saturation region of its *I-V* characteristic (i.e., beyond pinch-off). The value of I_D at saturation (called I_{DS}) depends on V_{GS}, as Fig. 12B indicates. To a good approximation, I_{DS} beyond pinch-off can be written as follows:

$$I_{DS} \simeq I_{DSS}(1 + V_{GS}/V_p)^2 \qquad (V_{GS} \text{ negative}) \text{ (Eq. 28)}$$

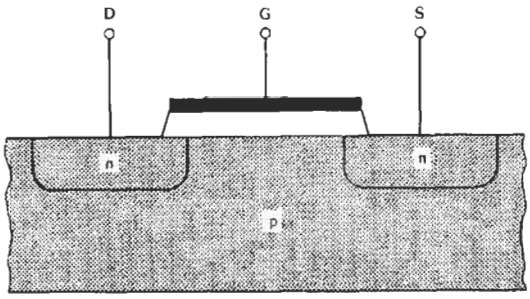
In this expression, I_{DSS} is the saturation value with the gate shorted to the source (i.e., with $V_{GS} = 0$). The term V_p is the pinch-off voltage defined as the gate bias required to pinch off the channel with $I_D = 0$. The quantity V_p is dictated by the device geometry and doping. For an n-channel device, V_{GS} is a negative number. Thus, Eq. 28 indicates that the saturation drain current, I_{DS}, is greatest (I_{DSS}) when V_{GS} is zero, and decreases to zero when V_{GS} becomes as negative as the pinch-off voltage V_p is positive.

MOS Field-Effect Transistors

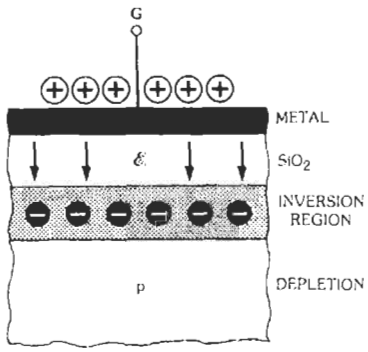
In the second class of FETs, the channel current is controlled by a voltage at a gate electrode that is isolated from the channel by an insulator. The resulting device is called an *insulated-gate field-effect transistor* (*IGFET*) (Fig. 13). Since the channel exists at the semiconductor surface, such a device is also called a *surface FET*. In the most common configuration, an oxide layer is grown or deposited on the semiconductor surface, and the metal gate electrode is deposited onto this oxide layer. This structure is commonly called a *metal-oxide-semiconductor transistor* (*MOST*).

The n source and drain regions of Fig. 13 are diffused into a high-resistivity p substrate. The channel region may be a thin diffused n layer, or more commonly an *induced inversion region*. If an n-type diffused channel is included between source and drain, the effect of the field is to raise or lower the conductance of the channel by either depleting or enhancing the electron density in the channel. If the gate voltage is positive, the conductivity of the channel is enhanced, whereas a negative gate voltage tends to deplete the channel of electrons. Thus a diffused-channel MOST can be operated in either the *depletion* or *enhancement* mode.

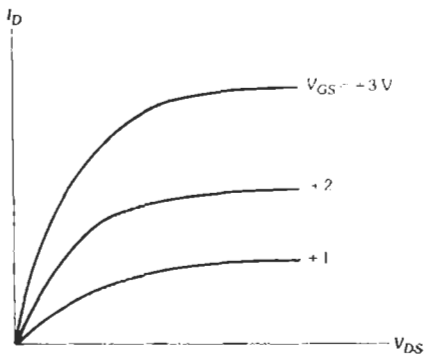
We shall concentrate on the *induced-channel MOST*, in which no diffused n-type region exists between source and drain at equilibrium. As with the JFET of the previous section, we shall consider an n-channel device; the corresponding p-channel case can be deduced from this discussion. When a positive gate voltage is applied to this structure, a depletion region is formed in the p material, and a thin layer of mobile electrons is drawn from the source and drain into the channel (Fig. 14A). Where the mobile electrons dominate, the material is effectively n-type. This is called an *inversion layer*, since that material was originally p-type. Once an inversion layer is formed near the semiconductor surface, a conducting channel exists from source to drain. The operation of the device is then quite similar to that of the JFET. The channel conductance is controlled by field $\mathscr{E}_i$ in the insulator, but the magnitude of this field varies along the channel as V_{Gx} varies from $V_{GS} - V_{DS}$ at the drain to V_{GS} at the source (Fig. 14C); this corresponds qualitatively to the variation in junction reverse bias along the channel for the JFET. Since a positive voltage is required between the gate and each point x in the channel to maintain inversion, a large enough value of V_{DS} can cause $\mathscr{E}_i$ to go to zero at the drain. This corresponds to the pinch-off condition. Once pinch-off is reached, the



(A) Cross-sectional view.



(B) Expanded view of the channel with positive polarity of gate bias.



(C) I-V characteristics as gate bias is varied.

Fig. 13. The induced-channel MOST.

saturation current remains essentially constant, as in the JFET.

The saturation drain current for the MOST is described by an equation of the same form as Eq. 28 for the JFET. For the MOS transistor with an induced channel,

$$I_{DS} = (\mu_n C_o/2L^2)\,(V_{GS} - V_T)^2 \quad \text{(Eq. 29)}$$

where,

μ_n is the electron mobility in the channel,
C_o is the capacitance between gate and channel,
L is the length of the channel from source to drain,
V_T is the *threshold voltage*, the gate bias that must be applied to induce a channel in the underlying semiconductor.

The value of the threshold voltage is dependent on several properties of the MOS structure. For example, differences in work function between the metal gate and the semiconductor must be balanced by the applied gate voltage. Furthermore, trapped charges at the semiconductor-oxide interface and in the oxide layer may induce image charges in the channel region that must also be overcome by the applied gate voltage. In many cases, several volts must be applied to the gate to create an inversion region (and therefore a conducting channel) in the semiconductor. The existence of such a threshold voltage can be a serious limitation in circuits that are designed to operate with low-voltage batteries. Therefore, much effort has been devoted to designing MOS structures with low values of V_T. Techniques used for this purpose include matching the work function of the gate and the underlying silicon by employing heavily doped polycrystalline silicon as a gate electrode, rather than the more common aluminum metal gate. Silicon crystals oriented along certain crystallographic directions that minimize surface-charge effects are also used to reduce V_T. One of the most successful methods for controlling the threshold voltage is the use of ion implantation in the channel region. For example, in a p-channel MOST, the source and drain regions are diffused with boron impurities, a thin gate oxide layer is grown, and then boron ions are implanted through the oxide region into the channel. Since the concentration of implanted impurities can be precisely controlled, a sufficient number of boron atoms can be implanted into the channel such that the gate bias required to create an inversion region is greatly reduced. Such low-threshold transistors can be used in circuits that are driven by quite low-voltage battery sources.

The MOS transistor has the advantage of extremely high input impedance between the gate and source electrodes, since these terminals are separated by an oxide layer. The input impedance of a MOST can be on the order of 10^{14} ohms, making this device very useful in amplifying signals delivered by circuits that are sensitive to loading.

The MOST is useful in integrated circuits utilizing silicon planar technology. For many years, it was difficult to control the surface charge and other effects in MOS structures, but these devices can now be manufactured in large numbers with good reproducibility, as discussed in Chapter 20.

Bipolar Junction Transistors

The BJT is a current-controlled device, in which the current through two terminals is controlled by a relatively small current in a third terminal. We shall begin the discussion by considering the reverse-biased pn junction. As discussed earlier, the reverse saturation current through a junction depends on the rate at which

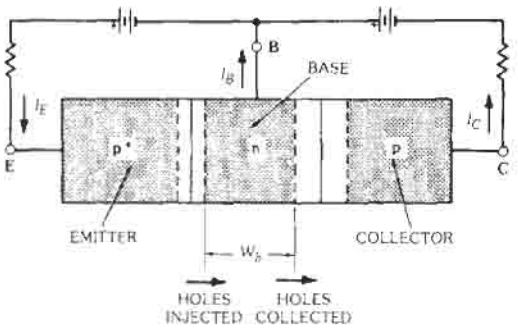
minority carriers are generated in the neighborhood of the junction. For example, the reverse current due to holes being swept from n to p is essentially independent of the size of the junction $\mathscr{E}$ field and hence independent of the reverse bias. The reason for this is that the hole current depends on how often minority holes are generated by EHP creation within a diffusion length of the junction, and not upon how fast a particular hole is swept across the depletion layer by the field. As a result, it is possible to increase the reverse current through the diode by increasing the rate of EHP generation. One convenient method for accomplishing this is optical excitation of EHPs with light, as in the photodiode. With steady photoexcitation, the reverse current will still be essentially independent of bias voltage, and if the dark saturation current is negligible, the reverse current is directly proportional to the optical generation rate, g_{op} (Fig. 10).

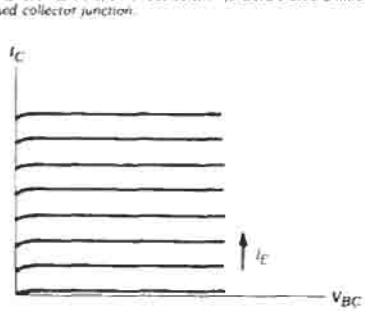
The example of external control of current through a junction by optical generation raises an interesting question: Is it possible to inject minority carriers into the neighborhood of the junction *electrically* instead of optically? If so, we could control the junction reverse current by simply varying the rate of minority-carrier

injection. For example, let us consider a hypothetical hole-injection device that can inject holes at a predetermined rate into the n side of the junction. The effect on the junction current will resemble the effects of optical generation. The current from n to p will depend on the hole injection rate (similar to the reverse current in Fig. 10) and will be essentially independent of the bias voltage. There are several obvious advantages to such external control of a current; for example, the current through the reverse-biased junction would change very little if the load resistance were altered, since the magnitude of the junction voltage is relatively unimportant. Therefore, such an arrangement should be a good approximation to a controllable constant-current source.

A convenient hole-injection device is a forward-biased p^+n junction (p^+ refers to a very heavily doped p region). The current in such a junction is due primarily to holes injected from the p^+ region into the n material. If we make the n side of the forward-biased junction the same as the n side of the reverse-biased junction, the p^+np structure of Fig. 15 results. With this configuration, injection of holes from the p^+n junction into the center n region supplies the minority-carrier holes to participate in the current through the reverse-biased np junction. Of course, it is important that the injected holes do not recombine in the n region before they can diffuse to the depletion layer of the reverse-biased junction. Thus we must make the n region narrow compared with a hole diffusion length.



(A) Schematic representation of PNP device with forward biased emitter junction and reverse biased collector junction.



(B) I-V characteristics of the reverse-biased np junction as a function of emitter current.

Fig. 15. A PNP transistor.

The structure we have described is a PNP bipolar junction transistor. The forward-biased junction that injects holes into the center n region is called the *emitter junction*, and the reverse-biased junction that collects the injected holes is called the *collector junction*. The p^+ region that serves as the source of injected holes is called the *emitter*, and the p region into which the holes are swept by the reverse-biased junction is called the *collector*. The center n region is called the *base*. The biasing arrangement of Fig. 15 is called the *common-base* configuration, since the base electrode (B) is common to the emitter and collector circuits.

To have a good PNP transistor, almost all of the holes injected by the emitter into the base should be collected. Thus the n-type base region should be narrow, and the hole lifetime, τ_p, should be long. This requirement is summed up by specifying $W_b \ll L_p$, where W_b is the length of the *neutral* n material of the base (measured between the depletion regions of the emitter and collector junctions) and L_p is the diffusion length for holes in the base, $(D_p\tau_p)^{1/2}$. With this requirement satisfied, an average hole injected at the emitter junction will diffuse to the depletion region of the collector junction without recombination in the base. A second requirement is that current I_E crossing the emitter junction should be composed almost entirely of holes injected into the base, rather than electrons crossing from base to emitter. This requirement is satisfied by doping the base region lightly compared with the emitter, so that the p^+n emitter junction of Fig. 15 results.

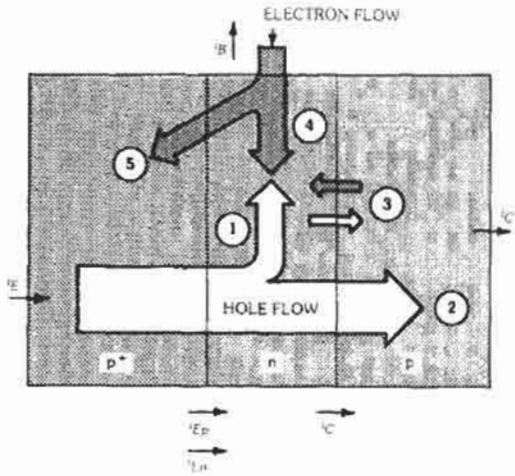
It is clear that current I_E flows into the emitter of a properly biased PNP transistor and that I_C flows out at the collector, since the direction of hole flow is from emitter to collector. However, base current I_B requires a bit more thought; I_B flows out since this current supplies electrons to the base region. In a good transistor, the base current will be very small since I_E is essentially hole current and the collected hole current, I_C, is almost equal to I_E. There must be some base current, however, due to requirements of electron flow into the n-type base region (Fig. 16). We can account for I_B physically by three dominant mechanisms:

(A) There must be some recombination of injected holes with electrons in the base, even with $W_b \ll L_p$. The electrons lost to recombination must be resupplied through the base contact.

(B) Some electrons will be injected from n to p in the forward-biased emitter junction, even if the emitter is heavily doped compared to the base. These electrons must also be supplied by I_B.

(C) Some electrons are swept into the base at the reverse-biased collector junction due to thermal generation in the collector. This small current reduces I_B by supplying electrons to the base.

The dominant mechanism in the base current is usually recombination, and we can often approximate the base current by calculating the recombination rate in



1 Injected holes lost to recombination in the base
2 Holes reaching the reverse biased collector junction
3 Thermally generated electrons and holes making up the reverse saturation current of the collector junction
4 Electrons supplied by the base contact for recombination with holes
5 Electrons injected across the forward-biased emitter junction

Fig. 16. Hole and electron flow in a PNP transistor with normal biasing.

the base. In a well-designed transistor, I_B will be a very small fraction (perhaps one-hundredth) of I_E.

In an NPN transistor, the three current directions are reversed, since electrons flow from emitter to collector and holes must be supplied to the base.* The physical mechanism for operation of the NPN device can be understood simply by reversing the roles of electrons and holes in the PNP discussion.

The BJT is useful in amplifiers because the currents at the emitter and collector are controllable by the relatively small base current. The essential mechanisms are easy to understand if various secondary effects are neglected. We shall use total current (dc plus ac) in this discussion, with the understanding that the simple analysis applies only to dc and to small-signal ac at low frequencies. We can relate the terminal currents of the transistor (i_E, i_B, and i_C) by several important factors. In this introduction, we shall neglect the saturation current at the collector (3 in Fig. 16) and such effects as recombination in the transition regions. Under these assumptions, the collector current is made up entirely of those holes injected at the emitter that are not lost to recombination in the base. Thus i_C is proportional to the hole component of the emitter current i_{Ep}.

$$i_C = Bi_{Ep} \qquad \text{(Eq. 30)}$$

*In the present discussion of device operation, we show the directions of the currents as they actually flow in normal operation. In circuit analysis, however, it is common to define all currents as flowing *into* the transistor, and incorporate minus signs where they are needed.

Proportionality factor B is simply the fraction of injected holes that make it across the base to the collector; B is called the *base transport factor*. The total emitter current, i_E, is made up of the hole component, i_{Ep}, and an electron component, i_{En}, due to electrons injected from base to emitter (5 in Fig. 16). The *emitter injection efficiency*, γ, *is*

$$\gamma = i_{Ep}/(i_{En} + i_{Ep}) \qquad \text{(Eq. 31)}$$

For an efficient transistor, B and γ should each be very near unity; that is, the emitter current should be due mostly to holes ($\gamma = 1$), and most of the injected holes should eventually participate in the collector current ($B = 1$). The relation between the collector and emitter currents is

$$i_C/i_E = Bi_{Ep}/(i_{En} + i_{Ep}) = B\gamma \qquad \text{(Eq. 32)}$$

The product $B\gamma$ is defined as the factor α, which represents the emitter-to-collector current amplification. There is no real amplification between these currents, since α is smaller than unity. On the other hand, the relation between i_C and i_B is more promising for amplification.

In accounting for the base current, we must include the rates at which electrons are lost from the base by injection across the emitter junction (i_{En}) and the rate of electron recombination with holes in the base. In each case, the lost electrons must be resupplied through the base current, i_B. If the fraction of injected holes making it across the base *without* recombination is B, then it follows that $(1 - B)$ is the fraction *recombining* in the base. Thus the base current is

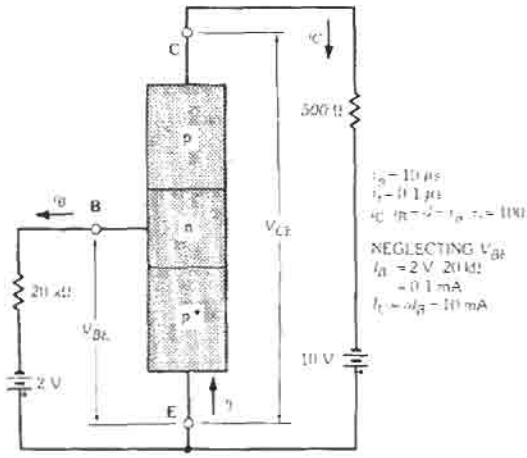
$$i_B = i_{En} + (1 - B)i_{Ep} \qquad \text{(Eq. 33)}$$

neglecting the collector saturation current. The relation between the collector and base currents is found from Eq. 30 and Eq. 33:

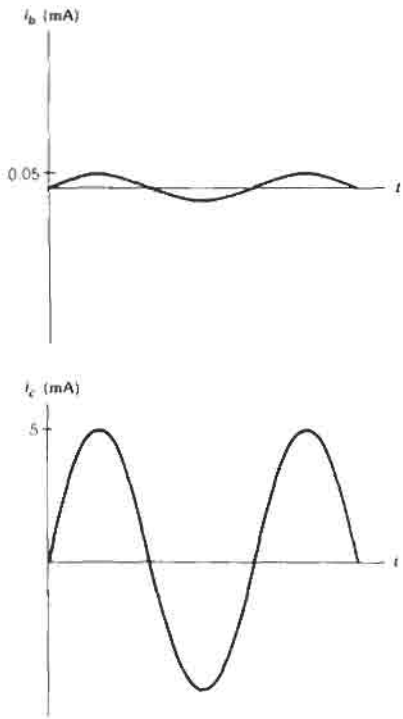
$$\begin{aligned} i_C/i_B &= Bi_{Ep}/[i_{En} + (1 - B)i_{Ep}] \\ &= B[i_{Ep}/(i_{En} + i_{Ep})]/\{1 - B[i_{Ep}/(i_{En} + i_{Ep})]\} \\ &= B\gamma/(1 - B\gamma) = \alpha/(1 - \alpha) \equiv \beta \end{aligned} \qquad \text{(Eq. 34)}$$

The factor β relating the collector current to the base current is the *base-to-collector current-amplification factor*. Since α is near unity, it is clear that β can be large for a good transistor, and the collector current is large compared with the base current.

It remains to be shown that collector current i_C can be controlled by variations in the small current i_B. In the discussion up to this point, we have indicated the control of i_C by emitter current i_E, with the base current characterized as a small side effect. In fact, we can show from space-charge-neutrality arguments that i_B can indeed be used to determine the magnitude of i_C. Let us consider the transistor of Fig. 17A, in which i_B is determined by a biasing circuit. For simplicity, we shall



(A) Biasing circuit



(B) Addition of ac variation of base current

Fig. 17. Example of amplification in a common-emitter transistor circuit.

assume unity emitter injection efficiency and negligible collector saturation current. Since the n-type base region is electrostatically neutral between the two transition regions, the presence of excess holes in transit from emitter to collector calls for compensating excess electrons from the base contact. However, there is an important difference in the times which electrons and holes spend in the base. The average hole spends a time τ_t, defined as the *transit time* from emitter to collector. Since the base width W_b is made small compared with L_p, this transit time is much less than the average hole lifetime, τ_p, in the base. On the other hand, an average excess electron supplied from the base contact spends τ_p seconds in the base (for simple recombination and equal excess carrier densities, τ_n and τ_p are equal). While the average electron waits τ_p seconds for recombination, many holes can enter and leave the base region, each with an average transit time τ_t. In particular, for each electron entering from the base contact, τ_p/τ_t holes can pass from emitter to collector while maintaining space-charge neutrality. Thus the ratio of collector current to base current is simply

$$i_C/i_B = \beta = \tau_p/\tau_t \qquad \text{(Eq. 35)}$$

for $\gamma = 1$ and negligible collector saturation current.

If the electron supply to the base (i_B) is restricted, the traffic of holes from emitter to base is correspondingly reduced. This can be argued in a simple way by supposing that the hole injection does continue despite a reduction of electrons from the base contact. The result would be a net buildup of positive charge in the base and a loss of forward bias (and therefore a loss of hole injection) at the emitter junction. Clearly, the supply of electrons through i_B can be used to raise or lower the hole flow from emitter to collector.

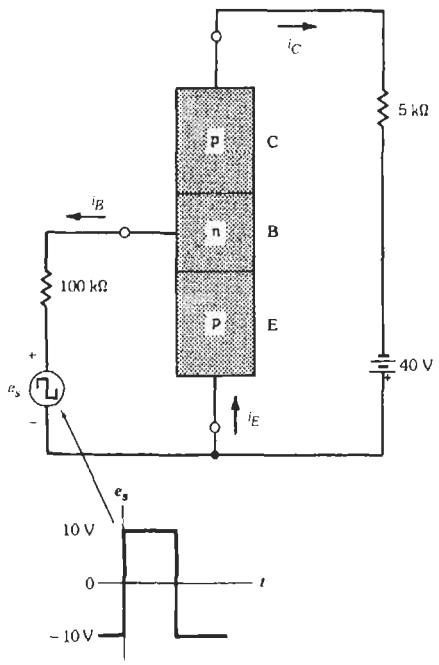
The base current is controlled independently in Fig. 17A. This is called a *common-emitter* circuit, since the emitter electrode is common to the base and collector circuits. The emitter junction is clearly forward biased by the battery in the base circuit. The voltage drop in the forward-biased emitter junction is small, however, so that almost all of the voltage from collector to emitter appears across the reverse-biased collector junction. Since v_{BE} is small for the forward-biased junction, we can neglect it and approximate the base current as 2 V/20 kΩ = 0.1 mA. If we assume $\tau_t = 0.1$ μs and $\tau_p = 10$ μs, β for the transistor is 100, and the collector current i_C is 10 mA. It is important to notice that i_C is determined by β and the base current, rather than by the battery and resistor in the collector circuit (as long as these are of reasonable values to maintain a reverse-biased collector junction). In this example 5 V of the collector-circuit battery voltage appears across the 500 Ω resistor, and 5 V serves to reverse-bias the collector junction.

If a small ac current, i_b, is superimposed on the steady-state base current of Fig. 17, a corresponding ac current, i_c, appears in the collector circuit (Fig. 17B). The time-varying portion of the collector current will be larger than i_b by the factor β, and current gain results.

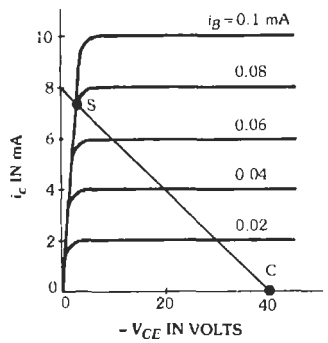
In a switching opertion, a transistor is usually controlled in two conduction states that can be loosely referred to as the *on* state and the *off* state. Ideally, a switch should appear as a short circuit when turned on and an open circuit when turned off. Furthermore, it is desirable to switch the device from one state to the other with no lost time in between. Transistors do not fit this

ideal description of a switch, but they can serve as a useful approximation in practical electronic circuits. The two states of a transistor in switching can be seen in the simple common-emitter example of Fig. 18. In this figure, collector current i_C is controlled by base current i_B over most of the family of characteristic curves. The *load line* specifies the locus of allowable (i_C, $-v_{CE}$) points for the circuit. The load line is obtained by writing a loop equation around the collector circuit, which results in a linear equation with an intercept on the $-V_{CE}$ axis ($I_C = 0$) and an intercept on the i_C axis ($V_{CE} = 0$).

If I_B is such that the operating point lies somewhere between the two end points of the load line (Fig. 18B), the transistor operates in the *normal active mode*. That is, the emitter junction is forward biased and the collector is reverse biased, with a reasonable value of I_B flowing out of the base. On the other hand, if the base current is zero or negative, the cutoff point (C in Fig. 18B) is reached at the bottom end of the load line, and the collector current is negligible. This is the *off* state of the transistor, and the device is said to be operating in the *cutoff* regime. If the base current is positive and sufficiently large, the device is driven to the *saturation* regime, marked S. This is the *on* state of the transistor, in which a large value of I_C flows with only a very small voltage drop V_{CE}. The saturation regime corresponds to the loss of reverse bias across the collector junction. In a typical switching operation, the base current swings from positive to negative, thereby driving the device from saturation to cutoff and vice versa.



(A) Biasing circuit.



(B) Collector characteristics and load line for circuit.

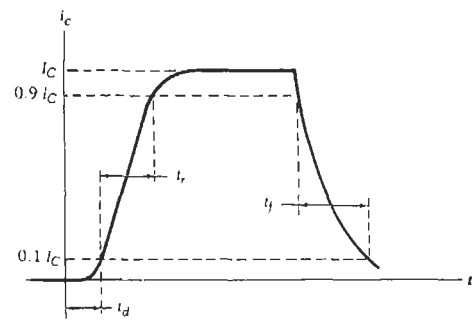
Fig. 18. Simple common-emitter switching circuit for a transistor.

The response of a BJT to switching signals is not instantaneous. Junction capacitance and charge-storage effects, discussed earlier, cause delays in switching response that must be taken into account in circuit design. A typical time response of collector current to the input square wave of Fig. 18 is shown in Fig. 19. An initial delay, t_d, is required for charging of the junction space-charge regions. Then a rise time, t_r, is required before the minority-carrier distribution is established in the base region. Similarly, a fall time, t_f, characterizes the decay of the minority-carrier distribution from the conducting state to the cutoff condition (in which the base is essentially depleted of minority carriers). Some switching transistors utilize gold doping to reduce carrier recombination times, thereby minimizing these switching delay times.

Circuit models of transistors and applications in electronic systems are discussed in Chapter 19.

OTHER ELECTRONIC DEVICES

The basic devices discussed thus far—diodes, transistors, and their applications in integrated circuits—form the foundation of modern electronics. However, there are a host of other devices that play important roles in electronic circuit and system design. Symbols for many solid-state devices are shown in Table 4. In



t_d Delay time while junction capacitance is charging
t_r Rise time from $0.1 \cdot 0.9 I_C$
t_f Fall time from $0.9 \cdot 0.1 I_C$

† This table gives many of the commonly used symbols for semiconductor devices. Standardization is incomplete, however, and other symbols are often used in the electronics literature.

this section, we will briefly consider a few devices that are particularly important in many electronic systems.

Display Devices

Many electronic systems require some means of displaying information. Such display may take the form of a printout, a cathode-ray-tube image, or various types of digital (*numeric*) or letter and number (*alphanumeric*) displays. Even analog displays, such as the indicator needle on a meter scale, are designed to present information from a circuit or system to the viewer. Most of these display methods are familiar and need no further elaboration. We will discuss here only a few of the newer displays that are currently being used.

Liquid crystal (LC) materials are made up of molecules that have considerable freedom of movement and can be aligned in various configurations by application of an electric field. Depending on the molecular alignment, light can be passed through the LC or can be scattered within it. A typical display cell is made up of the liquid crystal held between two glass plates with conductive coatings. The top plate is transparent, and the bottom plate is either reflecting or absorbing. By the application of appropriate voltages across the plates, incident light may be either scattered within the LC or transmitted through the cell and absorbed or reflected from the back plate. As a result, an array of LC cells can be made to reflect light in certain segments but not others. Typically, the array is in the form of a series of bars that can be selectively addressed to display numbers or letters.

Liquid-crystal displays require little power for their operation and can be made in rather large arrays. Certain LC systems can be made to reflect colors selectively, so that colored displays are possible. Disadvantages of the LC devices include the requirement of incident light, sensitivity to temperature variations, and relatively slow response time (milliseconds) to the control signal.

One of the most versatile display systems is the *light-emitting diode* (LED). As discussed earlier, carriers injected across a forward-biased pn junction recombine within approximately one diffusion length of the junction. If the semiconductor is a luminescent material, the energy given up when an electron-hole pair recombines results in a photon of light. For example, when an electron in the conduction band of GaAs recombines with a hole in the valence band, a photon is emitted with energy equal to the GaAs band gap (1.4 eV). A photon with this energy is in the infrared portion of the spectrum. Thus in a properly constructed GaAs

junction, forward bias results in considerable carrier injection, recombination, and the resulting emission of infrared light. The intensity of the light can be varied (with nanosecond response time) by changing the diode current; thus electrical signals can be converted into optical signals by the LED. Used in conjunction with a photodiode, the LED can send information from one point to another optically. Another application of the LED-photodiode is in an *isolator*. Since the signal transmission is optical, complete electrical isolation can be achieved. Such an isolator pair can be mounted on an insulating substrate and packaged to form a device that allows signal transfer between input and output while maintaining electrical isolation.

If the information receiver is the human eye, the display device must emit light in the visible part of the spectrum (approximately 4000 to 7000 Å in wavelength, or 3.1 to 1.8 eV in photon energy). Visible LEDs are built that cover the range from red to green. For example, the compound GaAsP has a band gap that can be varied from that of GaAs (1.4 eV) to that of GaP (2.3 eV) by choosing the appropriate mixture. When the phosphorus content is about 40% of the column V constituent, the band gap is 2 eV, in the red. This is the most common material for LED display fabrication. By using segments made up of GaAsP strips, a numeric display can be made that emits light in the appropriate segments to display numbers or letters. Such an LED display operates at very low voltage, has a long operating lifetime, and is highly reliable.

Microwave Devices

The use of transistors at high frequencies is generally limited to the range of a few gigahertz by capacitance and transit-time effects. Therefore, generation and amplification of microwave signals usually depend on special devices that can deliver high-frequency ac power to a resonant cavity or waveguide. Power is delivered to an ac signal if there is an increase in the motion of charge through a region where the field is changing such as to retard such motion. For charges in a solid or gas, this is called *negative differential conductivity*. As an example, suppose holes are drifting down a typical semiconductor bar in the direction of an electric field. If the field varies with time, the holes speed up or slow down as the field changes, and power is extracted from the field. However, if the arrival of holes at a certain point were to increase during a time interval in which the field at that point decreases, power would be delivered to the field, and the apparent conductivity $dJ/d\mathscr{E}$ would be negative. The object of microwave oscillators is to modulate the rate of arrival of electrons or holes at a point where the electric field is varying, such that the arrival coincides with the retarding half-cycle of the ac field.

A number of solid-state microwave devices have been introduced in recent years. Most of these devices are variations of the *IMPATT diode* and the *gunn diode*. In each of these devices, a negative conductance allows current oscillations that can be used to generate microwave signals.

The negative conductance in an IMPATT diode results from avalanche multiplication and transit-time effects. A simple version of the IMPATT structure is the N^+PIP^+ device shown in Fig. 20A. In this diode, the n^+ and p^+ regions are heavily doped, and the i region is essentially intrinsic. Assume the diode is biased such that avalanche multiplication at the n^+p junction begins at $t = 0$ in the voltage cycle (Fig. 20B). Then a positive ac voltage superimposed on the dc bias causes more multiplication. The avalanche-generated holes drift to the right and into the i region in the diagram of Fig. 20C. Since the hole pulse grows as long as the critical field, $\mathscr{E}_a$, is exceeded, the pulse reaches its maximum at $\omega t = \pi$ (i.e., the hole pulse grows during the entire

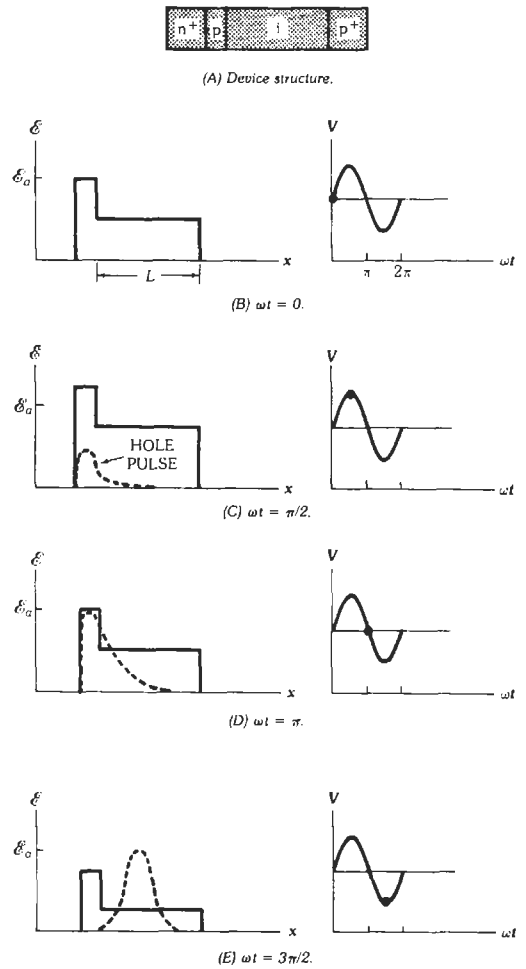

Fig. 20. Time dependence of the growth and drift of holes during a cycle of applied voltage for the N^+PIP^+ IMPATT diode.

positive half-cycle of the voltage). Then as v enters its negative half-cycle, avalanche ceases at the n^+p junction (Fig. 20D). However, the hole pulse drifts through the i region from left to right while the ac terminal voltage is negative. Since the holes are collected during the negative half-cycle of voltage, the ac conductance is negative during this period. If length L is chosen such that the pulse drifts through the i region for the full negative half-cycle of voltage, negative conductance will be obtained for the entire half-cycle. The IMPATT device can be placed in a resonant cavity tuned to the appropriate frequency, and microwave generation results.

Current pulses are created in a GaAs gunn diode by a mechanism that transfers electrons from one region of the conduction band to another. The conduction electrons in GaAs normally reside in a band 1.43 eV above the valence band. In addition, a subsidiary conduction band lies about 0.3 eV above the first. Of course, this higher-lying band is generally of little interest, since conduction-band electrons are usually found only in the lower-energy band. It is possible, however, to excite electrons into the upper conduction band by applying a sufficiently large electric field. The reason this transfer is of interest is that the mobility of electrons in the upper band is much smaller than the usual mobility of electrons in the lower conduction band. Thus, when electrons are transferred to the low-mobility subsidiary band, they actually *slow down*. At a critical threshold field, $\mathscr{E}_{th}$, electrons begin to transfer to the upper band,

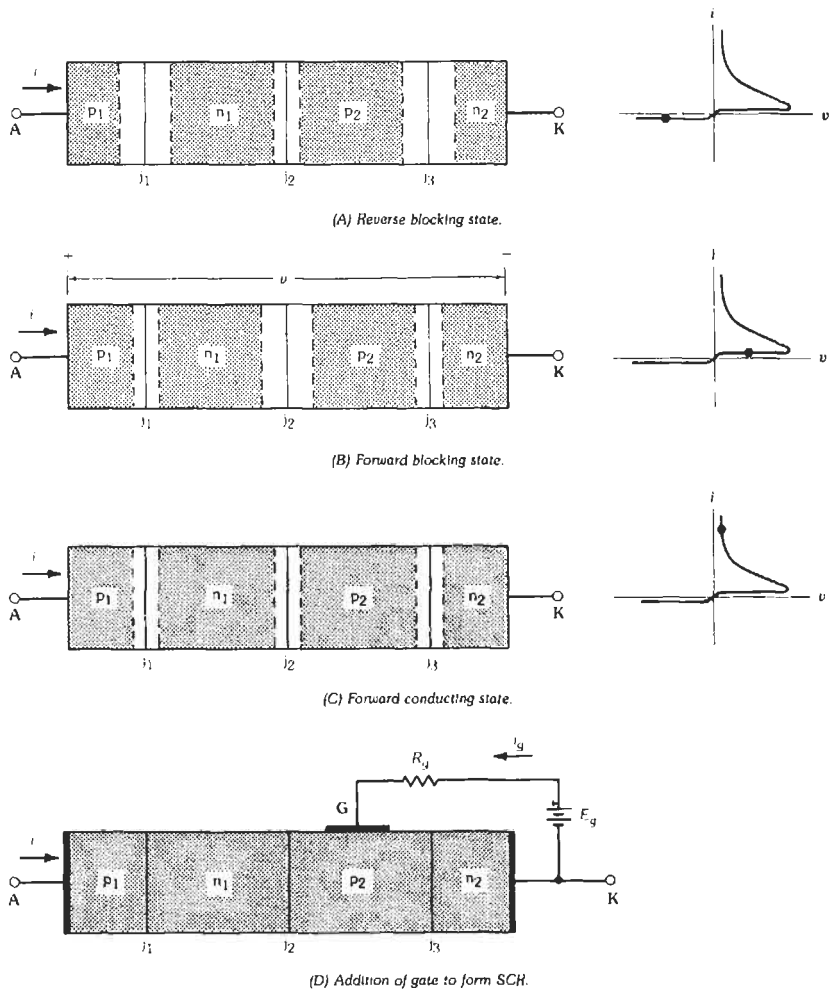

Fig. 21. Biasing of a PNPN device.

where their velocity is smaller. This transfer results in a negative differential conductance that can be used in microwave generation.

Switching Devices

Many electronic applications call for a device that can be switched from a nonconducting "off" state to a conducting "on" state. Several devices can be used in switching applications, and selection of the appropriate device depends on requirements of power level, switching time, and other factors. A common electronic switch is the bipolar transistor, which can be driven from cutoff to saturation by controlling the small base current, or the FET, which can be switched by controlling the gate voltage.

The most widely used controllable switch for large currents is the *semiconductor controlled rectifier (SCR)*. This is a four-layer PNPN device (Fig. 21) with terminals attached to the anode (A) and the cathode (K) and a third terminal attached to one of the central regions. This third terminal is called the gate (G). When the gate is left open, the SCR has the characteristic of Figs. 21A-C. With a negative applied voltage, junctions j_1 and j_3 are reverse biased (Fig. 21A), and current through the device is effectively blocked, even at high reverse voltage. With a positive voltage (A positive with respect to K), junctions j_1 and j_3 are forward biased, while j_2 is reverse biased (Fig. 21B). Initially, the device current is restricted to the small saturation current of j_2. This is called the *forward blocking state* and corresponds to the "off" condition of the switch. The SCR can be thought of as two coupled transistors ($p_1n_1p_2$ and $n_1p_2n_2$) with a common collector junction, j_2. If transistor action is initiated, holes injected into n_1 from the forward-biased emitter junction, j_1, can be transported across the base of the PNP structure into p_2. Such transistor action in effect feeds holes into the base of the NPN structure, thereby increasing electron injection from n_2 into p_2. Such injected electrons can then be collected across j_2 into n_1 by transistor action, and the process continues. The result is a combination of two saturated transistors, typified by high current at low voltage (the *forward conducting state*), as shown in Fig. 21C.

The initiation of transistor action (and therefore switching) can occur as a result of raising the bias to a critical value (V_p). At this voltage, avalanche multiplication at j_2 and base-width narrowing* in n_1 and p_2 combine to initiate transport of minority carriers across the two base regions. Alternatively, a small gate current i_g can supply sufficient base current to the NPN structure to initiate transitor action (Fig. 21D). The latter switching method is the most common type for an SCR. In this mode of operation, the device is nonconducting at forward voltages until a small pulse of current is applied to the gate. Such a pulse initiates transistor action in the device and switches it into the conducting state. The SCR remains in the conducting state until current I is dropped below a value called the *holding current* required to maintain transistor action. In addition, some SCR devices can be turned off by applying a negative current to the gate, thereby extracting carriers and terminating the transistor action within the device.

*Base-width narrowing occurs as the depletion region about j_2 grows due to the increased reverse bias. As the effective widths of n_1 and p_2 become smaller, base transport factor B increases.

19 Transistor Circuits

Horace G. Jackson

This chapter gives condensed descriptions of many types of circuits in which transistors are used. Also presented is design information that makes possible the determination of the various circuit parameters. In accordance with the accepted practice, upper-case variables with upper-case subscripts (V_{CE}) are used to indicate the static, or large-signal, quantities, and lower-case variables with lower-case subscripts (v_{ce}) are used to indicate the dynamic, or small-signal, values.

The overwhelming majority of transistor circuits are made with silicon devices; therefore, this is the assumed technology in this chapter. However, germanium and gallium-arsenide devices are also available to a limited degree.

DEVICE MODELS AND EQUATIONS*

This section presents the basic large-signal circuit models and equations for three common semiconductor active devices, namely:

(1) Bipolar junction transistor (BJT, or simply transistor)
(2) Junction field-effect transistor (JFET or FET)
(3) Metal-oxide-semiconductor field-effect transistor (MOSFET or MOS)

The first two are readily found in both discrete and integrated transistor circuits. Except for some high-power applications, the third is restricted to integrated circuits only.

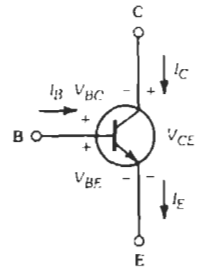
The symbol and large-signal model for an npn transistor are illustrated in Fig. 1. For a pnp transistor, the polarities of the terminal voltages, V_{BC}, V_{BE}, and V_{CE}, must be reversed; the direction of the junction diodes must be reversed; and the direction of all the currents must also be reversed. The model equations are listed in Chart 1. Typical values for the device parameters are given in Chart 2.

The symbol and large-signal model for an n-channel JFET are given in Fig. 2. For a p-channel device, the polarities of the terminal voltages, V_{GD}, V_{GS}, and V_{DS}; the direction of the junction diodes; and the direction of all the currents must be reversed. The model equations, given in Chart 3, assume that the JFET approximates a square-law device. Typical parameter values are listed in Chart 4.

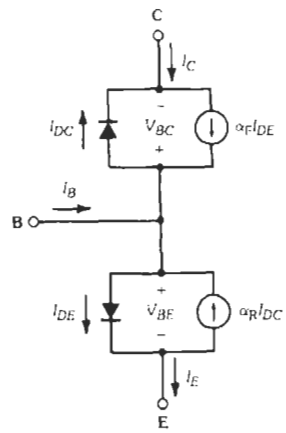
The symbol and large-signal model for an n-channel MOSFET are given in Fig. 3. For a p-channel device, the polarities of the five terminal voltages, V_{GS}, V_{GD}, V_{DS}, V_{BS}, and V_{BD}; the two junction diodes; and the currents must all be reversed. The model equations and parameter values are given in Chart 5 and Chart 6, respectively.

Note that a MOSFET may be one of two types:

A. Enhancement type: with $V_{GS} = 0$ V there is no conducting channel, and the drain current is zero.



(A) Symbol and nomenclature.



(B) Large-signal model.

Fig. 1. Symbol, nomenclature, and large-signal model for npn transistor (BJT).

B. Depletion type: with $V_{GS} = 0$ V there is a conducting channel, and the drain current is finite.

The FET terms I_{DSS} and V_T are graphically defined in the transfer characteristic of Fig. 4.

A summary of the operating modes for JFETs and MOSFETs is presented in Table 1.

BIAS TECHNIQUES†

Bipolar Transistor

As an amplifier, the BJT is normally operated in the forward-active region. That is, the base-emitter junction is forward-biased, and the base-collector junction is reverse-biased. Thus, with $V_{BE} >> 4V_T$ and $V_{BC} << -4V_T$ the equations in Chart 1 reduce to

$$I_E = (\beta_F + 1)(I_B + I_{CO})$$

$$I_C = \beta_F I_B + (\beta_F + 1)I_{CO}$$

where

$$I_{CO} = (1 - \alpha_F \alpha_R)I_{CS}$$

* References 1, 13, and 17.

† References 6 and 14.

CHART 1. MODEL EQUATIONS FOR AN NPN TRANSISTOR

$$I_E = I_{ES}(e^{V_{BE}/V_T} - 1)(1 + V_{BC}/V_A) - \alpha_R I_{CS}(e^{V_{BC}/V_T} - 1)(1 + V_{BE}/V_B)$$

$$I_C = \alpha_F I_{ES}(e^{V_{BE}/V_T} - 1)(1 + V_{BC}/V_A) - I_{CS}(e^{V_{BC}/V_T} - 1)(1 + V_{BE}/V_B)$$

$$I_B = I_E - I_C$$

Also,

$$\alpha_F I_{ES} = \alpha_R I_{CS}$$

where,

α_F = Forward current gain,

α_R = Reverse current gain,

I_{ES} = Emitter junction saturation current,

I_{CS} = Collector junction saturation current,

V_A = Forward-mode basewidth modulation factor,

V_B = Reverse-mode basewidth modulation factor,

V_T = Thermal voltage* = kT/q,

k = Boltzmann's constant = 1.38×10^{-23} J/K,

T = Absolute temperature = [273 + temp (°C)] K,

q = Electronic charge = 1.60×10^{-19} C.

* The thermal voltage, used with bipolar devices, is not to be confused with the threshold voltage (V_T) used with field-effect devices.

(B) Large-signal model.

Fig. 3. Symbol and large-signal model for n-channel MOSFET.

CHART 2. TYPICAL VALUES OF THE DEVICE PARAMETERS FOR A LOW-POWER SILICON BJT

$\alpha_F = 0.98$	$\beta_F = \alpha_F/(1 - \alpha_F) = 50$
$\alpha_R = 0.49$	$\beta_R = \alpha_R/(1 - \alpha_R) = 1$
$I_{ES} = 1 \times 10^{-14}$ A	$V_A = 20$ to 200 V
$I_{CS} = 2 \times 10^{-14}$ A	$V_B = 10$ to 100 V
	$V_T = 26$ mV at 27 °C

Good design of the bias circuit for a BJT requires that two deficiencies of the transistor be overcome. They are:

1. The transistor is a temperature sensitive device, in particular with respect to V_{BE} and β_F.

$$\Delta V_{BE}(\mathrm{T}) \approx -2.5 \text{ mV/°C}$$

$$\Delta \beta_F(\mathrm{T}) \approx +0.7\%/°\mathrm{C}$$

Also note that I_{CO} doubles for every 8 °C rise in temperature. But with silicon devices I_{CO} is usually so small that it may be neglected.

2. The parameters of a transistor are subject to process variation, in particular with respect to β_F. Typically $\beta_F = 30$ to 300 (or greater).

Generally, a constant collector current I_C and constant collector-emitter voltage V_{CE} are required. That is, the operating, or quiescent, point—the Q-point—of the transistor is designed to be insensitive to temperature and process variations. A self-bias, or emitter bias, circuit is illustrated in Fig. 5A. The circuit in Fig. 5B is the equivalent.

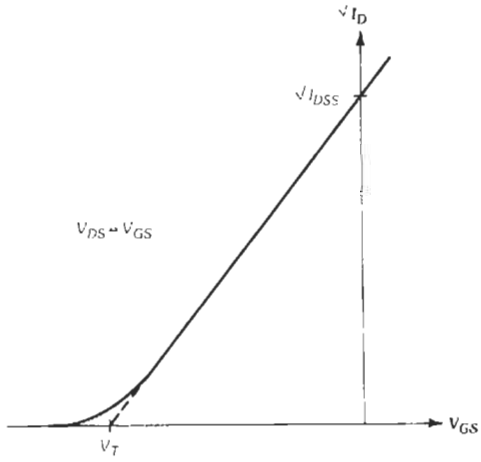

Fig. 4. Typical JFET transfer characteristic.

Given I_C, V_{CE}, and V_{BE}, the design procedure is as follows:

A. Choose R_E, where $R_E \geq 5\Delta V_{BE}/I_E$. Here, ΔV_{BE} is the change in V_{BE} over the temperature range of interest. This tends to desensitize the operating point to temperature variations of V_{BE}.
B. Determine R_B, where $R_B \leq \beta_F R_E/5$. Here, β_F is the nominal value. This tends to make the operating point independent of variations in the value of β_F.
C. Find R_C, from $R_C = [(V_{CC} - V_{CE})/I_C] - R_E$.
D. Using nominal values for V_{BE} and β_F, solve for

$$V_{BB} \approx V_{BE} + I_C[(R_B + \beta_F R_E)/\beta_F]$$

In an amplifier design, R_E is usually paralleled by a capacitor or by a series resistor-capacitor combination.

CHART 3. MODEL EQUATIONS FOR AN N-CHANNEL JFET

Nonsaturation region,* $V_{DS} < (V_{GS} - V_T)$:

$$I_D = \frac{I_{DSS}}{V_T^2}[2(V_{GS} - V_T)V_{DS} - V_{DS}^2](1 + \lambda V_{DS})$$

Saturation region,** $V_{DS} \geq (V_{GS} - V_T)$:

$$I_D = \frac{I_{DSS}}{V_T^2}[V_{GS} - V_T]^2(1 + \lambda V_{DS})$$

where,

I_{DSS} = Zero-bias saturation drain current, *i.e.*, $V_{GS} = 0$ V, $V_{DS} > (V_{GS} - V_T)$,

V_T = Threshold voltage,†

λ = Channel-length modulation factor.

* Also termed the linear, ohmic, or triode region.
** Also the constant current, pinchoff, or pentode region.
† Also the pinchoff voltage (V_P) or $V_{GS(off)}$. Not to be confused with the thermal voltage (V_T) used with bipolar devices.

CHART 4. TYPICAL DEVICE PARAMETERS FOR A LOW-POWER SILICON JFET

	N-Channel	P-Channel
$\lvert I_{DSS}\rvert$	1 to 10 mA	1 to 10 mA
V_T	−2 to −6 V	+2 to +6 V
λ	0.1 to 0.01 V^{-1}	0.1 to 0.01 V^{-1}

Field-Effect Transistor

The JFET is also a temperature sensitive device.

$$\Delta I_{DSS}(T) \approx -0.5\%/°C$$

$$\Delta V_T(T) \approx -2\ mV/°C$$

Due to process variations, I_{DSS} may range 3:1 and V_T may vary 2:1.

For a MOSFET, the parameters k and V_T have temperature and process dependence similar to those of I_{DSS} and V_T for a JFET.

In designing for a constant I_D and constant V_{DS} in the saturation region, the self-bias circuit shown in Fig. 6A can be used with JFETs or depletion-type MOSFETs. Since the gate current is negligible

$$R_S = -V_{GS}/I_D$$

$$R_D = [(V_{DD} - V_{DS})/I_D] - R_S$$

The circuit of Fig. 6A is unsuitable for biasing an enhancement-type MOSFET, since for an n-channel device V_T is positive and it is required that $V_{GS} > V_T$. Two alternative circuits for biasing an enhancement-type MOSFET are included in Fig. 6. In Fig. 6B, with negligible gate current $V_{GS} = V_{DS}$ so that the transistor is operating in the saturation region.

$$R_D = (V_{DD} - V_{DS})/I_D$$

$$R_G \geq 10R_D$$

When it is required that $V_{GS} \neq V_{DS}$, the circuit in Fig. 6C may be used.

As in the BJT case, in most amplifier applications R_S is paralleled by a capacitor.

SMALL-SIGNAL MODELS AND EQUATIONS*

For a BJT biased in the forward-active region, the basic small-signal model for the device is illustrated in Fig. 7. Included in the model are the bulk ohmic effects of the neutral base, collector, and emitter regions, designated r_b, r_c, and r_e. Typically, these are about 100 ohms, 50 ohms, and 1 ohm, respectively. The forward-biased base-emitter junction is modeled by r_π and C_π.

* References 2, 4, and 5.

CHART 5. MODEL EQUATIONS FOR AN N-CHANNEL MOSFET

Nonsaturation region, $V_{DS} < (V_{GS} - V_T)$:

$$I_D = \frac{k}{2}[2(V_{GS} - V_T)V_{DS} - V_{DS}^2](1 + \lambda V_{DS})$$

Saturation region, $V_{DS} \geq (V_{GS} - V_T)$:

$$I_D = \frac{k}{2}[V_{GS} - V_T]^2(1 + \lambda V_{DS})$$

where

k = Conduction factor = $(\mu\epsilon_{ox}/t_{ox})(W/L)$,

μ = Mobility of the conducting carriers,

ϵ_{ox} = Permittivity of the gate oxide,

t_{ox} = Thickness of the gate oxide,

W = Width of the conducting channel,

L = Length of the conducting channel,

V_T = Threshold voltage* = $V_{T0} + \gamma[\sqrt{|2\varphi_F| + |V_{BS}|} - \sqrt{|2\varphi_F|}]$,

V_{T0} = Zero-bias threshold voltage, *i.e.*, $V_{BS} = 0$ V,

$2\varphi_F$ = Surface potential ≈ 0.6 V,

γ = Body-effect factor,

λ = Channel-length modulation factor.

* Not to be confused with the thermal voltage (V_T) used with bipolar devices.

TABLE 1. SUMMARY OF OPERATING MODES FOR FET DEVICES

	JFET		MOSFET		
	N-Channel	P-Channel	N-Channel	P-Channel	N-Channel Depletion
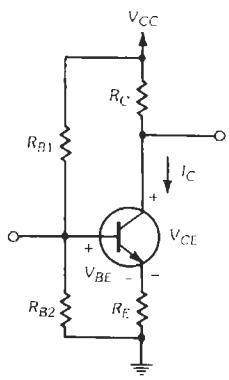
Symbol					V_T Polarity	Negative	Positive	Positive	Negative	Negative
V_{GS} Polarity	Negative	Positive	Positive	Negative	Neg or Pos
V_{DS} Polarity	Positive	Negative	Positive	Negative	Positive
Cutoff Region	$V_{GS} < V_T$	$V_{GS} > V_T$	$V_{GS} < V_T$	$V_{GS} > V_T$	$V_{GS} < V_T$
Nonsaturation Region	$V_{DS} < (V_{GS} - V_T)$	$V_{DS} > (V_{GS} - V_T)$	$V_{DS} < (V_{GS} - V_T)$	$V_{DS} > (V_{GS} - V_T)$	$V_{DS} < (V_{GS} - V_T)$
Saturation Region	$V_{DS} \leq (V_{GS} - V_T)$	$V_{DS} \leq (V_{GS} - V_T)$	$V_{DS} \geq (V_{GS} - V_T)$	$V_{DS} \leq (V_{GS} - V_T)$	$V_{DS} \geq (V_{GS} - V_T)$

CHART 6. TYPICAL DEVICE PARAMETERS FOR A LOW-POWER SILICON MOSFET

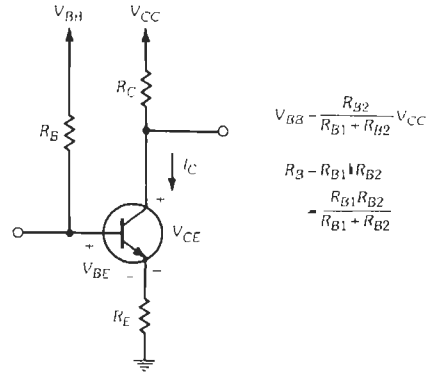
	N-Channel	P-Channel
k	$20(W/L)\mu A/V^2$	$7(W/L)\ \mu A/V^2$
V_{TEO}	+1 to +3 V	−1 to −3 V
V_{TDO}	−1 to −3 V	+1 to +3 V
$\lvert 2\varphi_F \rvert$	−0.6 to −0.8 V	+0.6 to +0.8 V
γ	+0.3 to +0.6 V	−0.3 to −0.6 V
λ	0.1 to 0.01 V^{-1}	0.1 to 0.01 V^{-1}

The reverse-biased base-collector junction is modeled by C_μ, and r_μ is due to the basewidth modulation effect. That the collector current is a function of the base-emitter voltage is modeled by current source $g_m v_\pi$ with output resistance r_{ce}. How these small-signal parameters relate to the operating point of the transistor is indicated in Chart 7.

The small-signal model for a JFET biased in the saturation region is given in Fig. 8. The ohmic resistances of the neutral gate, drain, and source regions are modeled by the linear resistors r_g, r_d, and r_s. Typically,

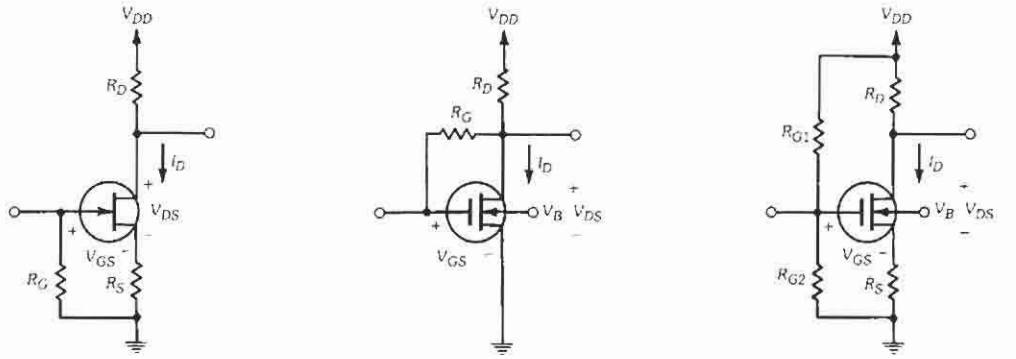


(A) Single voltage supply.



(B) Two-voltage-supply equivalent.

Fig. 5. Bias circuits for bipolar transistors.



(A) For JFET and depletion-type MOSFET. (B) For enhancement-type MOSFET with $V_{DS} = V_{GS}$. (C) Alternative circuit for enhancement MOSFET.

Fig. 6. Bias circuits for FETs.

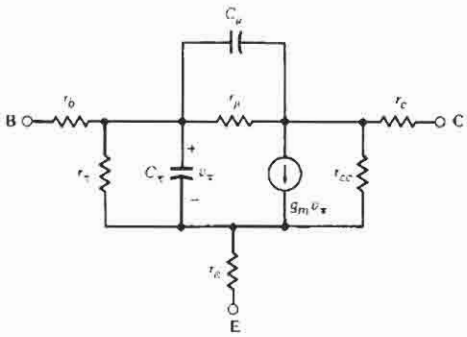


Fig. 7. Small-signal model for BJT.

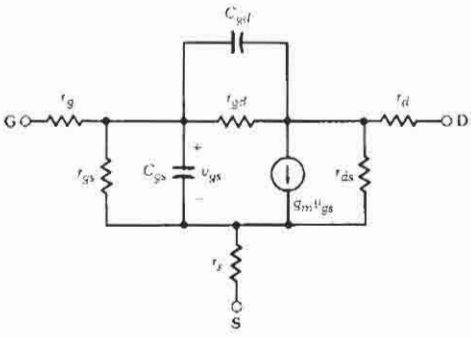

Fig. 8. Small-signal model for JFET.

these are 1 ohm, 10 ohms, and 10 ohms, respectively. In most applications they may be neglected.

The reverse-biased gate-source and gate-drain junctions of the JFET are modeled by r_{gs}-C_{gs} and r_{gd}-C_{gd}, respectively. The voltage-dependent drain-current generator is modeled by $g_m v_{gs}$ with an output resistance of r_{ds}. The equations for the latter two parameters are found in Chart 8.

For low-frequency applications, the charge-storage elements, C_{gs} and C_{gd}, may be neglected. Because r_{gs} and r_{gd} are generally very large, they also may be neglected in many applications.

The small-signal model for a MOSFET biased in the saturation region is given in Fig. 9. The ohmic effects of the gate, drain, source, and body regions are modeled by the linear resistors r_g, r_d, r_s, and r_b. Typical values are 1 ohm, 1 ohm, 1 ohm, and 10 ohms, respectively. In most applications they may be neglected.

CHART 7. SMALL-SIGNAL PARAMETERS FOR A BJT

$$g_m = i_c/v_\pi = \left.\frac{dI_C}{dV_{BE}}\right|_{OP} = I_C/V_T$$

$$r_\pi = v_\pi/i_b = \left.\frac{dV_{BE}}{dI_B}\right|_{OP} = \beta_F V_T/I_C = \beta_F/g_m$$

$$r_{ce} = v_{ce}/i_c = \left.\frac{dV_{CE}}{dI_C}\right|_{OP} = (V_A + V_{CE})/I_C$$

$$r_\mu = v_{cb}/i_b = \left.\frac{dV_{CB}}{dI_B}\right|_{OP} = (V_A + V_{CB})/I_B$$

$$C_\pi = (g_m/2\pi f_T) - C_\mu$$

CHART 8. SMALL-SIGNAL PARAMETERS FOR JFET

$$g_m = i_d/v_{gs} = \left.\frac{dI_D}{dV_{GS}}\right|_{OP} = (2I_{DSS}/V_T)(1 - V_{GS}/V_T) = (2/V_T)(I_D I_{DSS})^{1/2}$$

$$r_{ds} = v_{ds}/i_d = \left.\frac{dV_{DS}}{dI_D}\right|_{OP} = (V_A + V_{DS})/I_D$$

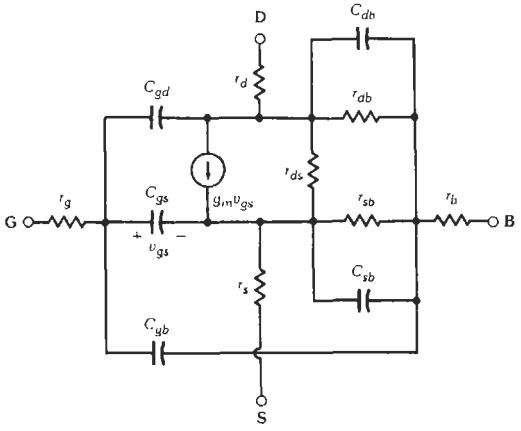

Fig. 9. Small-signal model for MOSFET.

Charge stored between the insulated gate and the source, drain, and body regions is modeled by the capacitors C_{gs}, C_{gd}, and C_{gb}, respectively. The reverse-biased source-body and drain-body junctions are included in the model by r_{sb}-C_{sb} and r_{db}-C_{db}. However, generally the resistance values are so large that their effect is usually neglected.

As with the JFET, the voltage-dependent current source is modeled by $g_m v_{gs}$ with an output resistance of r_{ds}. The equations for these parameters are found in Chart 9.

The general ranges of the small-signal parameters for each of the devices considered in this section are compared in Table 2.

SINGLE-STAGE AMPLIFIERS*

Small-Signal Characteristics

The three possible circuit configurations for a single-transistor amplifier are illustrated in Fig. 10. For clarity, the bias networks have been omitted. It is assumed that the bipolar transistor is operating in the forward-active region and the field-effect transistor is operating in the saturation region. The small-signal design equations listed in Table 3 are for the input resistance (r_i), output resistance (r_o), voltage gain ($a_v = v_o/v_i$), and current gain ($a_i = i_o/i_i$). The small-signal transducer power gain is obtained from $a_p = a_v a_i$. The second-order terms due to the bulk ohmic effects have been omitted. The equations for the FET apply for both the JFET and the MOSFET. Numerical values for each of the amplifier configurations are compared in Table 4.

CHART 9. SMALL-SIGNAL PARAMETERS FOR MOSFET

$$g_m = i_c/v_{gs} = \left.\frac{dI_C}{dV_{GS}}\right|_{OP} = k(V_{GS} - V_T)$$

$$= (2kI_D)^{1/2}$$

$$r_{ds} = v_{ds}/i_d = \left.\frac{dV_{DS}}{dI_D}\right|_{OP} = (V_A + V_{DS})/I_D$$

Frequency Response

In Figs. 11 through 13 are shown simple circuit schematics for each of the single-stage amplifier configurations. Included in each figure are the small-signal equivalent circuits appropriate for the three ranges of frequencies, low, middle, and high. The corresponding small-signal transfer functions derived from the equivalent circuits are listed in Tables 5 through 7.

For the common-emitter and common-source amplifiers, the low cutoff frequency (−3 dB) is due to the greater of ω_{l1} or ω_{l2}, provided the ratio of the two is greater than 10. In the high-frequency region, normally $\omega_{zh} >> \omega_{h2} >> \omega_{h1}$, so that ω_{h1} is the high cutoff frequency (−3 dB).

For the emitter-follower and the source-follower, there is only one low break frequency. In the high-frequency region, typically ω_{zh} is only slightly greater than ω_{h1}, though ω_{h2} is much greater than either. Hence, the high cutoff frequency is difficult to determine accurately. However, it is greater than ω_{h1}, which is approximately equal to ω_T of the transistor.

For the common-base amplifier, the determination

* References 2, 8, and 14.

$a_v(j\omega) = a_0 \dfrac{(1 + j\omega/\omega_{zh})}{(1 + j\omega/\omega_{h1})(1 + j\omega/\omega_{h2})}$	$a_v(j\omega) = a_0 \dfrac{(1 + j\omega/\omega_{zh})}{(1 + j\omega/\omega_{h1})(1 + j\omega/\omega_{h2})}$
where, $\omega_{zh} \approx 1/(C_\pi/g_m)$	where, $\omega_{zh} \approx 1/(C_{gs}/g_m)$
$\omega_{h1} \approx 1/\{[(R_1 + R_L)/(1 + g_m R_L)]C_\pi + R_1 C_\mu\}$	$\omega_{h1} \approx 1/\{[(R_1 + R_L)/(1 + g_m R_L)]C_{gs} + R_1 C_{gd}\}$
$\omega_{h2} \approx g_m/C_\pi + 1/(R_1 \| R_L)C_\mu$	$\omega_{h2} \approx g_m/C_{gs} + 1/(R_1 \| R_L)C_{gd}$

Note: In this analysis it is assumed
1. For the BJT circuit that $R_1 \ll R_B \gg r_\pi$.
2. For the FET circuit that $R_1 \ll R_G \ll r_{gs}$.

TABLE 7. SMALL-SIGNAL TRANSFER FUNCTIONS: COMMON-BASE AND COMMON-GATE

Bipolar Transistor	Field-Effect Transistor
Midfrequency	Midfrequency
$a_0 = v_o/v_s = \alpha_0 \dfrac{R_L \| r_{ce}[1 + gm(R_1)]}{R_1 + r_\pi/(\beta_0 + 1)}$	$a_0 = v_o/v_s = \dfrac{R_L \| r_{ds}\,[1 + gm(R_1)]}{R_1 + 1/g_m}$
Low Frequency 1. Due to C_1 (assume that C_B is a short-circuit)	Low Frequency 1. Due to C_1 (assume that C_G is a short-circuit)
$a_v(j\omega) = a_0/(1 - j\omega_{l1}/\omega)$	$a_v(j\omega) = a_0/(1 - j\omega_{l1}/\omega)$
where, $\omega_{l1} \approx 1/(R_1 + 1/g_m)C_1$	where, $\omega_{l1} \approx 1/(R_1 + 1/g_m)C_1$
2. Due to C_B (assume that C_1 is a short-circuit)	2. Due to C_G (assume that C_1 is a short-circuit)
$a_v(j\omega) = a_0(1 + j\omega/\omega_{z1})/(1 + j\omega/\omega_{l2})$	$a_v(j\omega) = a_0$
where, $\omega_{z1} \approx 1/R_B C_B$	
$\omega_{t2} \approx 1/\{R_B \| [r_\pi + (\beta_0 + 1)R_1]\}C_B$	
High Frequency	High Frequency
$a_v(j\omega) = a_0/(1 + j\omega/\omega_{h1})(1 + j\omega/\omega_{h2})$	$a_v(j\omega) = a_0/(1 + j\omega/\omega_{h1})(1 + j\omega/\omega_{h2})$
where, $\omega_{h1} \approx 1/(C_\mu/g_m + R_L C_\mu)$	where, $\omega_{h1} \approx 1/(C_{gs}/g_m + R_L C_{gd})$
$\omega_{h2} \approx g_m/C_\pi + 1/R_L C_\mu$	$\omega_{h2} \approx g_m/C_{gs} + 1/R_L C_{gd}$

Note: In this analysis it is assumed
1. For the BJT circuit that $R_1 \ll R_E \gg r_\pi$.
2. For the FET circuit that $R_1 \ll R_S \ll r_{gs}$.

of the low cutoff frequency is similar to the case of the common-emitter amplifier. However, note that for the common-gate amplifier there is only one low break frequency. In the high-frequency region, typically $\omega_{h2} >> \omega_{h1}$ so that ω_{h1} is the high cutoff frequency.

Large-Signal Characteristics

For large-signal operation, both bipolar and field-effect transistor amplifiers are classified as one of the following.

Class A—The transistor is conducting at all times. Essentially this describes a transistor operating in the linear region of the characteristic curves.

Class B—The transistor is conducting only one-half of the operating cycle, *i.e.*, for 180° of a sine-wave input. This operation is used in output stages to obtain a higher power-conversion efficiency than class A provides.

Class AB—Operation is similar to class B, but in the absence of an input signal the transistor is conducting a small quiescent current.

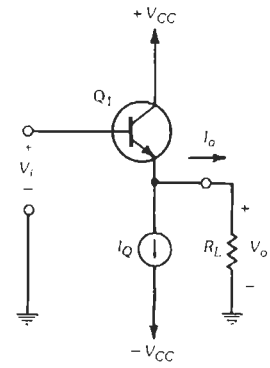
Class C—The transistor is conducting less than 180° of a sine-wave input. Class-C operation is used mostly in high-power amplifiers and oscillators.

Output Stages

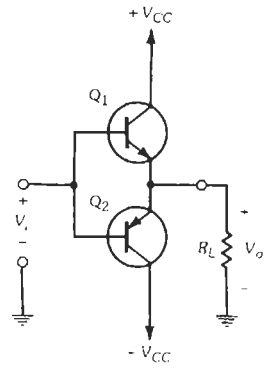
The simple emitter-follower of Fig. 14A illustrates a class-A output stage. From the maximum undistorted output voltage swing, where $|V_{max}| = |V_{min}|$, and the maximum output current swing, the maximum output power is $V_{rms}I_{rms} = V_{max}I_{max}/2$. For the ideal case ($V_{CE\,(sat)} = 0$ V for the output transistor and the current source is effective with 0 V across it) $V_{max} = V_{CC+}$ and $V_{min} = V_{CC-}$. With $|V_{CC+}| = |V_{CC-}| = V_{CC}$, the maximum output power is as listed in Table 8. Also listed in Table 8 is the average supply power for the output stage. The ratio of the output power to the supply power gives the power-conversion efficiency of the circuit. For a class-A amplifier this is 25% maximum, but a typical figure is about 15%.

A class-B output stage is shown in Fig. 14B. For this circuit, in the quiescent state neither transistor is conducting. On the positive half-cycle of an input sine wave, the npn transistor conducts and acts as a source of current to the load. On the negative half-cycle, the pnp transistor conducts and sinks current from the load. Hence, this configuration is known as a push-pull output stage. Since each transistor conducts only during one-half cycle of the input sine wave, the average supply power is as given in Table 8. For the class-B amplifier, the maximum power-conversion efficiency is 79%, but a typical figure is about 65%.

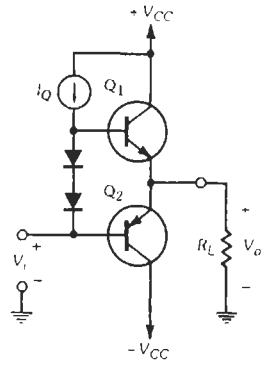
A problem with the class-B push-pull output stage is that each base-emitter junction must be forward biased before current can flow to the load. This gives rise to crossover distortion—a deadband of about $2V_{BE}$ around the zero axis of the output waveform. This problem can be avoided with the class-AB stage illustrated in Fig. 14C. The addition of a current source and two diodes permits a controlled quiescent current to flow in the two output transistors. The crossover distortion is improved at the cost of a small decrease in power-conversion efficiency.



(A) Emitter-follower (class A).



(B) Push-pull (class B).



(C) Push-pull (class AB).

Fig. 14. Output stages.

TABLE 8. OUTPUT CHARACTERISTICS FOR LARGE-SIGNAL AMPLIFIERS

	Class A	Class B
Output voltage swing	$V_{max} - V_{min}$	$V_{max} - V_{min}$
Output current swing	$I_{max} - I_{min}$	$I_{max} - I_{min}$
Maximum output power	$V_{max}I_{max}/2$ $= V_{CC}I_Q/2$	$V_{max}I_{max}/2$ $= V_{CC}I_Q/2$
Average supply power	$2V_{CC}I_Q$	$2V_{CC}I_Q/\pi$
Maximum conversion efficiency	25%	79%

Note: This analysis assumes that $|V_{CC+}| = |V_{CC-}| = V_{CC}$

Harmonic Distortion

For a common-emitter amplifier, the small-signal output voltage is given as

$$v_o = -g_m R_L v_i$$

But for large-signal class-A operation (Fig. 15),

$$V_o = -R_L(I_S e^{V_i/V_T} - I_Q)$$

where,

$$I_Q = I_S e^{V_{BE}/V_T}$$

and

$$V_i = V_s + V_{BE}$$

Therefore

$$V_o = -R_L I_Q(e^{V_s/V_T} - 1)$$

Expanding this in a power series

$$V_o = -R_L I_Q[(V_s/V_T) + (V_s/V_T)^2/2 + (V_s/V_T)^3/6 + \ldots]$$

$$= a_1 V_s + a_2 V_s^2 + a_3 V_s^3 \ldots$$

where,

$$a_1 = -R_L I_Q/V_T$$

$$a_2 = -R_L I_Q/2V_T^2$$

$$a_3 = -R_L I_Q/6V_T^3$$

Note that in this equation, with $V_s/V_T \ll 1$ the first term dominates and the circuit is essentially linear.

For a sine-wave input

$$V_s = \hat{V}_s \sin \omega t$$

Then

$$V_o = a_1\hat{V}_s \sin \omega t + a_2\hat{V}_s^2 \sin^2 \omega t + a_3\hat{V}_s^3 \sin^3 \omega t + \ldots$$

$$= a_1\hat{V}_s \sin \omega t + (a_2\hat{V}_s^2/2)(1 - \cos 2\omega t) + (a_3\hat{V}_s^3/4)(3 \sin \omega t - \sin 3\omega t) + \ldots$$

Hence, with large-signal operation, harmonics are introduced into the output voltage waveform due to the exponential relationship of the transfer characteristic for the bipolar transistor.

Equations for the second (HD_2) and third (HD_3) harmonic distortion for each of the bipolar transistor configurations are given in Table 9. Note, for example, that for the CE stage with $\hat{V}_s = 10$ mV, $HD_2 = 10\%$ and $HD_3 = 0.62\%$.

In an ideal push-pull amplifier stage, the positive half-cycle of the output waveform exactly matches the negative half-cycle. The result is that all even harmonic terms are balanced out, leaving the third harmonic as the prime source of harmonic distortion.

The transfer characteristic of an FET has a square-law relationship. Hence, ideally, only second-harmonic distortion appears at the output of a field-effect transistor amplifier. In practice, all FETs deviate somewhat from the ideal transfer characteristic and exhibit a third-order term. However, this term is usually very small. For a common-source amplifier

$$HD_2 = (1/4)(\hat{V}_s/V_T)(I_{DSS}/I_Q)^{1/2}$$

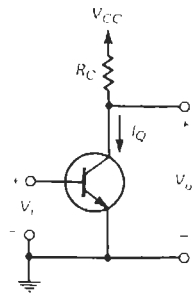


Fig. 15. Large-signal operation of common-emitter amplifier circuit.

TABLE 9. HARMONIC DISTORTION IN BIPOLAR TRANSISTOR AMPLIFIERS

Parameter	CE	CC	CB
HD_2	$\frac{1}{4}(\hat{V}_s/V_T)$	$\frac{1}{4}(\hat{V}_s/V_T)/(1 + g_mR_L)$	$\frac{1}{4}(\hat{V}_s/V_T)/(1 + g_mR_E)$
HD_3	$\frac{1}{24}(\hat{V}_s/V_T)^2$	$\frac{1}{24}(\hat{V}_s/V_T)^2 \frac{1 - 3g_mR_L/(1 + g_mR_L)}{1 + g_mR_L}$	$\frac{1}{24}(\hat{V}_s/V_T)^2 \frac{1 - 3g_mR_E/(1 + g_mR_E)}{1 + g_mR_E}$

The second harmonic in other FET single amplifier configurations follows from Table 9.

DIFFERENTIAL AMPLIFIERS*

A simple differential amplifier is exemplified by the BJT emitter-coupled pair illustrated in Fig. 16. A source-coupled FET pair could readily replace the bipolar transistors. Fig. 17 shows the small-signal difference and common-mode input voltages of the circuit. The relationship between the difference and common-mode operation is given in Table 10. The design equations are listed in Table 11.

CURRENT SOURCES†

A useful component in many circuits, but especially with differential amplifiers, is a transistor current source.

Current Mirrors

The concept of current mirrors is widely used in linear integrated circuits, where the matching and tracking of transistor characteristics are well controlled. The idea may also be used with discrete dual transistors that have the same matching and tracking characteristics as in ICs.

Four simple, but effective, current sources are shown in Fig. 18. Their characteristics are listed in Table 12.

In Fig. 18A, with $V_{BE1} = V_{BE2}$ and the characteristics of Q_1 closely matching those of Q_2, to a first order $I_R = I_{C1} = I_{C2}$. The effect of finite base currents is included in the equations given in Table 12, where, provided $\beta_F >> 2$, $I_{C2} = I_R$. The effects of base current are even further reduced in the improved circuit of Fig. 18B.

The output resistance of a transistor current source can be improved, as in the Widlar current source of Fig. 18C. For this circuit, note that typically $r_{\pi 2} > (1/g_{m1} + R_2)$; then the output resistance is simply given as $r_o = r_{ce}(1 + g_{m2}R_2)$. The solution of the transcendental equation for I_{C2} can be done readily by trial and error with one or two iterations, or with a programmable calculator. An even higher output resistance can generally be obtained with the Wilson current source of Fig. 18D, where, due to negative feedback, $r_o \approx \beta_0 r_{ce2}/2$.

The Widlar circuit is useful for obtaining small output currents, and the Wilson circuit is useful for obtaining high output resistance and low sensitivity to transistor base currents.

Each of these circuits is also viable with matching dual JFETs or MOSFETs.

Active Loads

Another useful application for current sources is as active loads in amplifier circuits. The output resistance of the current source provides a high collector resistance

TABLE 10. RELATIONSHIP FOR DIFFERENCE AND COMMON-MODE OPERATION

	Difference Mode	Common Mode
Input	$v_{id} = v_{i1} - v_{i2}$	$v_{ic} = (v_{i1} + v_{i2})/2$
Output	$v_{od} = v_{o1} - v_{o2}$	$v_{oc} = (v_{o1} + v_{o2})/2$
Gain	$a_{dm} = v_{od}/v_{id}$	$a_{cm} = v_{oc}/v_{ic}$
Input	$v_{i1} = v_{ic} + v_{id}/2$ $v_{i2} = v_{ic} - v_{id}/2$	
Output	$v_{o1} = a_{cm}v_{ic} + a_{dm}v_{id}/2$ $v_{o2} = a_{cm}v_{ic} - a_{dm}v_{id}/2$	

TABLE 11. DIFFERENTIAL AMPLIFIERS: SMALL-SIGNAL DESIGN EQUATIONS

Difference Mode	Common Mode
$a_{dm} = v_{od}/v_{id} = -g_m R_C$	$a_{cm} = v_{oc}/v_{ic} = -g_m R_C r_\pi/[r_\pi + (\beta_0 + 1)2R_{EE}]$
$r_{id} = v_{id}/i_{id} = 2r_\pi$	$r_{ic} = v_{ic}/i_{ic} = r_\pi + (\beta_0 + 1)2R_{EE}$
$r_{od} = 2R_C$	$r_{oc} = 2R_C$
CMRR (dB) $= 20 \log \lvert a_{dm}/a_{cm} \rvert$	

TABLE 12. CURRENT SOURCES

Type	Reference Current (I_R)	Output Current (I_{C2})	Output Resistance (r_o)
Simple	$(V_{CC} - V_{BE1})/R$	$I_R/(1 + 2/\beta_F)$	r_{ce2}
Improved	$(V_{CC} - V_{BE3} - V_{BE1})/R$	$I_R/[1 + 2/(\beta_F^2 + \beta_F)]$	r_{ce2}
Widlar	$(V_{CC} - V_{BE1})/R$	$(V_T/R_2) \ln (I_{C1}/I_{C2})$	$r_{ce2}[1 + \beta_0 R_2/(1/g_{m1} + r_{\pi 2} + R_2)]$
Wilson	$(V_{CC} - V_{BE2} - V_{BE3})/R$	$I_R[1 - 2/(\beta_F^2 + 2\beta_F + 2)]$	$\beta_0 r_{ce2}/2$

with a relatively small voltage drop. A basic circuit is illustrated in Fig. 19A.

Neglecting base currents, in this circuit

$$I_{C1} = I_{C2} = I_{C3} = I_{C4} = I_{C5} = I_{EE}/2$$

The effective load resistance for differential input signals is

$$R_{L1} = R_{L2} = r_{ce1} \| r_{ce3}$$

The output resistance of the current source may be further increased by adding resistances, $R_{E3} = R_{E4}$, in the emitter leads of Q_3 and Q_4, respectively. The effective load resistance then becomes

$$R_{L1} = R_{L2} = r_{ce1} \parallel [r_{ce3}\,(1 + g_{m3}R_{E3})]$$

Fig. 19B shows an amplifier with a differential input signal but a single-ended output signal. In this circuit, not only does Q_4 effectively provide a large collector resistance for Q_2, but also since the collector current of Q_4 mirrors that of Q_3, the small-signal change in the collector current of Q_1 is added to that of Q_2 to provide the full differential voltage gain of the stage at the single-ended output, v_o.

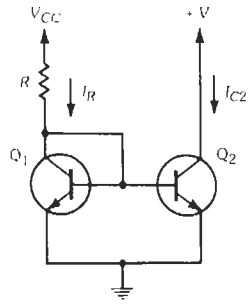
Each of these circuits may be designed with JFETs or MOSFETs. Also, many times it is advantageous to use JFETs as the amplifier devices and BJTs for active loads.

FEEDBACK AMPLIFIERS*

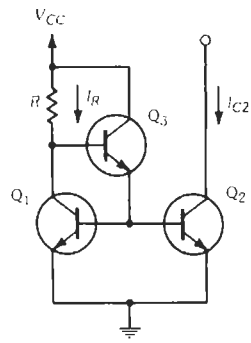
Negative feedback is widely used in amplifier design because it produces several benefits. Among these are:

Desensitivity against parameter changes
Improved input/output characteristics
Reduction in harmonic distortion
Increased frequency response

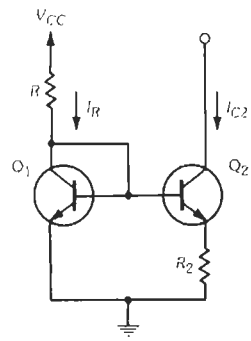
* References 7 and 15.



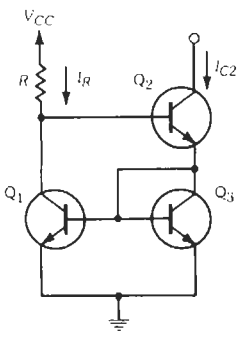
(A) Simple.



(B) Improved.



(C) Widlar.



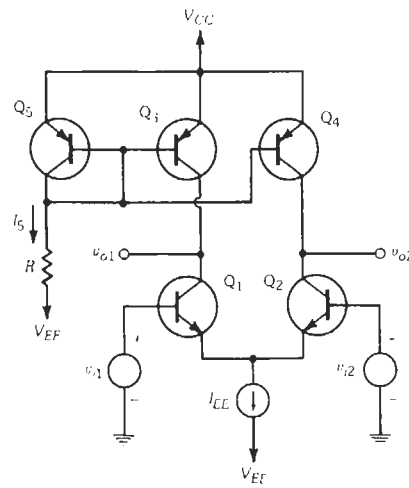
(D) Wilson.

Fig. 18. Current-mirror circuits.

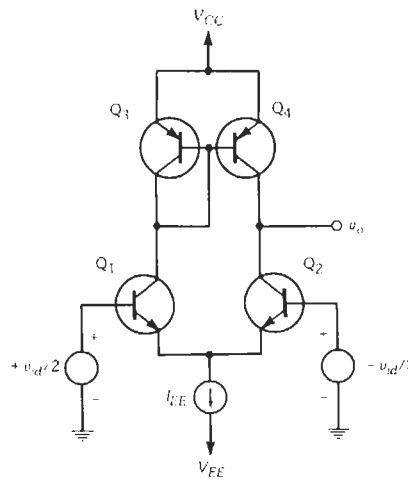
Unfortunately there are some disadvantages:
Reduced gain
Instability problems

Basic Properties

The basic properties of negative feedback are presented with the aid of the block diagram in Fig. 20. In this diagram, the gain of the basic amplifier, a, is controlled by undependable transistor parameters that are subject to considerable variation. It is assumed that gain a is much larger than needed. It is also assumed in the block diagram that there is no loading of one block by another block and the signal path is only in the direction of the arrows; *i.e.*, the gain of each block is unilateral.



(A) Differential amplifier pair with active load.



(B) Modified active load for differential amplifier pair.

Fig. 19. Active loads.

With *positive feedback:*

$$s_i = s_s + s_f$$

That is, the signals *add* and $s_i > s_s$.

With *negative feedback:*

$$s_i = s_s - s_f$$

That is, the signals *subtract* and $s_i < s_s$.

Also from the block diagram:

$$s_o = as_i$$

$$s_f = fs_o$$

Chart 10 presents the basic equation for negative feedback, along with other important definitions. Note from the basic equation that with negative feedback the open-loop gain is reduced by the factor $1 + T$. Further, if $T >> 1$ the closed-loop gain becomes $1/f$. It is common for the feedback network to be made up of stable, high-precision, passive components; the value of f is then well defined, and so is the overall amplifier gain.

Basic Feedback Circuit Topologies

Preliminary to the presentation of the feedback topologies, consider the circuit diagrams of four basic classes of amplifier (Fig. 21). The classification is based on the magnitude of the input and output impedance relative to the source and load impedance. The ideal characteristics for each class of amplifier are given in Table 13.

A feedback amplifier is described in terms of the way in which the feedback network is connected to the basic amplifier. There are four basic feedback circuit topologies. These are illustrated in the block diagrams of Fig. 22. Clearly, in Fig. 22A the feedback network is connected in *series* with the input terminals of the basic amplifier and in *shunt* with the output terminals. Notice:

CHART 10. BASIC EQUATIONS FOR NEGATIVE FEEDBACK

A	$= a/(1 + af) = a/(1 + T)$	$= a/D_s$
A	= closed-loop gain	$= s_o/s_s$
a	= open-loop gain	$= s_o/s_i$
f	= feedback factor	$= s_f/s_o$
T	= loop gain $= af$	$= s_f/s_i$
D_s	= desensitivity factor	$= 1 + T$

Note: The basic equation for negative feedback is often written as $A_{CL} = A_{OL}/(1 + A_{OL}\beta)$

TABLE 13. IDEAL AMPLIFIER CHARACTERISTICS

Parameter	Voltage Amplifier	Current Amplifier	Trans-conductance Amplifier	Trans-resistance Amplifier
Input resistance (r_i)	$\rightarrow\infty(>>R_1)$	$\rightarrow 0(<<R_1)$	$\rightarrow\infty(>>R_1)$	$\rightarrow 0(<<R_1)$
Output resistance (r_o)	$\rightarrow 0(<<R_L)$	$\rightarrow\infty(>>R_L)$	$\rightarrow\infty(>>R_L)$	$\rightarrow 0(<<R_L)$
Transfer characteristic (a)	$a_v = v_o/v_s$	$a_i = i_o/i_s$	$g_m = i_o/v_s$	$r_m = v_o/i_s$

Note: Transconductance (g_m) used here refers to an amplifier parameter, not necessarily just a device parameter.

With series feedback at the input, voltages v_s and v_f are algebraically summed.
With shunt feedback at the input, currents i_s and i_f are algebraically summed.
With series feedback at the output, a current i_o is sampled.
With shunt feedback at the output, a voltage v_o is sampled.

Included in Fig. 22 are simple examples of each feedback connection, implemented with bipolar transistors. Especially note the correspondence between each circuit schematic and the related block diagram. To avoid complexity, all biasing resistors have been omitted from the circuit diagrams, but it is assumed that all transistors are biased in the forward-active region to yield a high-gain amplifier.

Presented below is a method of analysis of feedback amplifiers. The design of a feedback amplifier would follow a similar procedure.

1. Identify the feedback topology:
   A. Is feedback signal s_f applied in series (v_f) or in shunt (i_f) with the signal source s_s?
   B. Is sampled signal s_o obtained at the output node (v_o) or from the output loop (i_o)?
2. Draw the basic amplifier circuit with the feedback set to zero; that is
   A. For the correct input circuit:
      (a) With shunt sampling, short-circuit the output nodes to set $v_o = 0$.
      (b) With series sampling, open-circuit the output loop to set $i_o = 0$.
   B. For the correct output circuit:
      (a) With series summing, open-circuit the input loop to set $v_f = 0$.
      (b) With shunt summing, short-circuit the input nodes to set $i_f = 0$.
3. Indicate s_f and s_o, and solve for the feedback factor ($f = s_f/s_o$).
4. Evaluate the open-loop gain function (a).
5. From a and f, find T, D_s, A, R_i, and R_o.

Information to aid in the analysis and design of feedback amplifiers is summarized in Table 14. Notice that the effect of negative feedback is to modify the open-loop parameters of an amplifier so that the closed-loop performance approaches the ideal characteristics as listed in Table 13.

BANDPASS AMPLIFIERS*

A bandpass amplifier selectively amplifies a narrow band of frequencies around a center frequency. The selectivity is indicated by

$$Q = \omega_0/\Delta\omega = \omega_0/(\omega_h - \omega_l)$$

where,

ω_0 is the center frequency,
$\Delta\omega$ is the bandwidth,
ω_h and ω_l are the high and low cutoff frequencies (−3 dB).

For a bandpass amplifier, typically $Q > 10$.

Single-Tuned Interstage

A single-tuned interstage is modeled in Fig. 23. Resistor R is the total shunt resistance at the output of an amplifying stage including the input resistance of the following stage. Similarly, capacitor C is the total shunt capacitance.

For a single-tuned interstage the general transfer function is

$$a_v(j\omega) = v_o/v_i = -g_m R/[1 + jQ(\omega/\omega_o - \omega_o/\omega)]$$

and

$$\Delta\omega = \omega_h - \omega_l = \omega_o/Q = 1/RC$$

At resonance:

$$\omega_o = 1/(LC)^{1/2}$$

* References 18 and 20.

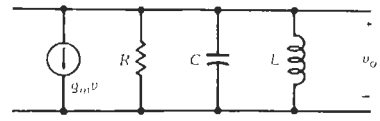

Fig. 23. Single-tuned interstage.

TABLE 14. FEEDBACK-AMPLIFIER ANALYSIS

	Series-Shunt	Shunt-Series	Series-Series	Shunt-Shunt
Input signal (s_i)	v_i	i_i	v_i	i_i
Feedback signal (s_f)	v_f	i_f	v_f	i_f
Output Signal (s_o)	v_o	i_o	i_o	v_o
To calculate loading of feedback network				
At input	Short output node	Open output loop	Open output loop	Short output node
At output	Open input loop	Open input loop	Short input node	Short input node
To calculate feedback factor	Drive feedback network with a voltage and calculate open-circuit voltage v_f	Drive feedback network with a current and calculate short-circuit current i_f	Drive feedback network with a current and calculate open-circuit voltage v_f	Drive feedback network with a voltage and calculate short-circuit current i_f
Feedback factor (f)	v_f/v_o	i_f/i_o	v_f/i_o	i_f/v_o
Open-loop gain (a)	$a_v = v_o/v_i$	$a_i = i_o/i_i$	$g_m = i_o/v_i$	$r_m = v_o/i_i$
Loop gain (T)	$a_v f$	$a_i f$	$g_m f$	$r_m f$
Closed-loop				
Gain (A)	$A_v = a_v/(1 + T)$	$A_i = a_i/(1 + T)$	$G_m = g_m/(1 + T)$	$R_m = r_m/(1 + T)$
Input resistance (R_i)	$r_i(1 + T)$	$r_i/(1 + T)$	$r_i(1 + T)$	$r_i/(1 + T)$
Output resistance (R_o)	$r_o/(1 + T)$	$r_o(1 + T)$	$r_o(1 + T)$	$r_o/(1 + T)$

and the center-frequency voltage gain is

$$a_v(j\omega_o) = -g_m R$$

With $Q >> 1$, the high and low cutoff frequencies may be determined from

$$\omega_h = \omega_o\,(1 + 1/2Q)$$

$$\omega_l = \omega_o\,(1 - 1/2Q)$$

For a cascade of n synchronous single-tuned stages that are unilateral and noninteracting, the magnitude of the center-frequency voltage gain is

$$|A_v| = a_v{}^n = (g_m R)^n$$

and the overall bandwidth is

$$\Delta\omega_n = \Delta\omega(2^{1/n} - 1)^{1/2}$$

Double-Tuned Interstage

A double-tuned interstage is modeled in Fig. 24. Here, R_1 and C_1 are the total shunt resistance and-capacitance at the output of an amplifying stage, and R_2 and C_2 are the total shunt resistance and capacitance at the input of the following stage. The transformer is loosely coupled so that the coefficient of coupling $k << 1.0$, typically < 0.1.

For a double-tuned interstage, the general transfer function is

$$a_v(j\omega) = v_o/v_i =$$

$$-g_m(R_1R_2)^{1/2}\,\frac{s}{[(1 + s^2)^2 - 2(s^2 - b/2)s^2 + a^4]^{1/2}}$$

where,

$$s = k(Q_1Q_2)^{1/2}$$
$$p = Q_1/Q_2$$

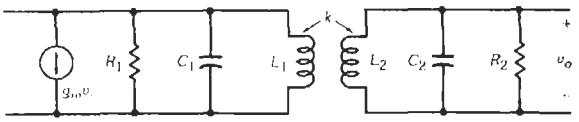

Fig. 24. Double-tuned interstage.

$$b = (Q_1/Q_2 + Q_2/Q_1)$$
$$a = (Q_1Q_2)^{1/2}\,(\omega/\omega_0 - \omega_0/\omega)$$

At resonance:

$$\omega_0 = 1/(L_1C_1)^{1/2} = 1/(L_2C_2)^{1/2}$$

The gain of the interstage is at a maximum with $s = 1$; the transformer is then critically coupled, and

$$a_v(j\omega_0) = -g_m(R_1R_2)^{1/2}/2$$

with

$$k_c = 1/(Q_1Q_2)^{1/2}$$

In practice, it is customary to use not the value of k which gives the maximum gain, but that value which gives the flattest selectivity curve. The circuit is then said to be transitionally coupled.

$$k_t = [(1/Q_1^2 + 1/Q_2^2)/2]^{1/2}$$

For a transitionally coupled circuit

$$a_v(j\omega_0) = -g_m(R_1R_2)^{1/2}[2p(1 + p^2)]^{1/2}/(1 + p)^2$$

and the bandwidth is

$$\Delta\omega = [(1 + p)/\sqrt{2}\,p]\;\omega_0/Q_2$$

With equal Q's, $Q_1 = Q_2 = Q_m$, it follows that $k_t = k_c = k_m$ and

$$a_v(j\omega_0) = -g_m(R_1R_2)^{1/2}/2$$

$$\Delta\omega = \sqrt{2}\;\omega_0/Q_m$$

and

$$k_m = \Delta\omega/\sqrt{2}\;\omega_0 = 1/Q_m$$

Comparing a double-tuned interstage (with $n = 1$) and a single-tuned interstage yields the same center-frequency gain, but the double-tuned circuit provides a squarer response over the passband.

For a cascade of n synchronous double-tuned stages that are unilateral and noninteracting, the magnitude of the center-frequency voltage gain is

$$|A_v| = a_v^n = [g_m(R_1R_2)^{1/2}/2]^n$$

and the overall bandwidth is

$$\Delta\omega_n = \Delta\omega(2^{1/n} - 1)^{1/4}$$

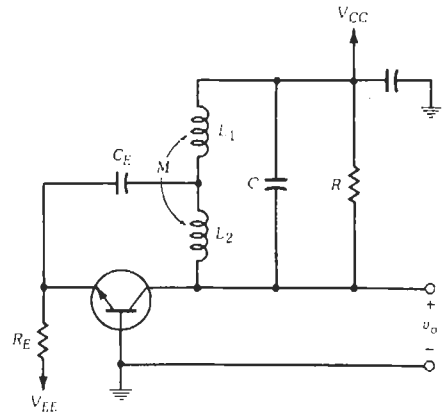
Fig. 25. Transformer-coupled feedback oscillators.

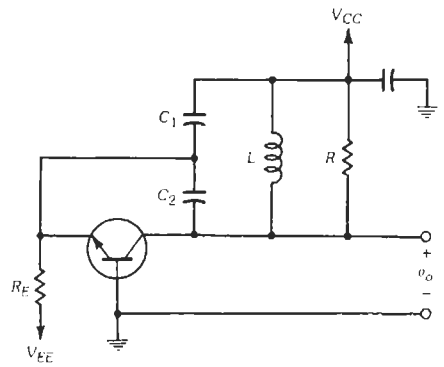
SINUSOIDAL OSCILLATORS*

In the section on feedback amplifiers, *negative* feedback was used to advantage to produce near-ideal amplifiers. In this section, *positive* feedback is used to produce near-ideal sinusoidal oscillators. Fig. 25 illustrates two transformer-coupled feedback oscillator circuits. In Fig. 26, the popular Colpitts and Hartley circuits are shown. These are LC tuned-circuit feedback oscillators. Two RC oscillator circuits are presented in Fig. 27. Equations for the oscillation frequency and conditions for oscillation are listed in Table 15.

* References 3 and 19.



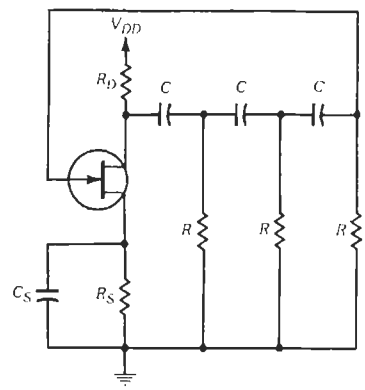
(A) Hartley.



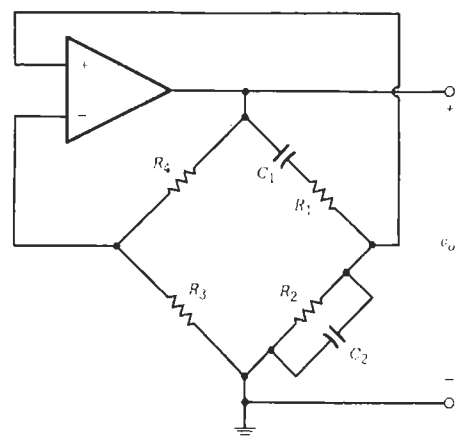
(B) Colpitts.

Fig. 26. Tuned-circuit feedback oscillators.

Tight coupling is used in the transformer-coupled oscillators so that coefficient of coupling k is close to 1.0. To sustain oscillations, but to prevent gross distortion in the output waveform, the ratio $g_m R/n$ is typically chosen to be about 3. The turns ratio for the transformer is not critical; a value of about 10 is appropriate. For the Hartley and Colpitts oscillators, "turns ratio" n is typically about 3.



(A) Phase-shift.



(B) Wien bridge.

Fig. 27. RC oscillators.

For the RC oscillators, loop gain T is equal to 1 at ω_0, provided that the voltage gain of the basic amplifier is as listed in Table 15. The RC oscillators are used at low frequencies, where the size of the inductor in an LC oscillator would be too large.

TABLE 15. OSCILLATOR EQUATIONS

Circuit	Oscillation Frequency	Condition for Oscillation
Transformer Coupled	$\omega_o = 1/(LC)^{1/2}$	$g_m R/n \geq 1$
Hartley	$\omega_o = 1/(LC)^{1/2}$ $L = L_1 + L_2$	$n \geq 1/\alpha_0$ $n = (L_1 + L_2)/L_1$
Colpitts	$\omega_o = 1/(LC)^{1/2}$ $C = C_1 C_2/(C_1 + C_2)$	$n \geq 1/\alpha_0$ $n = (C_1 + C_2)/C_2$
Phase-Shift	$\omega_o = 1/RC$	$a_v(j\omega_o) \geq 29$
Wien Bridge	$\omega_o = 1/R_1 C_1 = 1/R_2 C_2$	$a_v(j\omega_o) = 3$ *i.e.*, $R_4 = 2R_3$

Prime requirements of sinusoidal oscillators are (1) good amplitude stability', (2) good frequency stability, and (3) a low harmonic content in the output waveform.

A stable voltage supply and stable passive components are basic to good amplitude stability. Stable passive components are required also for a stable output frequency. In addition, the oscillation frequency should be much less than the effective f_T of the active device; the tank-circuit capacitance should be large compared with C_μ or C_{gd}; and, where the feedback is to the emitter or source, a small resistance ($R \approx 10/g_m$) is useful in the feedback path. The harmonic content at the output is minimized with a low L/C ratio. Also it should be noted that compared to a common-emitter or common-source connection a common-base or common-gate circuit gives better frequency stability and is generally less critical in adjustment.

For the best sinusoidal output, the collector current and load resistor R should be chosen so that the transistor just cuts off but does not saturate on the peaks of the waveform. However, this class-A operation does lead to a low power-conversion efficiency. An oscillator operated near class A has good frequency stability and a low harmonic content, but for a high power-conversion efficiency class-C operation is preferred.

The RC oscillators are normally used at frequencies below 1 MHz. The Hartley is a good general-purpose oscillator to about 10 MHz. The Colpitts oscillator has good stability and a low harmonic output. It is used almost exclusively at frequencies above 10 MHz.

PULSE CIRCUITS†

Pulse Shaping

The shaping of pulses by means of passive RC and RL circuits is common. Fig. 28 shows the response of

Fig. 30. Response curves for the RLC circuit of Fig. 31.

each of these simple networks to a step-voltage input and a sine-wave input. For a step input, $v_i = V$. With a step-voltage at the input of a simple high-pass network, the fall time between the 0.9 and 0.1 points on the output waveform is $t_f = 2.2\tau$. Similarly, for a simple low-pass network the rise time between the 0.1 and 0.9 points of the output waveform is $t_r = 2.2\tau$. The high-pass network also serves as a voltage differentiator, since $v_o(t) = \tau(dv_i/dt)$. The low-pass network serves as a voltage integrator, since $v_o(t) = (1/\tau) \int v_i dt$. The response of these shaping networks to an exponential voltage input, $v_i = V(1 - e^{-t/\tau})$, is illustrated in Fig. 29.

Fig. 30 shows the response of an RLC circuit (Fig. 31) to a step-voltage input. Parameter k in these curves is related to capacitance C or resistance R by the following equation:

$$k = (1/2R)\sqrt{L/C}$$

For the critically damped case, $k = 1$ and

$$v_o(t)/V = (4Rt/L)e^{-2Rt/L}$$

In the overdamped case $k > 1$, and with $T_0 \equiv 2\pi\sqrt{LC}$

$$v_o(t)/V = e^{-\pi t/kT_0} - e^{-4\pi kt/T_0} \approx e^{-Rt/L}$$

In the underdamped case, $k < 1$ and

$$v_o(t)/V = [2k/(1 - k^2)^{1/2}]\, e^{-2\pi t/T_0} \sin 2\pi(1 - k^2)^{1/2} t/T_0$$

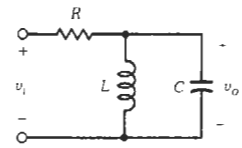

Fig. 31. RLC network.

Multivibrators

The three forms of a multivibrator circuit are bistable, monostable, and astable. Each of these operations is best performed with digital integrated circuits. However, discrete transistor versions of these circuits may be used, and some simple examples using saturating bipolar transistors are shown in Figs. 32–34.

For the bistable circuit of Fig. 32, typically $R_B \approx 10R_C$. Included in the figure is the truth table for this bistable latch circuit. Note that since $\overline{Q}$ is defined as the inverse of Q, the $R = S = 1$, $Q = \overline{Q} = 0$ state is not allowed.

In the monostable circuit of Fig. 33, a rectangular pulse is generated at v_{out} due to the trigger pulse at v_{in}. The output pulse width is given by

$$PW \approx 0.7R_xC_x$$

The width of the input pulse should be much less than the output pulse width.

The feedback biasing scheme in the astable circuit of Fig. 34 ensures that the astable will oscillate when power is initially applied to the circuit. For this circuit

$$PW_1 \approx 0.7C_1(R_1 + R_3)$$

$$PW_2 \approx 0.7\, C_2(R_2 + R_4)$$

With $PW_1 = PW_2$ the output at each collector of the astable is a square wave with a frequency of $1/2PW_1$.

The timing of these circuits may be improved if the transistors are prevented from saturating by connecting a Schottky-barrier diode, or other fast-recovery low forward-voltage diode, from the base to the collector. The anode of the diode is connected to the base terminal.

Finally, each of these multivibrator circuits may be implemented with field-effect transistors, especially complementary MOS(CMOS).

20 Integrated Circuits

Pallab K. Chatterjee, Satwinder D. S. Malhi, Michiel deWit,
Harold Hosack, Mark G. Harward, and Mehrdad M. Moslehi
Revised by Harold Hosack

INTRODUCTION

Progress in the complexity and usefulness of integrated circuits (ICs) has been extremely rapid over the past four decades. In fact, the pace of introduction of new ICs and new IC applications has continued to increase over this time. Currently ICs are a pervasive element in essentially all parts of commercial, scientific, and military systems. They have allowed major advances in such areas as computers, entertainment electronics, video cameras, global positioning systems, and innumerable other applications. The impact of ICs on society in the past forty years has been comparable to the impact of the industrial revolution. The rapid rate of change experienced during the recent past is expected to continue well into the next millennium. This chapter describes some of the basic concepts of integrated circuits, integrated circuit fabrication, designs, and a few applications.

DEFINITIONS AND TERMINOLOGY

access time: 1. Address-to-read output access time—The time delay in random-access memories from the application of appropriate address signal levels to the presence of valid data signal levels at the output. The signal to enable the memory chip enable is present. 2. Chip-enable-to-read output access time—With an appropriate address signal level present, the time delay in random-access memories from the application of appropriate signal levels to the enable inputs to the presence of valid data signal levels at the output.

adder: Switching circuit that combines binary bits to generate the sum and carry of these bits. Takes the bits from two binary numbers to be added (addend and augend), plus the carry from the preceding less-significant bit, and generates the sum and carry.

APCVD: Atmospheric pressure chemical vapor deposition.

ARC: Antireflection coating used in resist processing.

ash: Isotropic dry etching of resist with O_2.

avalanche breakdown: Reverse-voltage breakdown due to electrons gaining sufficient speed to dislodge valence electrons and thus create more current carriers.

backgrind: Process of removal of material from back side of wafers by grinding.

ball bond: Connecting wire from package to IC chip.

barrier layer: A thin layer deposited on contacts before metallization that prevents metal spikes from penetrating through thin junctions and causing unwanted shorts.

beta ratio: For all standard p-channel and n-channel MOS structures, the coefficient $(\mu\epsilon_{ox})/(2t_{ox})$ for the driver device is equal to that of the load device. In this equation, μ = majority carrier mobility, ϵ_{ox} = permittivity of the oxide, and t_{ox} = thickness of the oxide over the channel. Hence, the beta ratio simply becomes the ratio of $(W/L)_{driver}$ to $(W/L)_{load}$, where W = width of the channel and L = length of the channel in the direction of the current. Some engineers use the symbol K_R to denote this same ratio.

bias, forward: An external voltage applied in the conducting direction of a pn junction. This is accomplished by connecting the positive terminal of the source to the p-type region and the negative terminal to the n-type region.

bias, reverse: An external voltage applied in the nonconducting direction of a pn junction. The connections are opposite to those for forward bias.

binary coded decimal (BCD): A binary numbering system for coding decimal numbers in groups of four bits. The binary value of these four-bit groups ranges from 0000 to 1001 and codes the decimal digits 0 through 9. To count to 9 takes four bits; to count to 99 takes two groups of four bits; to count to 999 takes three groups of four bits; etc.

binary logic: Digital logic elements that operate with two distinct states. The two states are variously called true and false, high and low, on and off, or 1 and 0. In computers they are represented by two different voltage levels. The level that is more positive (or less negative) than the other is called the high level; the other is called the low level. If the true (1) level is the most positive voltage, such logic is referred to as "positive true" or "positive logic."

bipolar technology: Semiconductor fabrication involving an active semiconductor device with two or more pn junctions. Conduction is by a flow of electrons (in n-type material) or positive holes (in p-type material) across the junction of the two materials.

bird beak: Edge feature produced during local oxidation.

bistable element: Another name for flip-flop. A circuit in which the output has two stable states (output levels 0 and 1) and can be caused to go to either of these states by input signals, but remains in that state permanently after the input signals are removed. This differentiates the bistable element from a gate, which also has two output states but

which requires the retention of the input signals to stay in a given state. The characteristic of two stable states also differentiates the bistable element from a monostable element, which keeps returning to a specific state, and an astable element, which keeps changing from one state to the other.

bit: Binary digit.

boat: Wafer holder generally made of quartz or polysilicon used during furnace processes.

BTS: Bias temperature stress.

buffer memory: A memory system, usually of small capacity compared to a main-frame memory, that provides a buffer function between two digital activities.

bus: Long signal-carrying line.

byte: Eight bits.

CAD/CAE/CAM: Computer-aided design/computer-aided engineering/computer-aided manufacture.

CDI: Collector diffusion isolation. A bipolar semiconductor fabrication process that uses an epitaxial layer for the base structure (eliminating a base-diffusion step) and combines the deep collector diffusion contact and isolation steps.

Cell: A collection of devices that is repeated in a circuit. Mostly used to describe unit memory structures.

character generation: A design technique for integrated circuits that utilizes a fixed program in a storage element as the means for generating a dot matrix to represent alphanumeric characters on a CRT display.

charge-coupled device (CCD): A type of semiconductor device in which the presence or absence of charge represents the information. Charge-coupled devices store minority-carrier charges in potential wells created at the silicon surface and transport these charge packets along the surface by moving the potential wells.

chip enable: The control signal that activates a complete storage element. No reading or writing of data occurs unless this signal activates the storage element.

class N: Measure of particulate contamination in clean rooms. *N* particles of size greater than 0.3 μm per cubic foot.

clock: A timing control signal required by storage elements and memory systems.

CMOS: See complementary MOS.

C_o: Gate capacitance corresponding to the oxide layer over the channel area; $C_o = A(\epsilon_{ox}/t_{ox})$. A = channel area, ϵ_{ox} = permittivity of oxide, t_{ox} = thickness of oxide over channel.

column decoder: Circuits within the storage elements designed to route data from a column of storage cells.

complementary MOS: An MOS fabrication process that combines both p-channel and n-channel transistors on the same substrate. The n-channel transistor is usually the driver device, and the p-channel transistor is the load. Only one transistor of the pair is normally on, except during the switching mode.

complexity: The number of equivalent gates in a circuit.

Cu-low k: Description of advanced IC metallization that is composed of thin films of copper separated by a very low dielectric constant medium.

current, forward: The net current that flows across the forward-biased pn junction.

CVD: Chemical vapor deposition of thin films.

cycle time: 1. Read cycle time—The total time required between the application of address information for reading data number 1 and the application of address information for reading data number 2 with the memory in the read mode. 2. Write cycle time—Same as read cycle time, but for writing of data and memory in the write mode. 3. System cycle time—The time between memory cycle initiations. It usually is determined by the longest of the read or write access or read or write cycle times.

Czochralski: Crystal-pulling process from a melt using a single crystal seed.

Damascene processing: Metal application to ICs using a process where metal is deposited on a surface having grooves where metal is desired, and then the metal is polished from the wafer, leaving metal in the grooves.

decoder: A conversion circuit that accepts digital input information (in the memory case, binary address information) that appears as a small number of lines and selects and activates one of a large number of output lines.

deglaze: Removal of thin layer of SiO_2 by the use of weak HF.

depletion region: The region in a semiconductor in which the mobile-carrier charge density is insufficient to neutralize the net charge density of the fixed donor and acceptor ions.

descum: Anisotropic plasma removal of resist residues after development.

die-by-die alignment: Alignment mechanism in which each die is aligned separately.

diffusion current: The current produced when charges move by diffusion.

diffusion length: The average distance excess minority carriers diffuse between injection and recombination.

diode isolation: A method of producing a high electrical resistance between an integrated-circuit element and the substrate by surrounding the element with a reverse-biased pn junction. The method is also called junction isolation (JI).

diode, semiconductor: A two-electrode semiconductor device that conducts current more easily in one direction than in the other.

DIP: Dual in-line package.

direct mapping: A design technique, used in virtual memory design, that determines the way data are organized and transferred from primary memory to the buffer memory. Data are mapped directly as blocks.

dope: Introduction of different atoms (dopant) in a semiconductor structure, Q.

dose: Number of implanted or diffused ions per unit area.

dot matrix: A matrix of dots that is used to identify alphanumeric characters.

dRAM/sRAM: Dynamic (refreshed storage cells), static (V_{cc} only) RAM.

drift current: A current that is produced when the carriers move under the influence of an applied voltage, i.e., owing to a voltage gradient.

drive-in: Deeper thermal diffusion of dopants introduced during predeposition.

DSW: Direct step on wafer for step and repeat projection optical lithography.

dynamic storage elements: Storage elements that contain storage cells that must be refreshed at appropriate time intervals to prevent the loss of information content.

EAROM: Electrically alterable ROM. A fixed-program semiconductor storage element whose program can be altered by the application of external electrical or optical means.

E-beam: Electron beam (exposes resist to pattern masks or wafers).

E_C: Conduction-band energy level.

ECL circuits: Bipolar emitter-coupled logic; also called current-mode logic circuits.

ECL storage cell: A type of bipolar storage cell that is like the multiple-emitter cell but is used for ECL interface.

E_F: Fermi energy level.

E_g: Band-gap energy $= E_C - E_v$.

E_i: Intrinsic energy level; assumed to be at the center of the band gap.

electromigration: Metal line failure due to mass transport of metal under large dc electric field.

electron-beam lithography: Use of focused electron beam to delineate patterns in resist. Commonly used for mask making.

epitaxial growth: The deposition of a monocrystalline layer of material onto a substrate material such that the layer thus formed has the same crystal orientation as the substrate.

EPROM, EEPROM: Electrically programmable, electrically erasable and programmable ROM.

etch filament: Thin residue left along steps during anisotropic dry etching.

etch selectivity: Ability of an etchant to remove layers of certain material with minimal attack on others.

E_v: Valence-band energy level.

excess minority carriers: The number of minority carriers that exceeds the normal equilibrium number in a semiconductor.

factory-programmed ROM: A fixed-program semiconductor storage element that has been programmed at the factory with a unique bit pattern.

failure rate: The number of components that fail in a given amount of time, usually expressed as a percentage per 1000 hours.

fall time: A measure of the time required for the output voltage of a circuit to change from a high-voltage level to a low-voltage level once a level change has started.

fan-out: The number of loads connected to the output of a logic stage. (A load normally consists of the input impedance of a logic circuit.)

fiducial: Markers on reticles for aid in alignment in projection printers.

filming: Lifting of resist caused by lack of adhesion.

fixed-program storage (read-only memory or read-only store): A special application of random-access storage in which storage is fixed after programming.

flip-flop: A storage element—a circuit having two stable states and the capability of changing from

one state to another with the application of a control signal and remaining in that state after removal of signals. (*See* bistable element.)

flip-flop, D: The letter D stands for delay. A flip-flop whose output is a function of the input that appeared one pulse earlier; for example, if a 1 appeared at the input, the output after the next clock pulse would be a 1.

flip-flop, JK: A flip-flop having two inputs, designated J and K. At the application of a clock pulse, a 1 on the J input and a 0 on the K input will set the flip-flop to the 1 state; a 1 on the K input and a 0 on the J input will reset it to the 0 state; and 1 simultaneously on both inputs will cause it to change state regardless of the previous state. J = 0 and K = 0 will prevent change.

flip-flop, RS: A flip-flop consisting of two cross-coupled NAND gates and having two inputs designated R and S. A 1 on the S input and 0 on the R input will reset (clear) the flip-flop to the 0 state; 1 on the R input and 0 on the S input will set it to the 1 state. It is assumed that 0 will never appear simultaneously at both inputs. If both inputs have 1, the flip-flop will stay as it was. A 1 is considered nonactivating. A similar circuit can be formed with NOR gates.

flip-flop, RST: A flip-flop having three inputs designated R, S, and T. This unit works like the RS flip-flop, except that the T input is used to cause the flip-flop to change states.

flip-flop, T: A flip-flop having only one input. A pulse appearing on the input will cause the flip-flop to change states. Used in ripple counters.

float zone: Crystal growth process by repetitive melting and slow solidification.

fusible metallization: Utilization of a fusible metal, such as Nichrome, in the fabrication of semiconductor memory circuits. The metal interconnection is severed by a high current to program the storage element.

gate, AND: A logic circuit in which all inputs must have 1-level signals at the input to produce a 1-level output (assuming positive logic).

gate, NAND: A logic circuit in which all inputs must have 1-level signals at the input to produce a 0-level output (assuming positive logic).

gate, NOR: A logic circuit in which any one input or more than one input having a 1-level signal will produce a 0-level output (assuming positive logic).

gate, OR: A logic circuit in which any one input or more than one input having a 1-level signal will produce a 1-level output (assuming positive logic).

gate, XOR: A logic circuit in which any odd number of inputs having a 1-level signal will produce a 1-level output (assuming positive logic).

glass spray: Quartz particles generated by friction of boat with furnace tube during loading and unloading.

global alignment: Alignment mechanism in which only two geometries per wafer are aligned automatically, assuring requisite alignment of others.

g_m: Transconductance = $\delta I_D / \delta V_G |_{V_D}$.

GOI: Gate oxide integrity against applied voltage.

hillocks: Protrusions in deposited thin films.

Hilton haze: Hazy look on thin films caused by departure from stoichiometry, with appearance akin to Hilton Hotel symbol.

hold time: The time that address information and data information must be maintained after write-enable to guarantee successful writing of data in the memory.

hydrophilic: Surface readily wetted by water.

hydrophobic: Surface not wetted by water.

IGFET: Insulated-gate field-effect transistor.

input loading factor (ILF): The load that an input line presents to a driver. It may be expressed as a current, voltage, or impedance.

insulator: A material in which the outer (valence) electrons are tightly bound to the atom and are not free to move. No current can flow when a voltage less than breakdown is applied across the material.

integrated circuit: "The physical realization of a number of electrical elements inseparably associated on or within a continuous body of semiconductor material to perform the functions of a circuit." (EIA definition)

intrinsic concentration: The number of free electrons (or holes) per cubic centimeter in an undoped semiconductor at thermal equilibrium.

ion-beam lithography: Use of focused ion beams for pattern delineation.

ion implantation: An MOS semiconductor fabrication process often used to adjust threshold voltage values by implantation of dopant ions in the gate region, after source and drain formation. The implanted doping level is controlled by the ion accelerator beam current and implant time.

ion milling: Micromachining of thin films using mechanical motion of energetic ions.

isoplanar: A bipolar semiconductor fabrication process in which the p-diffused isolation regions are replaced by selectively grown oxide isolation.

junction avalanche: Utilization of an avalanche junction in the fabrication of fixed-program (read-only) semiconductor circuits. The avalanched junction forms a connection by high voltage and current to program the storage element.

junction barrier: The opposition to the diffusion of majority carriers across a pn junction caused by the charge of fixed donor and acceptor ions.

junction capacitor: A capacitor utilizing the capacitance of a reverse-biased pn junction.

junction transistor: An active semiconductor device with a base electrode and two or more junction electrodes.

KOOI effect: Inhibition of subsequent oxidation of silicon underlying Si_3N_4 caused by NH_3 formed during wet local oxidation.

L: Effective channel length (in direction of current) in a MOSFET.

large-scale integration (LSI): The simultaneous realization of large-area chips and optimum component packing density, resulting in cost reduction by maximizing the number of system connections done at the chip level. Circuit complexity above 100 gates.

laser anneal: Use of high-energy laser beam for local melting and recrystallization of semiconductors.

lifetime: The average time interval between the introduction and recombination of minority carriers.

loading factors: Specifically used here for memory systems. A numerical measure of the load that must be supplied to drive lines in a memory system.

load line: A line drawn on the family of collector characteristic curves of a transistor showing how the transistor collector voltage changes as the current through the transistor and load resistance changes.

LOCOS: Local oxidation of silicon. This refers to the use of silicon nitride to protect against oxidation.

logic swing: The voltage difference between the two logic levels, 1 and 0.

LPCVD: Low pressure chemical vapor deposition.

mainframe memory: The main memory of the digital system.

mechanically programmable semiconductor ROM: A fixed-program (read-only) semiconductor storage element that can be programmed by breaking interconnection by mechanical means (wiping metal away).

medium-scale integration (MSI): The realization of circuit complexities between 12 and 100 equivalent gates.

MEMS (micro-electro-mechanical systems): Integrated mechanical elements, sensors, actuators, and electronics that are fabricated using microfabrication technology similar to that used for integrated circuits.

MESFET: Metal gate Schottky field-effect transistor.

metallization: A thin-film pattern of conductive material (usually aluminum) deposited on a substrate to interconnect electronic components or to provide conductive contacts to which interconnecting wires may be bonded.

MINIMOS: MOSFET simulation program (available from University of Vienna).

mobile charge: Alkali ions that move through oxide under the influence of applied electric field.

mobility: The average velocity attained by a charge carrier under the influence of a unit electric field.

monolithic integrated circuit: An electronic circuit that has been fabricated as an inseparable assembly of circuit elements in a single structure that cannot be divided without permanently destroying its intended electronic function.

MOS capacitor: A capacitor formed by depositing a silicon-oxide dielectric layer and then a metal top electrode on the surface of a semiconductor region that forms the bottom electrode. The use of silicon as one of the capacitor plates makes the capacitance a function of applied voltage.

MOSFET (metal-oxide-semiconductor field-effect transistor): An active semiconductor device in which a conducting channel is induced in the region between two electrodes by a voltage applied to an insulated electrode on the surface of the region.

MOS, MIS: Metal-oxide-semiconductor, metal-insulator-semiconductor.

MTBF: Mean time between failures of an electronic system.

multilevel oxide: Insulating layer between two conductive layers.

multiple-emitter cell: A type of bipolar storage cell that uses a multiple-emitter transistor control for coupling to the bit lines.

N_A, N_D, N: Doping levels. (A = acceptor, D = donor.)

negative logic: Logic in which the more negative voltage represents the 1 state and the less negative voltage represents the 0 state. (*See* binary logic.)

nibble: Four binary digits.

NMOS, PMOS: Designations for n-channel, p-channel MOSFET.

noise immunity: A measure of the insensitivity of a logic circuit to triggering or reacting to spurious or undesirable electrical signals or noise, largely determined by the signal swing of the logic. Noise can occur in either of two directions, positive or negative.

nondestructive readout: Semiconductor memory designed so that readout does not affect the content stored. It is not necessary to perform a write after every read operation.

NOT: A Boolean logic operation indicating negation. Actually an inverter. If input is 1, output is *NOT* 1 = 0; if input is 0, output is *NOT* 0 = 1. Graphically represented by a bar over a Boolean symbol: $\bar{A}$. $\bar{A}$ means "when A is not 1."

n-type semiconductor: A semiconductor in which electric conduction is due to the presence of more free electrons than holes.

NVRAM: Nonvolatile RAM.

OC curve: Operating characteristic curve. For a particular sampling plan, the graph of the probability of acceptance for all values of percent defective. Completely describes the risks involved in using the plan.

ODE: Orientation dependent etch.

ohmic contact: A resistive contact area that permits aluminum to be used as interconnecting metal from one high-resistivity n-type region to another.

OR: Oxide removal (for contact openings).

oxidation: A process that converts the surface of a silicon wafer to silicon dioxide. This is accomplished by subjecting the wafer to an oxygen or steam atmosphere at very high temperatures.

P: Heavy p-type diffusion.

parallel: The technique for handling a binary data word that has more than one bit. All bits are acted upon simultaneously. It is like the line of a football team; upon a signal, all linemen act.

parallel operation: The organization of data manipulation within computer circuitry wherein all the digits of a word are transmitted simultaneously on separate lines in order to speed up operation, as opposed to serial operation.

parasitics: Stray components associated with the desired components diffused into an integrated circuit. Such parasitics may consist of capacitances, resistances, diodes, or transistors effectively in series or in shunt with the diffused components. They tend to limit the performance of the desired components in a circuit unless compensated for in device and circuit design.

passivation: Protection against penetration by impurity atoms. A silicon surface is passivated by covering it with a thin layer of variously doped films. This layer cannot easily be penetrated by impurities at normal processing and operating temperatures and, therefore, provides the necessary protection.

passive elements: Electronic components, such as resistors and capacitors, that simply introduce resistance or reactance into an electrical circuit but cannot change the waveform of an applied sine wave.

photomasking: A semiconductor-fabrication process in which a photographic negative is used to delineate selective chemical change to portions of the semiconductor surface.

pinholes: Weak spots in thin films due to defects or contamination.

Pirahna: A cleaning agent consisting of H_2O_2 and H_2SO_4.

PLA: Programmable logic array. An integrated circuit that employs ROM matrices to combine sum and product terms of logic networks.

planar transistor: A diffused-junction transistor in which the emitter, base, and collector regions all come to the same plane surface, with the junctions between the regions protected at the surface by a layer of material such as silicon oxide.

plasma: Ionized gas in which concentrations of positive and negative charge carriers are almost equal.

plasma etch: Use of a plasma of reactive ions to etch thin layers.

plug bar: Assortment of test structures added on IC mask for model extraction and diagnostic purposes.

pn junction: The region of transition between p-type and n-type semiconductor materials.

poly: Polycrystalline silicon.

potential barrier: The difference in potential across a pn junction.

precharge time (reset time): The timing pulse width within a memory cycle that is used for charging node capacitances to particular starting-point voltage levels.

PREDEP: Predeposition of dopants.

process flow: The detailed step-by-step sequence of a fabrication schedule.

propagation delay: The time required for a change in logic level to be transmitted through an element or a chain of elements.

PSG: Phosphosilicate glass.

p-type semiconductor: A semiconductor in which electric conduction is due to the presence of more holes than free electrons.

purge: Extended exposure to only a desired gas or a mixture of gases.

ϕ_F: Fermi potential; the amount the Fermi level is displaced from the intrinsic level or the center of the gap (as measured in the bulk). Units are volts.

ϕ_s: Surface potential; the amount the intrinsic Fermi level, at the surface, has been shifted with respect to the bulk Fermi level.

q: Electronic charge; 1.6×10^{-19} coulomb.

random-access memory (RAM): A memory from which information can be obtained at the output with approximately the same time delay by choosing an address randomly and without first searching through a vast amount of irrelevant data.

range: Depth of peak of implanted ion distribution.

rapid thermal processing (RTP): Process steps implemented by very sharp rises in temperature, short process times, and very steep cool down cycles. The complete process sequence is completed in a few tens of seconds.

ratio inverter: An inverter whose logic swing is determined by the beta ratio (β_R) of the load and driver devices.

ratioless inverter: An inverter whose logic swing closely approximates the power-supply voltage. ("Ratioless" because the load and driver device do not conduct simultaneously.)

ratioless-type shift register: Current does not flow through the inverter when the clock and data inputs are simultaneously at the logic 1 level.

ratio-type shift register: Current flows through the inverter when the clock and data inputs are simultaneously at logic 1.

reactive ion etching: Etching of films using plasma and mechanical motion of reactive ions.

reflow: High-temperature treatment of phosphosilicate glass that causes its mass flow.

refresh: Method that restores capacitance charge that deteriorates because of leakage.

register: Temporary storage for digital data.

reox: Oxide removal from heavily implanted region and its thermal oxidation for sake of passivation.

repair frequency: The rate at which an electronic system must be repaired, i.e., once/day, once/week, once/four weeks, etc.

reset: Also called "clear." Similar to set except it is the input through which the Q output can be made to go to 0.

resist: Photosensitive organic or inorganic resins.

resistivity: The (volume) resistivity ρ is the electric field E required to produce a unit current density J. That is, $\rho = E/J$.

rinse cascade: A series of containers with running deionized water used for wafer rinsing after chemical treatment.

ROM: Read-only memory.

row decoder: Circuits within the storage elements designed to route data from a row of storage cells.

SAG (self-aligned gate): An MOS fabrication process using a self-aligning gate formed from deposited silicon.

SAMPLE: Lithography and etch simulation program available from the University of Berkeley.

SATO (self-aligned thick oxide) process: An MOS fabrication process using nitride as the self-aligning gate material. Thus, the gate metallization does not have to withstand diffusion temperature.

Schmitt trigger: An input circuit with hysteresis. There is a higher threshold for positive-going inputs than for negative-going inputs.

Schottky barrier diode: Metal-semiconductor barrier diode.

segregation: Preferential accumulation of dopants in either silicon or oxide during thermal oxidation.

self-refresh: A circuit-design technique that incorporates the refresh method in the storage-element circuitry so that external refresh circuitry is not required.

SEM: Scanning electron microscope.

semiconductor: A material with conductivity roughly midway between that of conductors and insulators, and in which the conductivity

increases with temperature over a certain temperature range.

sense amplifier: A sensitive amplifier accepting linear voltage or current signals and producing logic-level outputs.

sequentially accessed memory: A memory from which information is received at the output in varying time delays from a reference point depending on the position of the data in a time sequence.

serial accumulator: A register that receives data bits in sequence and temporarily holds the data for future use.

serial operation: The organization of data manipulation within computer circuitry wherein the digits of a word are transmitted one at a time along a single line. The serial mode of operation is slower than parallel operation but utilizes less complex circuitry.

sheet resistance: The resistance per square of a sheet of material.

Silicon On Insulator (SOI): A wafer substrate composed of a thin layer of silicon (typically one micron or less) over a layer of insulating material (typically silicon dioxide, one half micron or less) over a silicon substrate. ICs are fabricated in the thin top layer of silicon.

SIM: Secondary ion microscope.

single crystal: A piece of material in which all the basic groups of atoms have the same crystallographic orientation.

sinter: Annealing treatment after metal etch to promote ohmic contacts.

slice: A single wafer cut from a silicon ingot, forming a thin substrate on which all active and passive elements for multiple integrated circuits have been fabricated by semiconductor epitaxial growth, diffusion, passivation, masking, photoresist, and metallization technologies. A completed slice generally contains hundreds of individual circuits, called chips or bars.

SOI: Silicon on insulator.

solid-state diffusion: The introduction of atoms of an impurity element into the surface regions of a solid semiconductor wafer.

SOS: Silicon on sapphire.

SPICE 2: Version of circuit simulation computer program (University of Berkeley).

state: The condition of an input or output of a circuit as to whether it is logic 1 or logic 0. The state of a circuit (gate or flip-flop) refers to its output. A flip-flop is said to be in the 1 state when its Q output is 1. A gate is in the 1 state when its output is 1.

static storage elements: Storage elements that contain storage cells that retain their information as long as power is applied unless the information is altered by external excitation.

step coverage: Ability of thin films to maintain thickness when going over feature steps.

stored-charge programmable semiconductor ROM: Utilizing a charge stored on a floating gate or a dielectric as a means of programming an MOS fixed-program (read-only) semiconductor storage element.

straggle: Standard deviation around the range of implanted ions.

substrate: The physical material on which an integrated circuit is fabricated. Its primary function is mechanical support, but it may serve some electrical function also.

SUPREM: Process simulation program available from Stanford University.

System in a Package (SIP): A single package that hosts several different computation modules (i.e., microprocessor, controllers, DSPs, I/O unit, RF modules ...) together with memory to perform a complete system function.

System on a Chip (SOC): A single chip that hosts several different computation modules (i.e., microprocessor, controllers, DSPs, I/O unit, RF modules ...) together with memory to perform a complete system function.

TEM: Transmission electron microscope.

thermal compression bond: A commonly used method for attaching a very fine wire to a point (usually a bonding pad) on an integrated-circuit chip.

thermal generation: The creation of a hole and a free electron by freeing a bound electron through the addition of heat energy.

three-state output: An output condition that has a low on impedance for driving to the high state, a low on impedance for driving to the low state, and an intermediate high-impedance off state.

throughput: Rate of material processed per hour.

TIRAM: Taper isolated random-access memory, an advanced dynamic RAM cell.

toggle: To switch between two states, as in a flip-flop.

t_{ox}: Oxide thickness.

trigger: A timing pulse used to initiate the transmission of logic signals through the appropriate circuit signal paths.

truth table: A chart that tabulates and summarizes all the combinations of possible states of the inputs and outputs of a circuit. It tabulates what will happen at the output for a given input combination.

TTL: Transistor-transistor logic multiple emitter bipolar semiconductor circuit. Bipolar semiconductor transistor–transistor coupled logic circuits.

two-level main memory: A memory system featuring two separate memories. One memory is a buffer store, or cache memory. The other memory is the primary storage. Coupled together, these form a virtual memory with the capacity of the primary memory and the speed of the buffer memory.

two-level metallization: A semiconductor fabrication process in which there are two levels of interconnecting metal on the surface of the integrated circuit.

ULSI: Ultralarge-scale integration; circuit complexity above 1 million transistors.

vacancy: Unoccupied position in bond structure receptive to substitutional occupancy.

V_{BG}: Back-gate bias.

V_{cc}, V_{dd}, V_{ss}: High, intermediate, low supply-voltage levels.

vector generation: A design technique for generating the coordinates for positioning the beam in a CRT display that uses only the changes in coordinates of the beam rather than the absolute coordinates.

VFB: Flatband voltage.

V_{GG}: Gate supply voltage.

V_{GS}: Gate-to-source voltage.

VHPIC: Very-high-performance integrated circuits (British program).

VHSIC: Very-high-speed integrated circuits.

VLSI: Very-large-scale integration; circuit complexity above 100 000 transistors.

V_{TD}: Threshold voltage of the driver device.

V_{TL}: Threshold voltage of the load device.

V_T (V_{BG}): Threshold voltage as a function of back-gate bias.

W: Effective channel width (perpendicular to current) in a MOSFET.

wafer flat: A flat portion of an otherwise circular wafer for orientation identification.

wafer stepper: Resist exposure system in which each die is focused and exposed separately.

word: Sixteen bits.

write enable: Also called read/write or R/W. The control signal to a storage element or a memory that activates the write mode or operation. When the device is not in the write mode, the read mode is active.

write time: 1. Address-to-write time—The time delay in random-access memories from the application of appropriate address signal levels until the write-mode control signal of an appropriate level is applied. 2. Chip-enable-to-write time—The time delay, with appropriate address signal levels present, from the application of appropriate signal levels to the enable inputs until the write-mode control signal of an appropriate level is applied. 3. The time that the appropriate level must be maintained on the write-enable line and that data must be present to guarantee successful writing of data in the memory.

yield: The percentage of acceptable circuits (chips) produced by a particular process, process step, inspection, or test.

zener: Breakdown in diodes due to tunneling.

IC FABRICATION

The process of producing ICs has three main components—design, processing, and assembly and test. Design is the step necessary to translate the desired electrical functions of the IC to the description of the physical structure required to produce those functions. Processing is the step needed to transform the description provided by design into a physical structure that is capable of providing the desired electrical functionality. Assembly is the step necessary to place the physical structure in a package that will protect it from environmental stresses and provide wires to connect it to the outside world, and test is the step that assures that the finished IC meets all of the desired functions. The subjects of IC design, processing, and assembly and test are extensive. In this chapter we will only describe the fundamentals of each of these areas. The reader is directed to the extensive literature on each of these areas for further details.*

IC PROCESSING

IC Processing is the step needed to transform the description provided by design into a physical structure that is capable of providing the desired electrical

* For example, References 1, 2, and 3.

functions. The discipline of IC processing is one that has been continuously and rapidly evolving, especially in the past decade. This section discusses processes that are currently, or are about to be, in widespread production use. New processes continue to be invented and developed, and to keep abreast of current understanding the reader is well advised to refer to pertinent technical journals. Since silicon-based circuits are the mainstream IC technology, the following discussion is set in the context of silicon IC processing. However, the concepts presented apply equally well to processing of other materials, such as gallium arsenide.

The silicon wafers used in IC processing are thin slices of a large silicon crystal. The wafers are round like a plate and have a small "flat" ground on them to allow indexing in IC fabrication equipment. These wafers are polished to a very fine mirrorlike finish to allow very small geometries to be printed on them by lithographic reproduction. Current production wafers are typically 200 mm in diameter. The mainstay of production is expected to be 300-mm-diameter wafers by the year 2005. The silicon wafers are cut to a typical thickness of a few hundred microns. The ICs usually occupy only the top few microns of the silicon wafer. The remaining thickness is necessary for mechanical stability during the wafer-processing steps. After the wafer has completed processing it is usually ground to a thickness of only a few tens of microns before the individual ICs are separated and assembled. The wafers are interchangeably called the "substrate" for IC fabrication.

Typical ICs are rectangular and are one centimeter or less on a side. They are produced by a process that is typically several hundred individual steps of repeated application of specific patterns and intervening process steps to produce structures in the silicon wafer in the form of the patterns. Since the individual IC is less than one square centimeter in area, and the wafers are several hundred square centimeters in area, many ICs are produced on a single wafer. This "mass production" is the key ingredient to being able to continuously decrease the cost of functionality available from ICs. After the wafer is completed with processing, it appears as a disc with a clearly repetitive pattern of small rectangles, each of which is an individual IC.

The following sections describe some of the key processes used in IC processing and provide a simple example.

Substrate-Cleaning Procedures

The performance characteristics of semiconductor devices are sensitive to cleanliness in processing. The removal of unwanted impurities from the wafer surface is important because such impurities may diffuse into the semiconductor during high-temperature processing, altering its bulk and surface properties. Many of the spurious impurities may be either donor or acceptor dopants, directly affecting the device characteristics. Other impurities may cause surface or bulk defects such as traps, stacking faults, or dislocations. Surface contaminants such as oil, grease, or other organic matter may lead to poor film adhesion. This requires a careful chemical cleaning of wafers at the initiation of the process and appropriate cleaning at various steps during processing.

The initial cleanup generally starts with wafer scrubbing to remove loose particulate contaminants. This is followed by treatment with organic chemicals to get rid of any possible organic impurities such as hydrocarbons and greases that may be remnants from the wafer-grinding process. Organic solvents such as methanol and ethanol are suitable for this purpose. The final cleanup consists of a variety of inorganic chemicals to remove heavy metals, etc. Most of these chemical mixtures are strong oxidants,* forming a thin oxide at the wafer surface. This oxide is then stripped so that impurities absorbed therein are removed. Table 1 lists some cleaning reagents commonly used in IC processing.

* Reference 4.

TABLE 1. CLEANING REAGENTS USED IN IC PROCESSING

Cleaning Agent	Boiling Point (°C)	Purpose
Ethanol	78.3	Remove organic contaminants
Trichloroethylene	87.2	
Acetone	56.2	
p-Xylene	138.4	
5 H_2O: 1 H_2O_2: 1 NH_4OH	—	Remove inorganic contaminants (heavy metals)
6 H_2O: 1 H_2O_2: 1 HCl	—	
1 H_2SO_4: 1 H_2O_2	—	
1 HCl: 1 HNO_3	—	

Thin Films

All IC processes involve the use of a number of thin films—insulators, semiconductors, and conductors. These films may form an essential part of a particular structure or just be of use in the implementation of a process step. The following means of achieving thin films are of widespread use.

Thermal Growth—This technique involves heating the substrate in a furnace at precisely controlled temperature and gas ambient. Generally, a high temperature, in the range from 800 °C to 1200 °C for silicon processing, is used to promote chemical reaction between the ambient gases and the substrate. The prominent example is the growth of SiO_2 on silicon in O_2 ambient. It is also possible to grow Si_3N_4 in an N_2 or, preferably, NH_3 atmosphere. It is possible to exercise extremely good control on absolute thickness as well as thickness uniformity across the wafer. Figs. 1 and 2 show the relationship between oxidation time and resultant oxide thickness in dry O_2 and steam, respectively.*

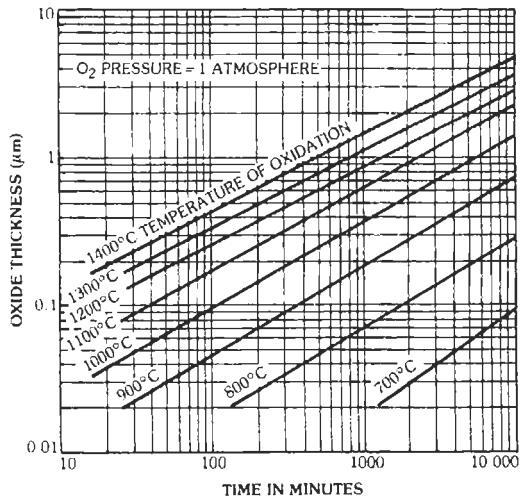

Fig. 1. Silicon dioxide growth rate in dry oxygen. (From A. M. Smith, "Experimental Measurements,"† in Burger and Donovan, Eds., *Fundamentals of Silicon Integrated Device Technology*, Vol. 1. Englewood Cliffs, NJ: Prentice-Hall, Inc.; Fig. 6-42.)

Chemical Vapor Deposition—The gas-phase reduction of highly reactive chemicals under low pressure forms a convenient way of obtaining very uniform thin films. This method is widely used for deposition of oxides, nitrides, and polycrystalline semiconductors. A conformal deposition around sharp edges is an important attribute of this technique. Table 2 lists constituent gases and suitable temperatures for the deposition of some common films.‡

Plasma Deposition—The production of thin films by electric discharge or plasma depends on the capability of a nonequilibrium but sustained plasma to generate chemically reactive species at low temperature. The plasma is typically sustained at 0.1 to several torr and exhibits free electron temperatures of tens of thousands of kelvins, while the temperature of the translational or rotational modes of atoms, radicals, or molecules is only hundreds of kelvins. Thus, deposition can be made at very low temperatures. The deposition scheme is in use for oxides, nitrides, carbides, and amorphous semiconductors. Table 3 lists gases used.§

Evaporation—Evaporation involves film deposition by vaporizing the material on heating it past its melting point under vacuum to produce enough vapor

TABLE 2. GASES AND TEMPERATURES FOR DEPOSITION OF FILMS

Film	Gases	Temperature (°C)
Polysilicon	SiH_4, N_2	650–700
(Si)	SiH_4, H_2	850–950
Silicon nitride	SiH_4, NH_3, N_2	750–800
(Si_3N_4)	SiH_2Cl_2, NH_3, N_2	750–900
Silicon dioxide	SiH_4, N_2O, N_2	750–850
(SiO_2)	SiH_4, CO_2, H_2	950–1000

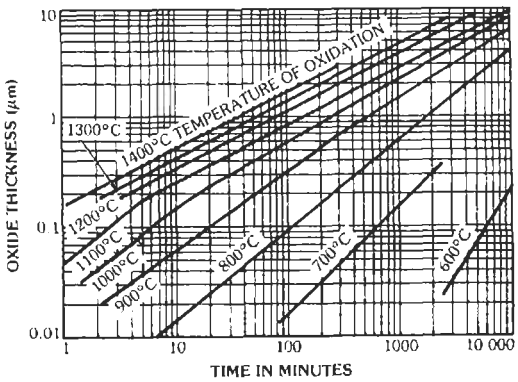

Fig. 2. Silicon dioxide growth rate in steam. (From A. M. Smith, "Experimental Measurements."* in Burger and Donovan, Eds., *Fundamentals of Silicon Integrated Device Technology*, Vol. I. Englewood Cliffs, NJ: Prentice-Hall, Inc.; Fig. 6-42.)

TABLE 3. GASES USED FOR PLASMA DEPOSITIONS

Film	Gases
Amorphous silicon (Si)	SiH_4, Ar
Silicon dioxide (SiO_2)	SiH_4, N_2O
Silicon nitride (Si_3N_4)	SiH_4, NH_3

pressure. Either resistive heating or E-beam heating is used to bring about melting. This technique is used mainly to deposit metals such as aluminum. A list of temperatures and support materials used to evaporate various elements is in Table 4.†

Sputter Deposition—In this scheme, the material to be deposited is bombarded with positive inert ions with kinetic energy far exceeding the heat of sublimation of the target material. This results in dislodging of target atoms and their ejection into the gas phase succeeded by deposition of the substrate, which may or may not be biased negatively. In widespread use are sputter deposition of metals and metal silicides.

Spin-On Deposition—The material to be deposited is mixed with a suitable solvent and spun coated on the substrate. The resulting thickness is a function of spin speed and viscosity of the solution used. Subsequently, an oven-bake drives out the solvent, leaving behind a stable layer. This procedure is used for deposition of layers of resists and doped or undoped oxides.

Rapid Thermal Processing (RTP)—The drive to smaller and smaller geometries for the individual transistors in ICs has produced a need for very thin deposited layers and very careful control of the location of impurities in the silicon wafers. This need has recently led to a new processing technique called Rapid Thermal Processing (RTP). Instead of the usual diffusion furnaces and other large equipment, where many wafers are processed at one time, this technique uses a bank of very high intensity lamps to rapidly heat a single wafer to temperatures of 500 °C to over 1000 °C in just a few tens of seconds. The wafers are held at the high temperature for only a short time and then cooled. This rapid heat treatment allows very thin layers to be grown with extreme precision and effective activation of implanted impurities with minimal diffusion.

Lithography

Lithography is the aspect of the IC fabrication process that deals with transferring onto a substrate the detailed features associated with individual components that collectively comprise an integrated circuit. The following lithographic steps must be implemented for each level of an IC fabrication schedule.

Mask Generation—A mask, or reticle, is a flat plate or a membrane that features a geometrical pattern with areas that are selectively transparent or opaque to a wavelength or a band of wavelengths used in a particular lithographic system. The pattern dimensions may be the same as the final size required in the circuit, or they may be larger by a factor N in an N:1 exposure system, where generally $N = 1$, 5, or 10. If $N > 1$, then the resolution requirements during the process of mask generation are relaxed, and less exacting equipment and techniques may be utilized to reduce costs.

The first step during mask making is the circuit layout. The goals of a good layout are to transform all designed components associated with a circuit into a geometrical layout that achieves the required packing density while keeping the parasitics small. The parasitics are those electrical circuit components that are not designed in but that inevitably originate owing to some features of a particular layout. Also, the performance of certain designs critically depends on well-matched components; therefore, such circuit elements must be laid out identically and close together.

First, the layout rules are established with the capabilities of a particular technology kept in mind. The layout may be accomplished by means of a variety of computer-aided design methodologies. All schemes utilize advanced pattern-generating capabilities. Various levels are denoted by differing colors. The geometries may be laid out explicitly or implicitly with a symbolic representation that is later converted into required geometries.‡ After the layout is completed, this information is fed into the mask-generation system. The mask generation in itself must utilize various lithographic steps, which are discussed in detail below.

TABLE 4. TEMPERATURES AND SUPPORT MATERIALS USED TO EVAPORATE VARIOUS ELEMENTS*

Element and Predominant Vapor Species	Temp (°C)		Support Materials		Remarks
	mp	$p^* = 10^{-2}$ Torr	Wire, Foil	Crucible	
Aluminum (Al)	659	1220	W	C, BN TiB_2, BN	Wets all materials readily and tends to creep out of containers. Alloys with W and reacts with carbon. Nitride crucibles preferred.
Antimony (Sb_4, Sb_2)	630	530	Mo, Ta, Ni	Oxides, BN, metals, C	Polyatomic vapor, $\alpha v = 0.2$. Requires temperatures above mp. Toxic.
Arsenic (As_4, As_2)	820	300	—	Oxides, C	Polyatomic vapor, $\alpha v = 5\times10^{-5}$ -5×10^{-2}. Sublimates but requires temperatures above 300 °C. Toxic.
Barium (Ba)	710	610	W, Mo, Ta, Ni, Fe	Metals	Wets refractory metals without alloying. Reacts with most oxides at elevated temperatures.
Beryllium (Be)	1283	1230	W, Mo, Ta	C, refractory oxides	Wets refractory metals. Toxic, particularly BeO dust.
Bismuth (Bi, Bi_2)	271	670	W, Mo, Ta, Ni	Oxides, C, metals	Vapors are toxic.
Boron (B)	2100 ±100	2000	—	C	Deposits from carbon supports are probably not pure boron.
Cadmium (Cd)	321	265	W, Mo, Ta, Fe, Ni	Oxides, metals	Film condensation requires high supersaturation. Sublimates. Wall deposits of Cd spoil vacuum system.
Calcium (Ca)	850	600	W	Al_2O_2	
Carbon (C_3, C_1, C_2)	3700	2600	—	—	Carbon-arc or electron-bombardment evaporation. $\alpha v < 1$
Chromium (Cr)	1900	1400	W, Ta	—	High evaporation rates without melting. Sublimation from radiation-heated Cr rods preferred. Cr electrodeposits are likely to release hydrogen.
Cobalt (Co)	1495	1520	W	Al_2O_3, BeO	Alloys with W; charge should not weigh more than 30% of filament to limit destruction. Small sublimation rates possible.
Copper (Cu)	1084	1260	W, Mo, Ta	Mo, C, Al_2O_3	Practically no interaction with refractory materials. Mo preferred for crucibles because it can be machined and conducts heat well.
Gallium (Ga)	30	1130	—	BeO, Al_2O_3	Alloys with refractory metals. The oxides are attacked above 1000 °C.
Germanium (Ge)	940	1400	W, Mo, Ta	W, C, Al_2O_3	Wets refractory metals but low solubility in W. Purest films by electron-gun evaporation.
Gold (Au)	1063	1400	W, Mo	Mo, C	Reacts with Ta, wets W and Mo. Mo crucibles last for several evaporations.

(Continued on next page)

TABLE 4 (CONT). TEMPERATURES AND SUPPORT MATERIALS USED TO EVAPORATE VARIOUS ELEMENTS*

Element and Predominant Vapor Species	Temp (°C)		Support Materials		Remarks
	mp	$p^* = 10^{-2}$ Torr	Wire, Foil	Crucible	
Indium (In)	156	950	W, Mo	Mo, C	Mo boats preferred.
Iron (Fe)	1536	1480	W	BeO, Al_2O_3, ZrO_2	Alloys with all refractory metals. Charges should not weigh more than 30% of W filament to limit destruction. Small sublimation rates possible.
Lead (Pb)	328	715	W, Mo, Ni, Fe	Metals	Does not wet refractory metals. Toxic.
Magnesium (Mg)	650	440	W, Mo, Ta, Ni	Fe, C	Sublimates.
Manganese (Mn)	1244	940	W, Mo, Ta	Al_2O_3	Wets refractory metals.
Molybdenum (Mo)	2620	2530	—	—	Small rates by sublimation from Mo foils. Electron-gun evaporation preferred.
Nickel (Ni)	1450	1530	W, W foil lined with Al_2O_3	Refractory oxides	Alloys with refractory metals; hence charge must be limited. Small rates by sublimation from Ni foil or wire. Electron-gun evaporation preferred.
Palladium (Pd)	1550	1460	W, W foil lined with Al_2O_3	Al_2O_3	Alloys with refractory metals. Small sublimation rates possible.
Platinum (Pt)	1770	2100	W	ThO_2, ZrO_2	Alloys with refractory metals. Multistrand W wire offers short evaporation times. Electron-gun evaporation preferred.
Rhodium (Rh)	1966	2040	W	ThO_2, ZrO_2	Small rates by sublimation from Rh foils. Electron-gun evaporation preferred.
Selenium (Se_2, Se_n: n = 1–8)	217	240	Mo, Ta, stainless steel 304	Mo, Ta, C, Al_2O_3	Wets all support materials. Wall deposits spoil vacuum system. Toxic. $\alpha v = 1$
Silicon (Si)	1410	1350	—	BeO, ZrO_2, ThO_2, C	Refractory oxide crucibles are attacked by molten Si, and films are contaminated by SiO. Small rates by sublimation from Si filaments. Electron-gun evaporation gives purest films.
Silver (Ag)	961	1030	Mo, Ta	Mo, C	Does not wet W. Mo crucibles are very durable sources.
Strontium (Sr)	770	540	W, Mo, Ta	Mo, Ta, C	Wets all refractory metals without alloying.
Tantalum (Ta)	3000	3060	—	—	Evaporation by resistance heating of touching Ta wires, or by drawing an arc between Ta rods. Electron-gun evaporation preferred.
Tellurium (Te_2)	450	375	W, Mo, Ta	Mo, Ta, C, Al_2O_3	Wets all refractory metals without alloying. Contaminates vacuum system. Toxic. $\alpha v = 0.4$

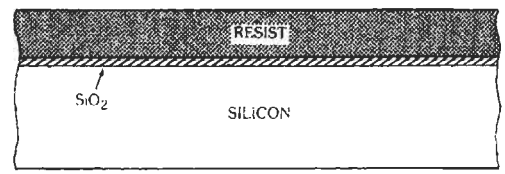
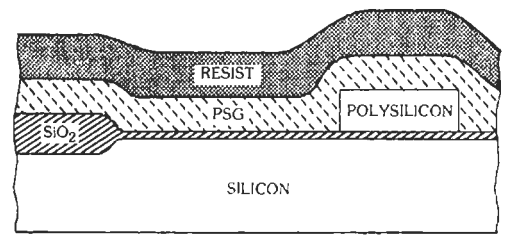
Resist Casting—The pattern on a mask is replicated on a substrate through the use of resists. Resists are organic or inorganic resins that are sensitive to a wavelength or a band of wavelengths used in a lithographic exposure system and, when exposed, undergo a chemical transformation so that selective removal can be accomplished. A resist is referred to as a positive resist if when exposed it is removed during development; it is referred to as a negative resist if when not exposed it is removable on development.

The resist application involves a thorough cleaning of the substrate to rid it of undesirable contaminants. After careful drying, the substrate is covered by a layer of resist, typically less than 3 μm thick, by spin-coating, spraying, or immersion.

The resist thickness uniformity is critical to obtaining high resolution in a lithographic system. With the advent of very-large-scale integration (VLSI), a tight line-width control has become of supreme importance. Often, the requirements of obtaining good line-width control, high resolution, and good step coverage are difficult to meet simultaneously. Good step coverage demands a thicker resist, whereas a thinner resist is necessary for good resolution. This is true for both positive and negative, as well as organic and inorganic, resists. The problem is shown schematically in Fig. 3. The resist thickness diminishes when the resist goes over steps. The effect becomes more pronounced in VLSI because of the larger ratio of line height to line width.



(A) The resist is uniform when the wafer does not have any topology.



(B) Resist thins as it goes over steps in the presence of surface features.

Fig. 3. Schematic cross sections showing details of resist-coated wafers.

Regardless of resist type, a thin coating and a flat resist surface are needed for high resolution and good

line-width control. Multilevel resist systems are being investigated to fulfill this need.* In a typical double-level resist system, a thick organic resist is first spun. This resist conforms to the wafer surface and is planar at the top. Then an intermediate layer such as SiO_2 is deposited. Now another thin coating of resist is made. This resist is capable of achieving high resolution and good line-width control. This is shown in Fig. 4.

After the resist coating is complete, an oven bake, called prebake, is carried out to drive out the solvents, increase sensitivity, and improve resistance to mechanical handling. This finishes the procedure of resist casting.

Resist Exposure—After prebake, the resist is ready for exposure. A wide variety of exposure systems are currently in production use or under development (Fig. 5).

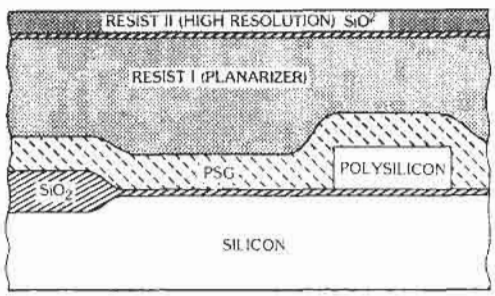


Fig. 4. Schematic cross section of a wafer coated with double-level resist system.

* Reference 10.

The contact printer refers to the scheme in which the mask is in intimate contact with the resist-covered wafer when exposure is made. Contact printers were the predominant lithographic exposure tool in production in the 1970s. They can be used reliably down to 3–4 μm geometries. In a projection printer, the mask or reticle is placed between the exposure source and the wafer to be exposed and does not make contact with the wafer. The mask image is reduced by a factor N and focused on the wafer. The scheme is suitable for high resolution. In a direct-write system, the need for a mask is completely eliminated. The resist is exposed by a finely focused particle beam that can be electrostatically scanned and blinked to form the required exposure pattern. This is inherently a slower procedure, and throughput therefore is adversely affected. Such systems, however, are uniquely suitable for mask generation.

A key feature of an exposure system is its capability to align a given level to an existing level on the wafer. This is done with the help of specially designed geometrical patterns (fiducials), which are placed on each level. When these patterns on the mask are made to overlap the corresponding structure on the wafer within reasonable bounds, a good alignment is said to have been made. The detailed features of alignment mechanisms differ, and the superiority of a particular system is partly determined by its capability to achieve alignment within tighter bounds.

Resist Development—After exposure, the resist is ready for development. Development refers to selective removal of resist as determined by the mask. It is accomplished either by immersing the wafer in a bath of developer or by spraying fine jets of developer on the wafer surface. Control of both the development time and temperature is important for reproducible

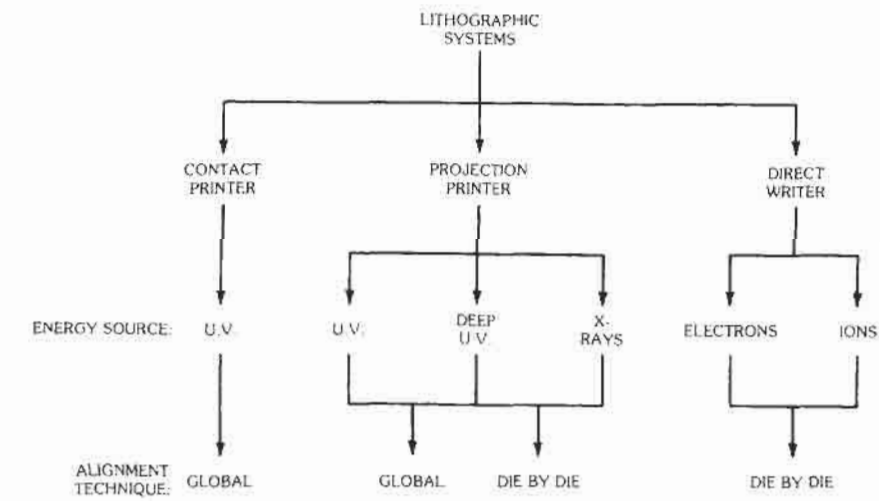

Fig. 5. Current lithographic systems.

line-width control. Fig. 6 shows schematically a positive-resist film after exposure and development. After development, the wafer is rinsed to remove all unwanted resist residues. Then the wafer is oven baked to make the resist more resistant to subsequent chemical etching (postbake). In multilevel-resist systems, only the top high-resolution resist is developed. With this resist used as a mask, the intermediate layer and thick planarizing resist must be dry etched to reveal the underlying films, as shown in Fig. 7.

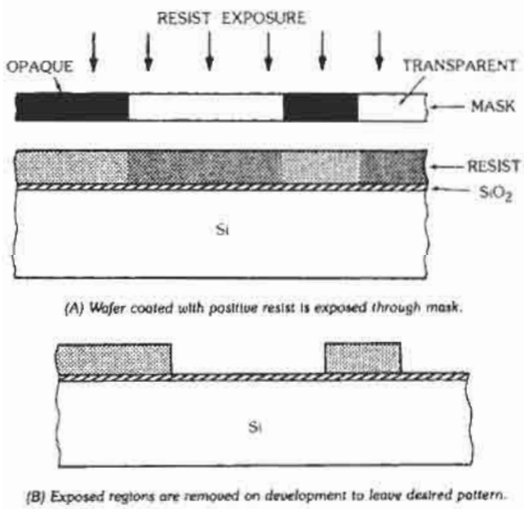
Etching

All components of an integrated circuit are made up of a selective arrangement of variously doped semiconductors, insulators, and conductors. This requires the capability to etch certain layers selectively without damaging others. The important features that determine the preferential choice of an etchant are:

(A) Etch rate
(B) Etch rate selectivity
(C) Directional selectivity

There are two prevalent categories of etchants in production use.

Wet Etching—Wet etching refers to the use of liquid chemicals. During the early days of IC development, this was the only kind of etchant in use. For many films in use, chemical etchants are available that provide acceptably controlled etch rates and high etch-rate selectivity to other layers. However, because of the very nature of the etching process, these etchants suffer from poor directional etch selectivity. Fig. 8 schematically depicts the line-width loss suffered from lateral etching with wet etches. This precludes their use in etching the narrow lines needed in VLSI. Nevertheless, for noncritical applications, such etchants find widespread use in etching resists, polycrystalline semiconductors, insulating layers such as oxides and nitrides, and metals such as aluminum. Table 5 lists etchants used in etching some common films.



(A) Wafer coated with positive resist is exposed through mask.

(B) Exposed regions are removed on development to leave desired pattern.

(C) After intermediate-layer and resist-I dry etching.

Fig. 7. Double-level resist systems.

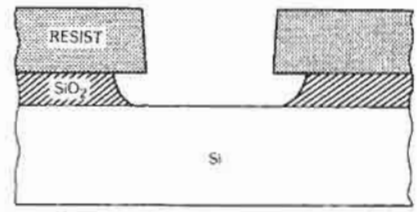

Fig. 8. Schematic cross section illustrating line-width loss from isotropic wet etch processes.

Dry Etching—Dry etching makes use of reactive plasmas to carry out etching in the gas phase.* The key advantages of this methodology are highly directional

TABLE 5. ETCHANTS USED WITH COMMON FILMS

Film	Etch	Composition	Temp. (°C)
Silicon	Planar etch	2 ml HF, 15 ml HNO_3, 5 ml CH_3COOH	25
Polysilicon	Iodine etch	50 ml HF, 100 ml HNO_3, 110 ml CH_3COOH, 0.3 g I_2	25
Silicon dioxide	Bell 2 etch	54 ml H_2O, 36 ml NH_4F, 10 ml HF	25

etch anisotropy and the facility to penetrate small resist openings; these make it suitable for etching the small geometries encountered in VLSI. By suitably adjusting the constituents and proportions of etchant species, a good etch-rate selectivity to other layers is achieved. Plasma etching of resists, SiO_2, Si_3N_4, Al, Poly-Si, and metal silicides is in extensive use in the industry today. Fig. 9 shows schematically small geometries etched through a resist mask. A list of gases commonly used for plasma etching is given in Table 6.*

Damascene Processing—The continued increase in speed and size of ICs has resulted in a change from the traditional aluminum metallization and SiO_2 interlevel metal insulation to copper metallization and lower dielectric constant insulators (called "low-k" insulators). The copper provides lower resistivity for the wires that interconnect individual transistors. The lower dielectric constant insulators provide reduced capacitance on these wires. Both of these factors decrease the RC delay of signals on the lines and therefore increase the speed capabilities of the circuits. The shift from aluminum/SiO_2 to Cu-low k has resulted in an alternative to the conventional thin film deposition, resist pattern application, and etching process sequence. This new process sequence is called damascene processing. In this process sequence the dielectric is deposited first, and the areas where copper conductors are desired are removed by the conventional resist application and etch process. This leaves the dielectric with trenches in a pattern desired for the copper metallization. The thick layer of copper metal is deposited to fill the trenched areas as well as depositing over the surface of the dielectric. The entire surface of the wafer is then polished by a chem-mechanical polishing process (called CMP) to remove the surface layer of copper, leaving the desired conducting wires only in the trench regions, separated by the low-*k* dielectric insulator. There are

many details and variants of damascene processes that may be found in the references.

Substrate Doping Procedures

All semiconductor devices rely on selective doping of various areas, either n-type or p-type, to a required concentration and depth. There are three predominant techniques of introducing dopants in a controlled manner.

Predeposition and Drive-In—The geometries to be doped are lithographically defined on the substrate in a mask layer such as oxide or nitride that is impervious to the given dopant. Then the wafers are exposed to the dopant source, which may be a gas, solid, or liquid, in a well-controlled furnace at high temperature. An inert gas such as nitrogen or argon is used as a carrier for the dopant species.

The doping density in the substrate is a function of predeposition temperature and time and is given by the equation

$$N(x,t_p) = N_s \operatorname{erfc}\left[x/2(D_p t_p)^{1/2}\right] \qquad \text{(Eq. 1)}$$

where

N is the doping density at a distance x below the surface,
t_p is the predeposition time,
D_p is the diffusion constant,
N_s is the surface concentration.

The surface concentration is usually equal to the solid solubility. The solid solubility and diffusion constant of common impurities in silicon are shown in Figs. 10 and 11.*

The total number of dopants introduced in the substrate per unit area is obtained, by integrating Equation 1 over the depth, to be the dose

$$Q_p = 2N_s(D_p t_p/\pi)^{1/2} \qquad \text{(Eq. 2)}$$

After the predeposition cycle, wafers are generally loaded in a different furnace at a higher temperature to drive in the impurities to obtain a required junction depth. A passivating layer such as an oxide is initially either grown or deposited on the wafers to prevent the escape of impurities. A redistribution of impurities takes place, and the doping density as a function of drive-in time is given by

$$N(x,t_d) = \left[Q_p/(D_d t_d)^{1/2}\right] \exp(-x^2/4D_d t_d) \qquad \text{(Eq. 3)}$$

where

t_d is the drive-in time,
D_d is the diffusion constant at the drive-in temperature.

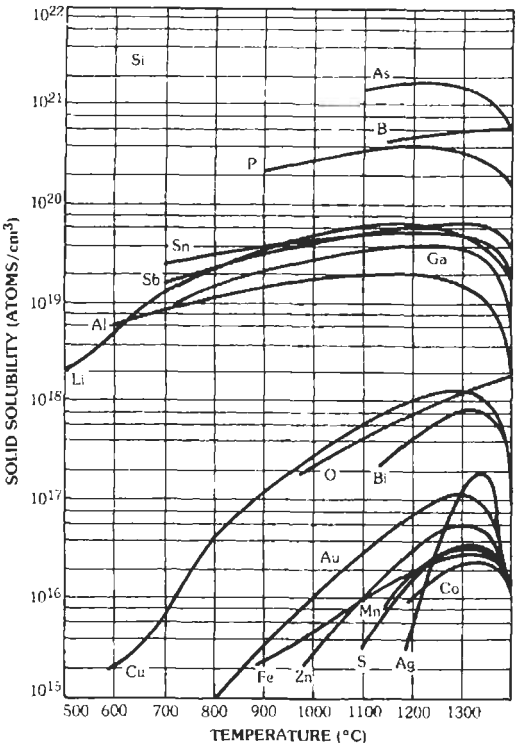

Fig. 10. Solid solubility of elements in silicon. (From F. A. Trumbore, "Solid Solubilities of Impurity Elements in Germanium and Silicon," *The Bell System Technical Journal*, Vol. 39, Jan. 1960, pp. 205–233. © 1960, AT&T; reprinted with permission.)

Equation 3 can be used to calculate the resulting junction depth if the background concentration is known.

Diffusion from Doped Oxides—Because of the solubility of the dopant at the surface, the standard two-step diffusion process is not suitable for obtaining shallow junctions of low doping concentration, as required in a number of applications. One alternative is to use doped glass as a diffusion source.† Doped glass containing the required doping can be either chemically deposited at low temperature and low pressure or spun-coated on the wafer surface. The impurities are then driven in at a higher temperature. By limiting the dopant concentration in the doped oxide, shallow junctions with low doping density can be realized.

Doping by Ion Implantation—There are certain limitations associated with the diffusion processes that can be overcome by ion implantation. Ion implantation is a technique of extracting dopant species from a source, separating the required ions from other spurious particles, accelerating them to the required energy,

(B) Acceptor impurities.

Fig. 11. Diffusion constant in silicon. (From A. S. Grove, *Physics and Technology of Semiconductor Devices*, New York: John Wiley & Sons, Inc., 1967.)

and embedding them in the substrate. The implantation energy determines the impurity concentration. To a good approximation, the implanted ions settle with a gaussian distribution given by Reference 15:

$$N(x) = (Q/\sqrt{2\pi}\Delta R_p)\exp -\tfrac{1}{2}\left[(R_p - x)/\Delta R_p\right]^2 \quad \text{(Eq. 4)}$$

where

$N(x)$ is the dopant concentration at a distance x below the surface,
Q is the ion dose,
R_p is the ion range,
ΔR_p is the range straggle.

The values for R_p and ΔR_p as a function of implant energy are available in published tables. Table 7 gives values for usual dopants in silicon.*

With this technique, it is possible to exercise a tight control on both the depth and the concentration of dopants, which is of prime importance in VLSI. By choosing multiple implant energies and doses, a variety of intended profiles can be approximated. The ion implantation is followed by a thermal anneal, which activates the dopants and anneals out the crystal damage produced by the process.

An IC Process Example—NMOS Process

The information presented above can best be consolidated by illustrating an IC fabrication process. For this purpose, we have chosen to discuss NMOS technology, whose typical basic process flow can be illustrated with the help of Fig. 12.

The starting material is p-type silicon in wafers that are carefully cleaned and thermally oxidized in steam to obtain an SiO_2 thickness of 300 Å. An LPCVD Si_3N_4 is now deposited to a thickness of 2000 Å. Next, the isolation regions are defined by using a moat mask as shown in Fig. 12A. Sequentially, dry plasma etching of nitride and oxide is carried out, with resist protecting the areas not to be etched. Resist is removed by J100 wet etch, and a low-energy boron implant is made that raises the p-type doping density in the opened windows but does not penetrate through the nitride and oxide stack, as illustrated in Fig. 12B. Slices are then cleaned and thermally oxidized in steam to oxidize the exposed regions to obtain an SiO_2 thickness of 7000 Å; nitride prohibits oxidation of other areas, as shown in Fig. 12C. Nitride is now wet etched in hot phosphoric acid, and an unmasked boron implant is made to adjust the threshold voltage of enhancement-mode devices, as shown in Fig. 12D.

The depletion-mode-device region is defined by a second mask in order to adjust the threshold voltage of depletion-mode devices. An arsenic implant dopes the exposed silicon areas n-type near the surface. This is

* Reference 16.

shown in Fig. 12E. The slices are now carefully cleaned, a high-quality 500 Å thermal oxide is grown in dry oxygen to serve as the gate insulator, and a 5000 Å LPCVD polycrystalline silicon layer is deposited. This polysilicon layer is doped heavily n-type (n+) by phosphorus diffusion; the wafer cross section at this step is shown in Fig. 12F. The polysilicon gate regions are patterned with a third mask and dry etched, as shown in Fig. 12G. The resist is wet etched, and a heavy arsenic implant is made that converts regions not covered by polysilicon or thick oxide to n+ type, as depicted in Fig. 12H.

A 7000 Å phosphosilicate glass (PSG) is deposited on cleaned wafers and patterned with a fourth mask, and the doped glass is dry etched to open contact areas, as shown in Fig. 12I. Resist is removed by wet etching, and the wafers are cleaned and subjected to a temperature greater than 900 °C, which causes the doped glass to flow so that all edges are smooth. Now a 10 000 Å aluminum film is evaporated or sputter deposited (Fig. 12J). A fifth mask patterns the aluminum interconnect, aluminum is dry etched, and resist is removed by wet etch (Fig. 12K). After careful clean-up, the aluminum is sintered at 450 °C in H_2 to promote good ohmic contacts. A 3000 Å layer of plasma nitride is now deposited (Fig. 12L). A sixth mask defines the bonding-pad regions, where the coated nitride is plasma etched to allow access to the bonding pads. The wafers are cleaned, and this finishes the fabrication process.

The circuits are tested for functionality and then diced. Good dies are bonded in appropriate packages, retested, and shipped to customers.

Yield Statistics

Only a fraction of a large number of chips on a silicon wafer are completely functional. Defects in the masks, dust particles on wafer surfaces, nonideality of the basic silicon material, and short or open circuits in the wiring all cause some of the circuits to be nonfunctional. With present design techniques, any single defect of sufficient size will kill an entire chip.

The simplest model for the yield, or the fraction of chips that do not have defects, assumes a random defect distribution across the wafer. If there are D fatal defects per unit area and the area of an individual chip

consequence of various steps involved in an NMOS process.

is A, then the probability that a chip has n flaws is, in the simplest case, given by the Poisson distribution $P_n(DA)$. The probability of a good chip is:

$$P_0(DA) = e^{-DA} \qquad \text{(Eq. 5)}$$

While this equation is not rigorously applicable to fabrication processes, it is a good approximate model for estimating the yield of various design alternatives.

IC DESIGN*

The design of integrated circuits requires the synthesis and analysis of a large number of active elements. The classical form of analysis can be extended to integrated circuits, whereas the focus of synthesis goes beyond the classical notions inasmuch as the geometric layout of the circuit topography for integrated circuits is a major fraction of the circuit synthesis. The electrical aspects of circuit design derive from the considerations that are laid out in Chapter 18, with certain constraints based on the scale of integration. The design of the circuit topography is unique to integrated circuits and has evolved as a major discipline.

Modeling and Simulation

The design of integrated circuits requires the electrical analysis of circuits that contain a large number of elements. For LSI or VLSI circuits, this involves the simulation of up to tens of millions of circuit elements if the total circuit response is to be examined. The evaluation of this class of circuits is extremely computer-intensive. In most cases, it is not practical to simulate the circuit with classical time- or frequency-domain analysis at the transistor level. The current practice for simulation and analysis of such classes of circuits is to adopt a hierarchical procedure with different levels of abstraction at each level. The design of an LSI logic circuit would involve a typical modeling hierarchy such as that in Chart 1.

The top of the hierarchy is an abstract definition of the architecture of the circuit, which is used to provide a guideline for the various ways of accomplishing the objective of the circuit. It trades off, for example, the use of pipeline processing versus serial processing. The behavioral level of simulation actually involves the definition of the major blocks of the circuit and their interaction, with the details of the overall data or control flow to accomplish the objective of the chip being examined. The functional level actually describes the overall logical response of the major blocks, relating the logical inputs and outputs with no details of internal realization of logic in the block. The logic-simulation level details the realization of each block at the gate level, provides logic minimization, and in some cases introduces the notion of relative timing. The transistor-level simulation considers the transient response of the circuit, including the detailed simulation of all elements of the circuit. The key to the usefulness of this hierarchical simulation is the ability to mix the different levels of abstraction to examine the performance of the entire circuit with focus on one block at a time. Such mixed-mode simulators are being evolved, and common hardware-description languages that operate on a unified data base that is accessed by any level of the hierarchy are now available.

Topological Realization of Circuits

The design of integrated circuits differs from the design of board-level circuits in the importance of the actual physical realization of the active elements and interconnections. Typical LSI circuits have many thousands of active elements and interconnections that must be topologically related to each other. This requires the interaction of the device physics, process technology constraints, and topological constraints. To obtain a practical solution to this complex interactive design environment, it is generally accepted practice to describe the process constraints in the form of a design rule package. This design rule package is a simple description of the lateral spatial relationship of the various active-element forming geometries as well as the wiring. A simple example of design rules is shown in Fig. 13. The original concept of the design rules was governed by the constraints of the technology only. However, the design data base for the geometrical description of the circuit for VLSI circuits is very large, and some constraints that limit the size of this data base have been introduced into the design rules.† This is simply a quantization of the minimum spatial distance describing any technology constraint. This kind of quantization is equivalent to the definition of the finest grid on which a geometry must fall.

There are two major approaches to the realization of the geometrical data base for an IC. The first is the classical approach in which the complete drawing of each individual section is introduced into the data base in detail. This is a tedious and inefficient way of generating data. The preferred approach to data entry is through a symbolic description of the layout in which the definitions of the often-used elements are

* Reference 9.

† Reference 9.

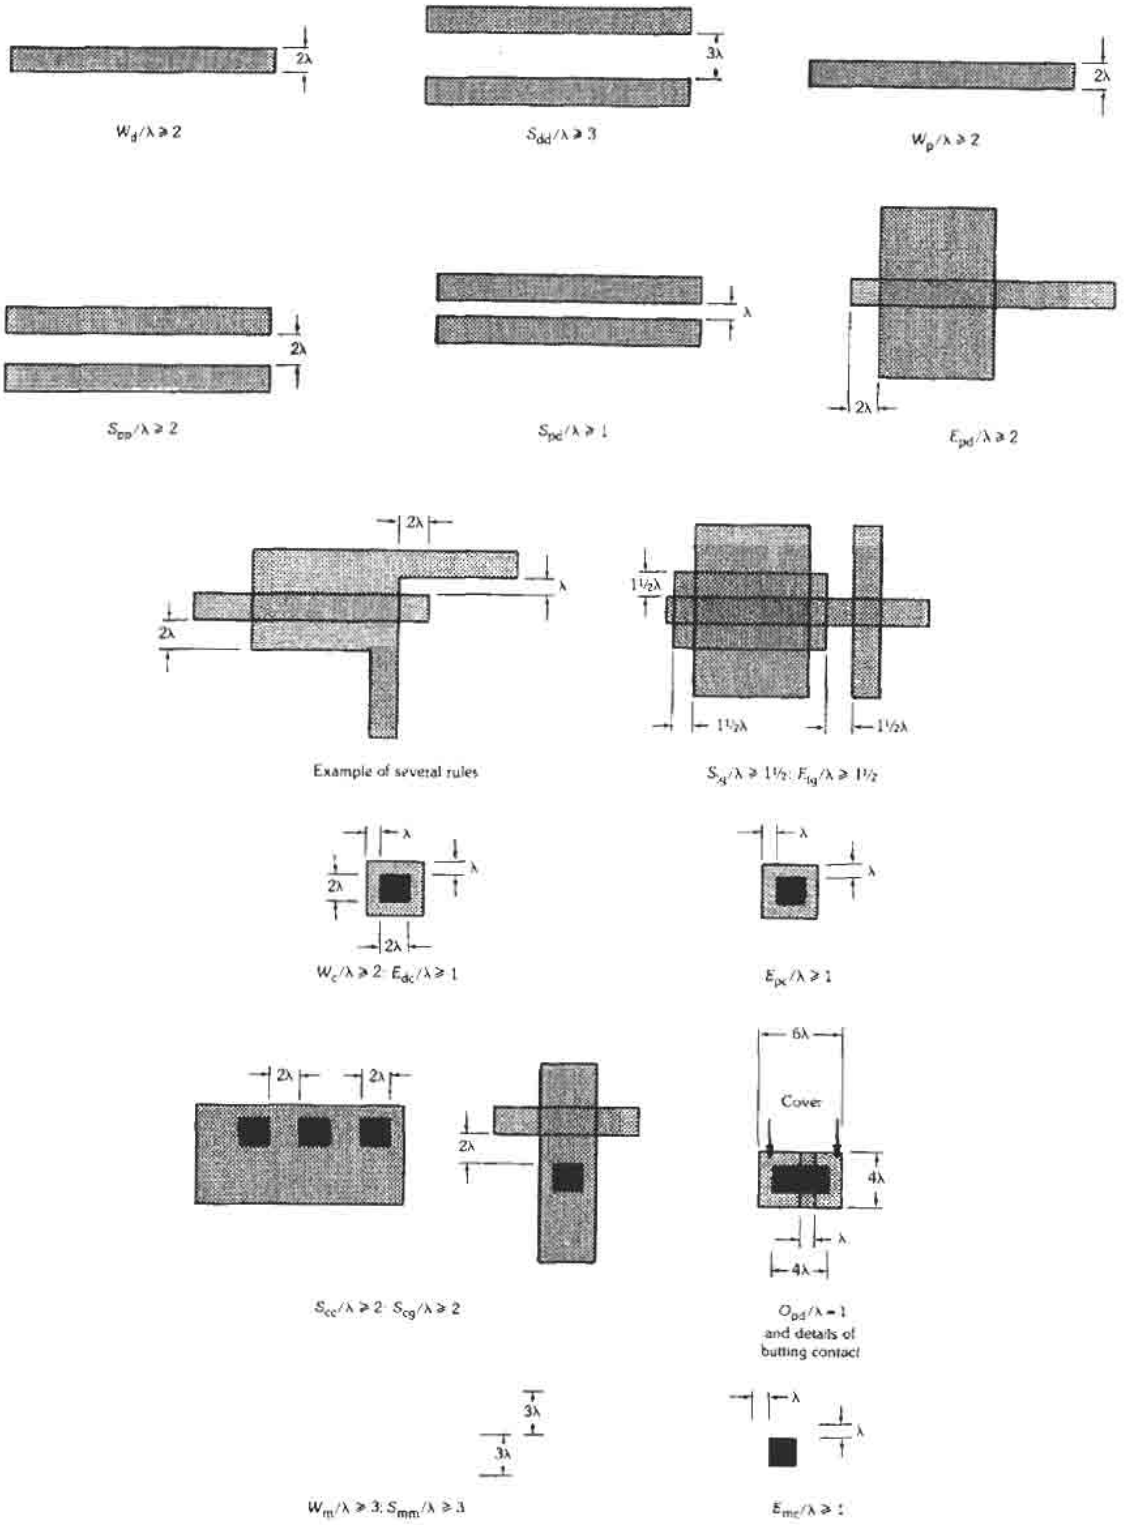

Fig. 13. An example of a design rule set. (From C. Mead and L. Conway, *Introduction to VLSI Systems*. Reading, MA: Addison-Wesley Publishing Co., Inc., 1980.)

built into the system and the designer calls up such elements and strings them together on a graphic entry system. These symbols are a modified description of the circuit elements much like the drawing of a classical circuit schematic (Fig. 14). The design rules are then used to generate automatically the full two-dimensional geometrical description from the symbolic description. The symbolic layout system is very efficient and suffers only from a 10–20% reduction of the packing density of circuit elements compared to a detailed customized input of the complete geometries. In an attempt to reduce this gap, software compaction of the design data base has been developed. The connection of geometries on a layout data base is another aspect of integrated-circuit design that has been traditionally inefficient. Automatic wire-routing software developed for multilayered printed circuit boards has been adapted for this purpose and is being used. The use of artificial-intelligence concepts in the realization of more efficient routing algorithms is under investigation.

Once the design data base has been created, the design task is to verify the validity of the data base geometrically and electrically. The geometric verification is a checking of all geometries for design-rule violations. This is achieved routinely by all layout systems through software analysis of the data base. The electrical validity of the geometrical data base involves the extraction of the electrical circuit schematic and the comparison of the electrical schematic to the various levels of hierarchy of the initial design. This upward feedback through the hierarchy is of crucial importance to the design cycle and requires the design and geometric data bases to be compatible. It is currently common practice to extract electrical schematics and parasitic resistances and capacitances from the layout data base and compare them to the design data base. The comparison occurs at the transistor level.

Various integrated design systems with the above functions are currently available.

PACKAGING INTEGRATED CIRCUITS

The standards for packaging integrated circuits and for allocation of functions to pins for the purposes of interchangeability are set by international committees EIA/JEDEC (Electronic Industries Association) and IEC (International Electrotechnical Commission). There are two major kinds of specifications for each type of package: mechanical and thermal. A variety of package types exist, the most popular of which will be described.*

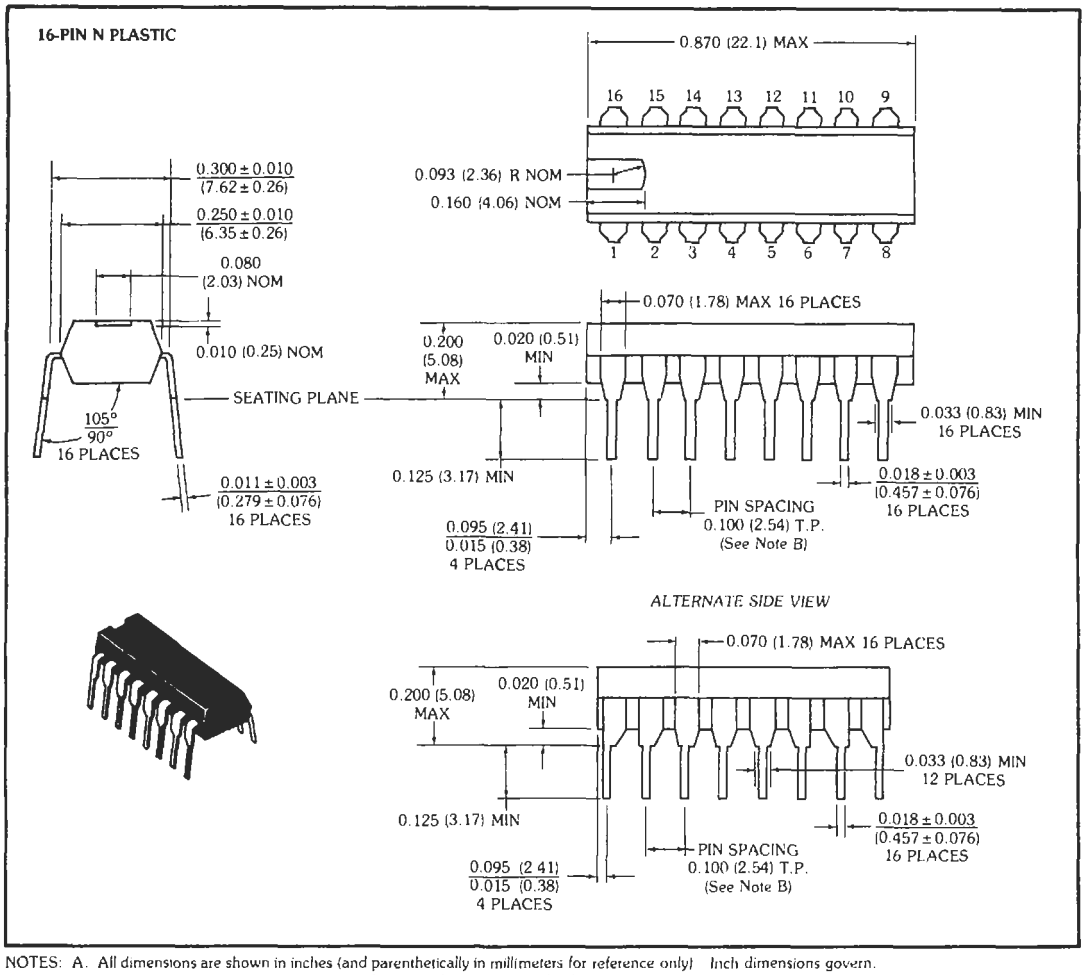
Plastic Packages

Plastic dual-in-line packages consist of a circuit mounted on a 16-, 18-, 20-, 24-, or 28-pin lead frame and encapsulated within an electrically nonconductive plastic compound. The compound will withstand soldering temperature with no deformation, and circuit performance characteristics remain stable when the device is operated in high-humidity conditions. These are the lowest-cost packages for integrated circuits. An example of a 16-pin plastic package is shown in Fig. 15.

Ceramic Packages

Another type of dual-in-line package is hermetically sealed and consists of a ceramic base, a ceramic cap, and a 16-, 18-, 20-, 24-, 28-, or 48-lead frame. Hermetic sealing is accomplished with glass. These devices are divided into two categories: side-braze and frit seal. An

* Details of packages can be found in integrated-circuit data books.



NOTES: A. All dimensions are shown in inches (and parenthetically in millimeters for reference only). Inch dimensions govern.
B. Each pin centerline is located within 0.010 (0.26) of its true longitudinal position.

Fig. 15. Dual-in-line plastic packaging for integrated circuits. (From *TTL Data Book*, 2nd ed. Dallas, TX: Texas Instruments, Inc., 1976; p. 4-6.)

example of the mechanical dimensions of a 16-pin dual-in-line ceramic package is shown in Fig. 16.

Ceramic Flat Package

Hermetically sealed ceramic flat packages consist of an electrically nonconductive ceramic base and cap and a 16- or 24-pin lead frame. An example of the mechanical dimensions of such a package is shown in Fig. 17.

Leadless Ceramic Chip Carrier

Leadless ceramic chip-carrier packages are emerging as the most popular for LSI and VLSI chips because of their board-level density advantage. An example of a 36-pad leadless ceramic chip carrier is shown in Fig. 18.

Flip-Chip Package

Flip-chip packages attach an IC to a chip carrier by placing solder balls on the interconnect pads and bonding the chip face down ("flipped") on the surface of a chip carrier or circuit board. The advantage of the flip-chip packaging approach is that it can be done with pads over the entire surface of the chip, all of the bonds can be done at one time, and the cost can be reduced by preparing the chips for final packaging in wafer form. This last item allows the use of the usual low-cost IC mass production techniques to replace some serial, more costly, packaging operations. Flip-chip packaging

is just being introduced into manufacturing, but it promises to rapidly advance in applications.

Thermal Resistance

The most important system specification of an IC package is its ability to conduct heat, since the IC dissipates power in the package. The thermal properties of a package are specified as a thermal resistance. Junction-to-ambient thermal-resistance values of dual-in-line packaging systems are shown in Fig. 19. This figure of merit is used to relate the internal chip temperature to the ambient system temperature.

DIGITAL INTEGRATED CIRCUITS

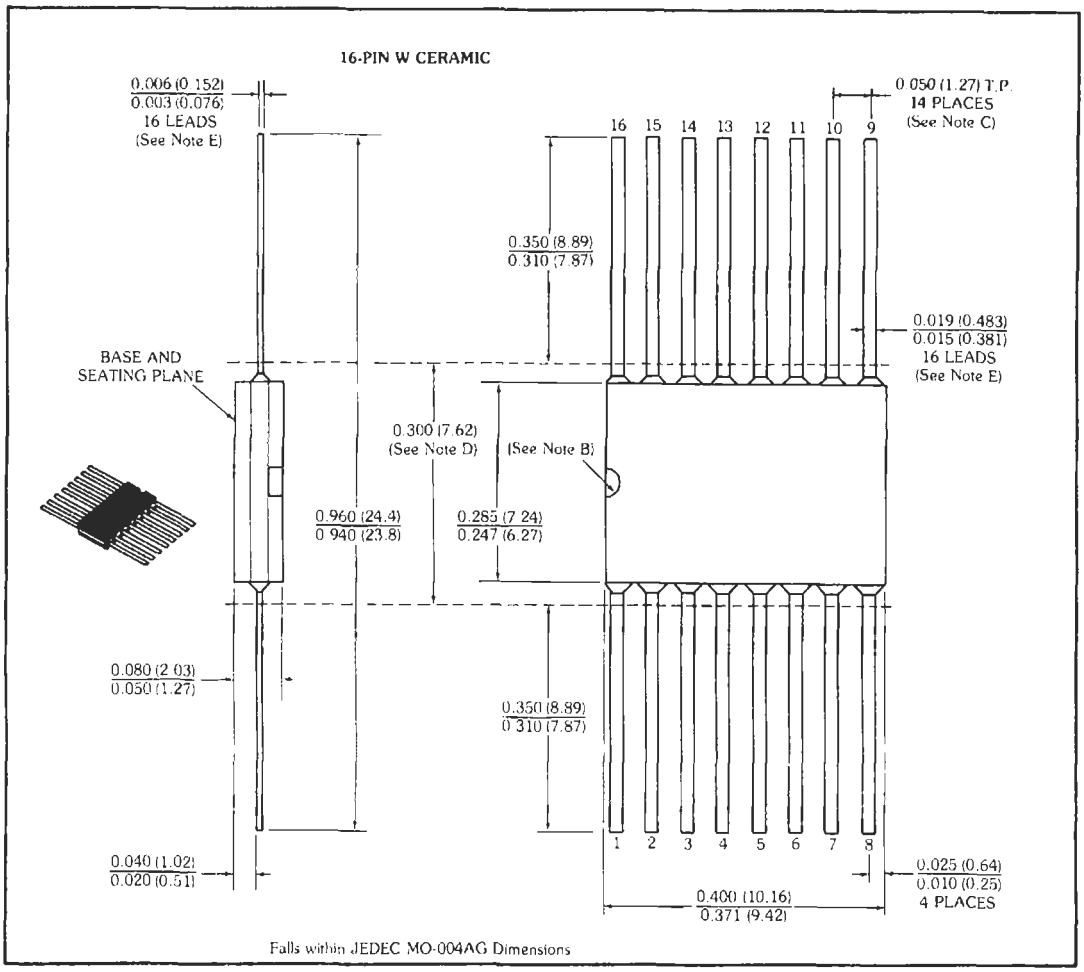
Digital logic functions can be realized in many different configurations. The traditional logic realization used resistors or diodes in conjunction with a transistor. This approach has been replaced in the current integrated circuits by the use of active transistors mostly, since these can be realized most efficiently in the technology. The logic realization is dependent on the property of the transistor used and will be categorized differently for bipolar and field-effect transistors.

The implementation of logic-integrated circuits requires the definition of the voltage, current, and timing standards. These have been defined in Table 8. A very large variety of digital logic circuits spanning SSI, MSI, LSI, and VLSI is commercially available. The various manufacturers' data books and applications books should be consulted for detailed information.

Bipolar Logic Families

Bipolar logic functions are commercially available as SSI and MSI circuits, and they are being developed for LSI and VLSI circuits. The different families described here are graded from the most popular SSI and MSI standard logic to the more advanced families used for LSI and VLSI.

Transistor–Transistor Logic (TTL)*—The most widely used logic family for SSI and MSI logic is transistor–transistor logic. A broad spectrum of TTL circuits are available that allow logic designers to optimize all portions of a system cost effectively.



NOTES: A. All dimensions are shown in inches (and parenthetically in millimeters for reference only). Inch dimensions govern.
B. Index point is provided on cap for terminal identification only.
C. Leads are within 0.005 (0.13) radius of true position (T.P.) at maximum material condition.
D. This dimension determines a zone within which all body and lead irregularities lie.
E. Not applicable for solder-dipped leads.
F. When solder-dipped leads are specified, dipped area extends from lead tip to within 0.050 (1.27) of package body.

Fig. 17. Ceramic flat packaging for integrated circuits. (From *TTL Data Book*, 2nd ed. Dallas, TX: Texas Instruments, Inc., 1976; p. 4-10.)

The basic schematic of generic TTL logic is shown in Fig. 20. This arrangement utilizes the base-emitter diodes and collector-base diode of the multiemitter transistor for logic and the output transistor for drive. This is very easily realized in planar bipolar technology. Although the basic TTL circuit consists of two transistors, additional components are necessary to increase circuit speed and fan-out capability (Fig. 21). Two major classes of TTL logic exist. These are called 54XX and 74XX series TTL. The 74XX series is a limited-temperature (0 °C to +70 °C) IC, and the 54XX series is a full-military-temperature (–55 °C to +125 °C) IC. A classification by low power and high speed in addition to the standard series exists.

An improvement in the TTL performance is achieved by the addition of a Schottky barrier diode that permits the transistor to operate in the nonsaturated mode; this reduces storage time and improves speed. Initially, the Schottky TTL was developed for high speed. Further evolution of the Schottky technology led to the low-power Schottky TTL family in

which Schottky diodes replace the multiemitter transistor as the input element. The Schottky TTL circuits are shown in Fig. 22.

Table 9 defines the voltage and current standards of various TTL logic families. Table 10 shows the performance characteristics of different TTL families.

Emitter-Coupled Logic (ECL)—The highest-speed, lowest-noise bipolar logic family is emitter-coupled logic. It is also known as current-mode logic (CML), since the circuit works on a current-steering principle. It is designed as a nonsaturating form of logic, which eliminates transistor storage time as a speed-limiting characteristic. The typical ECL gate shown in Fig. 23 comprises a differential-amplifier input, an internal bias reference, and an emitter follower output to restore dc levels. High-fan-out operation is possible because of the high input impedance of

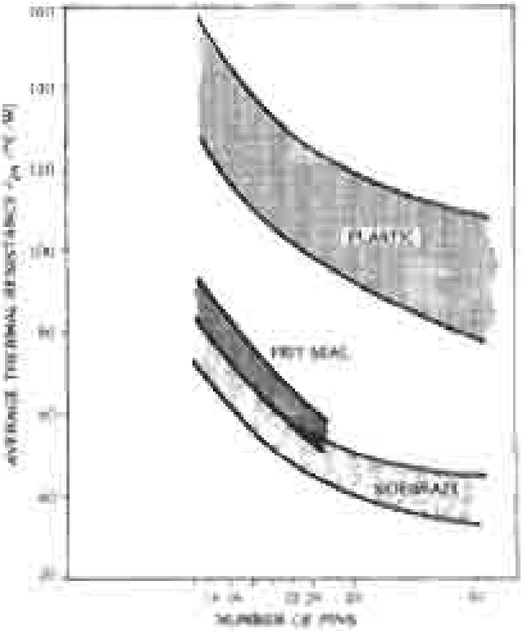

Fig. 19. Typical thermal resistance for various packages. (From *Motorola CMOS Data*, 1978, p. 5-3.)

TABLE 8. DEFINITIONS OF LOGIC STANDARD TERMINOLOGY

Parameter	Definition
V_{CC}	Most positive power supply voltage for a circuit
V_{BB}	Bias reference supply voltage
V_{EE}	Most negative power supply voltage for a circuit
V_{IH}	High (1) level input voltage
V_{OH}	High (1) level output voltage
V_{IK}	Input clamp voltage
V_{IL}	Low (0) level input voltage
V_{OL}	Low (0) level output voltage
V_{T-}	Negative-going threshold voltage
V_{T+}	Positive-going threshold voltage
V_O (off)	Off-state output voltage
V_O (on)	On-state output voltage
I_{IH}	High (1) level input current
I_{OH}	High (1) level output current
I_{IL}	Low (0) level input current
I_{OL}	Low (0) level output current
I_O (off)	Off-state output current
I_{OZ}	Off-state (high impedance state) output current of three-state output
I_{OS}	Short-circuit output current
I_{CC}	Supply current

the differential amplifier and the low output impedance of the emitter follower. Power-supply noise is virtually eliminated by the nearly constant current drain of the differential amplifier even during transition time. The logic-voltage standards for ECL are shown in Table 11. Note that CML circuits tend to adopt TTL voltage standards. Typical gate speed for ECL logic ICs is 2 ns at 100 mW power dissipation for commercially available circuits.

Integrated Injection Logic (I^2L)*—Integrated injection logic (I^2L), also known as merged transistor logic (MTL), is a bipolar logic comparable in density

and power dissipation with dynamic MOS logic. It is an LSI- or VLSI-caliber bipolar logic family. The basic I^2L gate is shown in Fig. 24. The basic cell is made up of a multiemitter NPN transistor operated in the inverted mode and a lateral PNP transistor whose base and collector are common to the collector and base of the first transistor. For logic operation, the PNP transistor is used both as an injector of base current for the NPN transistor in the same cell and as a current-source load for an NPN transistor in an adjacent cell. The operation of the basic cell as an inverter can be understood as follows. When V_{in} is high, all the current from the PNP transistor is used up by NPN transistor T_1 operating in the saturated mode, and no current is left for the base of NPN transistor T_2. Hence V_{O1} is low and V_{O2} is high. When V_{in} is low, the opposite situation applies. Typical gate delays of 5 ns per gate at 0.2 mW have been achieved at 2-micron geometries. Many advances based on self-aligned structures are being made that are enhancing the performance of this logic family.

Schottky Transistor Logic (STL)*—Schottky transistor logic, also called Schottky coupled transistor logic (SCTL) and complementary constant current logic (C^3L), is a generic diode transistor logic (DTL) implemented with Schottky logic diodes and a single NPN switch transistor. Fig. 25 shows a three-output STL gate. For relatively high-gain transistors ($h_{fe} > 10$)

and fan-out limited to one per logic diode, the signal-voltage swing is shown to be the difference in the Schottky-diode forward voltages. The STL characteristics are compatible with the supply voltages, power density, and speed requirements of VLSI circuits. Typical on-chip gate speeds of less than 2 ns at 10 μW of power are achievable with 2-micron technology.

MOS Logic Families*

There are two classes of MOS logic families, based on the operation of the logic: (A) static, or ratioed, logic and (B) dynamic, or ratioless, logic. The realization of these two classes of logic is further described by technology type: p-channel (PMOS), n-channel (NMOS), and complementary (CMOS). The unique feature of a MOS technology is the symmetric nature of the MOSFET. This has been utilized in logic circuits by the use of a pass transistor as shown in Fig. 26. The signal flow can be interrupted by the use of such a series switch when the switch is turned off. In the on state, the switch allows signal flow in either direction.

Static, or Ratioed, Logic—The generalized schematic of a static, or ratioed, logic gate is shown in Fig. 27A. It consists of a load device and a driver device or several driver devices that can be switched to perform a logic function. The ideal characteristic for a load device is a constant-current source. The typical device realization of the load in a PMOS or NMOS technology is an active depletion-type transistor with the gate and source connected as shown in Fig. 27B. The typical load line achieved by this technique is shown in Fig. 28. Note that the nonideal behavior is due to the change in the depletion-mode-device threshold voltage with source-to-substrate bias, commonly known as the body effect. This static circuit has a logic high level determined by the power-supply voltage, since the driver device is switched off in this state and only draws subthreshold current. The logic low level is determined by the ratio of the load current and the on current of the driver device. This ratio is a function of the threshold and aspect ratio of the load and the driver device defined as the beta ratio of the inverter. This is the most important design parameter for ratioed static logic.

$$\text{Beta ratio} = \frac{(\text{Width/Length})_{\text{driver}}}{(\text{Width/Length})_{\text{load}}}$$

The load current is constantly turned on in this circuit for the depletion load realization as in PMOS or NMOS. This causes a static power dissipation in one logic state. The static logic has the advantage of being totally asynchronous and requires no clock pulses. The power dissipation is drastically reduced by the use of CMOS technology (Fig. 27C). The load is a p-channel

* Reference 9.

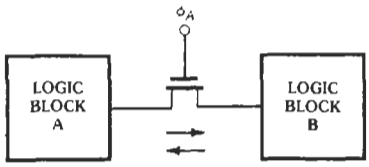

Fig. 26. Pass transistor in MOS logic.

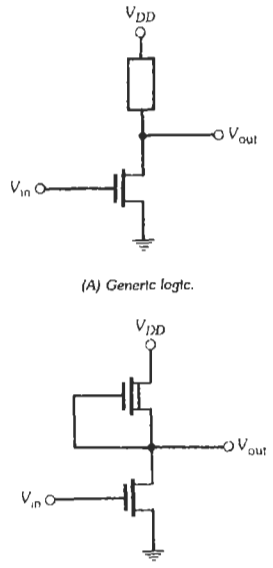

Fig. 27. Static, or ratioed, logic.

transistor, and the driver is an n-channel transistor. The CMOS inverter or logic gate draws power only during state transition. Note also that the CMOS static inverter has an inherently large ratio since one device is in the subthreshold regime in each state.

Dynamic, or Ratioless, Logic—The use of dynamic, or clocked, logic for MOS circuits is very attractive for low-power synchronous applications. Examples of dynamic logic gates realized in NMOS and CMOS technology are shown in Fig. 29. The use

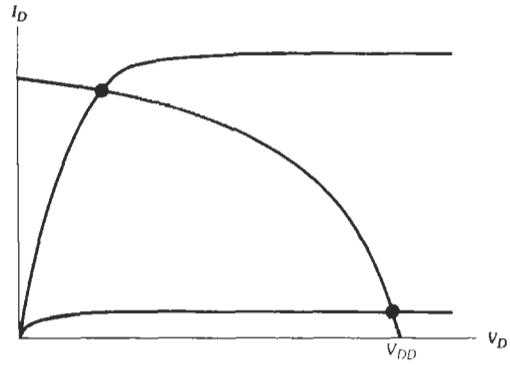

Fig. 28. Typical load line achieved with depletion load.

of two-phase clocks in synchronous systems is standard practice. The timing of these clocks is shown in Fig. 29A. The ϕ_A clock turns on the active load and precharges the output node to the supply voltage independent of the state of the input. The ϕ_B clock discharges the output only if the input logic combination is appropriate. This time-multiplexed logic is possible if the leakage rate through the clocked transistors does not discharge the output stage within a clock period. This scheme requires the generation of a two-phase clock for NMOS and PMOS circuits. However, for the CMOS circuit (Fig. 29B), single-clock operation is possible. The advantages of dynamic logic are the low power required and synchronous operation. It is assumed that the clock propagation speed on-chip is faster than the clock period. This requirement tends to limit the overall gate speed for a given technology.

Microprocessors and Minicomputers*

The implementation of logic in integrated circuits in the decade of the 1960s relied on providing building blocks that integrated unique functions. A major breakthrough in logic implementation was provided in the early 1970s by devices that controlled logic operations with a stored program. These devices made complete computing systems possible with a minimum number of ICs. A simplified block diagram of a microcomputer is illustrated in Fig. 30. The complete computing system consists of input/output (I/O), a central processing unit (CPU), and memory sections for the program and data. In early microcomputers these elements were all separate, and in most cases each element consisted of several different ICs. The function of each of these sections is as follows.

I/O section—The lines at the left of the I/O section shown in Fig. 30 connect the computer to the input and output devices, and receive instructions from the CPU.

* References 20 and 21.

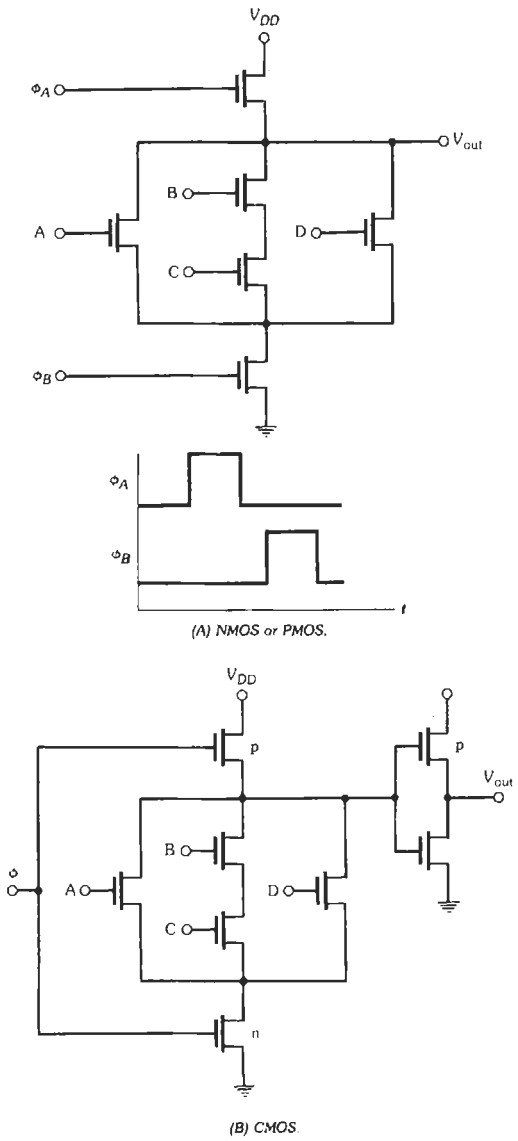

Fig. 29. Dynamic logic.

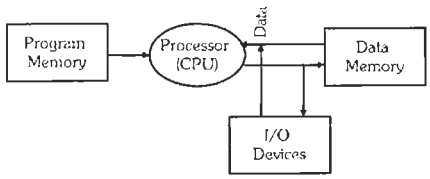

Fig. 30. Simplified block diagram of a computer system. (From H. Corporaal, *Microprocessors Architectures: From VLIW to TTA*. West Sussex, England: John Wiley & Sons, Inc., 1998.)

A simplified diagram of a typical I/O section is shown in Fig. 31. Input and output multiplexers (MPX or MUX), also known as data selectors, perform selection of the I/O devices. Output information is stored in the output buffers. The I/O register provides temporary storage during the transmission of information between the CPU and I/O sections.

CPU—The heart of this type of computer is the central processing unit, usually called the CPU. The CPU is the part of the computer that controls all the other parts. Designs vary widely but, in general, the CPU consists of the control unit, the arithmetic and logic unit (ALU) and memory (registers, cache, RAM and ROM) as well as various temporary buffers and other logic. The control unit fetches instructions from memory and decodes them to produce signals that control the other parts of the computer. This may cause it to transfer data between memory and ALU or to activate peripherals to perform input or output. A parallel computer has several CPUs that may share other resources such as memory and peripherals. The term "processor" is sometimes used in place of "CPU." Fig. 32 shows a

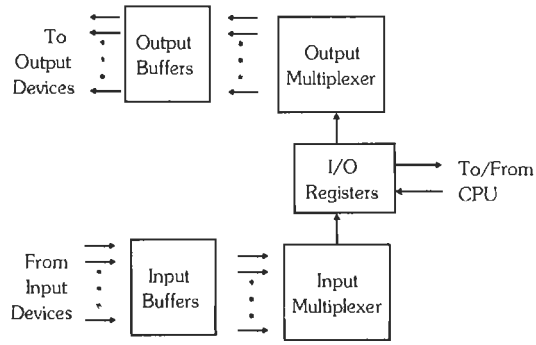

Fig. 31. Typical I/O section. (From R. Henle and B. Kuvshinoff, *Desktop Computers*. New York: Oxford University Press, Inc., 1992.)

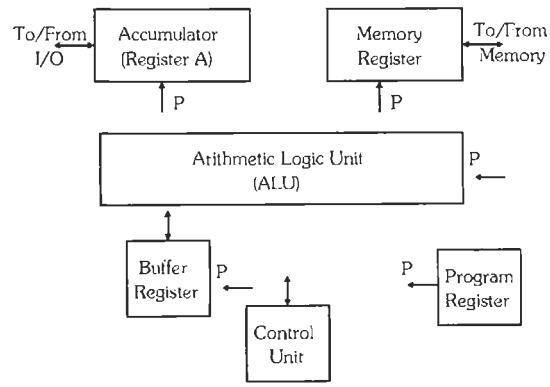

Fig. 32. The CPU. (From R. Henle and B. Kuvshinoff, *Desktop Computers*. New York: Oxford University Press, Inc., 1992.)

block diagram of the components of a very simple CPU. The connection between the arithmetic logic unit (ALU) and the accumulator and other registers determines the number of bits that the ALU can process in parallel. This is called the word length of the CPU. Word lengths of 32 and 64 bits are not uncommon. The ALU performs arithmetic operations, such as addition and subtraction, and logic operations, such as detection of equality. The CPU uses several registers as data registers, working registers, and scratch pad memory (A and B); these help in storing intermediate results and communicating with the I/O section and memory sections (M). A specific register (P) acts as the program counter and determines the operation sequence for the system. The program counter gives specific sequence instructions as it steps up during execution of the program. The control unit provides direction for the computer operation.

Memory—There are two sections for memory in a typical computer, one for data and one for instructions for what to do with the data, called the program. The I/O section and CPU contain several temporary storage registers for data in the form of digital information. The majority of the data, however, is stored in the Data memory. The details of memory functions will be discussed in the section on memory integrated circuits. The operations that transform the data have to be specified in a form that is directly "understandable" by the CPU. This language is called machine language, and a program written in this language is stored in the Program memory. When data is entered into the CPU, the set of operations defined by the program is performed on the data, and then the data is either returned to the Data memory, transferred to the I/O section, or both.

Available Microprocessors—A microprocessor is a computer whose entire CPU is contained on one (or a small number of) integrated circuits. The important characteristics of a microprocessor are the widths of its internal and external address bus and data bus (and instruction), its clock rate, its instruction set, and its available memory.

The first commercial microprocessor was the Intel 4004 that appeared in 1971. This was the CPU member of a set of four integrated circuits called the MCS-4, which was originally designed for use in a calculator but was marketed as a "programmable controller for logic replacement." The 4004 is referred to as a 4-bit microprocessor since it processed only 4 bits of data at a time (the word length). This very short word size is due mainly to the limitations imposed by the maximum integrated circuit density then achievable.

As integrated circuit densities increased with the rapid development of integrated circuit manufacturing technology, the power and performance of the microprocessors also increased. This is reflected in the increase in the CPU word size from the original 4 bits in 1971 to 64 and even 128 bits by the end of the century. The smaller microprocessors have relatively simple instruction sets, e.g., no floating point instructions, but they are nevertheless suitable as controllers for a very wide range of applications such as car engines and microwave ovens.

The Intel 4004 was followed with over ten generations of Intel microprocessors, with current devices being called Pentium III and Pentium IV class devices. Many other manufacturers of microprocessors have also become prominent. The larger, more recent microprocessor families have gradually acquired most of the features of large computers. As the microprocessor industry has matured, several families of microprocessors have evolved into de facto industrial standards with multiple manufacturers and numerous "support" chips including RAM, ROM, I/O controllers, etc. A single chip microprocessor may include other components such as memory (RAM, ROM, PROM), memory management, caches, floating-point unit, input/output ports, and timers.

In the early 1990s the Semiconductor Industry Association (SIA) began developing a roadmap for integrated circuit features and characteristics. This roadmap, now called the International Technology Roadmap for Semiconductors (ITRS), is updated each two years, and identifies the technological challenges and needs facing the semiconductor industry over the ensuing 15 years. This roadmap has been instrumental in identifying the desired performance of integrated circuits, particularly memories and microprocessors, and providing a set of challenges for the research community. A sample of the 2000 ITRS update for expected microprocessor performance for the next several years is shown in Table 12.

TABLE 12. MICROPROCESSOR CHARACTERISTICS*

Year of Production	1999	2001	2003	2005	2008	2011	2014

* Ref. *2000 International Roadmap for Semiconductors.*

A sampling of available microprocessor characteristics as of the year 2000 is shown in Table 13. These features compare well with the projections in Table 12.

It is clear from Tables 12 and 13 that the microprocessors of today will be significantly overshadowed by those of the future. In many respects, these microprocessors make the one-chip microcomputer a landmark development in computer technology because they reduce the computer to a small, inexpensive, and easily replaceable design component.

MEMORY INTEGRATED CIRCUITS*

The major advantages of semiconductor memories are that they can utilize the most advanced technology and they are required in very large volumes in all systems so that they provide the economies of scale in the learning process for the maturing of the technology in time. The large volume of memory integrated circuits thus acts as a catalyst in the timely development of the technology it uses and thereby allows increases in yield and decreases in unit costs, which in turn propels an increase in volume. The progress in the density of memories has been phenomenal because of this synergism between the system pull for more memory at low cost and the technology push via geometry scaling that allows improved bit density, improved performance, and decreased cost. Fig. 33 shows the actual and projected progression of memory integration vs. feature size over a 30-year time frame. There seem to be no fundamental physical roadblocks to prevent devices from being produced at least down to the 25nm feature size. The slight slowing of the growth is an indication of the substantial technological hurdles that must be overcome for very small device geometries.

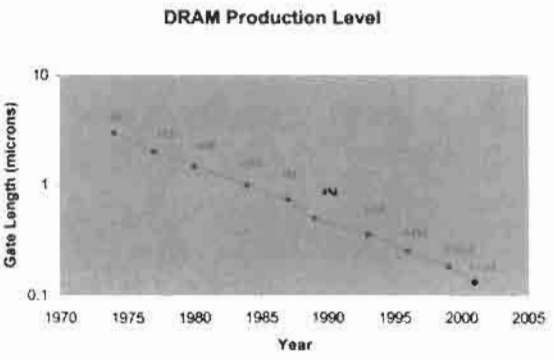

Fig. 33. DRAM density vs gate length and year. (after Iwai et al., *Microelectronics Engineering*, Vol. 28, 1995, p. 147.)

Semiconductor memories are classified according to their function as read-only memories (ROM) or random access memories (RAM). The use of serial access memories has been attempted, but has not been accepted due to both cost and performance limitations. Memories are also classified as static and dynamic. The static memories are able to hold data as long as power is applied (and sometimes even without power), while dynamic memories need to have each memory element periodically refreshed to retain data. The dynamic memories generally have smaller cell sizes, so are preferable for very high-density applications. The highest density memories are dynamic random access memories, called DRAM. Table 14 illustrates

the ITRS projections for these memory features over the next several years.

Externally, memory chips typically require the application of a binary address input to locate the information. A set of control or mode-setting signals is needed to tell the memory to read or write, and the memory circuit provides the desired information after a time interval that is called the access time for the memory. Memories are organized to provide either one bit of data at a time or one byte of data at a time. The choice of the data word is a system partitioning function. In addition, other system options such as power-down modes are common. Many different memories are available that fall into the categories described here. The various manufacturers' data books and applications books should be consulted for detailed information.

Read-Only Memories (ROM)

Read-only memories have information programmed into them during manufacture. They act as tables of data that can be accessed by the system at any time. This class of memories is extremely useful in the storage of programs, operating systems, fixed utilities for a system, etc.

The read-only memory function is realized by the use of single transistors as memory cells connected in an X-Y matrix as shown in Fig. 34. The gate of each transistor is turned on by an X address signal, and the current through the transistor is monitored through the Y address line. The programming of the memory results in the presence or absence of the transistor in a specific location. This may be done at various points in the fabrication process. The presence of current through the transistor is detected as a 1, and the absence of current is detected as a 0. Note that the memory cell in a ROM is a single transistor. Further, only a read function is required. For this reason, ROMs are the densest semiconductor memories.

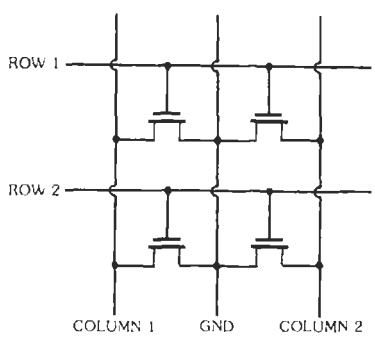

Fig. 34. A 2 × 2 ROM memory-cell array.

Nonvolatile Read-Only Memories

Nonvolatile read-only memories may be classified as "read-mostly memories." They are programmable after manufacturing. They are referred to as nonvolatile because they retain data even when no power is applied. Three subclasses of nonvolatile ROMs exist. The first is a programmable read-only memory (PROM), which can be electrically programmed. The second is an erasable and programmable read-only memory (EPROM), which can be programmed by electrical signals but erased only by exposure to ultraviolet light. The third is an electrically erasable and programmable read-only memory (EEPROM).

Generally, PROMs are constructed with bipolar technology. A simple 2 × 2 array of bipolar PROM cells is shown in Fig. 35. Programming is accomplished by applying a sequence of 20–30 mA current pulses to blow a fusible link.

Both EPROMs and EEPROMs are generally constructed by the use of MOS technology. The physical mechanism by which these memory cells store data is a storage of charge in the gate insulator of a MOSFET. This has been accomplished by two categories of transistor structures, shown in Fig. 36. The first structure incorporates multiple dielectric layers (Fig. 36A). The most common version of the multiple-insulator structure is the MNOS (metal-nitride-oxide-silicon) transistor. The oxide layer in contact with the silicon surface is very thin (2–3 nm). The charge is injected from the substrate into the nitride layer, by way of hot electron

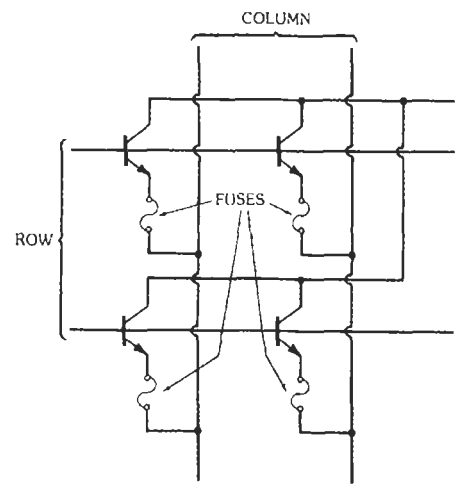

Fig. 35. A 2 × 2 array of bipolar PROM cells. (From G. D. Kraft and W. N. Toy, *Mini/Micro Computer Hardware Design*. Englewood Cliffs, NJ: Prentice-Hall, Inc., 1979; p. 97.)

tunneling through the thin oxide. The charge is trapped in the nitride layer, which generally has a large trap density. The band gap of silicon dioxide is larger than that of nitride, and thus the charge is unable to flow back into the silicon. This presence of charge in the insulator alters the threshold of the transistor, thus changing the transconductance and causing a differential in the current through the transistor in the presence or absence of charge. This is read much the same way as the ROM cell.

The second structure that achieves the same purpose is the floating-gate transistor (Fig. 36B). The charge is injected into the floating gate from the silicon by the application of the proper electric field. The charge on the floating gate provides the change in threshold voltage. The floating-gate structure has been used in both EPROMs and EEPROMs, since the floating gate acts as an equipotential surface and can be biased with a reversed electric field to result in an erase function. The control of the floating-gate process is easier than the control of the MNOS process, and most of the nonvolatile memories are fabricated this way. There are various subclasses of the floating-gate structure that are based on the biasing scheme or the injection mechanism used for the program and the erase modes.

Random-Access Memories (RAM)

A random-access memory is one in which data may be written in or read out at very high speed. The bit or set of bits into which data may be written is chosen randomly in an *X-Y* matrix. There are two types of random-access memories, static and dynamic. Static memories retain data indefinitely while power is applied to the chip; dynamic memories retain data for a short period of time, after which they must be refreshed. The system overhead associated with the refreshing of the memories is offset by the fact that dynamic memories are four times denser than static memories at the same design rules.

Static RAM—Static RAMs are realized from a memory cell with a bistable circuit. A simple flip-flop is commonly used for the memory cell, as shown in Fig. 37. Note that this can be constructed with either bipolar or MOS technology. The bipolar versions have traditionally been faster than the MOS versions. However, the bit density of MOS sRAMs has been larger than for bipolar versions. The important elements of the cell are the load (M_1, M_2) and the cross-coupled driver

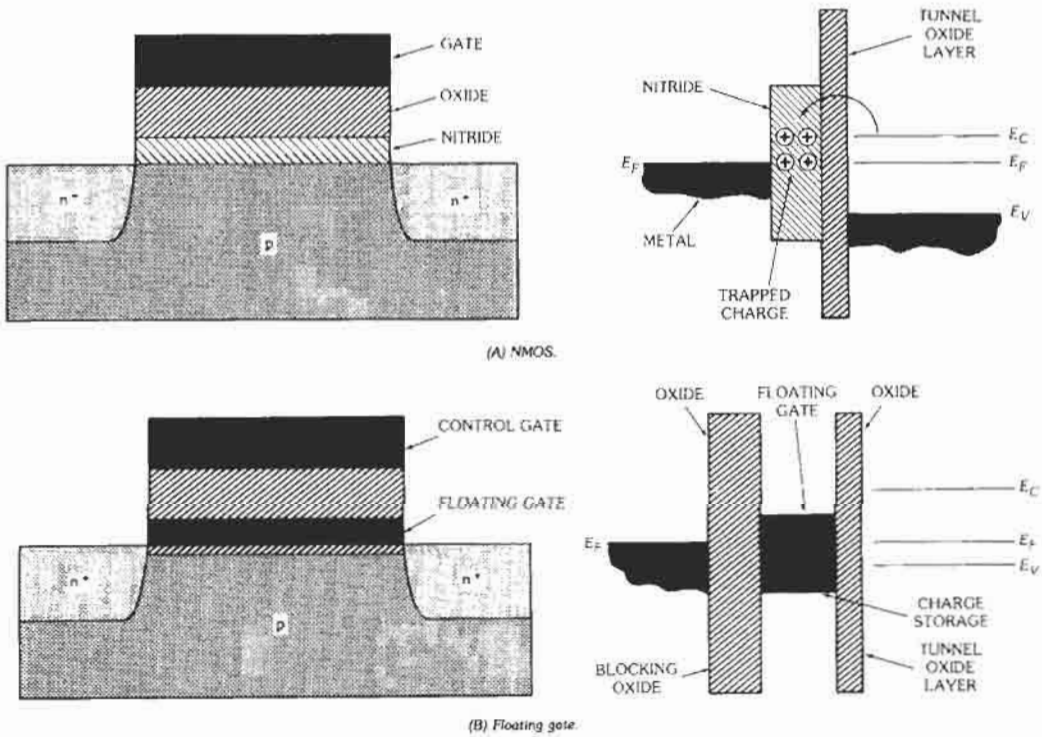

Fig. 36. Transistors for EPROM and EEPROM memories.

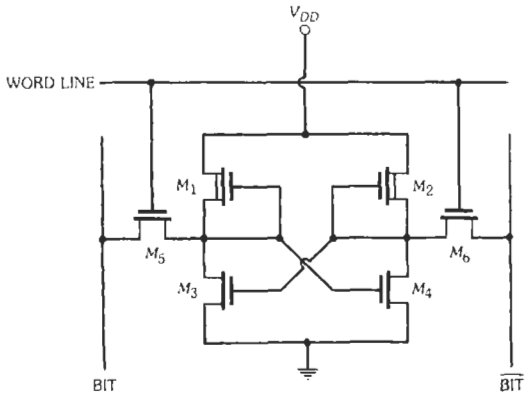

Fig. 37. A static RAM cell.

devices (M_3, M_4) that form the bistable latch. The access transistors (M_5, M_6) are used to address the cell. The major considerations in the design of an sRAM cell are power, speed, and data hold. The power in the cell is proportional to the load current. The load element has been realized as a depletion MOSFET in 4K-bit memories. However, it has been replaced by high-impedance resistors realized by undoped polysilicon, or by subthreshold current in a short-channel MOSFET, for higher-density memories. The sRAM cell with lowest power is realized from complementary MOS technology. These memories can hold data with extremely low power (50–1000 nW) and are being used with batteries as low-cost alternatives to nonvolatile memories in some systems. Because of the large number of elements and connections to the memory cell, static RAMs tend to be lowest in bit density per chip among semiconductor memories. However, the differential cell provides a large signal-to-noise ratio and very high-speed operation. Bipolar memories are all static and have demonstrated access times below 10 ns.

Dynamic RAM—Dynamic RAMs are constructed commercially with MOS technology only, and they represent the largest-volume, most widely used semiconductor memory. The memory is physically realized by the storage of charge on an MOS capacitor that is accessed by a MOSFET, as shown schematically in Fig. 38. The data bit is stored as a charge packet on the MOS capacitor. Since the MOS capacitor is not an ideal element and has nonzero leakage, it is discharged through these leakage mechanisms as a function of time. The design of dynamic RAMs is thus critically dependent on the reduction of leakage in the MOS capacitor. This requires the realization of very long carrier lifetimes in the semiconductor and very high crystalline quality. The signal-to-noise ratio depends on the ratio of the storage capacitor to the capacitance of the digit or bit line on which the charge is dumped when the cell is accessed. As the bit density per chip grows, this ratio is degraded, since the cell area is

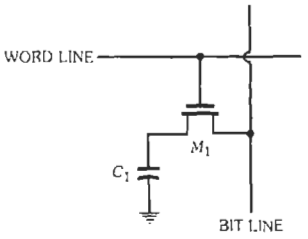

Fig. 38. The one-transistor/capacitor dRAM cell.

decreased and more cells are added on the bit line. It is thus important to store as high a voltage as possible on the cell capacitor and increase its capacitance per unit area as much as possible. The sensing of this small signal is one of the most difficult circuit design problems, and rather elaborate dynamic circuit techniques have been developed for the purpose.

New Developments

The growth of all the above-described memories following the scaling of MOSFET technology is on an evolutionary path. The state-of-the-art memories in the development stage include up to 2 gigabits of ROM and 2 gigabits of dynamic RAM. The memory market for all sectors except static RAM has been dominated by MOS technology and will continue to be so. However, the bipolar memories have had a strong edge in speed in the past. One-micron MOS static RAMs are speed-competitive with bipolar memories. However, the bipolar memories are significantly more radiation hard and will tend to have major applications in hostile environments.

LINEAR INTEGRATED CIRCUITS*

Unlike digital integrated circuits, which respond to and produce two-state logic signals, linear ICs give an output signal that can be made to vary linearly with respect to a varying input signal. Since linear ICs can be used in a variety of applications and new designs appear regularly, standardization of circuit elements as in the case of digital ICs is impractical. Several important families of linear ICs have evolved. They include the device categories described below. The various manufacturers' data books and applications books should be consulted for detailed information.

Differential Amplifier

The basic differential amplifier consists of two identical input transistors connected to respond to the difference between two input signals while simultaneously

* References 23, 24, 25, 26, and 27.

blocking the identical part of these signals. This common-mode rejection is useful in noisy environments. The amplifier may consist of a single stage or two stages and usually has a low-impedance output stage. The output is also differential. These amplifiers are typified by a wide bandwidth (dc to VHF), moderate gain (less than 1000 times) and moderate common-mode rejection ratio (CMRR) (50 dB). Internal feedback is provided for linearity control, and external feedback is difficult to apply without severely degrading the bandwidth. Applications include linear amplification, mixers, product detectors, amplitude modulators, frequency multipliers, voltage-controlled oscillators, and disk or tape memory read amplifiers.

Operational Voltage Amplifier

The basic operational amplifier, or op amp, is a dual-input differential amplifier followed by one or more direct-coupled gain stages and a low-impedance output stage. The typical op amp exhibits very high voltage gain at dc (80 to 120 dB) and a unity-gain bandwidth of 1 to 20 MHz. The op amp may be internally compensated, i.e., 100% negative feedback can be applied externally without oscillation problems, or pins may be provided to tailor the compensation for the application. Pins may also be provided to adjust the input offset voltage. Op amps are commonly made with a bipolar process but may have JFET or MOSFET input stages. Complete CMOS designs are also available.

Any op amp can be connected as shown in Fig. 39 to provide a linear voltage gain equal to R_f/R_{in}, provided the op amp is ideal and properly compensated. The ideal op amp would have the following characteristics:

1. A negligibly small differential input voltage can produce any desired output.
2. The input currents are negligibly small.
3. The output impedance is zero.

Application of these rules to negative-feedback circuits such as in Fig. 39 immediately leads to the ideal transfer function. No existing op amp has these ideal characteristics, but many come close to meeting one or more of them. A variety of op amps are available with emphasis on perfecting different properties such as low noise, low input-voltage offset, low input current, high slew rate, single-power-supply operation, and large power-supply-range operation.

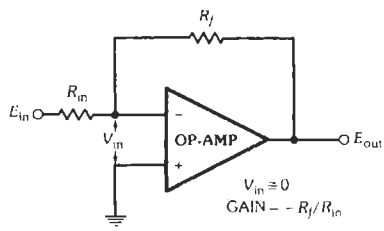

Fig. 39. Inverting dc amplifier.

The op amp was originally designed to perform such mathematical operations as integration, differentiation, comparison, summation, multiplication, and others. Though op amps are still used in these applications, complete ICs performing these functions are available. The use of various types of external feedback networks permits a vast array of additional applications. Accordingly, the op amp is the most versatile of linear ICs, and its circuit applications include analog-to-digital conversion, peak detection, averaging, function generation, oscillator and pulse circuits, biological function amplification, voltage-controlled oscillator circuits, automatic gain control, voltage comparators, active filters, precision diodes, sample-and-hold circuits, and numerous others. Many of these complete circuits in turn are available in IC form.

Fig. 40 summarizes some of the elementary op-amp circuit configurations and gives ideal formulas that describe the circuit performance. The op amp is used in a number of modes besides the basic operational one, such as a high-impedance buffer to minimize loading in RC filters or to compress the nonlinearity of other devices by the op-amp open-loop gain for voltage comparison.

Other Amplifiers

The operational transconductance amplifier (OTA) provides an output current in response to a voltage input. The OTA bias current controls the transconductance, and considerable control over the performance of an OTA is possible. The operating characteristics make the OTA usable in a wide variety of circuits such as multiplexers, sample-and-hold circuits, gain controls, modulators, multipliers, comparators, multistable circuits, and (with the addition of an output stage) high-gain op amps.

The current-differencing amplifier, or "Norton" amplifier, provides a voltage output proportional to the difference of two input currents. It is especially suited for single-power-supply operation without loss of common-mode range. Again, a large variety of circuit functions can be obtained.

Voltage Reference

Although classified under linear ICs, the voltage reference is a highly nonlinear device and provides a constant output voltage almost independent of input voltage, load current, temperature, and time. Output voltages range typically from 1.22 volts to 10 volts with a precision of 0.05% to 5%. Temperature coefficients range from 100 parts per million down to 0.5 ppm. Output current capabilities are less than 10 mA. Both fixed-output-voltage and programmable-output-voltage devices are available.

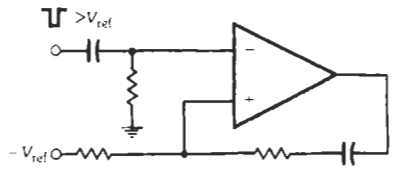
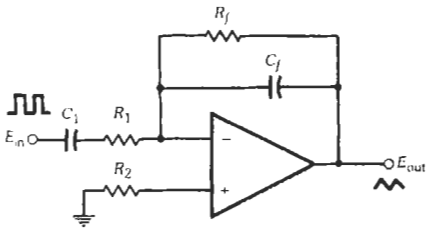
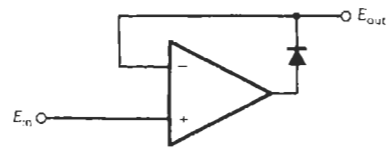
(E) Integrator.



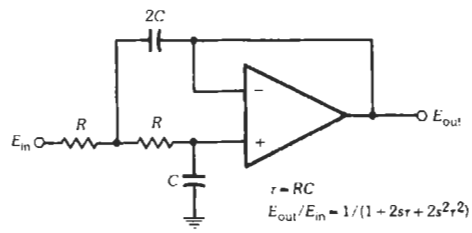
(F) Monostable multivibrator.



(G) Sweep generator.



(H) Precision diode.



(I) Low-pass filter.

Fig. 40. Simple ideal op-amp circuits.

Reference diodes also come in IC form and simulate the characteristic of a zener diode, but with a much sharper breakdown characteristic.

Some applications are amplifier biasing for temperature independence, constant-current-source circuits, level detectors, and low-voltage regulators.

Voltage Regulators

Bipolar voltage-regulator ICs incorporate a voltage reference and a sense amplifier and maintain the output voltage at a value almost independent of load, input voltage and ripple, and temperature. Both fixed- and programmable-output-voltage units are made. Voltages up to 50 volts can be regulated. Current capability is usually on the order of tens of milliamperes, and the IC is intended as the driver for large-pass transistors that can accommodate the higher currents and operating temperatures that occur in power supplies. External components for current limiting, noise reduction, and compensation are desirable additions in the design of a complete power supply.

Comparators

The voltage comparator is a differential amplifier design with a small delay time between the application of a differential input signal and the output transition. The output swing is made compatible with TTL inputs. Emphasis is placed on low-input bias current and its offset and low-input offset voltage, and the usual amplifier specifications are of lesser importance. Common applications are high-speed analog-to-digital converters, fast zero-crossing detectors, tape- and disk-file read channels, and differential line receivers.

Special-Purpose Linear Integrated Circuits

Since any circuit that can be assembled from discrete semiconductor components can almost always be duplicated or simulated with monolithic IC technology, a great many special-purpose ICs exist. These include custom designs for use in various kinds of commercial products as well as a wide range of off-the-shelf numbered units. The commercial units include such devices as music synthesizers, phase-locked loops, tone decoders and encoders, function generators, programmable filters, FM and video demodulators, IF detectors, subcarrier regenerators, AGC, FM stereo demultiplexers, AM-receiver functional blocks, timers, audio and power amplifiers, voltage-to-frequency converters, analog-to-digital and digital-to-analog converters, instrumentation amplifiers, and sample-and-hold circuits.

Though many of the ICs are dedicated to a specific application or function, the addition of a few external components can often result in a wide range of additional applications. The list of special-purpose linear ICs grows constantly, and the design engineer is well advised to consult current manufacturers' data and application literature.

Miscellaneous Linear ICs

Other useful building blocks are timers, transistor–diode arrays, digitally controlled analog pass-gates, optical isolators, bar or dot LED-display drivers, and analog shift registers.

TRENDS IN INTEGRATED CIRCUITS

Scaling and Miniaturization

The explosive growth of integrated circuits has been fueled by the ability to scale the minimum lithographic dimensions of an integrated circuit. This results in a threefold advantage:

1. Increase in density of circuit elements per chip
2. Increase in circuit performance due to increased device gain and reduced load capacitance
3. Decrease in cost per function, which provides economic incentive

The most significant improvement in integration complexity has been achieved in MOS circuits. An exponential growth of the number of circuit elements in time has been noted. This has been made possible by the simple scaling laws that relate the scaling of vertical and lateral dimensions to the scaling of doping and voltages. Table 15 shows three sets of scaling laws that have been used to various degrees. The first assumes that the electric field in the device must be held constant. The second is based on complying with currently set voltage standards, and the third proposes a change in the voltage standards only when the electric field is high enough to cause problems as the result of secondary effects. Another scaling theory has been proposed on the basis of the off-state switching behavior of MOS devices. Scaling of bipolar devices does not proceed along scaling laws because the base width that is the critical dimension is much smaller than all other dimensions. Scaling of bipolar technology is aimed at reduction of parasitic device capacitance.

Scaling of ICs has proceeded unabated for the past two generations, despite several predictions along the way that the "end of scaling is imminent." These predictions proposed unbreakable roadblocks along the way at minimum IC feature sizes of 1.0 micron, 0.5 micron, 0.25 micron, and smaller. In each case, ingenuity and hard work have overcome critical roadblocks. At the present time, manufacturing is occurring at 0.15-micron feature sizes, and 0.1-micron feature sizes are fully anticipated in manufacturing in 2005. The "end of scaling" is still being predicted, but at feature sizes in the .02 micron range.

Integration complexity in ICs has also benefited greatly from improvements in process equipment and

TABLE 15. DEFINITION OF SCALING LAWS

Scaling Law	Constant Field	Constant Voltage	Quasi-Constant Voltage
Dimensions (λ)	λ	λ	λ
Gate Oxide (λ_O)	λ	$\sqrt{\lambda}$	λ
Doping (λ_N)	λ	λ	λ
Voltage (λ_V)	λ	1	$\sqrt{\lambda}$

Full-scale ($\lambda = 1$) values of $L = 3\ \mu$m, $t_{ox} = 500$ Å, $N_A = 2.5 \times 10^{15}$ cm^{-3} are used.

process understanding over the past decades. This has allowed much larger silicon area to be used for a single IC, while still attaining acceptable yield and therefore acceptable cost. This trend to bigger chips is continuing even with reduced feature size to provide the continuing increases in functionality demanded by expanding applications. The decision between continued reduced feature size and increasing chip area is expected to be totally cost based.

Image-Sensing ICs

The application of solid-state devices to high-resolution imaging began in earnest with the invention of the charge-coupled device (CCD) at Bell Laboratories in 1969. Many approaches to the solid-state imaging problem have been undertaken. These approaches may generally be divided into three distinct areas: (1) memory arrays, (2) charge injection devices (CIDs), and (3) charge-coupled devices (CCDs). Memory arrays, as the name implies, are simply solid-state memory devices that have been packaged in a format that allows an image to be placed on the area that is the usual memory array. The primary advantage of the memory-array approach to solid-state imaging is the fact that these devices are *X-Y* addressed as well as being process compatible with other memory components. The primary disadvantage of this approach to solid-state imaging is the fact that memory-cell architectures as normally designed for digital applications have relatively high-capacitance sense nodes, and therefore they have relatively low sensitivity and high noise, which precludes these devices from being used for most high-performance applications.

Charge injection devices employ construction similar to memory arrays in that they are *X-Y* addressed, but the charge detection scheme is different. The device in its modern form consists of an array of charge-coupled pairs of capacitors as illustrated in Fig. 41. The readout is achieved by applying a capacitively coupled pulse to the row while a certain column is selected by lowering its potential.

The most widely explored architecture for solid-state imaging is the CCD. These devices store charge in a potential well and transfer the charge from one

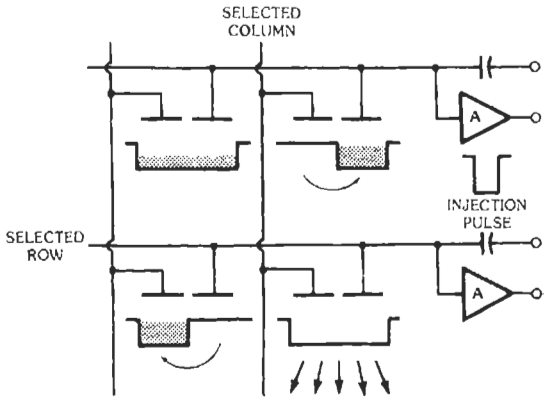


Fig. 41. Basic operation of a charge injection device.

electrode area to an adjacent electrode area by application of voltages with appropriate time and phase relationships, as illustrated in Fig. 42. The initial CCD devices employed three separately clocked phases to store and transfer charge in an MOS structure. The CCD concept has been extended, however, to include four-phase, three-phase, two-phase, and virtual-phase (one-phase) architectures, with significant advantages for devices with fewer gates. The construction of these different structures is illustrated in Fig. 43.

Solid-state imaging devices provide the combined advantages of high performance, low power, high reliability, and ease of use. These features are available in a wide variety of imagers fabricated as memory arrays, CIDs, and CCDs, and in a wide spectrum of formats and performance ranges. These features will combine to make solid-state imaging the mainstay of advanced imaging systems for future applications.

Speech-Synthesizer IC*

Speech is generated with these chips by the excitation of a time-varying digital filter. The excitation and

* Reference 28.

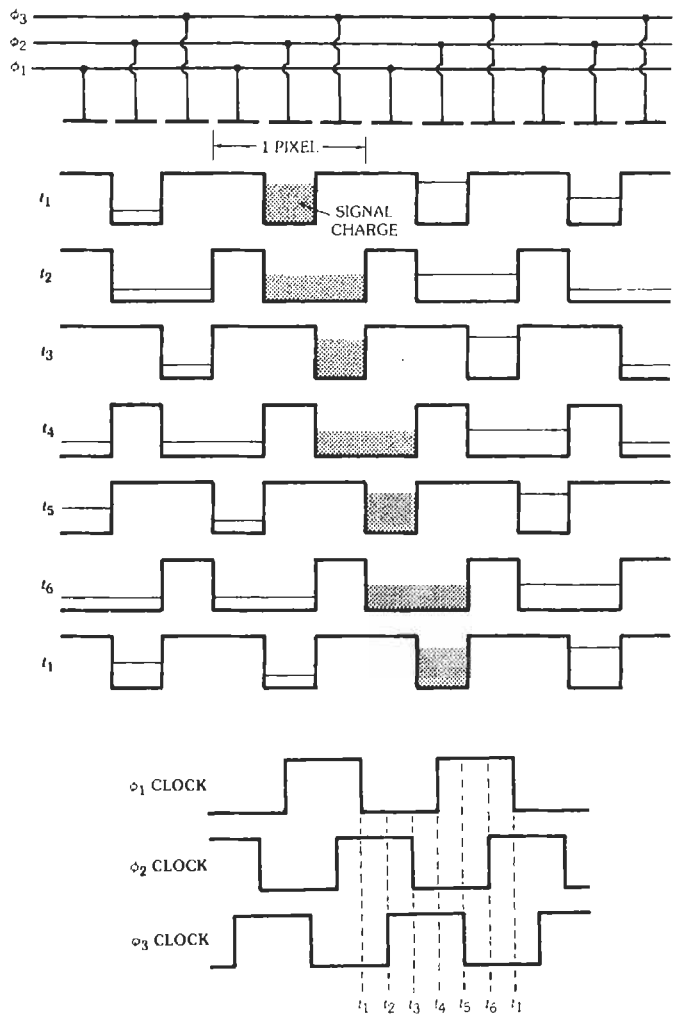

Fig. 42. Basic operation of a charge-coupled device.

filter parameters are stored in ROM, EPROM, RAM, or disk memory or are generated by a program. Overall control is provided by a microprocessor. The process is entirely digital up to the analog-to-digital converter, which provides the analog signal to drive a speaker.

An alternative to the variable-filter approach is to store digitized speech and sample the data at an 8-kHz rate, which leads to a digital data rate of about 100 kHz. Logarithmically compressed amplitude data could be used, analogous to digital telephone systems, which results in a rate of 64 kilobits/second with very good quality. The time-varying filter techniques provide acceptable speech quality but at a much lower digital input data rate, down to an average rate of 1200 bits/second for a ten-pole filter derived from a linear prediction model of speech.

The low data rates are made possible because of the redundancy in speech and by using a simplified simulator of the human speech-generating system. The vocal tract is simulated by a dozen or so connected pipes of differing diameter, and the excitation is represented by a pulse stream at the vocal-chord rate for voiced sound or by a random noise source for the unvoiced parts of speech. The reflection coefficients at the junctions of the pipes can be obtained from a linear prediction analysis of the speech waveform, and the names associated with the ICs, such as LPC or PARCOR, refer to the particular analysis used to obtain the coefficients for the equivalent electrical digital filter.

System in a Package (SIP) and System on a Chip (SOC)

As ICs continue to become pervasive in consumer applications, the need for smaller size and lower cost

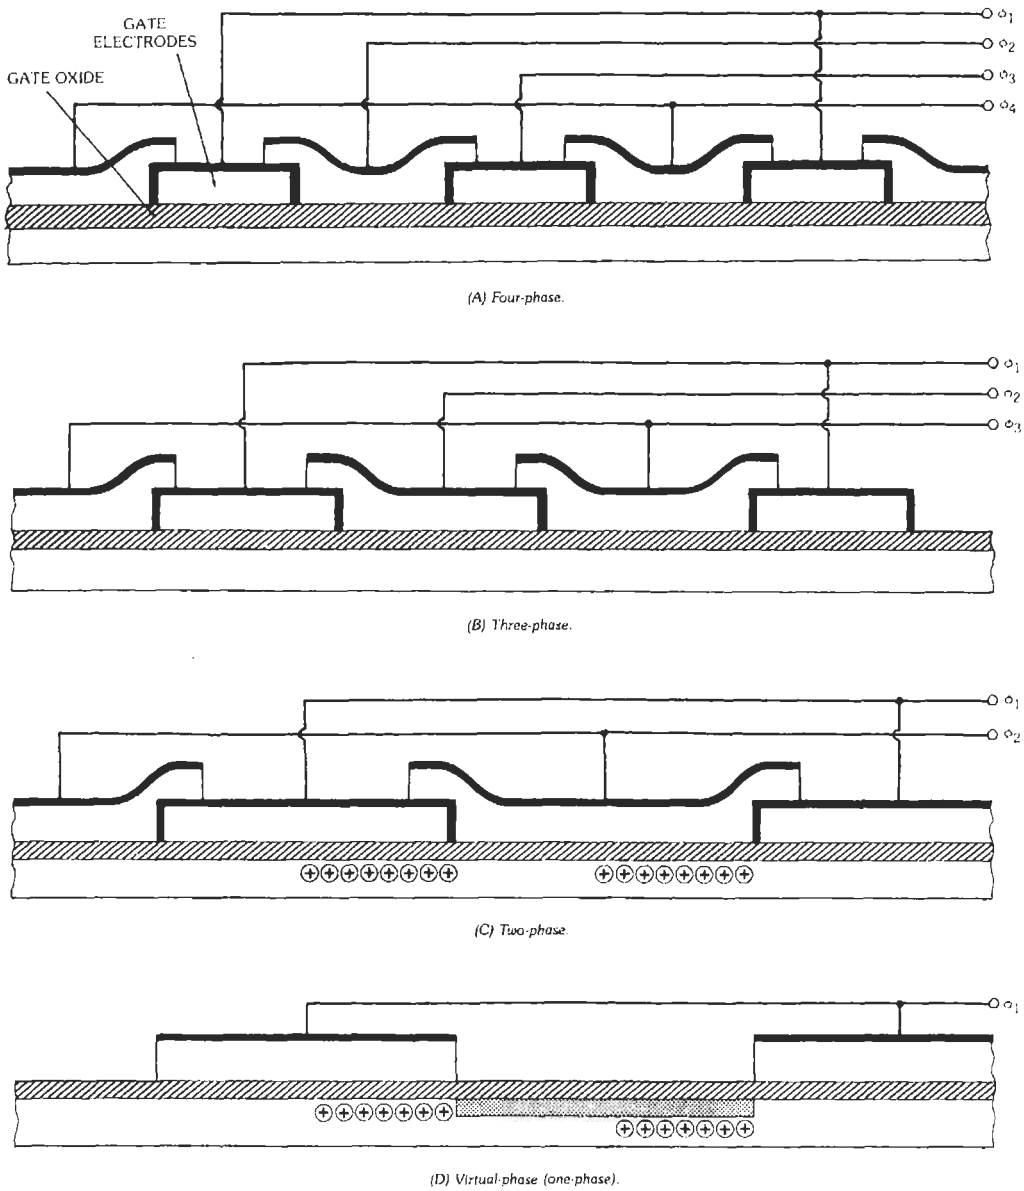

Fig. 43. Alternate structures for CCDs.

final products drives the need for fewer and fewer individual components to be assembled. This trend naturally leads first to a System in a Package (SIP) and then to a System on a Chip (SOC). In the SIP a single package will host a set of different computation chips (microprocessor, controllers, DSPs, I/O unit, RF modules, etc.), memory blocks, and interface elements such as capacitors, resistor, and inductors to perform a total system function. It is reasonable to predict that these components will be designed by different design teams in different companies to lower the costs and meet the stringent time-to-market requirements. To freely mix and match these different components will demand that each of them be "insensitive" to its environment at every level of abstraction.

In the SOC the same demands that were described above for a SIP will be placed on the individual chip. These demands will result in the individual chip having many more complex elements and using very complex processes in its manufacture. This will be a major challenge to the IC design and processing teams in the next few years.

Micro-Electro-Mechanical Systems (MEMS)

Micro-Electro-Mechanical Systems (MEMS) are integrated mechanical elements, sensors, actuators, and electronics that are fabricated using microfabrication technology similar to that used for integrated circuits. In most cases MEMS exist on a common silicon substrate; however, MEMS can be combined as discrete microcomponents in a single package. While MEMS electronics are fabricated using IC process materials and process sequences, many times the micromechanical components, sensors, and actuators are fabricated using compatible "micromachining" processes that deposit new layers or selectively etch away parts of the silicon wafer to form the mechanical and electromechanical devices. MEMS devices that are manufactured using batch fabrication techniques like those used for ICs provide the outstanding levels of functionality, reliability, and sophistication that have been demonstrated on ICs, with the coupled advantage of relatively low cost.

MEMS have emerged as significant contenders to satisfy the needs of several major existing and emerging markets. Probably the most familiar application to the IC industry is in the MEMS accelerometers that are quickly replacing conventional accelerometers for airbag deployment systems in automobiles. The conventional approach uses several bulky accelerometers made of discrete components mounted in the front of the car with separate electronics near the air bag. MEMS have made it possible to integrate the accelerometer and electronics onto a single silicon chip at a cost that is a factor of 10 below the mechanical counterpart. A second application that is receiving significant publicity is the TI DMD device that is used in projection displays. The high resolution and brightness provided for this application, combined with the low cost and ease of transport and modification of digital data, promises to revolutionize the movie and commercial display markets. A third MEMS application that has a major market potential is in optical switching. The recent emphasis on expanded optical communications to meet the requirements of wireless communications and the Internet is driving a wave of need for high-density, low-power, low-cost optical switches. This need is being met by the micromechanical optical switch, which is expected to serve a major market in the future. In addition to the applications noted above, MEMS are appearing in a multitude of special applications in such diverse fields as health care, metrology systems, defense, and space science applications.

APPLICATION SPECIFIC INTEGRATED CIRCUITS*

One of the fastest growing semiconductor market sectors is application specific integrated circuits (commonly referred to as ASICs).† The increasing use of ASICs continues to be market driven by the rapid advance of technology, which has shortened the useful life of most electronic products as improved and less expensive products make existing models quickly obsolete.‡ Furthermore, because most of the profit from electronic systems is earned early in the product life cycle, the penalty for being late to market is severe. The time required to design, manufacture prototype systems, and perform design revisions with ASICs is much less than with full-custom integrated circuits. ASICs are cost-effective solutions for all but the very highest volume products in which the smaller chip size of full custom design and layout can offset the advantages of ASICs if the product life is sufficiently long. The next paragraphs describe the major classes of ASICs, and then anticipated future trends in ASICs are discussed. The use of ASICs rather than "off-the-shelf" standard logic parts is also influenced by ASIC benefits such as reduced cost and size, and improved reliability resulting from higher levels of integration so that fewer system components are required. Systems based on proprietary ASICs are also much more difficult to replicate by competitors.

Gate Arrays

Gate arrays are the largest single ASIC market segment.§ They offer a good balance of cost, capability, time to initial silicon, and performance. A gate array is a chip from a master slice in which the active devices are regular arrays of digital logic "base cells" that can be interconnected into numerous types of simple and complex logic gates or sequential elements. The designer selects elements from a set of functional circuit blocks called the "macro library." Master slices are semiconductor wafers that have been fabricated through much of the IC process so that all active devices are present, though not yet connected by the metal layers. An inventory of wafers is built to provide manufacturing economies of scale; then the custom interconnect layers are patterned as orders are received.

There are two primary gate-array architectures: channelled and sea-of-gates. Channelled architectures disallow the use of selected rows and/or columns of base cells to use those regions as channels for the horizontal and/or vertical routing of signals and power supplies (Fig. 44). Triple-level metallization process technology has enabled the sea-of-gates architecture to begin replacing channelled gate arrays for higher-density applications that require more gates. With three interconnect layers, routing over utilized base cells is possible without setting aside channels. "Gate utilization" is a term that describes the percentage of

* This section was contributed by Mark G. Harward.

† References 29, 30, and 31.

‡ References 32 and 33.

§ Reference 29.

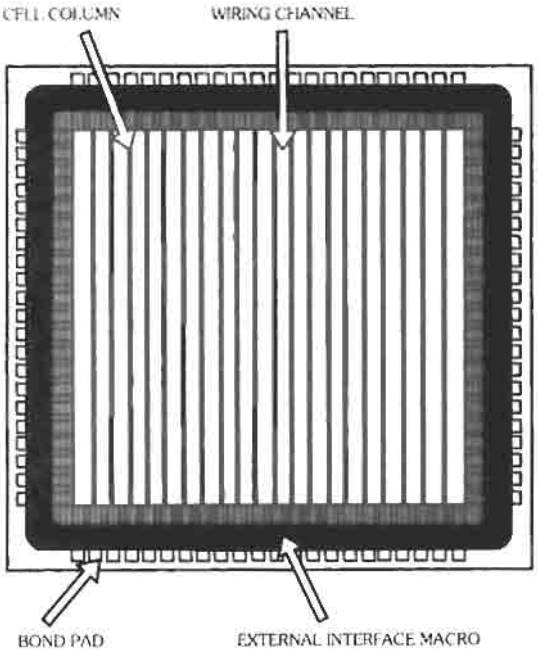

Fig. 44. Gate array—channelled architecture.

the available gates that can be utilized. Channelled gate arrays typically have approximately a 50% best-case gate utilization, including the cost of base-cell region lost to the channels. Sea-of-gates gate arrays with three levels of metal can achieve as high as 80% utilization to allow a more complex design to be done in a smaller chip size.

The gate-array manufacturer spends a great deal of engineering effort to devise the best possible base-cell design and layout. The base cell is required to efficiently implement as many different logic functions as possible by itself and in combination with other base cells (Fig. 45). As designs become more complex, there has been a need to incorporate more and more memory onto many gate-array designs. There are two means for this; the most common today is to use "memory compilers" provided by the vendor. Compilers use the base-cell arrays to implement memory and the support circuitry (address decoders, input/output, read/write paths) as efficiently as possible. The other technique is actually a hybrid combination of standard-cell and gate-array methodologies in which a complex standard-cell block of memory is embedded in the gate-array region that has the base cells removed. The embedded-memory method provides the advantage of custom memory design density but requires a full manufacturing process cycle and is more expensive. Interestingly, the base-cell design is greatly affected if embedded memory is the primary means of incorporating RAM, as the base cell then does not have to efficiently implement compiled memory cells.

A significant fraction of gate-array designs are input–output-pin limited rather than gate limited. This means that many users find their selection of gate array to be based on the number of I/Os rather than the utilizable gates of the chip. Recently, gate-array vendors have introduced families of chips to address this need that have a higher ratio of pads to gates, achieved either by using tighter pad pitch or by placing two rows of pads at the chip perimeter.*

The gate-array design flow is similar to that of standard cells, which are described below. The keys to correct designs are the same: thorough and correct description of the chip requirements, correct capture of the design, verification of the design with simulation of logic functionality and timing delays, generation of a set of test vectors sufficient to verify adherence to specification of the completed silicon, and generation of the test program.

Standard Cells—Designers select circuit blocks from a predefined library of standard cells that are custom designed and characterized for maximum density and performance. Automated placement and routing tools are used to define the circuit layout. There are no

* Reference 34.

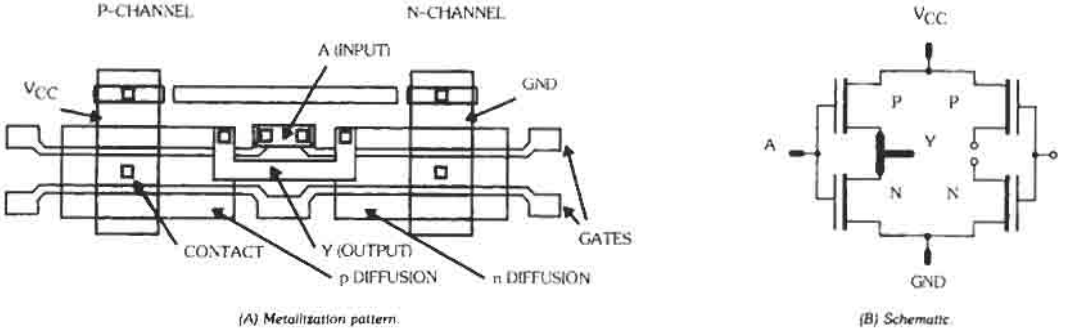

Fig. 45. CMOS gate-array base cell (configured as a 1 × drive inverter).

master slices prefabricated, as all levels must be generated to make the standard cells. Thus, of ASICs, standard cells cost the most and take the longest time to get initial silicon. However, the density, complexity, and performance of standard cells are typically greater than those possible with other ASICs because of the high complexity of the library elements compared to the gate-array macro library and nonoptimal architectures of PLDs.*

An example of a standard-cell chip arrangement is shown in Fig. 46. For maximum area efficiency, careful floorplanning is done manually or automatically by the placement and routing CAD tools. The idea is to group similar circuit blocks and select their relative locations to reduce the overhead area required for interconnections between the blocks of circuitry. The flow of data from input to output is also considered in order to minimize the wire lengths and the resultant parasitic capacitances that degrade circuit performance.

The library of standard cells typically includes "hardwired" cells (cells laid out and internally interconnected by the vendor) and "soft macros" (read as software-generated macros), which are circuit blocks of higher complexity that the computer-aided-design (CAD) tools generate (compile) to match the designer's specification. These compiled macros include complex circuit blocks such as single and dual I/O port static random access memory (sRAM), first-in–first-out (FIFO) data buffers, shift registers, and many of the standard TTL family of MSI logic blocks implemented in CMOS.

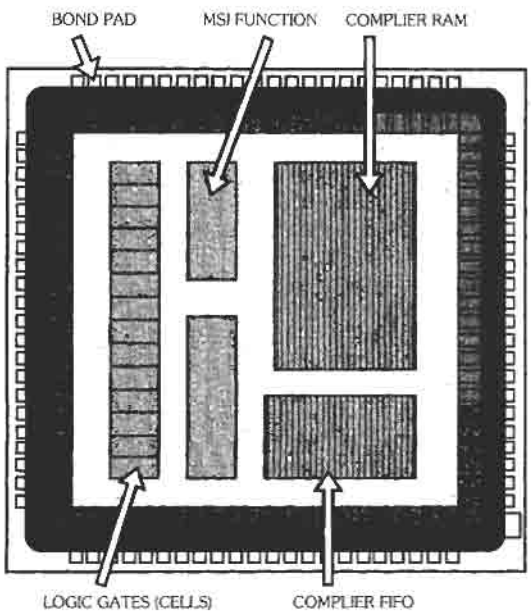

Fig. 46. Example of standard-cell chip arrangement.

An example of a typical standard-cell design flow is depicted in Fig. 47. There are many tasks required to assure properly functioning circuits. The foundation of a good design is always laid with a thorough design/product specification based on the finalized system requirements. The biggest relative weakness of standard cells compared to other ASIC solutions is the time required to receive prototype silicon from the vendor because all fabrication levels must be processed. Thus, it is most critical for standard-cell designs to be correct on first pass. Interestingly, multiple passes are more frequently the result of changes in system requirements or specifications than of design errors. However, design of functionally correct circuits that meet all specifications on the first pass is best achieved by rigid adherence to the vendor's design flow. This includes much simulation of logic functionality and timing to verify the design before the design is submitted for fabrication.

Programmable Logic Devices (PLDs)—Programmable logic devices are digital integrated circuits completely fabricated including the interconnection levels; the end-user configures the PLD using the on-chip programming circuitry and programming elements to specify the logic-circuit functions and the programmable interconnection points. Several types of programming elements are used by the many PLD manufacturers, including: fuses, EPROM, EEPROM, static RAM, and antifuses. Non-PLD ASIC families are collectively termed "mask-programmed" to differentiate the configuration methods. The history of programmable logic device architectures is nicely described in Roger Alford's *Programmable Logic Designer's Guide*.† This reference also gives a more detailed description of each PLD architecture than it is possible to present here. There are several classes of PLDs that must be understood by the designer considering a PLD solution. These include PLA (programmable logic array), PAL™ (programmable array logic), and FPGA (field programmable gate array).

User-programmable PLAs were invented in 1975 by Napoleone Cavlan at Signetics. This combined a programmable fuse element with National Semiconductor's mask-programmed logic-array architecture of a programmable AND array combined with a programmable OR array, which allowed digital designers to form Boolean sum of product (SOP) logic terms. An example of the PLA architecture is shown in Fig. 48. The PLA architecture allowed the flexibility of programming both the AND and OR arrays, but this resulted in large die area (i.e., high cost), which required a wide-body DIP package, and in relatively long propagation delays of 50 ns. The other factor that

* Reference 37.

† Reference 36.

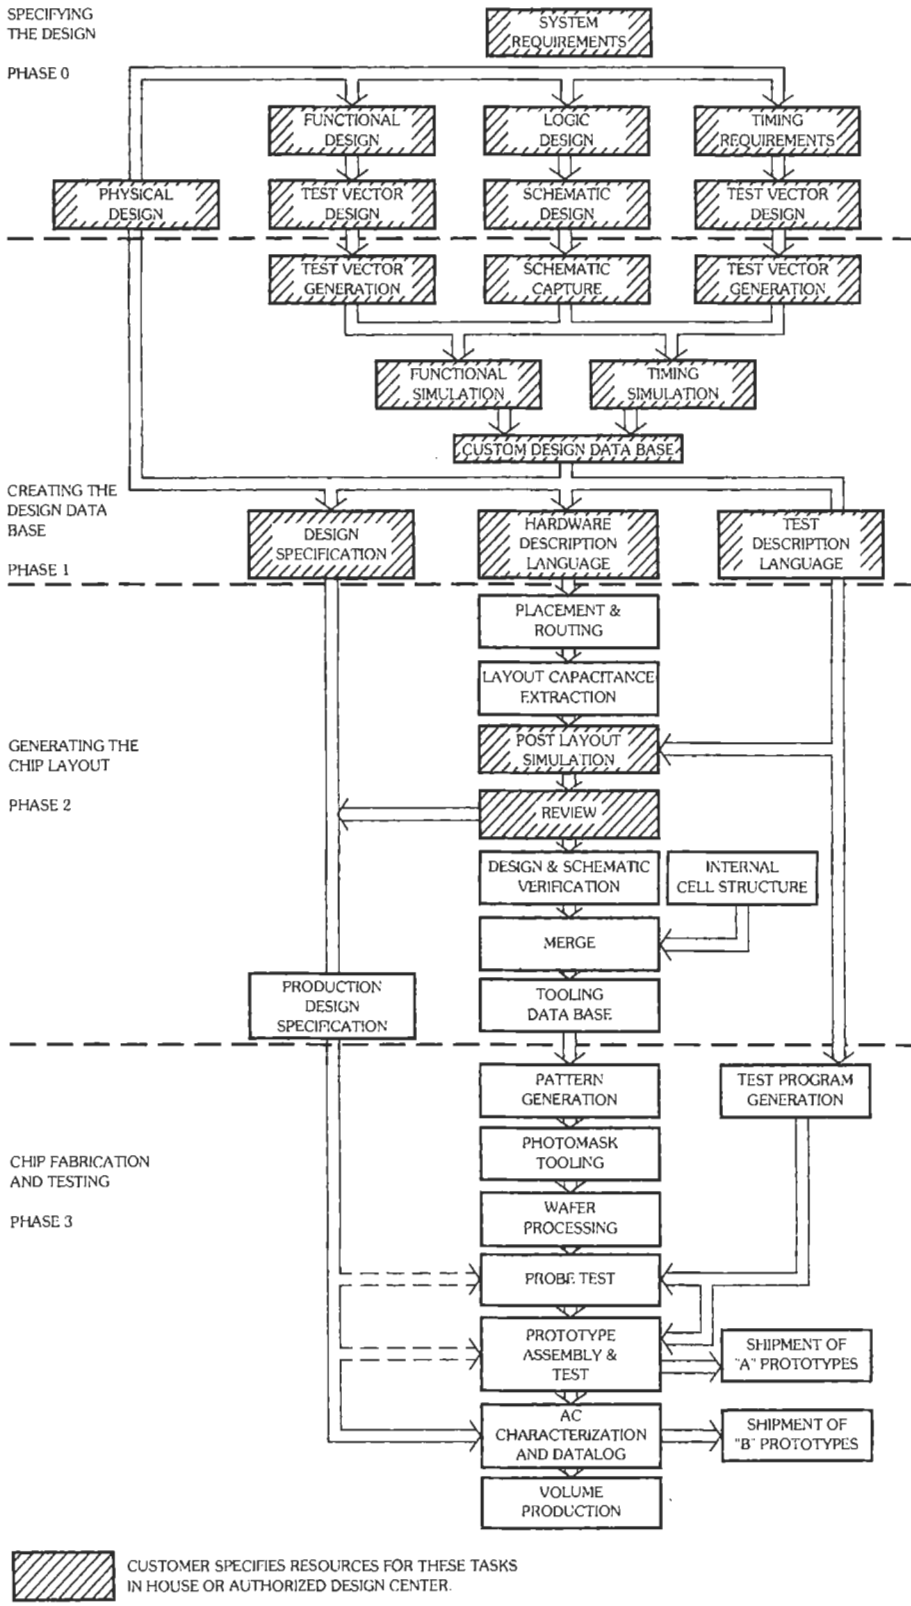

Fig. 47. Typical standard-cell design flow.

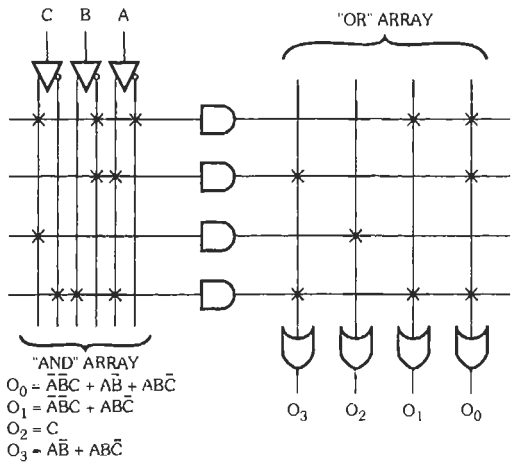

Fig. 48. PLA™ architecture.

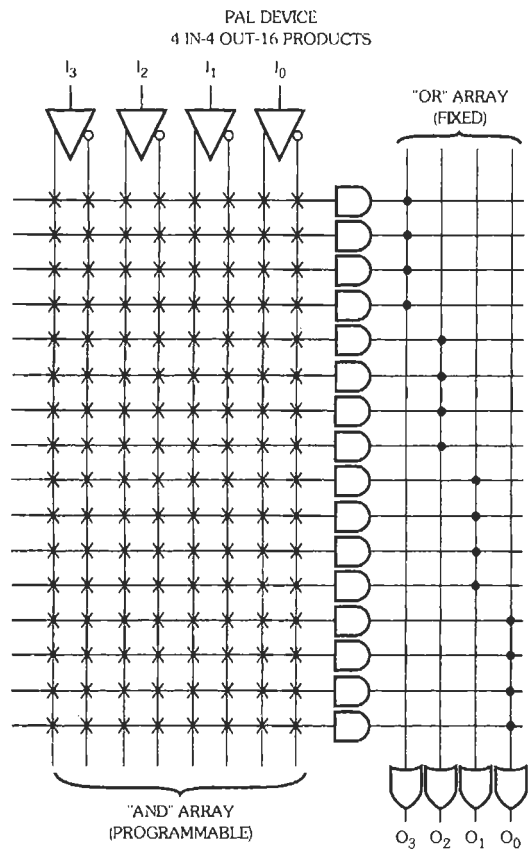

Fig. 49. PAL™ architecture. (*Copyright © 1986 Advanced Micro Devices, Inc. Reprinted with permission of copyright owner. All rights reserved.*)

retarded market acceptance of the PLA was the lack of software tools to ease the PLA user's design entry task.

John Birkner invented the PAL™ at Monolithic Memories Inc. (MMI) after much experience with the problems of digital system design using discrete components and study of the PLA weaknesses. The basic PAL architecture still had an AND array followed by an OR array with a fuse programming element, but with the fundamental difference of reduced flexibility by allowing programming only in the AND array. Birkner decided this trade-off was worthwhile based on a study of his digital system design work, which showed that a limited number of product (AND) terms input into each OR gate was acceptable if over eight (Fig. 49). Thus, significant die size reduction was achieved. Advanced Micro Devices, Inc. improved on the PAL with its 22V10 architecture, which introduced the concept of programmable output macrocells (Fig. 50). To better address the needs of designers to perform multiple levels of logic, Signetics unveiled the folded architecture in 1985; this allowed the outputs of the single array of NAND gates to be "folded back" to the inputs of the NANDs. Several variations of "folded" PAL and FPGA architectures have since been marketed.

The next major PLD architecture innovation was the field programmable gate array. There are several very different architectures that fit into the FPGA category. Several of the FPGA architectures resemble arrays of PALs with programmable interconnect resources provided to wire between the individual PALs. Altera's architecture shown in Figs. 51, 52, and 53 depicts this well. Altera employs an ultraviolet-light-erasable EPROM programming element. Xilinx introduced the logic cell array (Fig. 54) in 1985 using an sRAM cell programming element. Actel introduced the next major FPGA architecture in 1988 based on its antifuse programming element* (Figs. 55 and 56). This architecture most resembles a gate array because of the smaller granularity of its logic module and highly segmented routing architecture. New FPGA architectures based on new antifuse technologies have been announced by start-ups QuickLogic† and CrossPoint.‡

Analog ASICs—Analog and mixed digital/analog ASICs are emerging as an important new family of integrated circuits as CAD tools and design methodologies have been improved and adapted from the digital IC domain.‡ This is significant, as analog integrated circuit design has historically required much handcrafting, which virtually precluded the availability of application specific analog ICs. The main classes of

analog ASICs fall into these classes, each of which is also valid for merged digital/analog:*

1. Analog arrays: A chip from a master slice in which analog or a combination of analog and digital circuit elements are fabricated. The interconnection layers are defined by the end-user designer as in gate arrays.
2. Analog standard cells: Fully predesigned analog circuit blocks that reside in a library from which the user can select the needed items. This is the same concept as digital standard cells discussed previously.
3. Analog parameterized cells: Partially predesigned analog circuit blocks that allow the user not only to select suitable circuit blocks from the standard-cell library but also to set key parameters such as gain via mask-programmable connections of circuit elements.
4. Analog programmable chips: Similar to programmable logic devices in that they are completely fabricated and configured by the user. The programmable elements are configured by the end user to set the functional parameters of blocks of predesigned analog circuitry and to define the requisite interconnectivity.†

Future Trends in ASICs

Application Specific Memory—Application specific memory is based on a random access memory (RAM) chip that utilizes ASIC techniques to allow configuration of such attributes as input/output bit width (1, 4, 8, ...). Normal commodity static and dynamic memory chips require very large amounts of engineering to achieve the necessary performance while minimizing chip area to reduce cost due to the *very* high volumes of generic memories. Memory suppliers are beginning to develop and introduce products that leverage the engineering deployed on generic RAMs while adding the capability of customizing some aspects for applications such as video RAM and image processing.‡ It is interesting to note that one approach to application specific memory is to embed an array of logic gates, the converse of embedding RAM inside gate arrays as previously described.

Multiple-Chip Modules (MCM)—Multiple-chip modules may become an ASIC growth area for the most complex and volume/performance-sensitive systems. These devices have multiple chips attached to a common substrate and are then interconnected

together with advanced packaging technologies such as tape-automated bonding (TAB). Multiple-chip modules may become an ASIC-like solution as ever more complex chips become available for commodity use as in today's standard cell library.*

Field Programmable Gate Arrays—Field programmable gate arrays are expected to continue to be one of the fastest growing and most dynamic areas of ASIC for the near future as new architectures† and technologies are introduced to advance FPGA density and performance closer to those of gate arrays while reducing the relative cost.‡ Accelerated displacement of the gate-array market by FPGAs has occurred as FPGA cost reductions proceed faster than those for gate arrays.

Merged Analog and Digital ASICs—The next volatile area of growth may be merged analog and digital ASICs, both mask-programmed and programmably configurable versions. Many high-volume consumer products such as personal stereos and

televisions benefit from merged linear/digital ASIC product advances.*

Silicon Compilers—Silicon compilers provide automatic design and layout from high-level circuit descriptions. This has been a promising full-custom design methodology for some time that has not yet proved to be a popular design solution. The great success of other ASIC solutions may have retarded the demand for development of silicon compilers to date. Silicon compilation may become more widespread as IC complexity increases and the IC design task shifts to the system designer who will demand CAD tools that accept high-level design specifications and early access to the latest IC technology. The rapidly increasing computation power of engineering workstations should also aid commercialization of silicon compilers.

SINGLE-WAFER INTEGRATED DEVICE PROCESSING†

This section presents an overview of various single-wafer fabrication techniques for integrated processing of microelectronic devices. Numerous processing modules, sensors, and associated fabrication processes have been developed for advanced semiconductor device manufacturing.‡ Specific developments and results will be presented in the areas of rapid thermal processing (RTP), dry and vapor-phase surface cleaning, epitaxy, plasma processing, and in situ sensors.

Single-Wafer Semiconductor Manufacturing

The continuing demands for higher chip packing densities and enhanced system-level performance are the main technology and device scaling drivers. The

† This section was contributed by Mehrdad M. Moslehi.

‡ References 49 and 50.

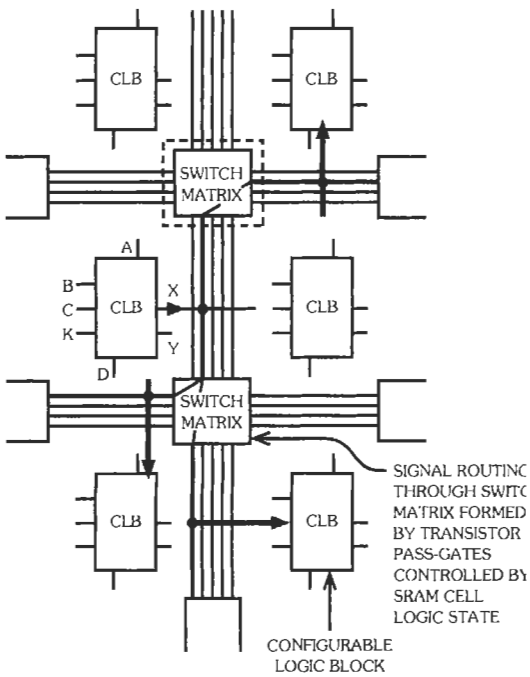

Fig. 54. Xilinx FPGA architecture. (*Courtesy Xilinx, Inc.*)

high-performance processor and dense memory chips now require device integration levels on the order of 100–1000 million transistors based on advanced submicron (e.g., 0.13–0.18 μm) CMOS and BiCMOS technologies. This level of integration density places stringent demands on the processing equipment, device fabrication processes, and manufacturing process control. State-of-the-art semiconductor manufacturing factories usually employ batch equipment for high-throughput wafer processing. The high manufacturing throughputs (e.g., thousands to over 20,000 wafers/month) and stringent manufacturing process control requirements are achieved at the cost of reduced flexibility as well as rapidly escalating cost of new generations of advanced processing equipment. Semiconductor technology scaling also affects wafer size. Currently, the state-of-the-art chip factories are set up for 200-mm wafer processing. The wafer size is expected to grow to 300 mm by 2005.

Single-wafer processing (SWP) is an alternative to batch equipment for various device fabrication processes. As the wafer size increases beyond 200 mm, advanced SWP equipment will be preferred for many applications. The factors in favor of SWP include compatibility with multichamber cluster equipment for vacuum-integrated processing, improved fabrication cycle time, and enhanced process repeatability. An argument against SWP has been its inferior processing throughput compared with the batch equipment.

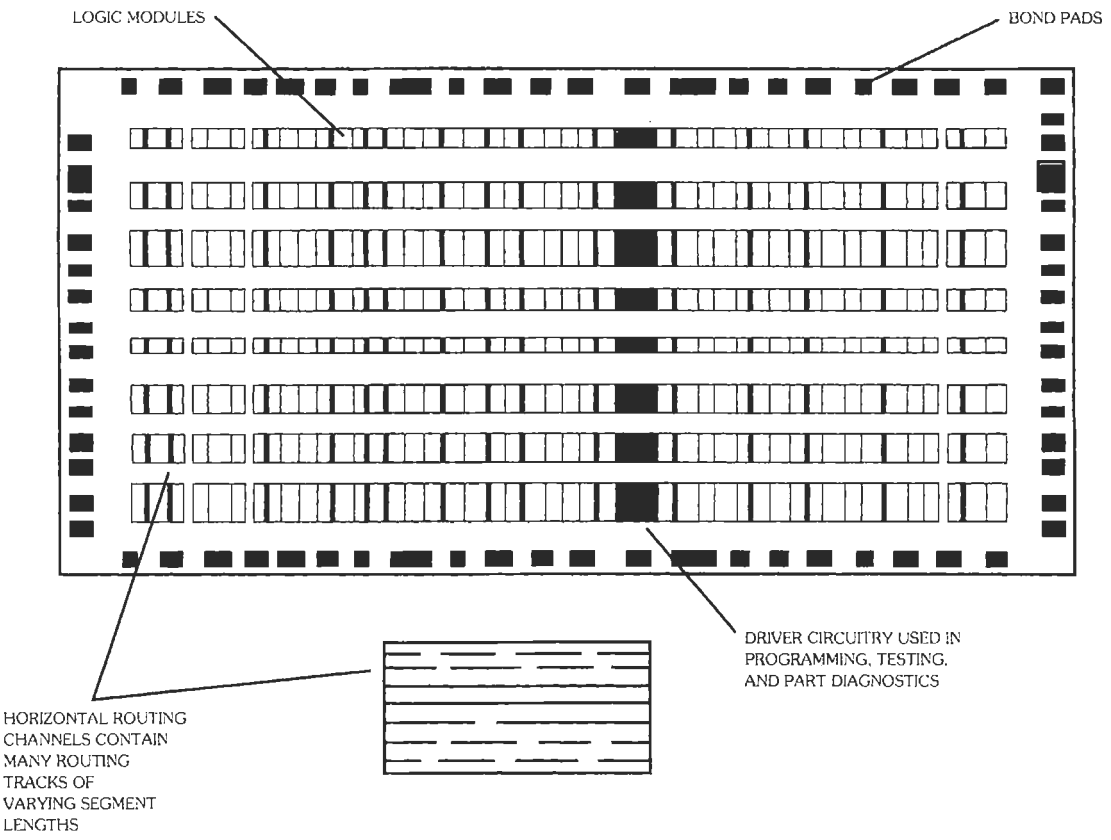

Fig. 55. Actel FPGA antifuse based logic module architecture.

However, many applications can afford somewhat lower throughput in return for capabilities for integrated processing and improved manufacturing process control.

As a result, an alternative semiconductor-device manufacturing methodology and associated techniques have been developed to meet several objectives, including: (1) lower overall factory cost due to the use of single-wafer processors, (2) sensors for process control/diagnosis based on computer-integrated manufacturing (CIM) methods for enhanced factory utilization and flexibility, (3) rapid manufacturing cycle time due to SWP and real-time process control techniques, and (4) enhanced flexibility for manufacturing numerous products based on different technologies. The following subsections will describe some selected elements of the single-wafer semiconductor minifactories and their impact on advanced submicron technology integration.

Integrated Device Manufacturing

The combination of in situ monitoring sensors, SWP, vacuum-integrated cluster tools, and computer-integrated manufacturing (CIM) can provide a suitable fabrication environment for flexible and high-yield semiconductor device manufacturing. The use of in situ sensors for monitoring of equipment, process, and wafer parameters results in increased equipment/process up-time, reduced process and device parameter spread, improved cluster tool reliability and functionality, and reduced overall device manufacturing cycle time. This subsection will present an overview of the features and impact of sensors for semiconductor device manufacturing applications. Specific examples will be presented for the use of critical sensors in conjunction with cluster tools for advanced CMOS device processing.

Sensors: Motivations and Impacts—Semiconductor factories usually employ well-established statistical process control (SPC) techniques to minimize the process parameter deviations and to increase the device fabrication yield. The conventional fabrication environments rely on controlling a limited set of critical equipment and process parameters; however, most of the significant wafer, process, and equipment parameters of interest are not monitored in real time or in situ. These critical parameters may include conductive

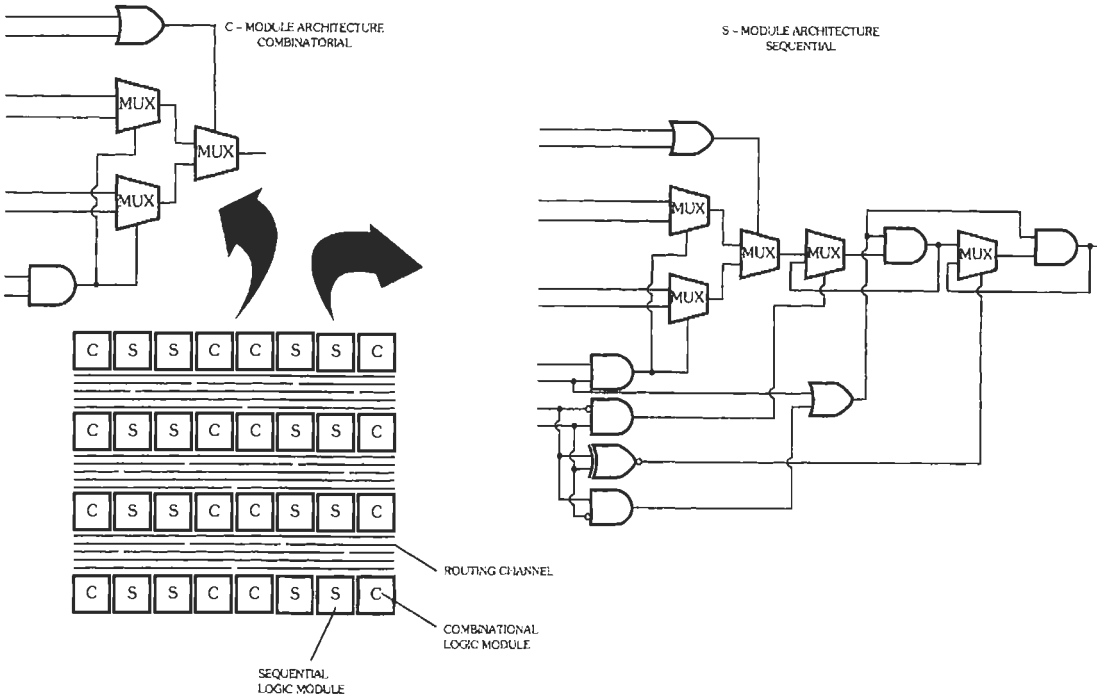

Fig. 56. Actel FPGA logic modules and examples of array configurations.

layer sheet resistance values, film thicknesses, process uniformity, equipment cleanliness, etc. The existing commercial processing equipment usually lacks suitable in situ sensors for real-time equipment diagnosis and prognosis. In many cases, the processing reactors have not been designed for modular implementation of new sensors. As a result, the detrimental effects of any unexpected process parameter variations and equipment-related drifts are not detected in real time. The relatively long time delays between detection of process or equipment problems and implementation of suitable corrective measures increase the overall chip manufacturing cost.

The conventional SPC techniques operate based on extensive ex situ or off-line measurements on pilot and device wafers. These off-line measurements provide useful statistical data related to the status of equipment and various wafer lots in process. However, the off-line measurements are usually time consuming and labor intensive and degrade the device manufacturing cycle time. In general, the following trends and driving forces affect the semiconductor technology evolution in microelectronics manufacturing: (1) increased chip fabrication yield, (2) reduced device manufacturing cycle time, (3) real-time process control to maintain process and wafer parameters within specified bounds, (4) improved semiconductor device reliability and performance, and (5) reduced manufacturing cost per chip.

The practical limitations and high cost of the conventional SPC methodology in conjunction with the above-mentioned driving forces as well as the rapidly rising costs of new semiconductor processing equipment and factories have promoted the evolution of flexible semiconductor minifactories based on in situ sensors and vacuum-integrated cluster tools. Cluster systems consisting of single-wafer processing modules and in situ sensors allow sequential integrated processing in the CIM-supervised factories. In situ sensors improve the manufacturing cycle time by eliminating the need for the off-line measurements and by enhancing the process and equipment reliability. Moreover, the in situ sensors employed for equipment and process diagnosis/prognosis will increase the equipment/process up-time and improve the cluster equipment reliability and functionality. Real-time in situ process and wafer monitoring sensors are also very effective in reducing the process and device parameter spread, resulting in manufacturing yield improvements.

Sensor Hierarchy for Semiconductor Processing—Fig. 57 shows the sensor hierarchy for various semiconductor device processing applications. The process control sensors can be divided into the invasive and noninvasive groups. The invasive sensors are intrusive to the process environment and/or wafer surface within processing equipment and, as a result, are not suitable for in situ process monitoring applications. For

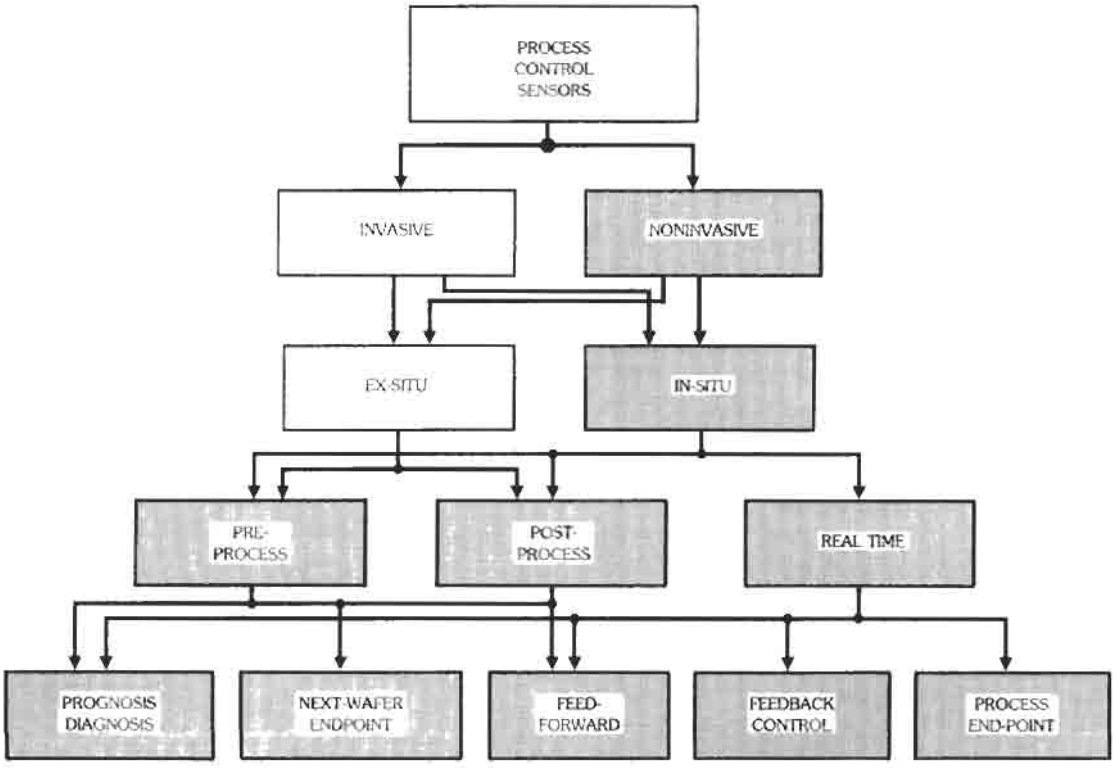

Fig. 57. Hierarchy of process monitoring and control sensors for semiconductor manufacturing.

example, most contact-type sensors that require direct mechanical contact to the wafer surface (e.g., thermocouples for wafer temperature measurements) are invasive. On the other hand, the noninvasive in situ sensors are the most suitable type for device fabrication process control needs. These sensors usually employ noninvasive probe beams or characteristic detected beams of energy with well-defined physical signatures (e.g., optical, acoustical, electronic, and electromagnetic) to monitor the desired parameters based on a known physical phenomenon. The ex situ sensors are essentially for off-line preprocess and postprocess monitoring applications; however, the in situ sensors are designed for real-time as well as on-line pre- and postprocess monitoring and process control.

As indicated in Fig. 57, the real-time in situ sensors can be employed for process end-point detection, real-time feedback control, and process/equipment diagnosis and prognosis. For instance, an in situ real-time sheet resistance sensor can be used within a metal CVD process module to provide feedback process control (for instance, to control the deposition rate) and to achieve precise process end-point detection. The same sensor may also provide data to feed-forward links and to expert systems for equipment and process prognosis/diagnosis purposes. The in situ preprocess and postprocess sensors are mounted within a load-lock chamber or a dedicated sensor (metrology) module interconnected to the vacuum-integrated cluster equipment. These sensors are useful for next-wafer (delayed) process end-point control, feed-forward links, and equipment/process prognosis/diagnosis. The specific choice of various types of in situ sensors depends on various factors such as the application and cost. For instance, depending on the process application, the task of in situ dielectric thickness measurement may either be performed in real time (for real-time rate control and/or end-point detection) or following the process by a postprocess sensor (for delayed end-point control and feed-forward links).

The in situ sensors are intended to monitor various parameter sets within three domains. These domains are associated with the equipment, process, and wafer parameters. Depending on a specific application, the critical equipment parameters to be monitored may include gas showerhead temperature (e.g., in PECVD TEOS oxide), background contamination (e.g., in epitaxial Si growth and PVD processes), quartz window temperature (in lamp-heated RTP systems), chamber wall deposits, and energy source status (e.g., status of

lamps and the total lamp power in RTP). Additional equipment parameters are the gas flow rate and pressure settings in a processing reactor. However, the process parameters are directly governed by the equipment parameters (both controlled and uncontrolled parameters). Depending on a specific application, the process parameters of interest to monitor may be wafer temperature, process gas flow field, plasma density, and plasma electron energy. In general, a semiconductor wafer exposed to a process contains the most important parameters that have to be controlled. This is due to the fact that the wafer parameters have a direct impact on device performance and yield. For example, in a CVD or PVD (sputter deposition) process used for deposition of dielectric or conductive films, the important wafer-level parameters include film thickness, refractive index, stress, conductive-layer sheet resistance, and thickness uniformity.

Among the above-mentioned three parameter domains, the equipment parameters are the easiest to monitor. The equipment parameters can be directly adjusted and controlled, whereas the process and wafer parameters are dependent variables. Monitoring and control of the desired process and wafer parameters require specialized noninvasive in situ sensors and advanced control techniques. Proper adjustments of process and wafer parameters are usually performed by varying the equipment parameters. The process parameters are functions of the equipment variables via equipment models, and the wafer parameters are determined by the process parameters via process models.

Sensors for Direct and Indirect Feedback Process Control—Fig. 58 shows the direct and indirect methods of parameter measurement and device manufacturing process control. The conventional methods of manufacturing process control employ equipment-level sensors to monitor the equipment parameters. These measurements (e.g., lamp power, mass-flow controller settings, etc.) provide the necessary real-time signals for an indirect feedback control loop that maintains the critical equipment parameters at or near the desired predetermined set-point values. The use of closed-loop control based on measured equipment parameters usually provides a significant improvement (in terms of process parameter spread) over the open-loop mode of operation; however, this type of process control relies on two levels of equipment and process models in order to relate the equipment parameters to the wafer parameters that are the ultimate parameters of interest for manufacturing process control. These models or the process-vs.-equipment and wafer-vs.-process relationships can be affected by various

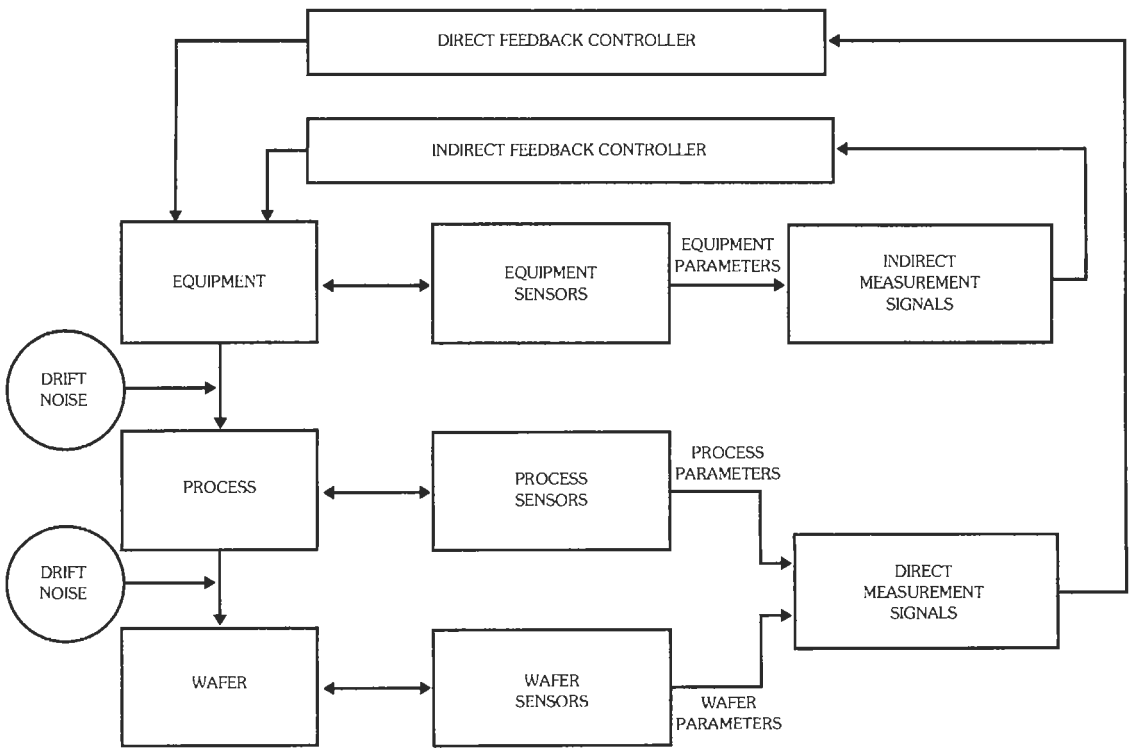

Fig. 58. Schematic illustration of direct and indirect process control techniques.

sources of drift and noise resulting from the uncontrolled variables. For instance, the optical/vacuum quartz window temperature in an RTP system behaves as an uncontrolled variable that can cause process drift. Although the uncontrolled equipment parameters are not controlled directly by an operator, most of them should be monitored to further refine the equipment model for improved process control. For example, real-time monitoring of the optical/vacuum quartz window temperature in an RTP system can provide a useful signal for improved closed-loop wafer temperature control and for equipment diagnosis.

As illustrated in Fig. 58, the direct process control techniques employ suitable in situ sensors to directly measure the important process and/or wafer parameters. These direct measurement signals are fed to a controller, which continuously adjusts the equipment parameters in real time to minimize the differences between the measured signals and the process and/or wafer parameter set points. It is evident that the direct control methods should result in a much more robust process control and smaller process and/or wafer parameter spread. This is because the direct feedback control loops contain the drift/noise sources within the overall control loop. When in situ noninvasive sensors are used for real-time monitoring of the desired wafer parameters, the process control feedback loop will minimize the error signal representing the difference between the measured and set-point wafer parameter values. As a result, the equipment-related drift effects will be essentially eliminated.

As described earlier, the indirect equipment-related process control signals are related to the direct process/wafer-related process control parameters via the process and equipment models. As an example, Fig. 59 illustrates some representative equipment and process/wafer parameters in a typical plasma deposition or etch process. The plasma process and wafer parameters (direct process control signals such as plasma density, ion flux, wafer temperature, and processing rate) are related to the plasma equipment parameters (indirect process control signals such as RF/microwave power, dc bias voltage, and susceptor temperature) via the specific plasma equipment model. Of course, the functional relationships between the wafer and process parameters are established by the physics of plasma and the plasma process model. In general, a good knowledge of the equipment and process models is necessary to ensure optimal and fast real-time process control based on either direct or indirect feedback control techniques.

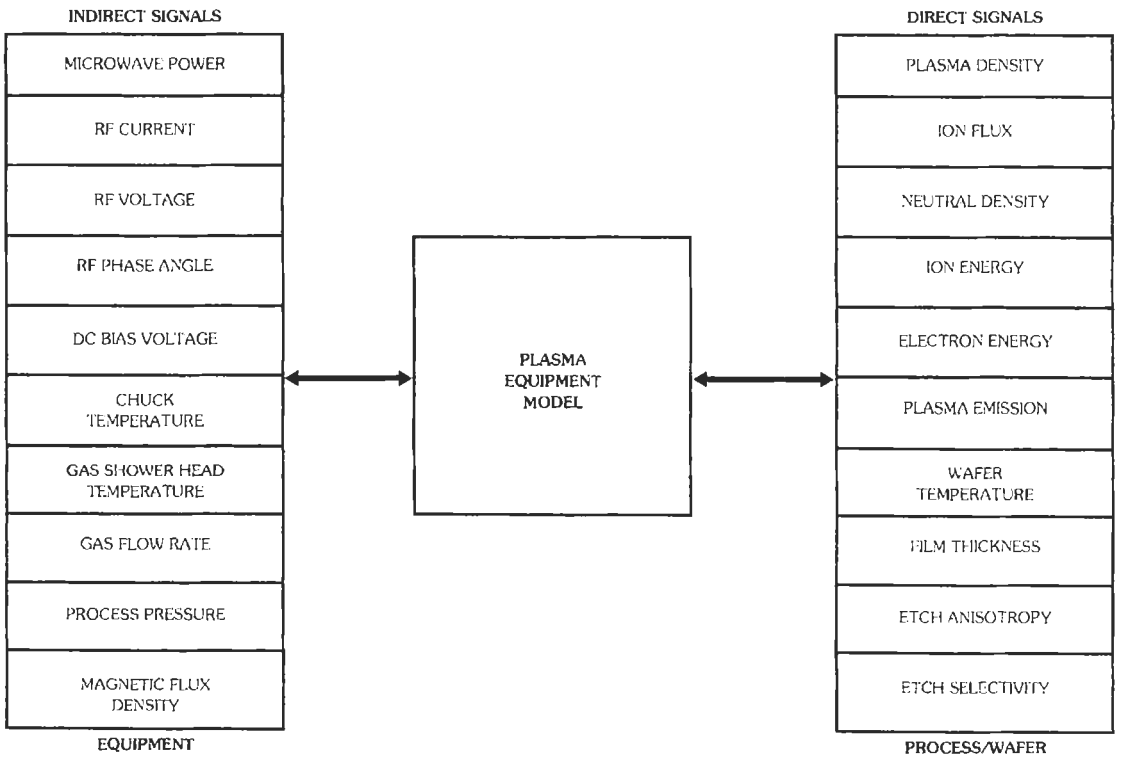

Fig. 59. Typical wafer/process and equipment parameters in a plasma process.

Critical Sensors for Device Fabrication Process Control—The critical in situ process control sensors required for a given fabrication process are determined based on various considerations such as the impact of the specified process on the overall device performance and fabrication yield. The process requirements for a given process indicate if any real-time and/or pre- and postprocess in situ sensors must be utilized to meet the target specifications for the process and wafer parameters. Fig. 60 illustrates various single-wafer processes and their associated "critical" in situ process control sensors. For example, consider an RTP module used for CMOS gate dielectric formation by rapid thermal oxidation and nitridation (RTO/RTN) processes. Thickness, growth temperature, and uniformity of gate dielectrics are the main critical wafer and process parameters that can influence the overall device performance and fabrication yield. As a result, one important sensor is a real-time multipoint temperature sensor for closed-loop temperature control to improve process repeatability. Another very useful sensor is an in situ ellipsometer for postprocess measurement of gate dielectric thickness and refractive index. This sensor will help to further reduce the overall gate dielectric thickness spread via delayed (next-wafer) feedback. An additional postprocess in situ sensor may be used for monitoring the gate dielectric thickness uniformity. The in situ postprocess uniformity sensor will assist in meeting the process uniformity specification and can provide delayed feedback process control information for process uniformity control, assuming the RTP module employs a multizone illuminator for dynamic and real-time uniformity control. If the temperature sensor monitors multiple points on wafer for dynamic uniformity control during the gate dielectric formation process, the postprocess uniformity sensor will be rather noncritical.

Various blocks shown in Fig. 60 illustrate some selected critical in situ sensors for CVD processes (metals, dielectrics, amorphous and polycrystalline silicon), epitaxial growth, plasma etch (anisotropic and isotropic), resist processing, ion implant processing, dry surface cleaning, glass reflow, and silicide formation. As another example, consider the critical sensor needs for metal CVD processes such as tungsten CVD using rapid thermal CVD (RTCVD) modules. Again, a temperature sensor is needed for real-time wafer temperature control. Precise control of wafer temperature and its uniformity in the CVD tungsten temperature range (300–550 °C) are critical requirements because of their impact on the deposition rate and process uniformity. Another very useful sensor is a noninvasive sheet resistance sensor for real-time monitoring of tungsten sheet resistance during the RTCVD process. This sensor will provide the process end-point information and will help to reduce the process parameter spread. Besides these real-time sensors, the process can benefit from two postprocess sensors for in situ monitoring of the metal film thickness and/or its surface roughness.

Intelligent Cluster-Tool-Based Device Manufacturing—The earlier discussions have indicated that the use of low-cost in situ sensors in conjunction with single-wafer vacuum-integrated cluster equipment can provide a fast-cycle-time processing medium to manufacture advanced semiconductor devices. This type of factory relies on intelligent real-time process control based on in situ sensors to minimize the device parameter spread and to enhance the overall equipment reliability and process up-time.

Fig. 61 shows the simplified block diagram of a CMOS process flow and its associated cluster equipment for a fully cluster-based fabrication sequence. Each cluster equipment contains three or four process modules. It is expected that increasing the number of process modules on a cluster equipment much beyond four to six may result in reduced equipment reliability and increased cost. The process flow starts with the CMOS tank (or well) formation module and is followed by the isolation, pregate, CMOS gate, source/drain, silicide, planarized interlevel dielectric, contact, metal, and passivation modules (assuming one metal level). As shown, the CMOS tank module can be completed using two cluster tools: one for microlithography marker pattern formation, and another one to complete the CMOS well formation. The device isolation module employs three cluster tools: one to complete the oxidation mask stack deposition, another cluster equipment for completion of the patterned oxidation mask, and a third module for field oxidation and oxidation mask removal. Other process modules employ suitable cluster tools, as indicated. This CMOS process flow employs a total of about 16 cluster tools (each with three or four individual process chambers) besides some additional equipment requirements such as the wet cleaning stations, ion implanter, and microlithography stepper. Appropriate sensors are included in each cluster equipment to allow real-time process control and device manufacturing based on intelligent equipment and factory control.

Figs. 62 and 63 show schematic diagrams of two different cluster tools with some real-time and pre- and postprocess in situ sensors for the two CMOS flow modules shown in Fig. 61. Fig. 62 illustrates a three-module cluster tool for CMOS gate structure formation. The first step in the process sequence uses the preclean module (such as vapor-phase clean) to remove surface contaminants including native oxide. Then, the RTP module is used to form the gate dielectric by RTO. The subsequent step is silicon gate deposition by LPCVD. All three modules require real-time temperature sensors (critical for RTP and LPCVD/RTCVD but less critical for the preclean module) for wafer temperature measurements and process uniformity control. The preclean module may also employ an ultraviolet-light intensity sensor for photochemical cleaning process monitoring and control. Moreover, the RTP module uses a real-time thickness sensor for process end-point detection. An alternative option would be to use a postprocess in situ thickness sensor. Similarly, the

LPCVD silicon process module also uses a silicon thickness sensor for process end-point detection. The load-lock (or metrology) chamber contains a slip sensor for postprocess monitoring of possible RTO-induced slip dislocations. A sheet resistance sensor may be used for postprocess monitoring of LPCVD in situ–doped silicon sheet resistance. Another load-lock sensor can be used to monitor the effectiveness of the surface preclean process.

Fig. 63 illustrates the example of a four-module cluster tool for self-aligned silicide formation. The process sequence employs preclean for native oxide removal, refractory metal sputtering, RTP silicide formation, plasma etch for removal of unreacted refractory metal and metal nitride, vapor-phase clean, and finally another RTP cycle for silicide annealing. All the critical real-time and pre- and postprocess sensors are also shown.

RTP for Integrated Device Processing

Conventional and state-of-the-art semiconductor factories employ batch furnaces for many thermal fabrication steps. Various applications include gate and field oxidations, low-pressure chemical-vapor deposition (LPCVD) (e.g., for polysilicon and silicon nitride), and thermal anneals (e.g., for junction formation and glass reflow). A significant number of other fabrication processes, however, are already based on SWP. Examples include plasma etch and deposition, ion implantation, and microlithography. The current trend toward replacement of batch processes with SWP is evident from the increasing market share for cluster tool equipment with SWP modules. RTP is an obvious choice to replace batch furnaces for thermal processing in a semiconductor minifactory environment. Advanced RTP tools are based on modular designs compatible with vacuum-integrated cluster equipment. High-performance multizone illuminators with cylindrical symmetry have been applied to various processes including RTO, CVD of tungsten and amorphous/polycrystalline silicon, silicide formation, sinter, epitaxy, as well as high-temperature rapid thermal annealing (RTA).* Concurrent use of multizone illuminators and multipoint temperature sensors provides a capability for real-time wafer temperature control and process uniformity optimization.† Moreover,

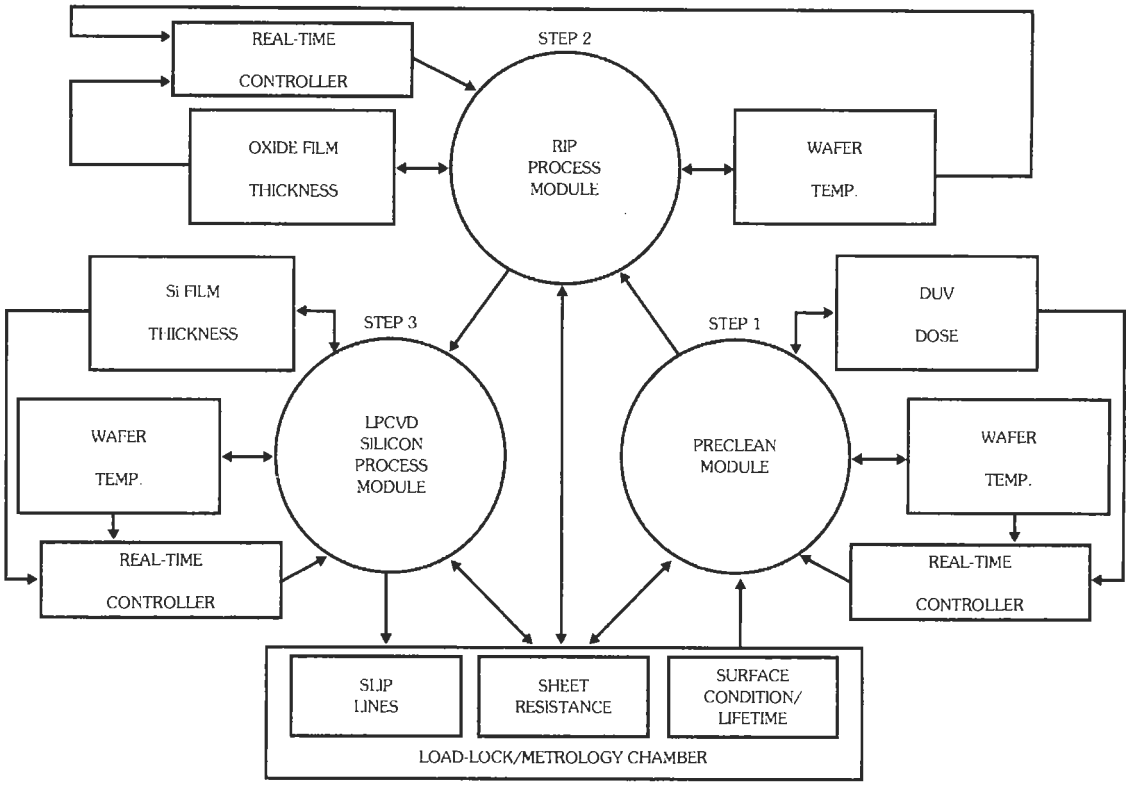

Fig. 62. Schematic illustration of a cluster equipment for CMOS gate structure formation.

numerous in situ process monitoring sensors have been developed to meet the RTP monitoring and control requirements. Some process applications of advanced load-locked single-wafer RTP techniques and associated sensors will be described.

Multizone RTP Illuminators—The known RTP systems mostly employ single-zone tungsten–halogen or arc lamp modules for wafer heating. The illuminator is usually designed to provide relatively uniform steady-state wafer heating over a narrow range of wafer temperatures. The conventional RTP illuminators provide real-time lamp power control capability for only a single zone. This has been known to impose major limitations in terms of dynamic wafer temperature uniformity and slip dislocation control.‡ For a given optical flux distribution on a semiconductor wafer, temperature uniformity can be affected by various additional parameters such as gas flow rates and process pressure. Moreover, the transient heat-up and cool-down temperature uniformity of a wafer can be quite different from the steady-state uniformity.‡ These observations imply that the conventional single-zone lamp RTP systems may not be able to meet the stringent wafer temperature and process uniformity requirements over an extended domain of process parameters. Some developments in the area of RTP equipment have addressed these requirements. One approach has been to use a crossed lamp configuration, which employs two parallel crossed banks of linear tungsten–halogen lamps above and below the wafer.§ This technique is superior to the conventional single-zone RTP designs; however, owing to lack of cylindrical symmetry, only a limited real-time uniformity control can be achieved.§ This limitation is due to the circular shape of semiconductor wafers and linear/crossed configuration of the lamps.

Another approach has been to employ multizone illuminators with overall cylindrical symmetry. As an example, Fig. 64 shows a schematic illustration of Texas Instruments' Advanced/Automated Vacuum Processor (to be called TI-AVP) using a three-zone illuminator. The TI-AVP three-zone illuminator employs a

* Reference 50.

‡ Reference 52.
§ Reference 53.

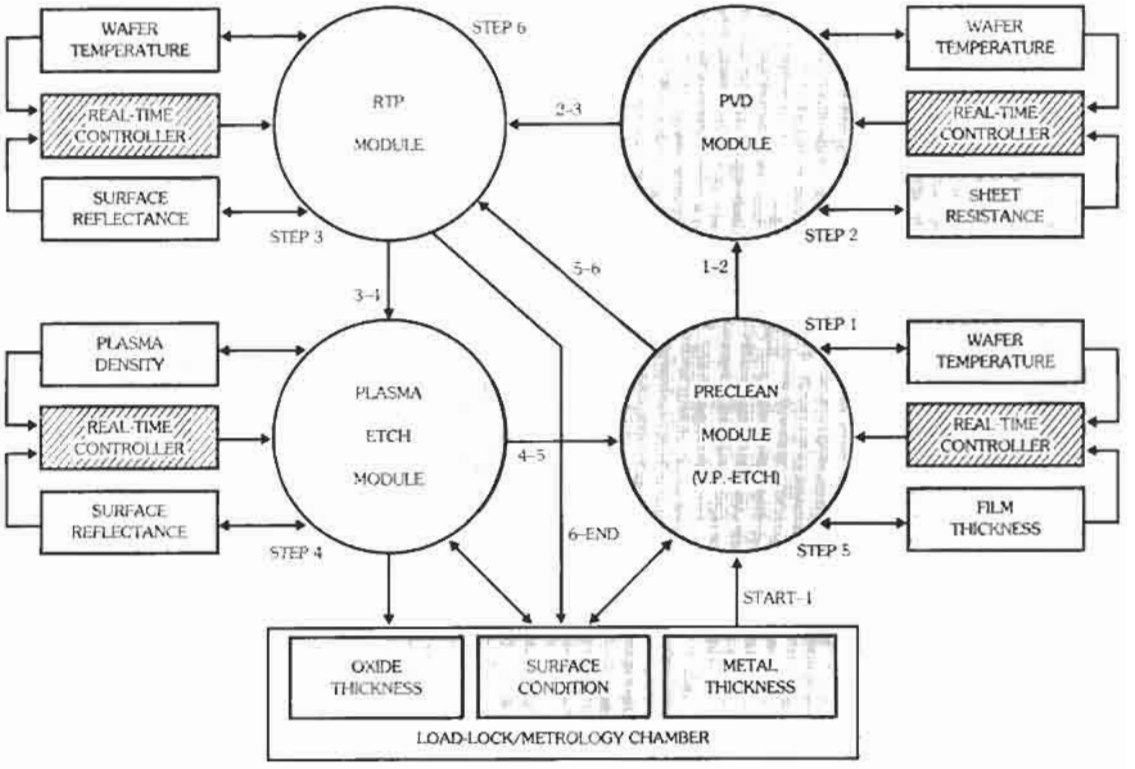

Fig. 63. Schematic picture of a cluster equipment for self-aligned silicide formation.

single center lamp, a first ring of 12 lamps, and an outer ring of 24 lamps. The combination of the point-source lamps in each ring simulates a continuous optical flux ring. All the zones are concentric with the central axis of the reactor process chamber and the center of the semiconductor wafer. The multizone lamp module heats the semiconductor wafer from the rear. Each lamp zone can be controlled independently in real time via its dedicated remote and computer-controlled power supply. The illuminator design provides multiple hollow light-pipe holes through the illuminator housing and associated reflector assembly for multipoint real-time wafer temperature measurements and control. This feature is important because various RTP fabrication processes are performed over an extended process parameter domain (e.g., 0.25–760 torr pressure for LPCVD and RTO processes). Recent modeling results have shown that the process pressure and gas flow rates can have significant effects on wafer temperature uniformity, particularly near the wafer edge.* In the RTP examples presented here, wafer processing and heating is performed face-down. Fig. 65 shows a representative open-loop response of four radially distributed temperature sensors over a 150-mm wafer using a three-zone RTP illuminator (1 torr/250 sccm [standard cubic centimeters per minute] flow of nitrogen). With optimum zone power ratios, this illuminator provides temperature nonuniformity of less than ±1.5 °C.

Multipoint Temperature Sensors—RTP applications require accurate and repeatable real-time control of wafer temperature. The most commonly used noncontact temperature measurement technique is optical pyrometry. The advantages of optical pyrometry for RTP include its noninvasive nature and relatively fast measurement speed. Both of these requirements are critical for proper control of transient heat-up and cool-down temperature ramps and accurate and repeatable temperature control. The fundamental disadvantage with conventional pyrometry, however, is its dependence on the wafer surface roughness and emissivity. Surface roughness is typically wafer dependent, while emissivity depends on a range of parameters, including temperature and chamber reflectivity, as well as wafer-doping characteristics and surface optical condition.† Further, the direct reflection of heating lamp light from the wafer surface must be eliminated from the pyrometer measurement. Similarly, the heat-

ing of any optical chamber windows through which the wafer radiance is monitored, and any ensuing changes in the window index of refraction and transmission characteristics, must be corrected for in the measured radiance. Without proper compensation, these factors can result in large temperature-measurement errors. Frequent calibrations against thermocouple instrumented wafers have allowed somewhat improved temperature control for a specific process/reactor but are not satisfactory in general. Preprocess measurement of wafer reflectance and backside roughness may be used to correct for wafer-to-wafer changes in surface optical conditions. The use of preprocess wafer reflectance measurements has been reported for improved pyrometry measurements.* Real-time wafer emissivity measurement has been developed to allow correction for emissivity changes. Aside from the above issues affecting pyrometry measurement accuracy and repeatability, wafer temperature uniformity is a key requirement to prevent slip dislocations in high-temperature RTP.† Multipoint fiber-optic pyrometry allows real-time monitoring and control of wafer temperature using multizone lamp heat sources.‡

Fig. 66 is a schematic diagram of a three-zone lamp-heated RTCVD reactor with multipoint temperature measurement and control. The wafer is processed face-down to minimize particulate deposition on the device side. A three-zone tungsten–halogen lamp source provides radiant heating to the back side of the wafer. A quartz window provides a vacuum seal and allows for optical access to the wafer. Multiple pyrometers are arranged at various radial positions, each looking at the back side of the wafer through a 3.3-μm interference filter and a suitable fiber light pipe. The light pipe is water cooled to prevent excessive heating caused by reflection and radiation from the hot wafer. The pyrometer/light pipe assembly detail is shown in Fig. 67. The light pipe material used for 3.3-μm transmission is either a sapphire rod or a fluoride fiber bundle.

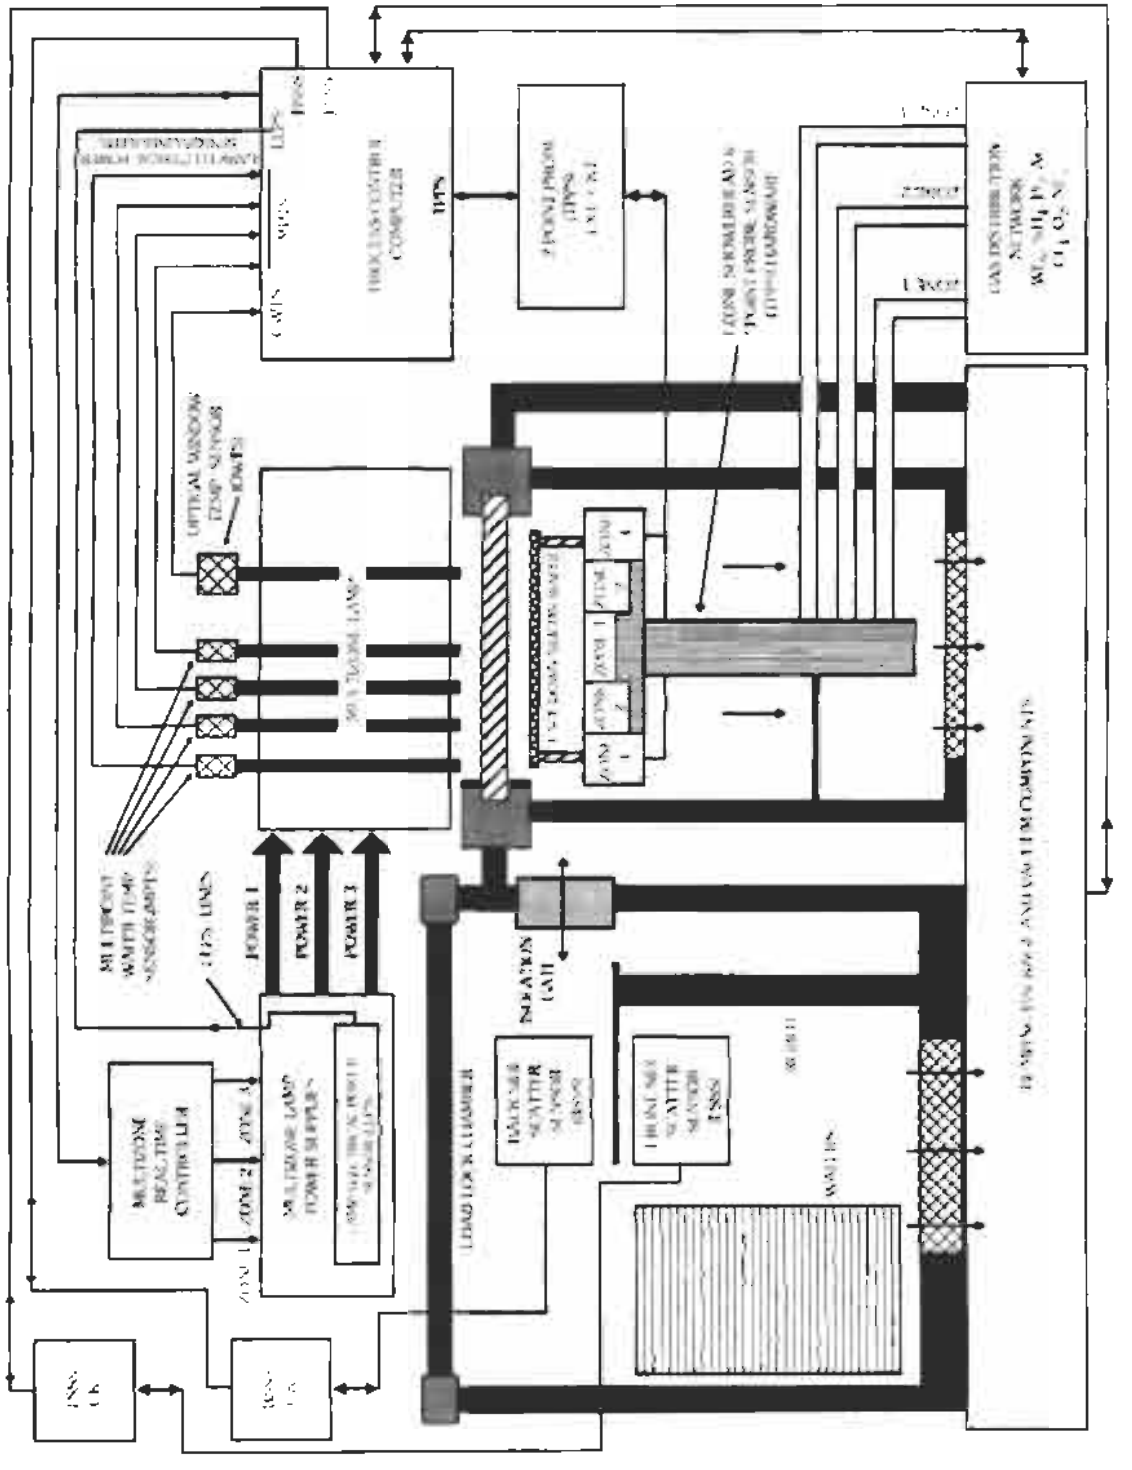

Fig. 66. Schematic diagram of an RTCVD reactor used for tungsten deposition. Various sensors are shown for temperature monitoring and CVD-W process control.

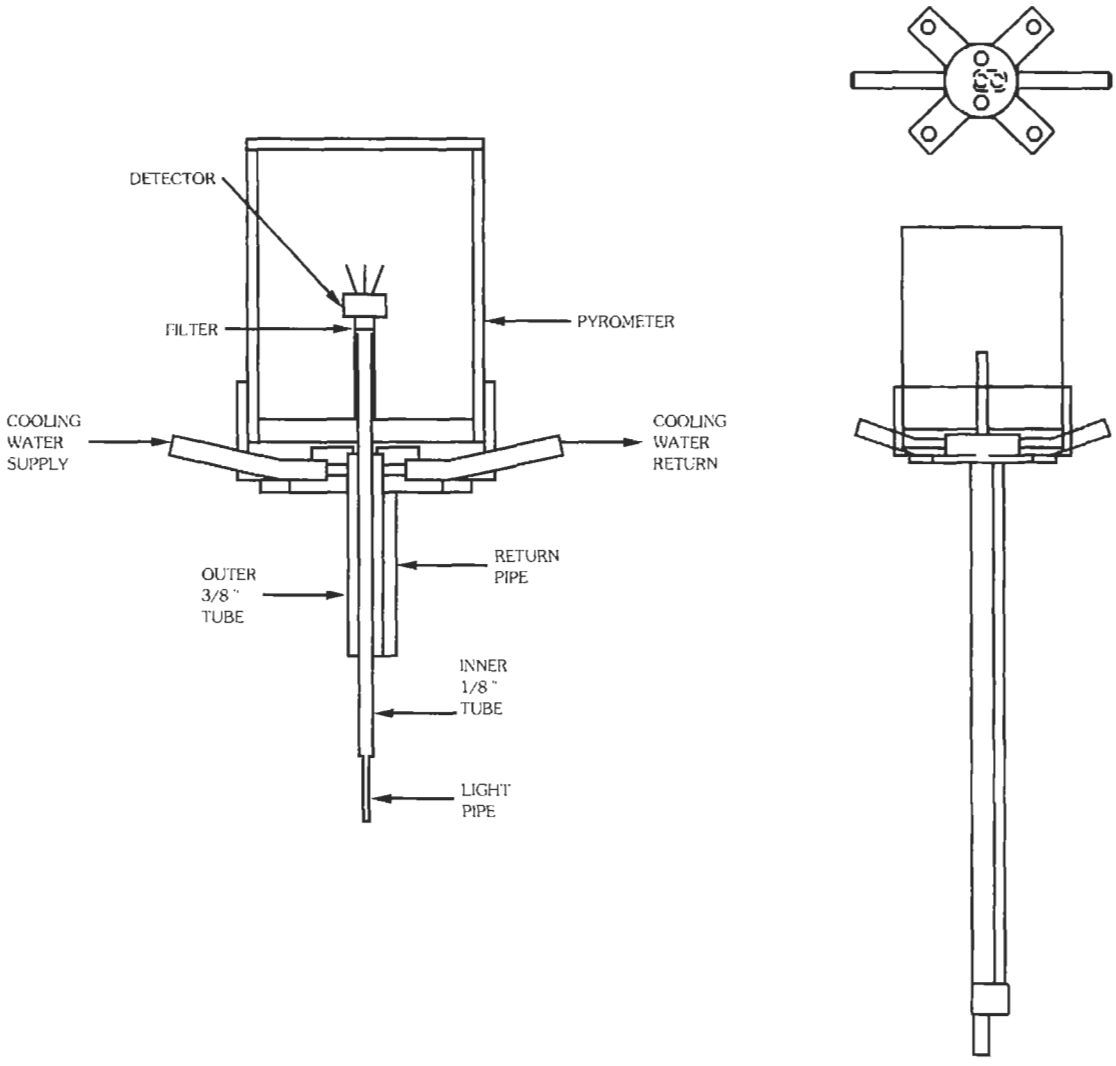

Fig. 67. Detail of a water-cooled light pipe, filter, and pyrometer assembly for multipoint temperature measurement.

The temperature of the water-cooled light-pipe tip, facing the wafer, is maintained at less than 80 °C. The temperature readout from each pyrometer is relayed to the process equipment with the process computer providing a temperature set-point to the controller. Any corrections for surface roughness, emissivity, lamp interference, or window temperature are then used to correct the pyrometer temperature reading.

The real-time emissivity measurement system is shown in Fig. 68.* This technique involves the use of a chopped CO laser beam, at 5.4 μm, to probe the wafer back-side surface during processing. This choice of wavelength eliminates the measurement of reflected lamp light, since the quartz jackets of the tungsten–halogen lamp bulbs provide a necessary cutoff of direct filament light at above 3.5 μm. The incident laser beam power is measured using a ZnSe beam splitter and an infrared (IR) detector. The light transmitted through the beam splitter is then focused onto a chalcogenide fiber and transmitted to the probe tip at the wafer end. Light that leaves the fiber tip and is transmitted through the chamber window arrives at the wafer. The chamber window is typically fused quartz, which has a small thermal expansion coefficient. The window material where the 5.4-μm beam is incident, however, needs to allow maximum transmission at this wavelength. A thin (1 mm) sapphire section is ideal, given the inertness of sapphire. The light arriving at the wafer surface is partly reflected, absorbed, or transmitted. Since the transmitted portion is essentially

* Reference 51.

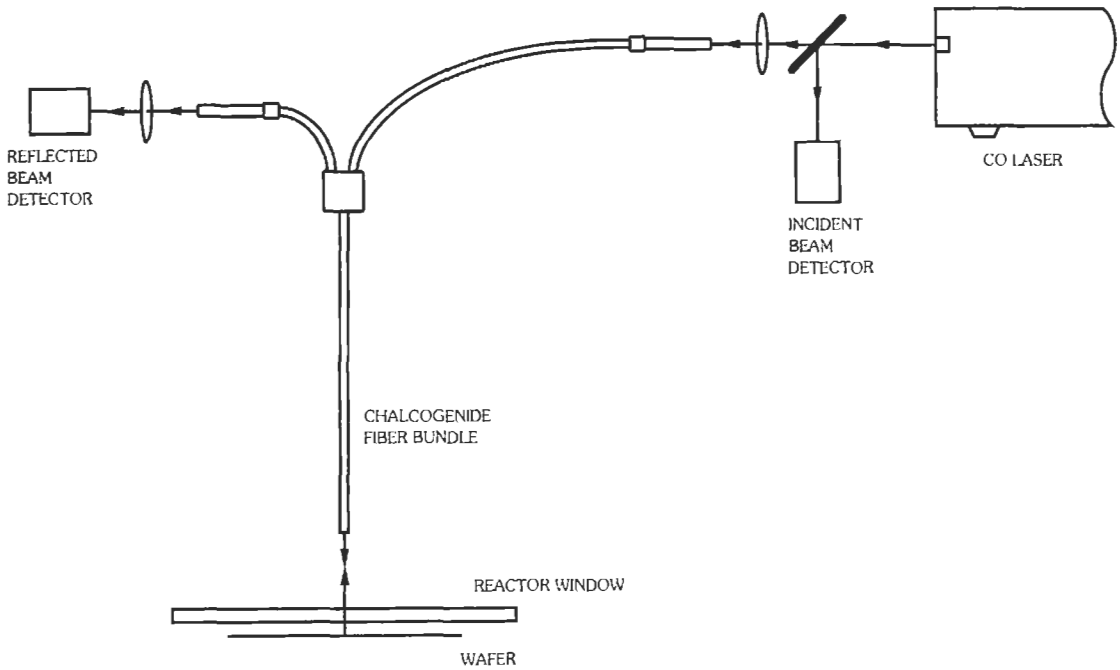

Fig. 68. Schematic of a 5.4-μm laser based emissivity and temperature measurement system, using chalcogenide IR fiber.

eliminated above 600–700°C, it can be neglected in most RTP applications. Additional optical hardware can be arranged to measure the transmitted portion if the operating temperature is sufficiently low. However, the transmission measurements are not required at all if the semiconductor substrates are heavily doped (e.g., p^-/p^+ epi material used for CMOS/BiCMOS technologies). Therefore, with the transmission neglected, the reflected light is collected via a fiber bundle arrangement at the probe tip and relayed back to a suitable detector. Spectral wafer emissivity can be extracted based on measurements of the reflected and the incident beam power levels. The reflected beam detector is also used to measure the light emitted by the heated wafer at the 5.4-μm wavelength, such that radiance and emissivity are measured simultaneously, allowing precise calculation of wafer temperature.

It is essential to note that the surface roughness of the back side of the wafer affects the measurement of the reflected light, since the scattering profile of the reflected light generally depends on the surface roughness. The reflection from a typical wafer back side at 5.4 μm contains a strong specular component, with a smaller but significant diffuse component. The diffuse component is not measured by the reflection bundle; consequently, a preprocess surface roughness measurement is used to provide a ratio of expected diffuse-to-specular reflection.

Fiber-Optic Scatter Sensor—The optical reflection and transmission properties of semiconductor wafers have important effects on various process variables such as wafer temperature, dynamics of wafer heating and cooling, and fabrication process uniformity in RTP. For instance, knowledge of these properties is required to evaluate substrate emissivity and temperature. Reflection and transmission parameters depend not only on the intrinsic properties of the surface films but also on the roughness present on the wafer surface. Surface roughness may be due to the wafer back side or a polycrystalline film present on the wafer (front side or back side). Reflection and transmission of wafers with a smooth surface will be essentially specular or coherent. In wafers with a rough surface film (or a rough back side), only a fraction of the reflected signal will be specular; the remaining fraction will be scattered within a space cone angle around the specular direction. The latter will increase as the surface roughness increases (or the light wavelength decreases). Surface roughness can also have an effect on the substrate emissivity and should be taken into consideration in any real-time pyrometry-based temperature sensor. In situ preprocess/postprocess measurement of the surface scattering characteristics and reflection properties of a wafer can be used to monitor its surface roughness and spectral emissivity. An important application of this technique is that measurement of these properties can be used in the real-time determination of the emissivity and temperature of a silicon substrate at different steps during a process flow. Another important application relates to measurements of CVD films on silicon wafers. For

instance, it has been shown that surface roughness of LPCVD W films is directly proportional to the film thickness.* Thus, an in situ noninvasive sensor that can evaluate surface roughness and spectral reflectance of semiconductor wafers can be used as a tool to monitor thickness and quality of LPCVD W (and other polycrystalline films). This can be done both for process control and for process prognosis/diagnosis purposes.

An in situ sensor to determine surface roughness, reflectance, and spectral emissivity of silicon wafers with various surface films has been developed.† The sensor has been designed for implementation in the vacuum load-lock chambers of SWP reactors. Operation of this in situ sensor is based on the relation between the surface roughness and the specular and scattered reflection properties of semiconductor wafers for an incident monochromatic electromagnetic wave. Thus, measurement of the total reflectivity as well as the scattering and specular parameters can be correlated to surface roughness and spectral emissivity of silicon substrates with various surface films. These parameters depend on the type and thickness of films on both the front side and back side of these substrates.

Metal Sheet Resistance Sensor—Wafer-to-wafer repeatability of CVD processes including CVD metal is of primary concern in ULSI manufacturing. This subsection describes a sensor device that can perform real-time monitoring of the CVD metal process with a high degree of accuracy and reliability.‡ A variation of the well-known four-point probe technique commonly used to measure metal-film sheet resistances ex situ has been employed to measure the mean sheet resistance of blanket metal films across the entire wafer during metal CVD. These measurements are used to determine the deposition process end point, thus improving wafer-to-wafer repeatability compared to standard timed process end points. This method differs from four-point probe measurements in that the driving current is passed between the same probe points across which the voltage drop is measured. As the current is passing through the voltage measurement probes, there is an inherent contact potential between the probe and the measurement surface. This technique is viable only if this contact potential is repeatable enough to be accounted for in the conversion algorithm. Extensive experimentation indicates that this is indeed the case.

A linear equation relates the mean (room temperature) sheet resistance to the voltage drop across the blanket metal film for a given current:

$$V_p = A(T) \times R_{sh} + B(T) \qquad \text{(Eq. 6)}$$

where

V_p is the measured probe voltage,
R_{sh} is the mean room-temperature sheet resistance,
$A(T)$ and $B(T)$ are temperature-dependent coefficients that are linear functions of temperature.

This equation underscores the importance of accurate temperature measurement for taking full advantage of this technique. Excellent agreement with experimental results has been achieved for CVD-W films. This agreement continues to hold even at elevated temperatures. An example of this is given in Fig. 69, which plots the probe voltage at 450 °C versus the mean room-temperature sheet resistance.

One possible problem relates to the effect of contacting metal pins with the wafer edge surface during the deposition process. There is a shadowing effect if the 0.8-mm diameter probe is kept in contact with the wafer edge during the entire process. The probe acts as a heat sink and shadow mask at that location, inhibiting tungsten nucleation. To overcome this effect, the probe can be retracted from contacting with the wafer when measurements are not being taken, especially at the beginning of the process when nucleation is taking place. Measurements may then be taken at various points during the process, indicating when the desired process end point is near. At this time, the probes are finally extended to measure the exact CVD process end point, with negligible disturbance to the wafer.

The initial experiments utilizing this technique for CVD process end-pointing have resulted in improved wafer-to-wafer repeatability by a factor of four over the conventional timed end-pointing technique. It is also effective for process prognosis and diagnosis, providing real-time information about the deposition rate.

RTP for Integrated CMOS Processing—The RTCVD processes described here prevent back-side depositions by wafer back-side and window purge. The RTCVD process modules (LPCVD amorphous and polycrystalline silicon, LPCVD tungsten, LPCVD oxide, LPCVD nitride) require in situ chamber cleaning for improved wafer-to-wafer process repeatability and reduced particle counts. Various RTP and RTCVD processes (e.g., dry and wet RTOs, LPCVD amorphous silicon, LPCVD polysilicon, source/drain and gate anneal, and CMOS well formation) have been developed that use wafer rotation for enhanced process uniformity.§ In situ sensors can be used to monitor wafer emissivity, film thicknesses, and conductive layer sheet resistance values.

An important requirement in RTP-based process integration is good temperature and process uniformity control throughout the entire integrated process flow. Conventional integrated processes based on the batch equipment (or a combination of batch and SWP) modify the wafer back-side structure repeatedly throughout

* Reference 59.
† Reference 51.
‡ Reference 51.
§ Reference 50.

the process flow. For instance, at various process steps the wafer back sides may be bare or may have a combination of silicon dioxide, silicon nitride, and/or polysilicon layers. Moreover, the thicknesses of these layers can vary as the process flow proceeds owing to many wafer cleaning and etch processes (wet and plasma). The integrated process flow can also cause back-side layer thickness nonuniformities. These variations translate into large-scale wafer back-side emissivity changes, which can cause significant RTP temperature and uniformity control problems. The process-control difficulties can be somewhat alleviated by using multipoint pyrometry with real-time emissivity compensation. Even with emissivity compensation, the wafer back-side nonuniformities can degrade RTP uniformity as the result of distorted or modified optical energy absorption and radiative losses.

To minimize the above-mentioned complications, a sub-0.50 μm CMOS process integration has been performed that uses starting silicon wafers with customized back-side seal layers.* The p^- epi/p^+ wafers are processed to receive a uniform back-side stack of 1300 Å silicon nitride on 1000 Å silicon dioxide. This back-side seal serves several useful purposes. (1) It prevents dopant outdiffusion from the heavily doped substrate; (2) it prevents back-side emissivity variations during oxidation and oxide deglaze processes (due to the oxidation and etch resistance of silicon nitride); and (3) it ensures uniform and stable back-side emissivity throughout the entire integrated RTP-based process flow. It should be emphasized that the one-sided depositions in RTCVD processes help to maintain a relatively constant and uniform back-side emissivity on the wafers in process. The above-mentioned back-seal process also eliminates any process nonuniformities caused by nonuniform wafer emissivities. Small wafer-to-wafer back-side emissivity variations are easily tracked and compensated via suitable in situ sensors. All the RTP-based processes described here employ reflective showerheads facing the front side of the wafer. As a result, the front-side pattern effects on process uniformity are essentially eliminated (as the result of the optical black-body cavity produced between the wafer front side and the reflective showerhead).

Numerous RTP-based fabrication processes have been developed for an SWP-based sub-0.5 μm twin-well double-level metal CMOS technology.† Fig. 70 shows a schematic cross-sectional view of this technology. Two technology versions have been investigated: one has buried-channel PMOS and surface-channel NMOS transistors without salicide and with silicided contacts; the other has surface-channel NMOS and PMOS transistors with salicide. This device cross section shows multiple RTP-fabricated device regions including: (1) gate electrode (LPCVD amorphous and polycrystalline silicon), (2) gate

* Reference 50.

† Reference 50.

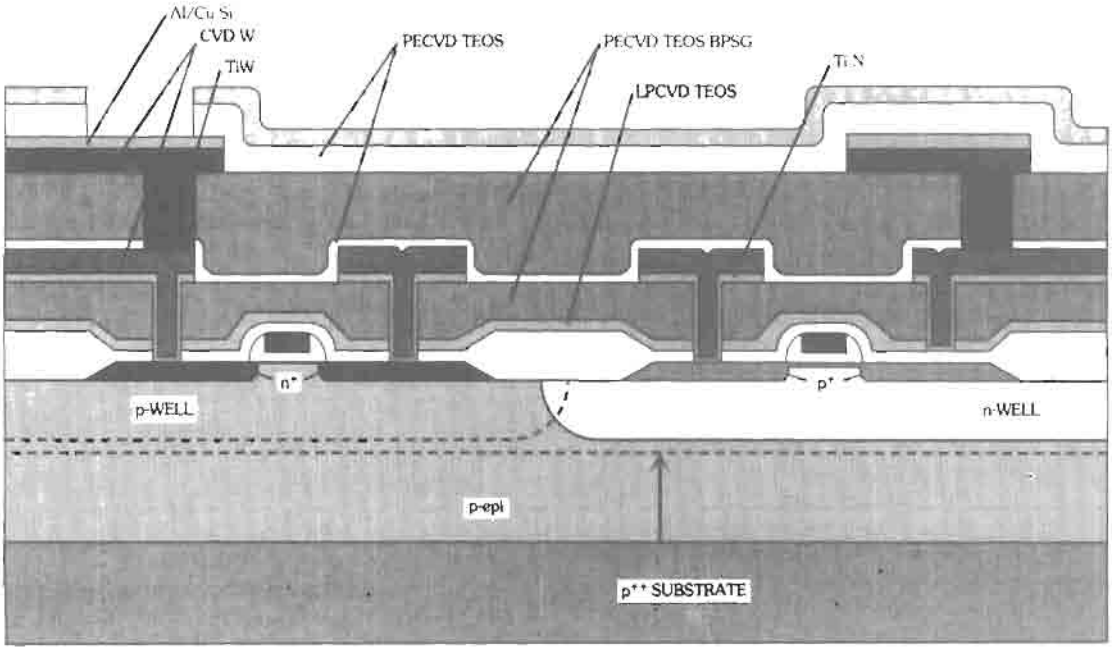

Fig. 70. Schematic cross-sectional diagram of a sub-0.50 μm RTP-based CMOS technology.

dielectric (dry RTO), (3) n and p wells (wet RTO for initial oxide and RTP oxynitridation-enhanced diffusion for well formation), (4) source/drain junctions (S/D RTA), (5) silicided contacts (RTP silicide react), (6) poly-buffer-LOCOS or PBL isolation (LPCVD silicon nitride on LPCVD polysilicon on dry RTO oxide oxidation mask), (7) oxide spacers (LPCVD silicon dioxide), (8) RTP forming gas anneal, and (9) double-level metal system (includes LPCVD tungsten). The total number of RTP steps (depositions, oxidations, and anneals) in the integrated CMOS flow exceeds 15. A single-wafer RTCVD-based epitaxial growth process was also developed for blanket boron-doped epitaxial silicon deposition to fabricate starting epitaxial wafers.*

RTP-Based Process Development Overview—Table 16 shows a list of various RTP-based processes developed for an integrated sub-0.50 μm CMOS flow† along with their specific applications and process parameter domains.

The epitaxial growth process was developed using SiH_2Cl_2 (DCS)/H_2 chemistry at low pressures (5–15 torr). A typical in situ–doped process employs an initial low-temperature (650–750 °C) in situ oxide removal process step (GeH_4/H_2) followed by epitaxial silicon deposition ($DCS/H_2/B_2H_6$) at 1000 °C for blanket p epi on p$^+$ substrate.

The RTO processes are used for oxide growth in the thickness range of 75 to 250 Å. Gate oxide (80 Å) and PBL initial oxide (90 Å) are grown by using dry RTO. It was determined that the dry and wet RTO processes should not be performed in the same process chamber because of possible cross-contamination and process memory effects of steam. As a result, dedicated reactors were used for these two processes. The wet RTO process employs an external pyrogenic steam generator where H_2 and O_2 flow rates can be controlled. The wet RTO process is used to grow the initial 250 Å oxide for CMOS well formation. The well implants are performed through this oxide. Moreover, this oxide provides the oxynitridation-enhanced diffusion (ONED) effect for well formation using ammonia anneal. Wet RTO is also used to grow a sacrificial (dummy) gate oxide after the isolation process module and before the dry gate oxidation step. To maintain reasonable process throughputs, both dry and wet RTO processes are performed near the atmospheric pressure (650 torr). Much lower pressures are not acceptable because the oxidation rates are significantly reduced and the resulting RTO times become excessively long.

Source/drain rapid thermal anneal (S/D RTA) is used for activation and formation of shallow p$^+$n and n$^+$p source/drain junctions. This process is performed at 950–1000 °C in argon ambient. Although the process can be performed at lower pressures (1 torr), high pressures (650 torr) are preferred in order to ensure sufficient cooling of the showerhead plate facing the wafer. This choice degrades the process throughput in

TABLE 16. RTP-BASED PROCESSES DEVELOPED FOR A SUB-0.5 μm CMOS TECHNOLOGY

RTP-Based Processes	Applications	RTP Parameter Domain
Epitaxy/in situ clean	epi material (p^-/p^+)	700–1000 °C, low-pressure DCS/H_2, GeH_4/H_2
Dry RTO	Gate oxide, PBL oxide	1000–1050 °C, 650 torr oxygen ambient
Wet RTO	Thick oxides (ONED tank)	900–950 °C, 650 torr pyrogenic steam
Source/drain RTA	S/D activation, gate doping	900–1000 °C, 80–650 torr argon ambient
RTP tank formation	CMOS n & p well formation	1050–1100 °C, 650 torr ammonia ambient
LPCVD polysilicon	CMOS gate formation	650–700 °C, low pressure SiH_4/Ar, Si_2H_6/Ar, (SiH_4/H_2)
LPCVD amorphous Si	CMOS gate formation	500–590 °C, low pressure SiH_4/Ar, Si_2H_6/Ar, (SiH_4/H_2)
LPCVD tungsten	Multilevel metal	300–550 °C, low pressure $SiH_4/H_2/WF_6$
TiN/TiSix RTA react	Salicide, silicided contacts	600–750 °C, low pressure N_2 or NH_3 ambient
RTP sinter (FGA)	Forming gas anneal	450–500 °C, low pressure FGA or N_2 ambient
LPCVD nitride	PBL nitride deposition	800–850 °C, low pressure DCS/NH_3 or SiH_4/NH_3
LPCVD oxide	Oxide spacers, undoped oxide	700–750 °C, low pressure $TEOS/O_2$

standard mode of processing, mainly because of the time intervals required to ramp up and ramp down the chamber pressure between vacuum (for wafer transport) and process pressure (for wafer processing).

CMOS n and p well formation is accomplished by RTA in an ammonia ambient following the n and p well implants. This process is the highest "Dt" RTP fabrication step used in this integrated CMOS flow. It is usually done at 1100 °C for 5 minutes in 650 torr of ammonia in the presence of a 250 Å oxide grown using a wet RTO process. The ONED effect reduces the time/temperature needed to form the well profiles with the desired junction depths. It is essential that the RTP/ONED process is performed at higher pressures (e.g., 650 torr) to induce the maximum ONED effect for reduced RTP time.

LPCVD polysilicon and α-Si processes are used for gate electrode formation based on a split-deposition gate process. Both of these processes are performed at a low (15 torr) pressure using a mixture of SiH_4/Ar. Argon is preferred over hydrogen as a carrier gas. This is because the deposition rates are somewhat higher in SiH_4/Ar than in SiH_4/H_2 (hydrogen causes a chemical retardation effect since it is a byproduct of the deposition process). Moreover, hydrogen may cause some gate oxide reliability degradation at higher temperatures (above 650 °C). The polysilicon and amorphous silicon deposition processes are performed at 650 °C and 560 °C, respectively. The lower α-Si deposition temperature ensures continuous, thin (≈200 Å), crystallite-free layers of α-Si directly over the thin gate oxide for its protection during a subsequent photoresist processing and patterned ion implantation step. Deposition processes based on an alternative disilane/argon chemistry have also been developed. The disilane-based LPCVD-Si processes provide deposition rates comparable to those of the silane-based processes using smaller Si source gas flows.

Tungsten LPCVD is employed at low pressures (0.5–8 torr) for use in a double-level metal system. The first metal (CVD-W) level is deposited directly over an RTP-reacted TiN layer using a two-step process (silane-reduced WF_6 followed by a hydrogen-reduced WF_6). The second metal layer employs a layered structure including an underlayer of CVD-W, also deposited by RTCVD.

The $TiN/TiSi_2$ react process has been the most widely used application for RTP and the first RTP used for commercial product manufacturing. The RTP react process described here is performed at 650–750 °C in a low-pressure (1 torr) nitrogen ambient. This process can also be done at higher N_2 pressures (e.g., 650 torr) and/or in an ammonia ambient. It is used for formation

of silicided contacts to the source/drain junctions as well as formation of TiN contact barrier and nucleation layer for the metal-1 CVD-W layer.

The RTP sinter process is performed in a forming gas ambient at 1–650 torr and at 450–475 °C. The higher process pressures (e.g., 650 torr) enhance the amount of hydrogen flux to the gate dielectric interface. This process step is used to reduce the gate oxide surface-state density and restore the desired subthreshold and threshold voltage characteristics. The RTP sinter process is used following the last damage-producing plasma etch process in the integrated flow (e.g., after metal 2 etch and/or after the passivation-overlayer etch).

The nitride LPCVD process can be performed in SiH_4/NH_3 or DCS/NH_3 ambients. This process is usually carried out at 800–850 °C and at low pressures (1–5 torr). The oxide LPCVD process is performed at 700–750 °C with $TEOS/O_2$ used for dielectric spacer formation.

The above-mentioned RTP-based processes can be conducted in one of two modes of operation: (1) standard pressure cycling (SPC) mode, and (2) reduced pressure cycling (RPC) mode. The SPC mode operates as follows: (1) transfer the first wafer from the vacuum load-lock to the vacuum process chamber, (2) start process gas flows and stabilize pressure, (3) start wafer processing by activating the lamp energy source, (4) stop the process by inactivating the lamp energy source, (5) stop the gas flows and pump down to vacuum, (6) transfer the processed wafer from the process chamber to the vacuum load-lock chamber, and (7) proceed with processing the next wafer in the cassette. As a result, the process throughput in the SPC mode is limited by the time intervals needed to ramp the chamber pressure between vacuum and process pressure. This is particularly true for the higher-pressure processes such as RTO. The RPC mode of operation can increase the effective process throughput by eliminating these pressure cycling segments from wafer to wafer. For instance, in a dry RTO process, the load-lock chamber and process chamber are first pumped down to vacuum after loading the wafer cassette into the load-lock chamber. Before or after transferring the first wafer to the process chamber, oxygen flow is initiated into both the load-lock and process chambers, and their pressures are stabilized at the desired process pressure. Wafer processing and transport are done at constant pressure without any pressure cycling. This mode of operation will increase the effective process throughput. The RPC mode is compatible with the dry oxidation and anneal processes that employ oxygen, argon, ammonia, nitrogen, and forming gas (e.g., dry RTO, S/D and gate RTA, RTP/ONED tank formation, silicide). However, the SPC mode is the preferred choice with all the RTCVD processes because of safety and reactor cleanliness/reliability considerations.

The RTP reactor count and process partitioning should be done based on the considerations to minimize the number of RTP modules without compromising the quality of fabrication processes and without cross-contamination issues. As a result, the RTP modules used in an integrated CMOS flow and their dedicated processes may be chosen as follows:*

- LPCVD-Si module for LPCVD α-Si, polysilicon, and in situ germane cleaning
- Dry RTO module
- Wet RTO module
- S/D and gate RTA and ONED tank module
- Metal anneal module for silicide react and sinter
- LPCVD tungsten module
- LPCVD silicon nitride module
- LPCVD silicon dioxide module
- Epitaxial growth module (with germane cleaning)

These are a total of nine RTP modules used for the integrated sub-0.5 μm CMOS flow. Besides these modules, one other thermal process module is also employed. A single-wafer high-pressure oxidation system (SWP-HIPOX) has been used to grow thick field oxides (rates of 1000–3000 Å/min) and to perform BPSG reflow. This can be considered a tenth RTP module even though the SWP-HIPOX module employs resistive wafer heating.

In this minifactory, wafer transport between critical sequential steps (e.g., from gate RTO to LPCVD-Si gate electrode) is performed in a controlled vacuum environment to minimize native oxide growth and particles.

Selected RTP Results—As discussed earlier, the wafer back-side emissivity has significant effects on RTP uniformity and control. Fig. 71 shows the thickness of gate oxide grown at 1000 °C (for a fixed time) with closed-loop pyrometry control without in situ emissivity compensation versus thickness of back-side oxide layer (back-seal layer with 1300 Å nitride on top of oxide with varying thicknesses). These data indicate well over 10% variation in gate oxide thickness when the back-side oxide thickness varies between 800 Å and 1400 Å. The use of a stable back-seal structure in conjunction with in situ emissivity measurement and compensation is an effective solution to this problem.

Compared to dry RTO, wet RTO is capable of growing oxides under reduced temperature/time conditions. As an example, Fig. 72 shows the oxide thickness versus wet oxidation time at an oxidation temperature of 950 °C and a total pressure of about 600 torr. These oxidations were performed using a nonstoichiometric hydrogen-to-oxygen ratio of 1. Therefore, the oxidation ambient consisted of a mixture of pyrogenic steam and excess oxygen. Under these conditions, a 5-minute process could grow about 250 Å of oxide. A 950 °C/5 min dry RTO process would grow about 80 Å.

The wet RTO growth rate is also affected by the hydrogen-to-oxygen flow ratio. Fig. 73 shows the

* Reference 50.

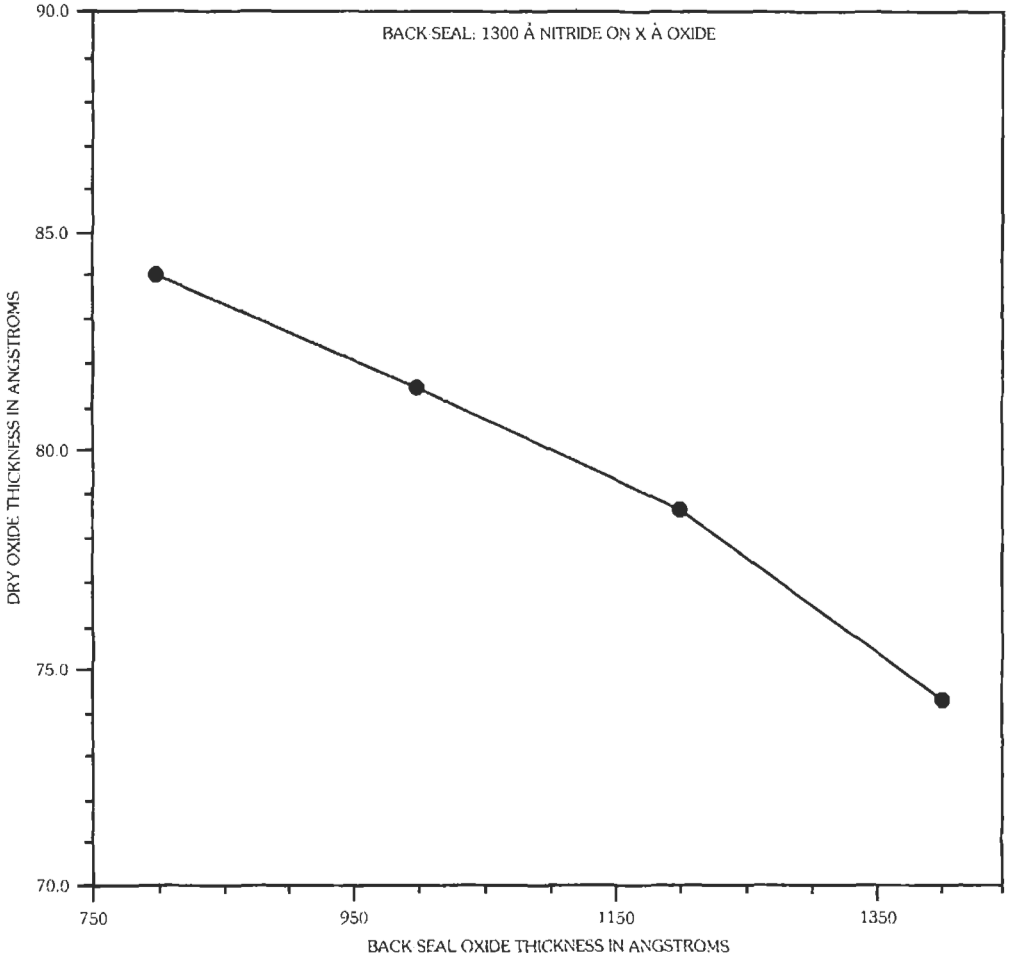

Fig. 71. Effect of variation in back-side film thicknesses on gate oxide thickness.

oxide thickness data versus flow ratio for 950 °C/5 min oxidations at 600 torr. A flow ratio of zero corresponds to steam-free dry oxidation, and a flow ratio of 2 corresponds to stoichiometric steam generation in the torch. The oxide thickness corresponding to a flow ratio of zero is over 100 Å. This is thicker than the thickness expected for a fully dry RTO process under similar temperature and time conditions. The difference can be attributed to the residual water vapor in the wet RTO process chamber, which causes some growth rate enhancement. This is clearly a good reason for not using one chamber for both dry and wet RTO processes. A stoichiometric flow ratio of 2 offers the largest thickness because it has the highest steam partial pressure (600 torr without any excess oxygen). For process repeatability reasons, a flow ratio of 1 has been observed to be superior to the stoichiometric ratio of 2. The local minimum corresponding to a flow ratio of 1.4 may be attributed to steam condensation on cold surfaces, resulting in reduced steam partial pressure in the process chamber.

Figs. 74 and 75 show examples of metal-oxide-semiconductor (MOS) breakdown distribution data for capacitors with various gate electrode formation process splits (80 Å gate oxides). The silicon gates were formed in two separate deposition steps (split-deposition process): a first layer of thin (≈200 Å) amorphous silicon and a second layer of polysilicon (≈2800 Å). The data in Fig. 74 are for split-deposition gate MOS capacitors with various gate electrode processing conditions, with and without an in situ germane-based native oxide removal process. In this figure, "PR" represents photoresist processing (coat and strip) over the initial amorphous Si layer, and "HF" represents wet HF native oxide removal (in dilute HF), before the subsequent polysilicon RTCVD (AVP poly) at various temperatures. The photoresist process was used to simulate photoresist-induced contamination over the gate α-Si layer.

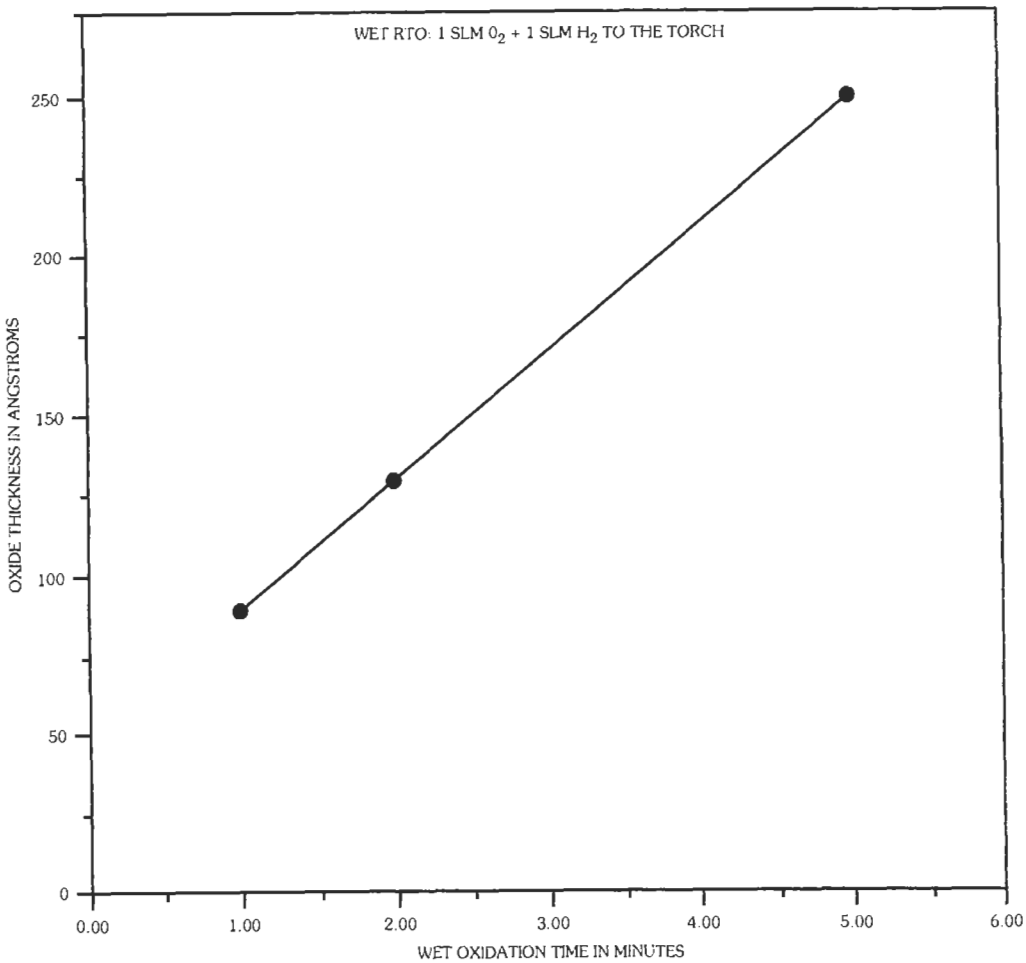

Fig. 72. Oxide thickness vs wet RTO time at 950 °C and 600 torr. The oxidations were performed using 1 slm (standard litre per minute) of O_2 and 1 slm of H_2 to the pyrogenic steam generator.

These data indicate that the devices with in situ germane cleaning (prior to polysilicon RTCVD) have breakdown distribution comparable to that for other devices without germane cleaning. The use of germane cleaning ensures MOS process reproducibility and repeatable gate patterning by removing the oxide from the original α-Si/polysilicon interface. The devices with gate polysilicon deposited at various temperatures (590, 620, and 650 °C) also show comparable breakdown characteristics. The low-field breakdowns in Fig. 74 could be mostly attributed to particles. The breakdown distribution data in Fig. 75 are for split-deposition gate devices with various methods of gate formation. These include RTCVD (silane versus disilane chemistry) and furnace (silane chemistry) α-Si processes, and RTCVD (silane versus disilane chemistry) polysilicon processes at various temperatures. The breakdown distributions are nearly comparable and indicate acceptable characteristics for silicon RTCVD.

RTP has also been employed to form silicided shallow source/drain junctions with low leakage current densities (as low as 5 nA/cm^2).* The buried-channel PMOS version of the integrated sub-0.50 μm CMOS flow employs nonsalicide source/drain junctions with silicided contacts whereas the surface-channel PMOS/NMOS version consists of salicided structures. Figs. 76 and 77 show the sheet resistance values of RTP-reacted titanium layers over doped (p^+ and n^+) silicon and silicon dioxide, respectively. The RTP react processes were performed in 1 torr nitrogen using various one-step and two-step processes. For an initial titanium layer thickness of 400 Å, the two-step processes result in TiN/$TiSi_x$ sheet resistance values of less than 4 Ω/sq. on n^+p (As/P doped) and p^+n junctions. For 800 Å starting titanium on oxide, the RTP react process results in a relatively oxygen-free TiN layer with

* Reference 50.

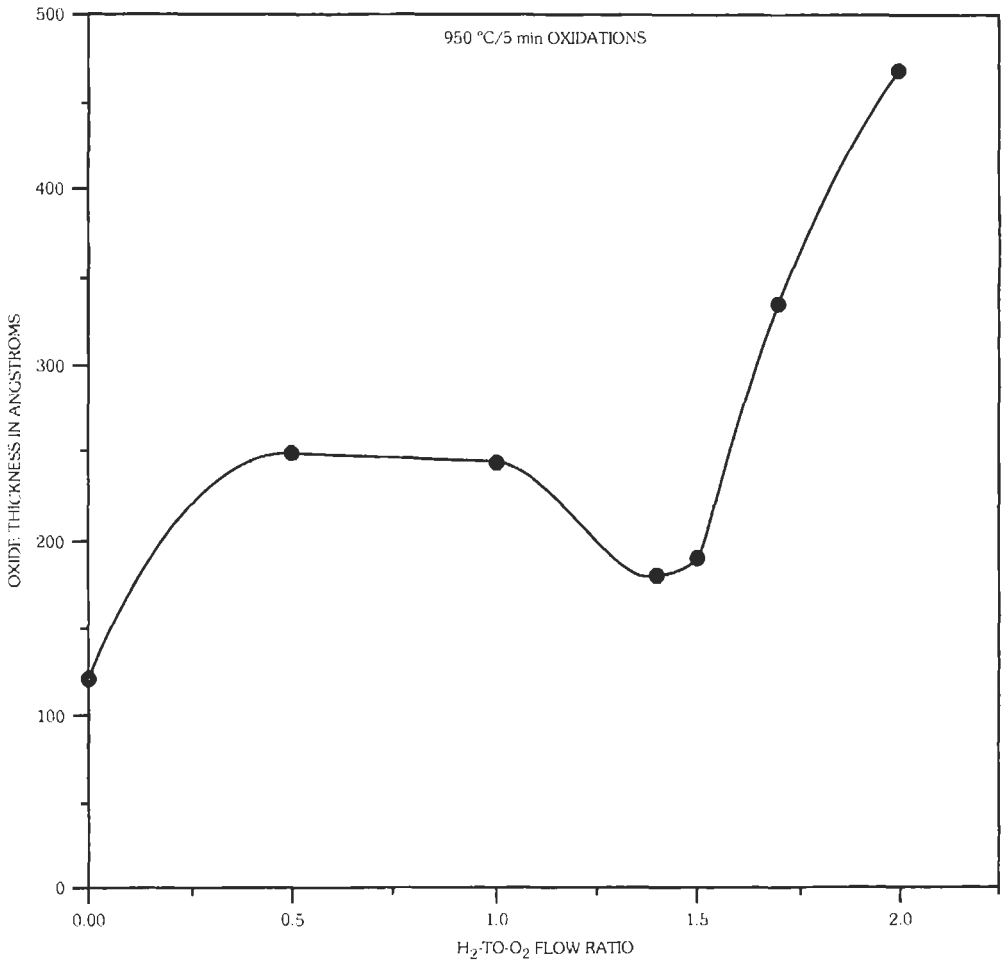

Fig. 73. Effect of hydrogen-to-oxygen flow ratio on wet oxide thickness for 950 °C/5 min oxidations at 600 torr total pressure.

sheet resistance values on the order of 20 Ω/sq. The first RTCVD tungsten metal layer is deposited over the RTP-reacted layer (TiN over the interlevel oxide dielectric and TiN/$TiSi_2$ in the contact holes).

Suitable tungsten RTCVD processes have been developed for a double-level metal system for the sub-0.50 μm CMOS technology. For the first metal level, RTCVD tungsten is used to fill the contact holes and form the metal lines over TiN (using the same deposition step).

Single-Wafer Surface Cleaning

Many steps in the processing of silicon devices are preceded by a "clean" to remove trace surface contaminants or to chemically pretreat the wafer surface. Traditionally, such cleans have been based nearly entirely on chemical solutions,* which selectively attack and remove the surface contaminants. A number of factors render these "wet" cleans increasingly undesirable. The chemical wastes generated by such processes are hazardous to the environment, and their proper treatment and disposal are expensive. Besides the environmental and economic concerns, stringent requirements on device performance also dictate a trend to integrate the processing steps with the corresponding precleans, so that exposure to uncontrolled ambient can be minimized. Equipment and process incompatibility has prevented such integration involving the wet cleans.

Alternative cleans based on gas-phase/vapor-phase chemistries are more amenable to the desired process integration. Notable examples of such "dry" cleans are (1) the incorporation of an in situ high-temperature hydrogen and HCl bake prior to silicon epitaxy and (2) slight contact sputter etch prior to the deposition of metal interconnections. In the remainder of this

* Reference 60.

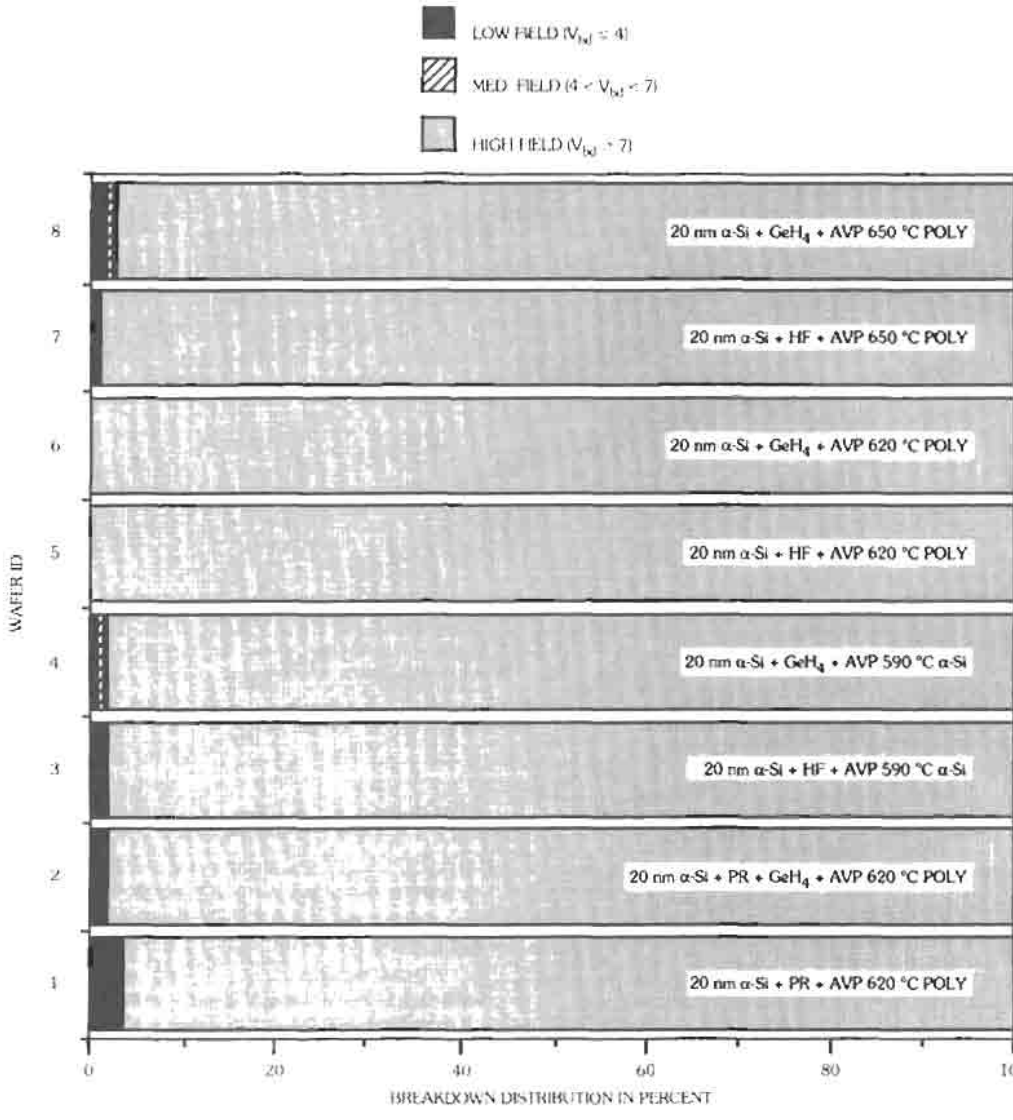

Fig. 74. Breakdown characteristics for split-deposition gate MOS capacitors with 80 A gate oxides and various polysilicon RTCVD processes. The data are for devices with various surface treatments between the initial amorphous silicon and the subsequent polysilicon RTCVD (germane cleaning, wet HF deglaze, and photoresist coat/strip).

subsection, the possible alternative dry cleans will be discussed along the traditional classification of surface contaminants: native/chemical oxides of silicon, trace organic, and trace metallic contaminants.

Surface Cleaning in IC Manufacturing—The microstructure, material purity, and electrical properties of various interfaces between different layers (semiconductor/dielectric, semiconductor/semiconductor, metal/semiconductor, and others) strongly influence the overall reliability and performance characteristics of ULSI circuits. The critical device interfaces include polysilicon/single-crystal Si (in bipolar transistors), Si/SiO_2 (in MOS and bipolar transistors), silicide/single-crystal Si, and others. As a result, high-performance device fabrication requires effective preprocess and postprocess cleaning of the semiconductor surfaces to remove thin native oxide layers and other contaminants such as residual metallic and organic impurities.

Fig. 78 shows various possible sources of surface contamination and damage in device processing (represented as "causes") and their corresponding effects (shown as "effects") on the semiconductor surface.

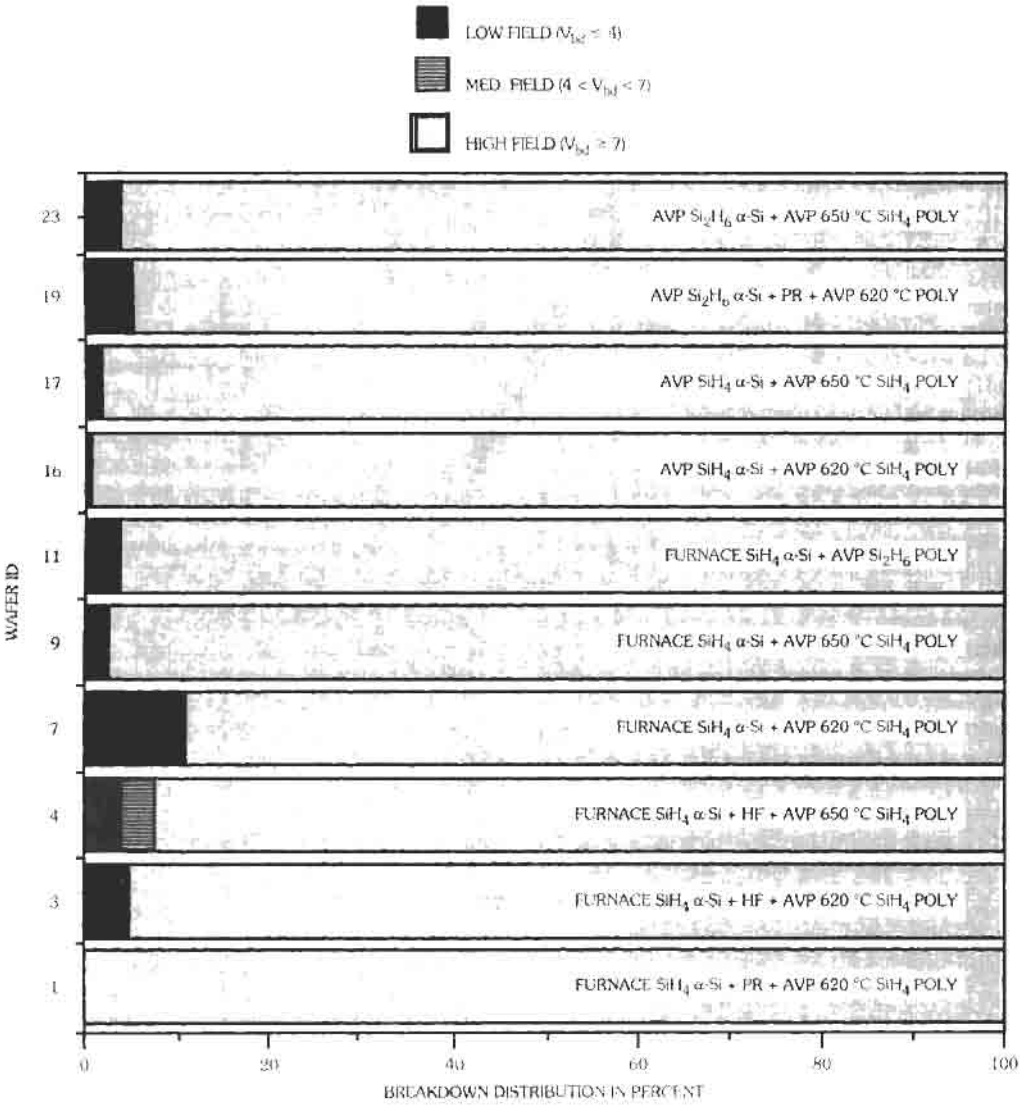

Fig. 75. Breakdown characteristics for split-deposition gate MOS capacitors with 80 A gate oxides and various amorphous silicon and polysilicon deposition processes.

The dark bullets show definitive cause–effect correlations, and the light bullets represent likely cause–effect links. Wet chemical treatments (e.g., NH_4OH:H_2O_2), atmospheric ambient exposure, low-purity process gases, and poor process equipment base pressure can form thin (up to ≈30 Å) native oxide layers on silicon surfaces.* The precise thicknesses of these native oxide layers depend upon the specific source; for instance, oxides resulting from ambient exposure are usually less than 12 Å thick,† whereas the chemically grown native oxides resulting from exposure to hot NH_4OH:H_2O_2 may be as thick as 17 Å or more.‡ Native oxide layers are usually detrimental to device performance and increase device parameter spread owing to process repeatability problems.§ A dilute HF treatment is usually used as the last prefurnace cleaning

step to remove any residual native oxide layer.* Poor processing equipment base pressure and vacuum integrity can also result in oxygen incorporation and/or formation of surface native oxide layers.† Fig. 78 also summarizes various possible sources of other contaminants in silicon device processing. For example, metallic contaminants may be incorporated into a semiconductor substrate by wet chemicals, reactive-ion etching, photoresist processing, and ion implantation. The current semiconductor device manufacturing environments essentially rely on wet cleaning techniques for removal or reduction of various types of contaminants including the metallic impurities (e.g., Ni, Cr, Fe, Cu, Zn). The wet chemical cleaning processes used prior to the gate oxidation and other high-temperature furnace processing steps are known to have significant effects on the device manufacturing yield and reliability characteristics.‡

Fig. 79 presents a list of different processing techniques for removal of native oxide layers from semiconductor substrate. The common procedure for removing native oxides (and other contaminants) prior to epitaxial silicon (or polysilicon contact) deposition involves an ex situ aqueous cleaning (such as the so-called RCA cleaning and a final HF dip), followed by an in situ high-temperature (around 900–1200 °C) hydrogen prebake.§ However, some UHV-CVD epitaxial growth and silicon deposition techniques essentially depend on the effectiveness of an ex situ cleaning and native oxide removal process and maintaining an atomically clean silicon surface in the absence of any form of in situ cleaning process." A suitable wet cleaning step is expected to remove most of the native oxide and other trace contaminants, while a high-temperature H_2 prebake process removes residual native oxide left on the semiconductor surface caused by ambient exposure and/or chemical cleaning. As shown in Fig. 23, other native oxide removal processes have been developed that operate at lower substrate temperatures compared with the high-temperature hydrogen bake process. The germane-assisted native

oxide removal process is in the low-temperature chemical dry cleaning category.

Fig. 80 shows the effectiveness of various surface cleaning techniques (as specified by the process energy sources and/or cleaning chemistries) for removal of surface contaminants (e.g., native oxides) and other undesirable surface effects (e.g., damage, unwanted surface passivation bonds such as Si–F). The dark bullets represent strong cleaning action for removal of the specified contaminant or undesirable surface effect using the specified processing technique. Moreover, the light bullets demonstrate possible cleaning effect for the specified linked pair of process technique and surface contaminant. All the shown techniques can be quite effective for removal of native oxide layers. Thermal cleaning techniques such as the germane process may also be useful for removal of some metallic and organic contaminants besides native oxide layers. Another example is the ECR plasma surface cleaning technique which has proven effective for removal of native oxide and organic contaminants.*

Low-Temperature Germane-Based Surface Cleaning—A low-temperature (650–750 °C) dry surface cleaning process is described for in situ removal of native oxide layers and other surface contaminants.† The cleaning process chemistry consists of a mixture of germane (GeH_4) and hydrogen (H_2) gases with very low germane-to-hydrogen flow ratio (10–20 ppm). The germane-based surface cleaning process can be integrated with various thin film growth and deposition processes such as epitaxial growth, gate dielectric formation, and polycrystalline or amorphous silicon deposition for MOS and bipolar device fabrication.

The stacking fault density measurements on epitaxial Si films grown following the in situ germane-assisted native oxide removal have indicated that the two most significant cleaning process parameters are the substrate temperature and GeH_4:H_2 gas flow ratio. Substrate temperatures much below 600 °C result in insufficient native oxide removal and, as a result, higher stacking fault densities in the grown epi layers (for the range of small GeH_4:H_2 flow ratios). Moreover, temperatures in excess of 850–900 °C result in increased stacking fault density in the grown epi layers. The latter is probably due to nucleation of germanium on the silicon surface during the in situ cleaning

* References 75 and 76.

† Reference 49.

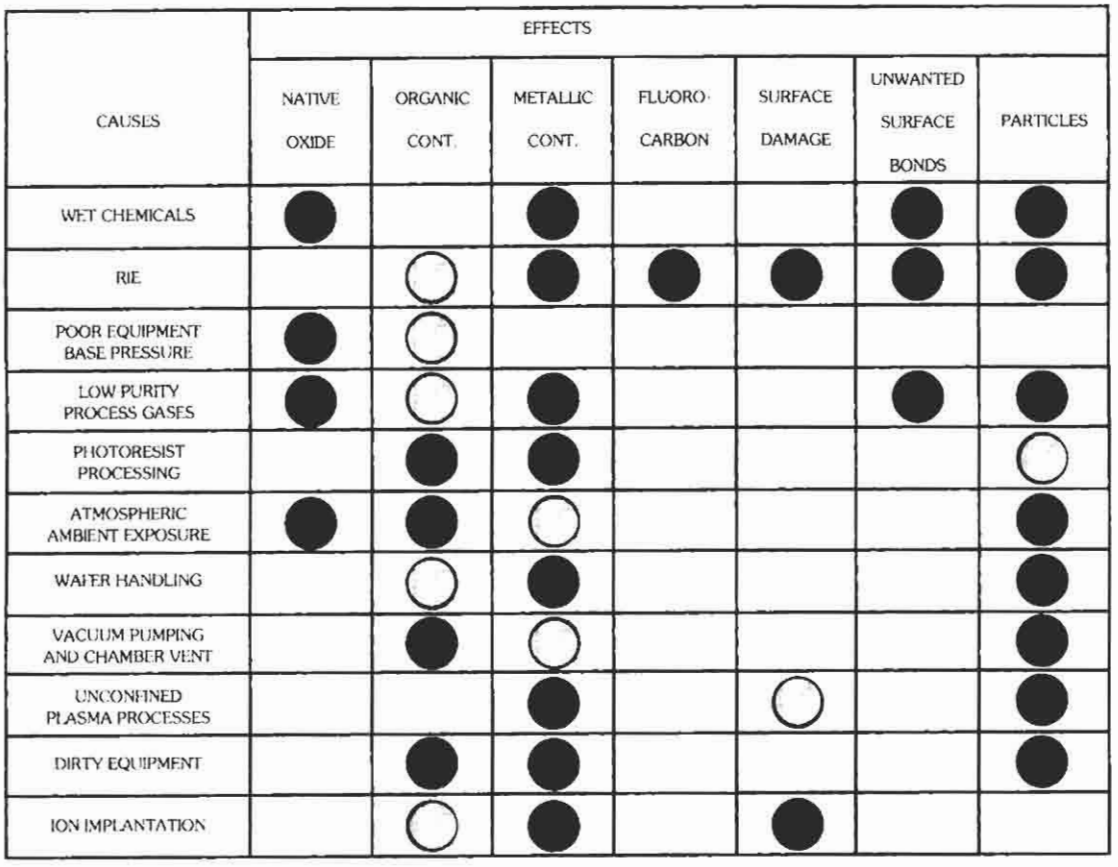

Fig. 78. Sources of surface contaminants and damage in semiconductor device processing.

process. The germane-assisted cleaning processes work well in the temperature range of 650–750 °C.*

For a given substrate temperature, process pressure, and total gas flow rate, there is a critical GeH_4:H_2 flow ratio beyond which germanium can nucleate on the surface during the cleaning process. Germanium nucleation can be prevented by reducing the germane-to-hydrogen flow ratio below the critical values. As the total process pressure increases, the germane-to-hydrogen flow ratio may have to be further reduced to prevent germanium deposition or nucleation during the in situ cleaning cycle. The experimental results have indicated that GeH_4:H_2 flow ratios in the range of 10–20 ppm (e.g., 12.5 ppm) work well for effective native oxide removal processes at 5 torr and in the substrate temperature range of 650–750 °C. The germane cleaning process can selectively remove native oxide layers without etching thermal oxides. This selectivity makes the germane-based cleaning processes superior to the fluorine-based native oxide removal techniques.

It is expected that the GeH_4/H_2 processes clean the substrate surface by direct reaction of germane with the "loose" native oxide layer. The possible oxide reduction reactions are the ones that produce volatile germanium oxide species (GeO). The presence of a large partial pressure of hydrogen balances the cleaning process and prevents germanium nucleation during the in situ cleaning process.

Native and Chemical Oxide Cleans by Vapor-Phase HF—The vapor-phase equivalent of the aqueous HF has been extensively investigated.† Among the advantages of this approach are low chemical consumption, low particle addition, and improvements in electrical performance as measured by a number of parameters, such as silicide sheet resistance and thin oxide stress endurance. More than 3000 wafers processed in a four-month period using only 1 liter of

azeotropic HF solution resulted in excellent particle performance (Fig. 81). Gate oxides grown after vapor-phase HF cleaning have shown several times improvement in oxide endurance under constant-current stress compared to aqueous HF pregate cleaning.*

Comparison of Various Native Oxide Removal Techniques—Table 17 summarizes the overall features of various native oxide removal processes. Among these processes, the conventional hydrogen prebake process requires the highest substrate temperature.† Its native oxide removal selectivity with respect to thermal oxide and silicon is good; however, thermal oxide undercut on patterned substrates may be a problem. The hydrogen prebake technique is essentially a simple process and compatible with the conventional epitaxial growth reactors and processes. Sputter etch processes using RF or ECR plasmas (Ar or Ar/H_2 ambients) can also be used for native oxide removal.‡ These processes require medium substrate temperatures, on the order of 750–850 °C, in order to eliminate sputter-induced surface damage. The sputter etch techniques offer poor etch selectivity with respect to thermal oxide and silicon and are not usually compatible with the conventional thermal CVD equipment. For in situ cleaning applications, the use of sputter etch native oxide removal modules may be acceptable in vacuum-integrated cluster tools for some applications.

According to Table 17, the chemically enhanced ion-assisted ECR or RF plasma native oxide removal processes are effective for low-temperature ($T \leq 500$ °C) removal of native oxide layers without leaving any residual surface damage.§ Hydrogen or a mixture of hydrogen and silane have been used for chemically enhanced plasma removal of native oxide layers. These processes require special plasma equipment

modules and are incompatible with standard epitaxial growth or deposition equipment. Remote plasma-enhanced processes such as those with remote hydrogen plasma can remove thin native oxide layers at relatively low temperatures (150–500 °C).* These processes require special plasma modules and are rather ineffective for removal of thicker (e.g., over 10–15 Å) native oxides. They may also generate particles if a quartz discharge tube is used.

As shown in Table 17, the low-temperature thermal native oxide removal processes based on the fluorine-containing gases (e.g., NF_3 or ClF_3) require special corrosion-resistant equipment and offer rather poor native oxide etch selectivity with respect to thermal oxide and silicon.† Another potential problem with these processes is the possibility of formation of Si–F surface passivation bonds and/or residual chlorine remaining on the surface. Special care is needed to prevent surface etch pits. Substrate heating in a UHV environment such as in an MBE chamber can remove thin native oxide layers at medium temperatures with relatively good etch selectivity with respect to thermal oxide and silicon;‡ however, this technique requires expensive UHV hardware and is not compatible with the conventional silicon processing equipment. In situ deposition of a submonolayer of germanium or silicon on the substrate prior to a UHV heating cycle can help to further reduce the substrate temperature required for removal of thin native oxide layers.§

Vapor-phase removal of native oxide layers is performed based on the HF/H_2O chemistry at room temperature." One advantage of the HF-based vapor phase processes is the capability for providing very good native oxide etch selectivity with respect to other material layers including thermal oxides; however, the HF/H_2O-based vapor-phase processes cannot be performed in the conventional processing equipment and

require a dedicated special process chamber. As shown in Table 17, photochemical cleaning refers to the ultraviolet-enhanced processes for native oxide removal at medium temperatures.* These processes are excellent candidates for low-temperature removal of metallic and organic contaminants as well. They require special photochemical equipment and are incompatible with the standard thermal processing equipment. Finally, as indicated in Table 17, the germane-based native oxide removal process is compatible with the conventional silicon processing equipment. This process is effective for native oxide removal at low to medium substrate temperatures and provides good native oxide etch selectivity with respect to thermal oxide layers and silicon.

Organic Cleans—The removal of trace organic contaminants using ozone and atomic oxygen generated by irradiating an oxygen containing ambient with deep UV† is now firmly established as a viable substitute for the traditional wet organic clean. The photoactivation of oxygen and the subsequent generation of

TABLE 17. FEATURES OF VARIOUS NATIVE OXIDE REMOVAL PROCESSES

Oxide Removal Process	Characteristics			
	Process Temperature	Selectivity to Thermal Oxide and Silicon	Equipment Technology	Comments
Hydrogen Prebake	High ($T > 900$ °C)	Good	Simple	Oxide undercut problem Not suitable for prepoly clean Works for ultrathin oxides
Sputter Etch (ECR, RF) (Ar, Ar+H_2)	Medium ($T > 750$ °C)	Poor	Special module (plasma)	Residual surface damage Incompatible with std. equip. Narrow process window
Ion-Assisted Chemical (ECR: H_2, H_2+SiH_4)	Low ($T = 400$–500 °C)	Poor–Fair	Special module (plasma)	Superior to microwave H_2 Incompatible with std. equip. Can integrate with ECR dep.
Remote Plasma Clean (Microwave H_2)	Low ($T = 150$–500 °C)	Good	Special module (plasma)	Works for ultrathin oxides Incompatible with std. equip. Must prevent particles
NF_3 Oxide Removal	Low ($T = 580$ °C)	Poor	Special module corrosion-res.	Corrosive chemistry Special chamber passivation Si–F surface bonds
ClF_3 Oxide Removal	Very Low ($T = 25$–60 °C)	Poor	Special module corrosive-res.	Corrosive chemistry Special chamber passivation Surface Cl and F and pitting
UHV Heating	Medium ($T > 750$ °C)	Good	Special module (UHV chamber)	Works for ultrathin oxides Expensive UHV equipment Must prevent surface pitting
Reaction With Adsorbed Layers of Si or Ge	Low–Medium ($T = 625$ °C)	Good	Special module (UHV chamber)	Works for ultrathin oxides Superior to UHV-only bake Expensive UVH-MBE equipment
HF/H_2O Oxide Removal	Very Low (Room temp.)	Good	Special module (vapor-phase)	Special process chamber Can control selectivity Must prevent surface residues
Photochemical Clean	Medium ($T = 730$ °C)	Fair–Good	Special module (UV photochem.)	Incompatible with std. equip. Better for organic/metallic Must prevent DUV damage
Germane-Assisted Surface Cleaning	Low–Medium ($T = 650$–750 °C)	Good	Simple	Compatible with std. equip. Simple and effective Requires scram room set-up

ozone and excited oxygen atoms are summarized in the following equations:

$$O_2 + h\nu(185\ nm) \rightarrow 2O(^3P) \quad \text{(Eq. 7)}$$

$$O(^3P) + O_2 \rightarrow O_3 \quad \text{(Eq. 8)}$$

$$O_3 + h\nu\,(254\ nm) \rightarrow O_2 + O(^1D) \quad \text{(Eq. 9)}$$

Both the ozone and the atomic oxygen are powerful oxidizing agents that react with trace organic contaminants via the following reaction:

$$organic\ contaminant + O/O_3 \rightarrow CO_2 + H_2O \quad \text{(Eq. 10)}$$

Instead of using deep UV activation, oxygen radicals can also be generated in a plasma ambient. Wafers can be placed downstream from the plasma generator

to minimize possible ion-induced damage. This well-proven technique forms the basis of a number of commercial photoresist ash reactors.

Metallic Cleans—To keep the contaminants at or accessibly close to the surface of the wafer and because most metallic elements are fast diffusers at moderately elevated temperatures, the chemistries chosen for trace metallic removal must be able to form volatile reaction products with the metallic contaminants without requiring too much thermal activation.

Various halogen-based techniques have been investigated in this regard. Some success has been achieved by photochemically activated chlorine chemistry.* Since most chlorides of metals are not volatile at low temperatures, it is believed that the cleaning action is achieved by the slight etching of the silicon substrate and that the metallic contaminants are "lifted off" the surface of the wafer together with the volatile chlorides of silicon. As in the case of trace organic clean, chloride chemistries based on plasma activation have also been investigated and have achieved some degree of success. Alternative nonhalogen-based chemistries have also been investigated by using a reactor with sources for both the deep UV irradiation and the remote microwave plasma activation.† Gases can be injected into the reactor with or without the UV or the plasma excitation. The chemistries are chosen so that the reaction products are sufficiently volatile at relatively low temperatures and so that the etching of exposed silicon can be reduced to a minimum. The cleaning efficiencies of these chemistries have been verified by using trace amounts of radioactive isotopes of some of the most commonly encountered contaminant elements (Fe, Cu, etc.) plated onto bare silicon surfaces.

Single-Wafer Epitaxy

Single-wafer RTCVD technology has been used for fabrication of in situ–doped homoepitaxial Si and heteroepitaxial Si/Ge_xSi_{1-x} multilayer structures. Epitaxial Si films have been grown in a mixture of DCS, H_2, and the dopant gas at 5 torr.‡ Fig. 82 shows the thickness of undoped epitaxial films grown on heavily doped p^+ ⟨100⟩ wafers versus the DCS flow rate in 200-second runs at ≈1000 °C. These data cover a DCS:H_2 flow ratio range of 1–6%. Under these process conditions, the deposition takes place in the mass-transport-limited regime and, as a result, the growth rate and uniformity are sensitive to the DCS flux in the process chamber. A wide range of controlled growth rates up to more than 1 μm/min can be achieved. Thermal switching of the process temperature provides a useful capability for growth of multilayer epitaxial structures with fairly abrupt interfaces.§ Fig. 83 plots the secondary ion mass spectroscopy (SIMS) boron concentration depth profile for a seven-layer step-boron-doped epitaxial structure grown following a low-temperature $GeH_4 + H_2$ surface cleaning (total of eight process steps integrated in situ). This structure was grown at ≈1000 °C on a p^+ substrate and consists of: (1) an undoped epi layer, (2 through 5) four successively higher step-boron-doped layers, (6) an undoped epi layer, and (7) a heavily doped layer at the surface. The SIMS profiles were obtained with an oxygen primary beam under conditions that provided poor depth resolution. The layer-to-layer transition width for the top two layers is 280 Å/decade of dopant concentration. The actual transition width is smaller than the observed SIMS value because of the SIMS broadening effects. The transition widths are affected by the growth temperature and the thermal treatments during the subsequent growth cycles. Growth of the epitaxial layers at lower temperatures with remote microwave plasma excitation should significantly reduce the transition widths in multilayer epitaxial structures. Growth of the same structure shown in Fig. 83 without thermal switching (temperature kept at 1000 °C even during gas switching) results in much wider transition widths because of the long process gas stabilization times.

Fig. 84 plots the B and Ge SIMS concentration depth profiles in a seven-layer structure consisting of a strained p^+-Ge_xSi_{1-x} layer. This structure was grown after a GeH_4-assisted in situ surface cleaning. The first five layers are $i/p^+/i/p^+/i$ silicon regions (i = intrinsic), each grown at ≈1000 °C. The B_2H_6 flow rate during the growth of the first two p^+ layers was ramped in time, which is one reason for the gradual B concentration transition between the adjacent i/p^+ layers. The sixth and seventh layers are strained $p^+ - Ge_xSi_{1-x}$ and n^+ Si, respectively. Because of the overall thermal treatments and SIMS broadening, the first intrinsic layer near the p^+ substrate interface cannot be detected very clearly. The SIMS Ge depth profile indicates a Ge fraction of $x = 6\%$ in the Ge_xSi_{1-x} layer. The GeH_4:DCS flow ratio during the growth of this Ge_xSi_{1-x} layer was 2.5 sccm:100 sccm and the growth was performed at 650–700 °C. The net B_2H_6 flow rate was about 0.0003 sccm. The B concentration depth profile indicates a Ge_xSi_{1-x} doping concentration on the order of 1×10^{18} cm^{-3}. Based on the SIMS data, the B-to-Ge concentration ratio in the grown Ge_xSi_{1-x} film is nearly equal to the ratio of the number of B and Ge atoms available in the gas phase (or twice the B_2H_6 flow rate divided by the GeH_4 flow rate).

Single-Wafer Plasma Processing

Plasma processes are routinely used in semiconductor fabrication for etching of submicron geometries, deposition and growth of thin films, and in situ organic and metallic contamination removal. Gas composition, pressure, and flow rates define the overall chemistry,

† Reference 49.
‡ Reference 49.
§ Reference 84.

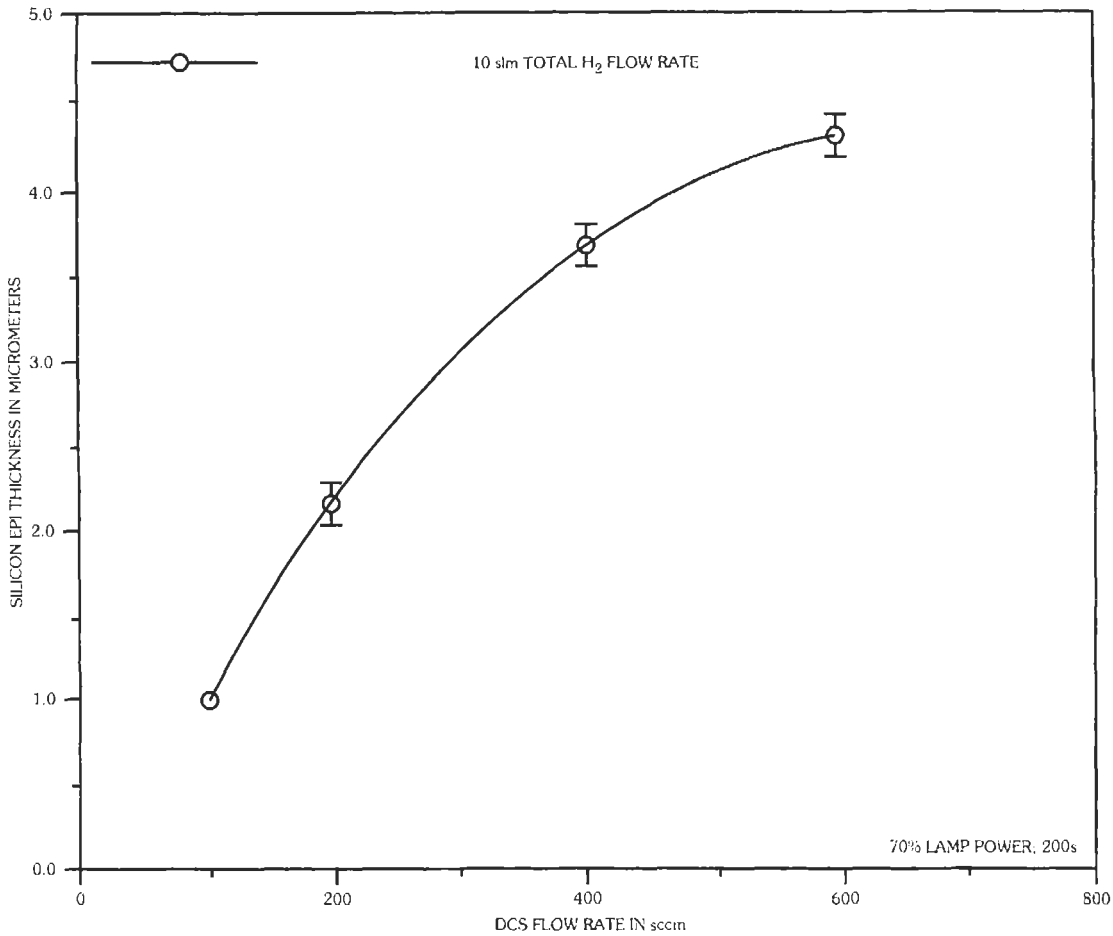

Fig. 82. Dependence of the epitaxial silicon layer thickness on SiH_2Cl_2 flow rate in 200-second growth runs performed at ≈1000 °C.

but the mechanisms and kinetics are strongly influenced by the plasma parameters. Many chemical reactions in the plasma are initiated by plasma electrons, while surface reactions are often ion-activated. Some of the important plasma parameters are the electron and ion concentrations, the mean electron energy, and the energy and flux of ions incident on the surface. Processes that provide high etch selectivity, good anisotropy, good uniformity, low ion-induced damage, and low particulate contamination and that meet throughput requirements are essential for the etching of submicron features.

Capacitively Coupled Discharges—Capacitively coupled RF plasma sources generate large volume plasmas of moderate densities. Although these systems operate over a wide range of pressures (50 mtorr–1 torr), few of the plasma parameters can be independently controlled. For a given RF power, gas pressure, and gas composition, all the plasma parameters with the exception of the ion energy are fixed. These attributes make it very difficult to engineer processes that simultaneously attain high selectivity, good anisotropy, and low ion-induced damage. The potential for improved uniformity, reduced microloading effects, reduced contamination, and improved anisotropy are driving discharge operation to lower pressures. Deterioration in plasma confinement limits the minimum operating pressure to 30 mtorr. These factors have accelerated the use and development of alternative plasma sources.

Two alternative configurations are derived from standard capacitively coupled RF discharges: the hollow cathode discharge and the magnetron-enhanced etch system. A hollow cathode discharge is formed when two electrodes parallel to each other are powered by the same RF source. Secondary electrons released by primary ion bombardment of either electrode

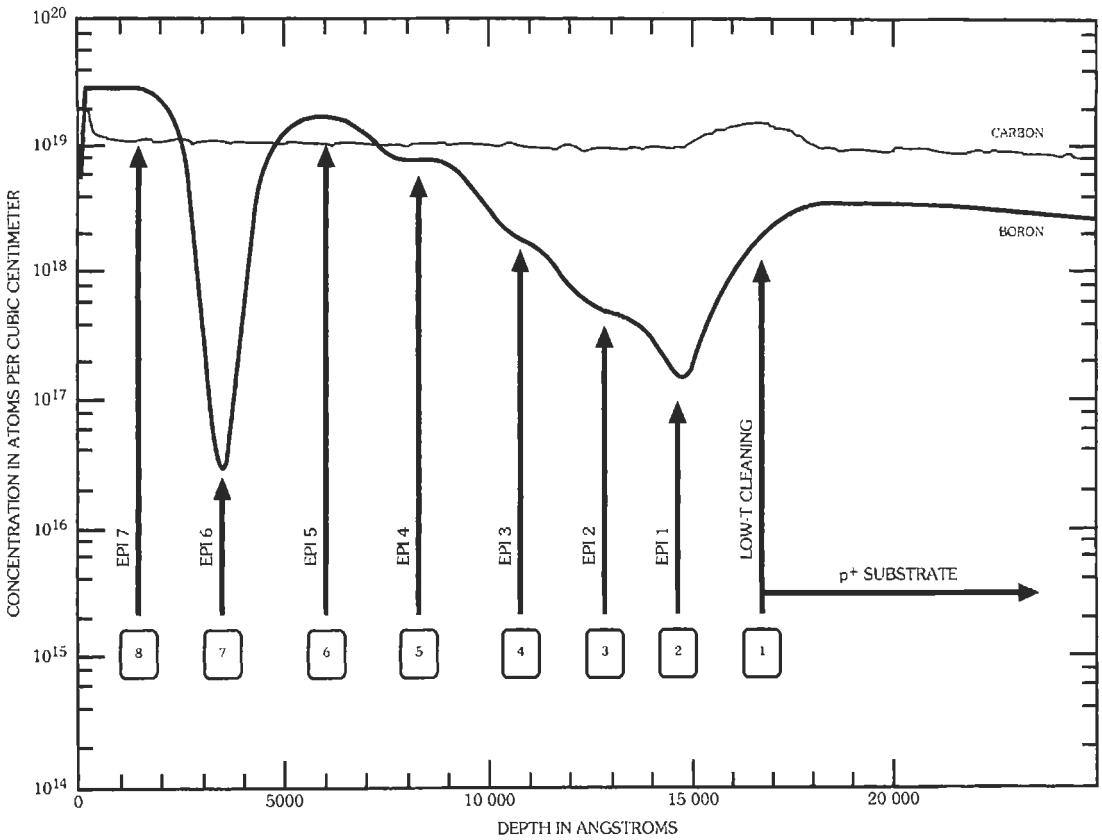

Fig. 83. The SIMS boron concentration depth profile for a seven-layer epitaxial structure grown at ≈ 1000 °C with multiple rapid switching of the wafer temperature following a low-temperature GeH_4+H_2 pregrowth cleaning cycle.

bounce back and forth between the equipotential electrodes, enhancing the ionization.* This translates into an enhanced plasma density, a large radical production rate, and lower sheath voltages.† Impressive etch and deposition results from hollow cathode systems have been reported. For example, SiO_2 etch rates in excess of 1 μm/min with selectivity to Si in excess of 50:1 and uniformities of 1% have been reported.‡ In addition, hollow cathode systems are ideal for processes involving simultaneous etch and deposition, either for etch chemistries that rely on passivation through polymer on side walls to achieve anisotropy and selectivity or in the deposition of planarized films.‡ Sputtering and deposition on the counter electrode and plasma instability have prevented this discharge from gaining wide acceptance, although methods for alleviating some of these problems have been reported recently.§

The magnetron-enhanced RIE system employs magnetic fields either parallel or perpendicular to the surface of the powered electrode, to boost the ionization efficiency and hence the plasma density. Since the magnetic field reduces the electron mobility, discharge operation can be extended to lower pressures (< 30 mtorr), plasma confinement is improved, and the sheath voltage decreases. The magnetron-enhanced system is described more fully below. The hollow cathode and magnetron systems provide good selectivity (because of the large radical flux and low ion energies), while the high ion flux ensures that anisotropy is not sacrificed. The low ion energies also imply reduced ion-induced damage. Throughput is also enhanced.

Some of the limitations of capacitive coupling cannot be overcome; sheath voltages increase with power. The obvious solution is either to use inductive coupling (inductively coupled RF discharges) or to use higher frequencies (microwave discharges).

Inductively Coupled Discharges—Two generic types of inductively coupled RF discharges have evolved. The first is based purely on induction coupling.

§ Reference 109.

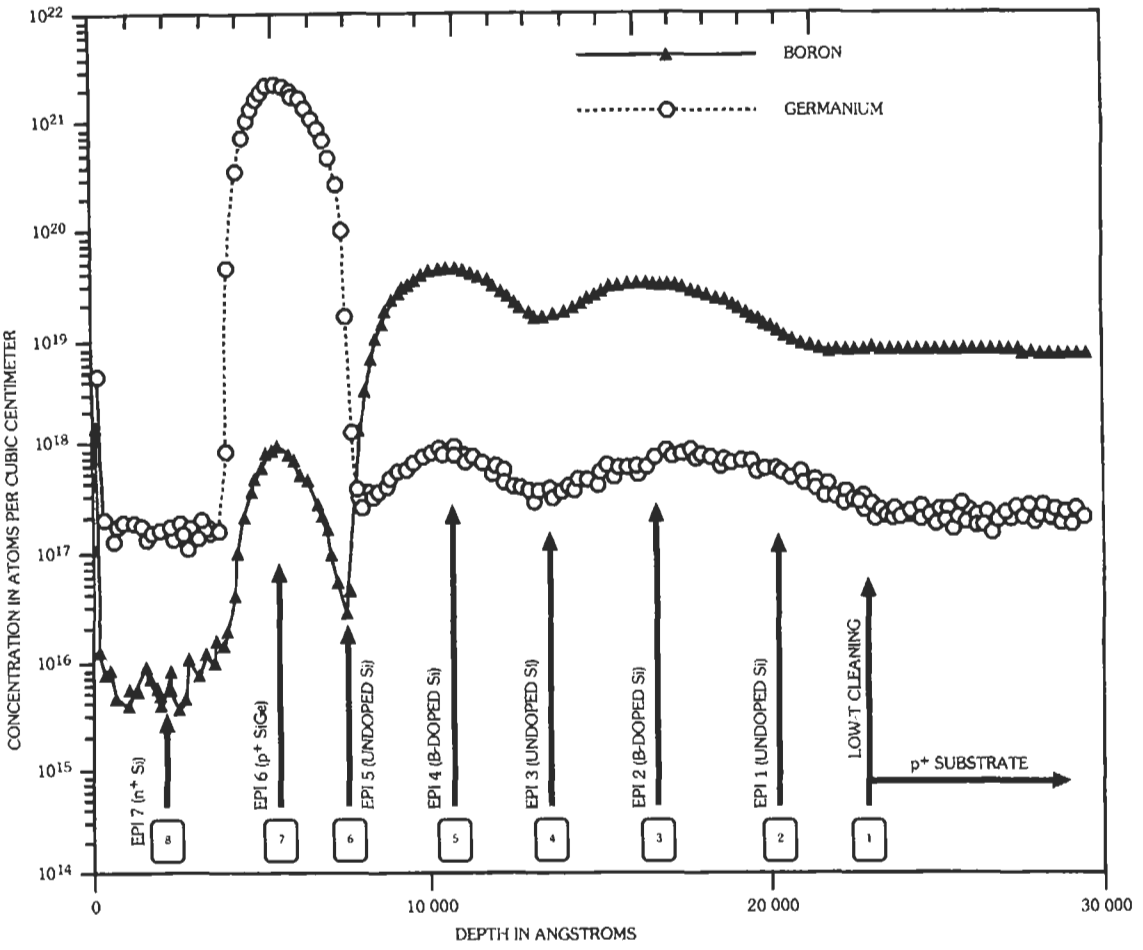

Fig. 84. The SIMS concentration depth profiles for boron and germanium in a seven-layer heteroepitaxial structure with a strained Ge_xSi_{1-x} layer grown at ≈675 °C. The surface layer is n^+ Si, and the structure was grown on a p^+ substrate.

An RF-powered antenna coil placed around the periphery of the chamber induces eddy currents that sustain the plasma.* With magnetic plasma confinement, plasma densities in argon exceed 5×10^{11} cm^{-3} with low ion energies (< 50 eV), over a wide pressure range (0.5–50 mtorr).† If a uniform magnetic field region exists in the vicinity of the coil, energy coupling becomes extremely efficient since helicon or whistler waves are excited in the plasma. With resonant coupling, the ionization efficiency peaks, and a very dense plasma is generated.‡ Extremely high plasma densities exceeding 10^{12} cm^{-3} have been reported with low intrinsic ion energies (< 30 eV).§ Preliminary process results are impressive for both these systems. Etch rates for most materials including Si, SiO_2, and Si_3N_4 exceed 1 μm/min." The ion energy is independent of RF power and can be increased from its intrinsic value by RF biasing the substrate. The high radical generation rates and low ion energies result in high selectivity with no ion-induced damage, while the high ion flux promotes anisotropy.# The generation region becomes increasingly concentrated owing to skin effects as the plasma density increases. The wafer is located remotely from the source for good uniformity (< 5%, 1σ).** Also, large RF voltages across the antenna coil may sustain subsidiary capacitively

coupled discharges that cause sputter damage of the chamber walls and possible contamination.

Magnetron-Enhanced Discharges—Magnetron effects induced by external magnetic fields extend discharge operation to lower pressures. Electron mobility along a direction perpendicular to the magnetic field is reduced by the factor*

$$1/\left(1+\omega_b^2/\nu_m^2\right) \qquad \text{(Eq. 11)}$$

where

ω_b is the electron cyclotron frequency,
ν_m is the electron momentum transfer collision frequency.

The reduced electron mobility produces better plasma confinement and a reduction in sheath voltages. In addition, the ionization efficiency of secondary electrons emitted from the powered electrodes is enhanced. Both these effects lead to an increase in the plasma density. A factor of 10 enhancement in plasma density is possible with moderate fields (≈ 250 G).† Because of the significant dissociation, the plasma chemistry can differ between RIE and magnetron-enhanced systems.‡

Various configurations have been investigated. Magnetron systems have traditionally been used for sputtering applications, where discharge operation at submillitorr pressures is vital. The most common configurations include the planar magnetron discharge, with the magnetic field perpendicular to the electric field, and cylindrical magnetron discharges. The magnetic field is generated by permanent magnets or electromagnets located behind the powered electrode. Typically the magnetic field is oriented so that the $E \times B$ electron drift forms a closed loop, thereby trapping the electrons in the vicinity of the electrode.§ In the conventional planar magnetron, a disk magnet surrounded by a ring magnet produces radial magnetic fields. The magnetic field parallel to the wafer is most intense at midradius. Plasma nonuniformity is a big concern in these systems. Because the plasma is most intense in regions where the magnetic field component parallel to the wafer is a maximum, it causes a race track etch characterized by a fast etch at midradius.§ While this configuration results in $E \times B$ drift currents that form a closed loop, the severe nonuniformity" has prompted the use of alternative magnetic field patterns. One of the options is to keep the magnetic field lines parallel to each other and to the electrode. To counter the effect of the asymmetric $E \times B$ drift, the magnets or wafer can be rotated or scanned.#

An adjustable field planar magnetron discharge has been reported.** Rare-earth permanent magnets located behind the wafer induce a magnetic field parallel to the wafer surface. Also, the field lines are parallel to each other in the region of the wafer. The magnet lengths are scaled so as to achieve a uniform magnetic field over the wafer. Movable soft-iron slugs can be used to tailor the magnetic field distribution further. The slugs are located between the magnets and behind the powered electrode. The magnetic field at the wafer is ≈ 500 G. The magnetron RIE system is otherwise similar to a parallel plate system. In addition to powering the electrode, a cylindrical ring around the counter electrode can also be powered with a low-frequency or high-frequency RF power supply. Grounding or RF biasing the ring can be used to optimize uniformity and vary the energy of ions incident on the substrate. In addition, a contoured counterelectrode further improves the etch uniformity. For ion-assisted processes there is an optimum field strength. For very strong fields, the ion energy is too low, and the etch is hindered.†† However, the plasma density increases with increasing field strength. The cylindrical ring permits operation with strong fields without the attendant reduction in etch rate. By manipulating the slugs and the ring, the location of fastest etch can be moved progressively from the wafer center to the wafer edge. This flexibility may be exploited to compensate for nonuniformities resulting from previous process steps.

This magnetron RIE system has been specifically optimized for DESIRE, a dry develop lithography process. The basic steps involved in DESIRE are as follows. Exposed photoresist is exposed to a silylating agent such as HMDS (hexa methyl disilane). This causes silicon to be incorporated in the resist. The depth of silicon incorporation is a function of exposure dose. When this resist is exposed to an O_2 plasma, the silicon in the photoresist is converted to SiO_x. Ion bombardment continuously sputters the SiO_x as it is formed. Ultimately the sputter etch depth in the unexposed (or marginally exposed) regions exceeds the depth of silicon incorporation, and no further SiO formation occurs. The etch now proceeds rapidly as the photoresist is consumed by the O_2 plasma. In the strongly exposed regions, the SiO_x that is continually formed forms the etch mask that hinders the etch.

The nature of this process places very stringent demands on the capabilities of the etch process. The ion energy has to be sufficiently low for reasonable etch selectivity between SiO_x and the photoresist. At the same time, a very high etch selectivity exaggerates etch nonuniformities and promotes residue formation. Selectivities between 5:1 and 8:1 are ideal. Since the silylation depth does not exhibit any strong thresholding behavior with respect to exposure, the budget for etch nonuniformities is very small. The requirements

* Reference 116.
† Reference 117.
‡ Reference 118.
§ Reference 119.
" Reference 120.
Reference 121.

** Reference 49.
†† Reference 117.

become especially tight for contact patterns. To engineer an acceptable process, the resist etch and SiO sputter etch uniformity have to be within 4% (1σ). Finally, vertical etch profiles with no undercut require high anisotropy. Undercut can be eliminated by reducing the O_2 flow and cooling the wafer to below –35 °C. These requirements of good selectivity and high anisotropy uniformity preclude the use of an RIE etch system. The magnetron-enhanced RIE system with adjustable magnetic fields and ion energies appears to be a good choice. Good results have been reported for 0.4 μm lines and spaces processed using such a system.* Nominal process conditions were 115 W, 3 mtorr, 40 sccm O_2, and a DC bias of –85 V. A similar system may be used for implementing other etch processes that are also tightly constrained.

Microwave Discharges—Microwave discharges have almost become synonymous with electron cyclotron resonance (ECR) discharges. However, cavity based microwave discharges still maintain their niche for afterglow plasmas. A remote microwave plasma is a copious source of radicals and is generally used in conjunction with a capacitively coupled plasma to enhance the etch or deposition rates.

ECR discharges are a source of large volume dense plasmas. At the resonance condition that occurs for a magnetic field of 875 G for 2.45 GHz microwave excitation, the power coupling becomes resonant. At resonance, the electron cyclotron frequency and the microwave frequencies are synchronized, so that electrons are continuously accelerated by the electric field. ECR is most effective for pressures between 10^{-2} and 10 mtorr, when an electron can undergo several orbits before suffering a scattering collision. Typical plasma densities exceed 10^{11} cm^{-3}, with ion current densities to the wafer in excess of 10 mA/cm^2.† At the same time, the intrinsic ion energy is fairly low (< 30 eV), which can be increased by RF biasing the wafer. Even in the absence of cyclotron resonance, magnetized plasmas can still couple microwave power. However, the mean electron energy and consequently the ionization efficiency is much lower. For a given input power, the higher the ionization efficiency, the higher is the plasma density. Thus the size and coupling efficiency of the ECR region can dramatically affect the plasma density for a given input power.‡ Still, magnetized microwave plasmas generate high plasma densities compared to capacitively coupled discharges.

ECR plasmas offer tremendous process flexibility. High-quality etching of a range of materials including Si,§ SiO_2," Al," resist,# and III–V materials** is possible. Similarly, deposition processes can also be accomplished at comparatively low temperatures.††

Various types of ECR sources have been developed.‡‡ Perhaps the most common source uses a set of electromagnets around the discharge chamber that generate axial magnetic fields.§§ A divergent or mirror magnetic field configuration can be attained with appropriate solenoid and pole-piece configurations. The axial magnetic field is tailored so that it is a maximum at the microwave input end and decreases toward the wafer. The microwave coupler launches the right-hand circularly polarized wave, which couples very efficiently into the plasma, generating a dense plasma."" The ECR region is fairly large since the axial magnetic field is quite uniform in the radial direction and decreases away from the microwave coupler. The axial magnetic field also enhances the ion current density at the wafer but may degrade uniformity and directionality of ions.## Remote wafer location is required for good uniformity. However, placing the wafer too far away reduces the radical flux and affects throughput. A third electromagnet in the process chamber can be used to mitigate some of these trade-offs.***

Another option is to use a set of permanent magnets that generate a multipolar cusp field around the periphery of the discharge chamber.††† The ECR region is then a thin shell around the inside of the plasma formation chamber. Because the plasma formation regions are much closer to the wall, and the size of the ECR region is limited, the attainable plasma densities appear to be lower. Since the plasma diffuses freely from the chamber toward the wafer, good uniformity can be attained much closer to the source.‡‡‡

The last option is to combine the plasma formation chamber with the process chamber as in the distributed ECR design (DECR).‡‡‡ Permanent magnets establish a multipolar cusp field around the periphery of the process chamber. Multiple microwave antennas are placed around the periphery of the chamber. The ECR region once again is a thin shell around the inside of the process chamber. The plasma diffuses radially toward the wafer, which is located centrally in a field-free region. However, the plasma densities reported for such a source are a factor of five lower than those obtained with other sources. The discharge behaves more like a magnetized microwave plasma, with resonant power coupling occurring in a very small region.

A star-shaped ECR source has been reported* that combines the advantages of the various configurations. It consists of a six-chambered source in a star configuration. Each chamber is surrounded by permanent magnets that generate cusp fields so that a broad spherical resonance region is formed around the center of each formation chamber. The cusp fields also confine the plasma. The six-chambered source opens into a multipolar bucket chamber with the wafer located at the far end. Each chamber is powered by a separate microwave antenna. The six antennas are connected to a six-way microwave power divider. The multipolar bucket provides a very high transfer efficiency (Fig. 85). The ion and electron concentrations were measured by a Langmuir probe. Most of the measurements have been made along the center of the system, where the magnetic field is zero. The plasma density as measured by a Langmuir probe decays exponentially as expected. The plasma density decays by a factor of 10 over 8 inches at 1 mtorr (the source is located 10 inches from the wafer). As the pressure is increased, the plasma density at the source does not change appreciably, but the plasma is better confined to the source (Fig. 86). Consequently, the plasma density at the wafer decreases. Because the diameter of the multipolar bucket is 8 inches, good uniformity is obtained over a 6-inch wafer merely 6 inches from the source.

This chamber design provides dense uniform plasmas at the wafer without the use of axial magnetic fields. In addition, the design can easily be scaled for larger wafers by moving the individual chambers radially outward. Finally, since the ECR region does not intersect the walls of the chamber, as it does in some of the other designs, sputtering contamination is reduced.

Cryogenic Magnetron Etch—The drive toward higher device integration density presents stringent requirements on the anisotropy of etch profiles and on the precise control of the widths of etched lines and spaces. This is to be achieved while maintaining the necessary selectivity and etch rate specifications. One process technology that is expected to achieve the above requirements is RF-assisted remote microwave plasma etch. It is well recognized that this etch technology allows the achievement of fast etch rates, high selectivity, as well as low damage. However, it is also recognized that this technique suffers from unacceptable etch

profile anisotropy, particularly at room temperature, as evidenced by the observed isotropic etching of the sidewalls. Tachi et al.* demonstrated the sensitivity of the isotropic etch component to wafer temperature. Specifically, by cooling the wafer down to cryogenic temperatures (−100 to −150 °C) the isotropic sidewall etch was completely eliminated.

The achievement of these temperatures is not possible with conventional liquid-coolant-based (e.g., Freon) refrigeration equipment. To meet this temperature requirement, as well as to maintain a cooling load up to 1 kW at the wafer, a liquid nitrogen (LN2) based cryogenic cooling system has been reported.† The system uses high-pressure helium gas as a coolant, which is pumped in a closed loop between a low-temperature reservoir—an LN2 dewar—and the wafer chuck. Temperature control is achieved by a bypass valve that allows the necessary fraction of the helium flow to bypass the LN2 dewar, and then mix with the colder helium leaving the dewar on the way to the chuck, to achieve a required temperature at the wafer. The schematic of the cryogenic cooling system is shown in Fig. 87. A helium compressor provides the required pumping action in the system. Cold He returning from the chuck must be brought up to ambient temperature before entering the compressor. The heat exchanger does this effectively by precooling the He stream leaving the compressor to the LN2 bath. An in-line electrical heating element upstream of the compressor is used to maintain a safe inlet He temperature, in case the heat exchanger output falls below the required value. After being precooled in the heat exchanger, the gas leaving the compressor is driven through a copper pipe loop immersed in liquid nitrogen to provide further required cooling. The two valves shown above the LN2 dewar provide the temperature control capability. Maximum cooling capacity and lowest temperatures are achieved by operating with the bypass valve fully closed and the main valve fully open. Higher temperatures are achieved by allowing a fraction of the flow to go through the bypass path. The LN2 level in the dewar is maintained by an automatic LN2 fill system. The cold He leaving the dewar is routed to the wafer chuck, where it maintains the required temperature, and then returns to the compressor via the heat exchanger.

The system has been used successfully to provide cooling down to −160 °C, with a sustained heat load of

* Reference 135.

† Reference 49.

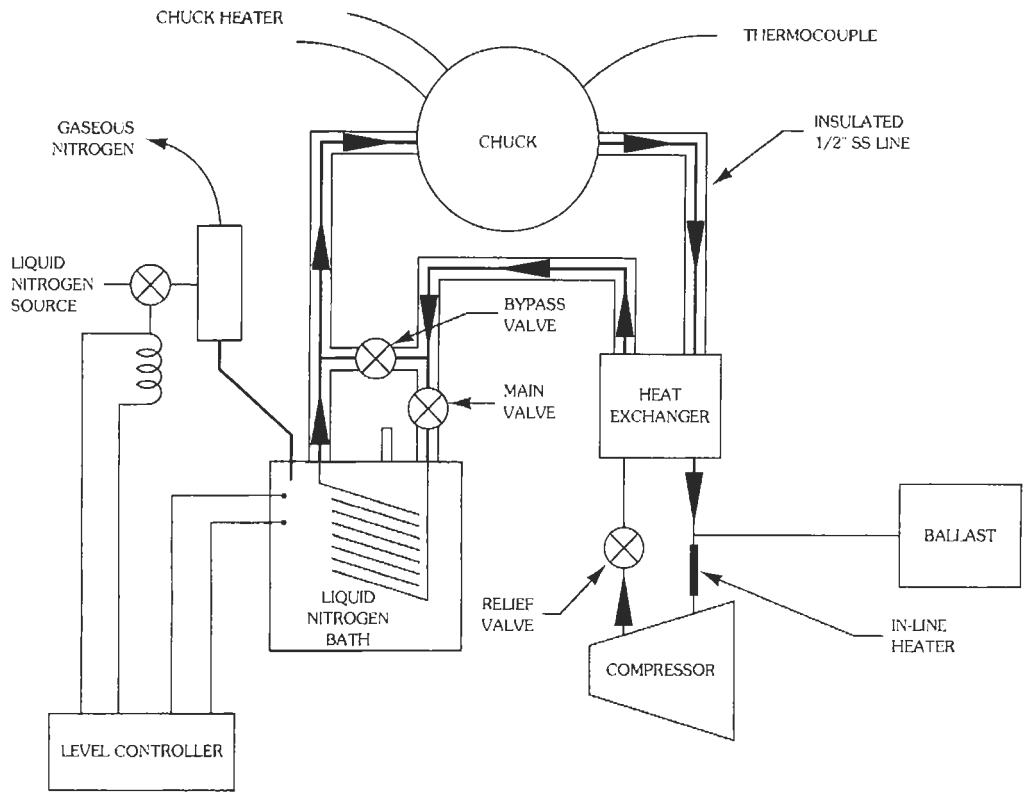

Fig. 87. Schematic diagram of the cryogenic cooling system showing the closed-cycle pumping loop for the high-pressure helium gas coolant. Major system components are indicated.

500 watts. This was done with a loop pressure of around 250 psig and a He mass flow rate of 6 g/s (79 scfm). The heat exchanger effectiveness was 0.75, and the He stream was precooled by 120 °C, down to −110 °C, before arriving at the LN2 dewar. The rate of use of LN2 is no more than 0.4 gpm per 1 kW of cooling load, in this operating range. Initial results with magnetron SF_6 etching of silicon at −150 °C, using this system, confirm the transition to an anisotropic etch regime in this low temperature range.

SWP-Based Process and Device Integration

The greatest potential advantage of SWP for circuit/device design is improved control of structural dimensions and materials quality. Dry etching has shifted to SWP and away from batch processing because each wafer can be etched under the same conditions, thereby decreasing variability between wafers. Furnace operations such as CVD depositions and anneals are now changing to single-wafer RTP for much the same reason. The use of RTP offers some potential advantages for design of MOS devices with design dimensions in the submicron regime where heat treatments must be short to prevent excessive diffusion of dopants.

One major fabrication control problem that seriously impacts device performance is variability in polysilicon gate linewidth. Control margins on linewidth must be held in the range of 10% of the target linewidth. Variability in linewidth across a wafer is a serious problem that can be controlled by improved in situ monitoring of etchant species and temperatures as a function of location on the wafer.

Other serious control problems addressed by SWP with in situ monitoring are contact, via, and metal interconnect etching. It is difficult to know when a contact opening has been sufficiently etched through an interlevel insulator when the opening height-to-width ratio is very large. Another difficulty often encountered is filaments or runners of metal left between patterned and etched metal lines where they run over topographic steps in the insulator: this also can be improved by in situ monitoring. Single-wafer processing can also reduce variability between wafers.

In many cases, quality and parameter control can be improved by grouping several processes into a module to be processed in a cluster tool without manual wafer handling that could introduce particles and

contaminants or cause native oxides to form on silicon. This subsection will be divided into subsubsections discussing groupings of process steps that could be adapted to device fabrication in cluster tools.

SWP techniques can be usefully applied to CMOS, bipolar, or any BiCMOS-like combination. The application to CMOS device processing will be discussed here as an example of the application of SWP. The interrelationship between CMOS device design parameters and SWP with in situ process control will be discussed with reference to Fig. 70. The process modules will be discussed in the order used in fabrication: the discussion will start with the features at the bottom of Fig. 70 and work toward the features at the top of the figure.

Starting Material and CMOS Well Formation — The bottom portion shows the formation of the CMOS n-well and p-well in a lightly doped silicon epitaxial layer deposited on top of a p^+ silicon substrate. In other cases, the CMOS wells may be formed in silicon without an epitaxial layer over p^+ silicon, but this design is more sensitive to CMOS latchup. The use of epitaxial silicon is often avoided for low-cost commodity parts by using n^+/p^+ diffused guard bands around the wells of input/output circuits to prevent CMOS latchup. The epi thickness is set such that the boron diffusing up from the p^+ substrate just reaches the bottom of the n-well and p-well.

To prevent punchthrough for sub-0.5 μm transistors, the well dopant concentration is greatly increased. All dimensions must be scaled, including the n-well depth into the silicon. By using a 5-min at 1100 °C well drive/anneal in an ammonia ambient (ONED), it is possible to obtain a sufficiently deep n-well to leave an undepleted region of electrons with a sheet resistivity of 1.3 kΩ/square when the n-well is at 3.3 V and the p^+ source/drain and substrate are at zero volts. The short RTP anneal/drive time results in less up-diffusion of boron from the p^+ substrate with the result that: (1) the epitaxial silicon thickness can be decreased to 2.5 μm and (2) the substrate dopant gradient is increased. Both results are useful for preventing CMOS latchup. The phosphorus and boron implants can be both masked by resist patterns and implanted near 300 keV and at a component at lower energy. It is important to note that scaling a design to submicron dimensions requires the use of higher concentration CMOS wells, which then permits the use of implants in the 300 keV regime without long anneal/drive times. For circuits with larger design dimensions, the lower concentration wells would have required the use of MeV implant energies to obtain wells deep enough to leave sufficient undepleted electron concentration in the n-well if short RTP anneal/drive times are used.

It is also important that the p-well concentration reach the boron up-diffusing from the p^+ substrate. This is essential for preventing the formation of an intervening high resistivity layer that would cause premature CMOS latchup. The proper p-well/p-substrate structure is obtained for the same anneals used for the n-well cases.

Active Area Isolation—The field oxide regions are shown in Fig. 70 isolating the active regions, which include the transistor gates. The field oxide shown is formed by the PBL process, but many other techniques have been used. In the PBL process, an oxide/poly/nitride layer is deposited, patterned, and etched followed by the growth of a thick (0.6 μm) layer of oxide in the isolation regions. Later, the nitride and poly layers remaining after field oxidation must be removed. Several parts of this process are adaptable to implementation in a cluster tool.

Most CMOS fabrication processes use modifications of LOCOS such as PBL, MF3R, or similar but not identical processes. These processes are easily controlled and result in a narrow "bird's beak" region of gradual increase in field oxide thickness at the edge of the active region. At the time when the poly gate is patterned and etched, the smoothness of the transition makes it easy to etch away undesired polysilicon without leaving any residue.

It is difficult to scale LOCOS isolation to the deep submicron regime for which the isolation regions must be 0.4 μm wide or less. For the deep submicron regime, several shallow trench isolation techniques have been demonstrated. All of these shallow trench techniques share a common problem in that a planarizing etchback must be carefully controlled to prevent topographical steps (up or down) at the edge of the trench. This is an ideal case for the use of SWP with in situ control of the etchback to obtain the exact surface required.

Gate Oxide and Polysilicon Electrode Deposition—One of the most critical steps in CMOS processing is the formation of a high-quality gate oxide and the subsequent deposition of a polysilicon layer that will form the MOS gates. Before these steps, a dummy gate oxide is usually grown and then etched away before growing the gate oxide. The growth of gate oxide and deposition of polysilicon is one of the best candidates for implementation in a cluster tool. If no implants are to be made through the dummy gate oxide, the growth and removal of the dummy gate oxide could also be incorporated into the cluster operation.

In most cases, dopants are added to both the NMOS and PMOS channels to set threshold voltage and increase the punchthrough voltage. The dopants are usually added by implanting through the dummy gate oxide. One of the major design considerations for submicron CMOS is whether to use a surface channel or a so-called buried-channel PMOS device. Both the NMOS and PMOS transistors shown in Fig. 70 are surface-channel. For surface-channel operation, the NMOS gate must be doped n-type and the PMOS gate must be doped p-type. This is usually accomplished by doping the gate only with the implants used to create

the NMOS and PMOS source/drains. For a PMOS "buried-channel" transistor, the polysilicon is doped n-type for both the NMOS and PMOS transistors. For buried-channel, a boron implant must be made into the surface of the silicon. This creates a pn junction immediately underneath the gate oxide. For a properly designed transistor, the boron implant is shallow enough that the p-type region is completely depleted by the built-in voltage of the pn junction. This depleted region makes it easier for the drain voltage to reduce the potential barrier at the source with resultant excess subthreshold leakage for very-short-channel PMOS transistors. For very-short-channel PMOS devices, the surface-channel device is the best choice because the depletion layer is much thinner for surface-channel than for buried-channel.

It is especially important to grow the gate oxide at a low temperature when a buried-channel PMOS device is fabricated by using a boron implant through the dummy gate oxide. If the oxidation temperature is too high, boron diffusion will make it difficult to keep the boron profile shallow. This is especially true for transistors designed for the deep submicron where the pn junction may need to be 0.05 μm deep or less. Surface-channel PMOS design seems better adapted to RTP in dry oxygen ambient at high temperatures. In this case, the boron is implanted into the poly after the growth of the oxide so boron diffusion does not limit the choice of RTP parameters for gate oxidation. Boron diffusion through oxide is enhanced by the presence of hydrogen or fluorine, and this must be considered in the design of the subsequent process steps.

Gate Structure Formation—Following the deposition of polysilicon, the gate is patterned and etched. Later, one or two layers of oxide will be deposited and etched anisotropically to form sidewall spacers at the side of the gate as shown for the NMOS gate and PMOS gate in Fig. 70. As stated earlier, the control of poly linewidth is the most critical parameter in CMOS fabrication. SWP with multiple sensors for etchant species and temperature will be required to obtain sufficient control of linewidth to build transistors with 0.35 μm linewidths and below. It is also extremely important that the etch removes all polysilicon from regions not covered by resist during the etch: sensors are needed to determine when the poly has been removed from all regions, including topography step regions where the poly will be thicker after conformal deposition.

In some cases, the sidewall oxide spacer may be formed by thermal oxidation rather than by deposition. In most cases, implants of light or medium dose may be made before the deposition of one of the sidewall oxide spacers. These so-called LDD or lightly doped drain implants must go under the edge of the gate by lateral straggle at implant or later diffusion. Also of major importance is that the LDD junction be as shallow as possible to decrease the ability of the drain voltage to influence the source potential barrier.

As a final step, a pad oxide will be deposited before the implants of the next module. This pad oxide protects the silicon from contaminants in the photoresist process, randomizes the source/drain implants to minimize channeling, and protects the silicon during anneal of the source/drain implants.

Source/Drain Junctions with or without Silicide—Relatively high-dose arsenic and/or phosphorus implants must be made for the NMOS source/drains and a boron implant for the PMOS source/drains. These implants go through the pad oxide and must be blocked by the field oxide, poly gates, and sidewall oxide spacers adjacent to the gates so that the source/drains are formed only in the active areas not covered by gate. A particular design concern for surface-channel CMOS is that the poly must be thin enough that the source/drain dopants reach the bottom surface of the poly (after anneal). Rapid thermal anneal of the source/drain implants is an obvious choice for SWP. This is particularly important when the junctions must be kept shallow.

Many CMOS processes include the formation of silicide over the active regions and the polysilicon gates. After anneal of the source/drain implants, an additional oxide may be deposited and anisotropically etched to increase the width of the sidewall oxide spacer before silicide processing (see Fig. 70) and leave the polysilicon and active areas free of oxide. In the "salicide" direct react process, titanium metal is deposited; layered titanium nitride/titanium silicide is formed by reacting in a nitrogen ambient; the titanium nitride is etched away leaving silicide over exposed silicon and polysilicon; and finally the remaining silicide is annealed at a slightly higher temperature to obtain the lowest possible sheet resistivity from the $TiSi_2$ compound. Precise control of titanium thickness, ambient pressures, and react/anneal temperatures is required for this silicide process, making this process an obvious choice implementation with a cluster tool.

It should be noted that the formation of a silicide over the source/drain junctions requires that these junctions be deep enough to prevent shorting by the silicide. Usually when silicide is used, it is not desirable to have very shallow junctions for source/drain; the shallow junction for the CMOS transistors is obtained by the LDD structure formed earlier in the process.

Metallization and Interlevel Isolation—Fig. 70 shows a schematic representation of the formation of two levels of metal interconnect separated by interlevel insulators. The first metal may use tungsten plugs in the vias with copper-doped aluminum as the top interconnect level. The use of other combinations of metals is being investigated. The interlevel insulators will be combinations of deposited undoped and doped oxides. In some processes, a layer of oxide doped with phosphorus and/or boron will be reflowed at a moderate temperature to smooth the insulator surface before

subsequent deposition of a metal layer. Phosphorus-doped oxides also play an important role in preventing contamination to the gate oxide by mobile ions. In other cases, a resist coat or spin-on glass followed by etchback planarization will be used. Etchback planarization processes in general require very accurate measurement of oxide thicknesses and feedback control on etch duration.

One of the most critical problems that can be addressed by SWP with sensors for feedback control is etch of contact and via. For devices designed for deep submicron dimensions, the height-to-width aspect ratio can be in the range of 2–3. This can be a special problem for contacts from metal-1 because the aspect ratio will be different for contacts to active area and to poly over field oxide (see Fig. 70). Vias always connect metal-1 and metal-2, so the height–diameter ratio should be the same for all vias.

If silicide is used to clad the active areas, it is extremely important to limit the temperatures used in the metal/interlevel oxide processes. The problem is that the dopants in the source/drains will diffuse into the silicide. The problem is especially severe for PMOS, in which case it is best to keep these later temperatures 700 °C or lower. In some applications, temperatures as high as 800 °C can be used.

Gate oxide is subject to damage during processing steps after poly gate etch. Dry etching of oxides and metals using high-energy ions can cause radiation damage to the gate oxide. Mechanical stress from subsequent layers can influence the effect of radiation damage on the gate oxide. The effect of damage to the gate oxide is most noticeable for NMOS transistors and can affect the resistance of the NMOS transistor to hot carrier stress. It is well known that hydrogen will weakly bond to the damage centers and also make it easier to create additional damage centers. Hydrogen can also accelerate boron diffusion through gate oxide if the temperatures are too high. In principle, it is desired to minimize the use of hydrogen ambient during later processing, but this is difficult to accomplish. It is important to limit processing temperatures if an ambient with considerable hydrogen partial pressures is used. All of the above parameters should be monitored during SWP.

Protective Overcoat Layer—The final step after etch of the last metal interconnect is to place a protective layer over the metal and remove the protective overcoat over the bond pads.

SILICON-ON-INSULATOR TECHNOLOGY AND DEVICES*

Silicon-on-insulator (SOI) technology is a primary candidate to provide the improved performance, cheaper processing, and unique device structures required for future generations of ICs.† Development of this technology has been significantly enhanced by the fact that in addition to improved performance and yield, devices fabricated on SOI substrates exhibit significantly increased tolerance to transient radiation and single event upset (SEU).‡ This radiation tolerance has resulted in considerable interest in SOI technology development for devices useful to both space science missions and military electronics.

SOI Material Options

The unique feature of SOI is fabrication of the entire integrated-circuit structure in a thin film of high-quality silicon on the surface of an insulating layer, as illustrated in Fig. 88. This construction provides advantages in both performance and yield for both bipolar and MOS IC structures. Current SOI materials can be considered as follow-ons to the early dielectric isolation technology and SOS technology. The advantages of devices fabricated on these isolated substrates have been demonstrated in both bipolar and CMOS technologies; however both of the prior substrate technologies have significant limitations. The dielectric isolation scheme relies on separation of individual devices by "V" grooves, which are etched into the wafer using an orientation-dependent etch. These "V" grooves require spacings of several mils between devices, which is not compatible with densities required for VLSI circuits. In addition, the thickness tolerances obtainable with dielectric isolation technology do not provide the thin silicon films required for most CMOS device applications.

SOS substrates can be fabricated with thin silicon films and are routinely used for isolated-substrate CMOS device applications. However, the SOS substrates are costly and not readily available in large volumes required for VLSI applications. In addition, until recently the silicon films on SOS were not available in subhalf-micron thicknesses, as anticipated to be required for advanced CMOS devices. A further limitation of SOS technology has been the reluctance (due to concern for cross contamination) of device manufacturers to run SOS in high-volume front ends designed for silicon wafer fabrication.

The current view of SOI materials is a silicon substrate with a "buried oxide" layer in the 200–1000 nm range, covered by a single-crystal silicon film with a thickness from less than 100 nm to greater than 2000 nm. The lower values of buried oxide and silicon film thickness are used for CMOS device applications, while the thicker layers are used for bipolar device applications. This material is illustrated in Fig. 89. This construction is very similar to the dielectric isolation case, without the "V" groove isolation. The advantage of this construction over the conventional dielectric isolated technology is that isolation can now

* This section was contributed by H. H. Hosack.

† References 136–139.

‡ Reference 140.

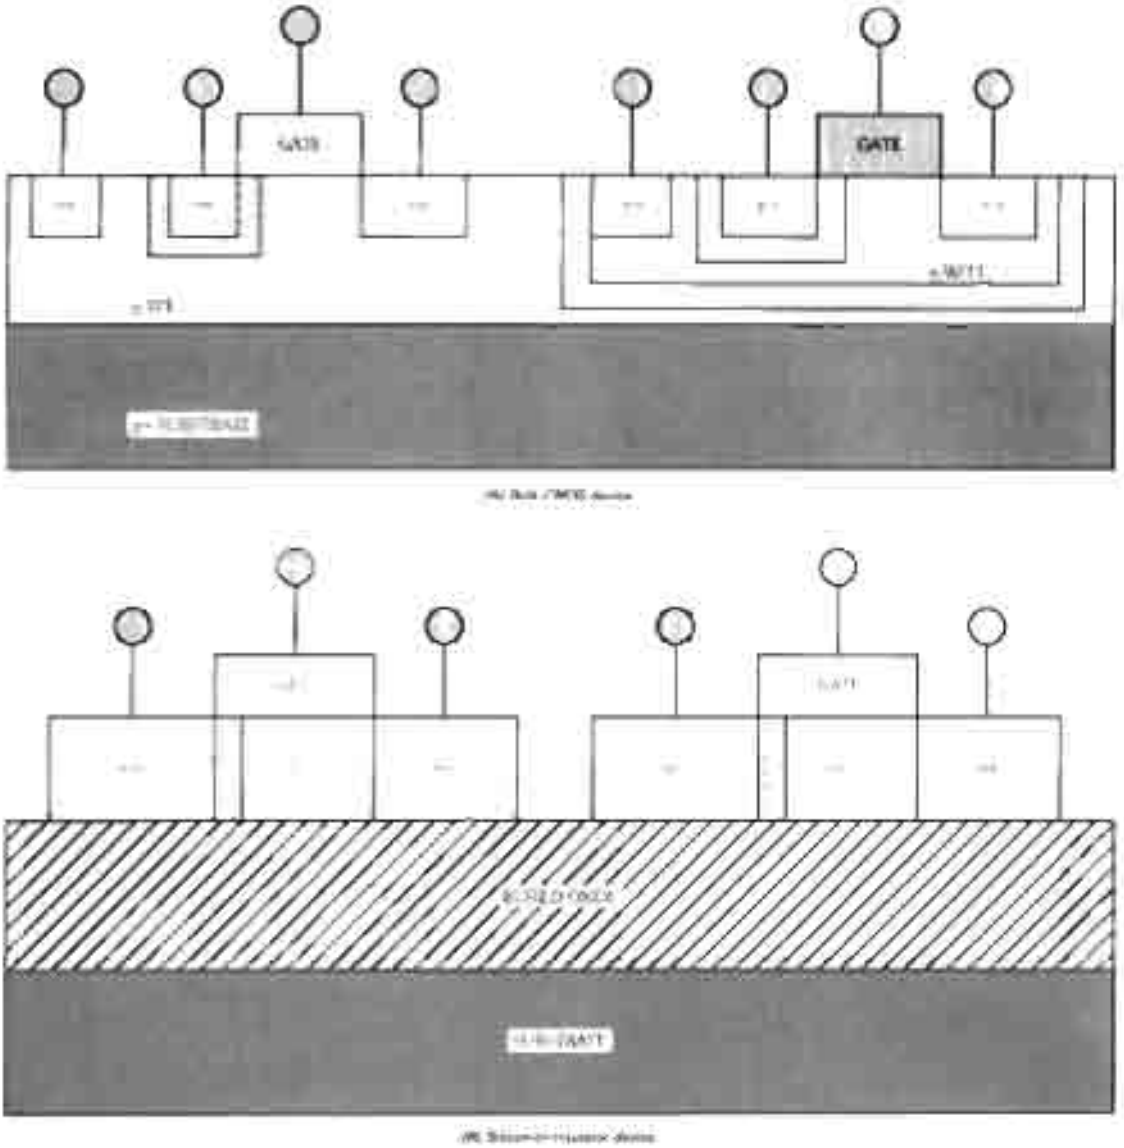

Fig. 88. Silicon-on-insulator device structure.

be provided by simply etching the silicon layer to form "mesas" around isolated silicon islands, which can be accomplished at geometries as narrow as allowed by lithographic tools. The advantage of the current SOI materials over SOS is that the all-silicon construction ensures compatibility with large volume front ends designed specifically for silicon technologies, as well as allowing potential availability from commercial silicon wafer manufacturers.

Several alternative constructions have been proposed and investigated for producing SOI materials.* Among these are Separation by IMplantation of OXygen (SIMOX), Bond and Etchback (BESOI), Zone Melt Recrystallization (ZMR), Field Isolation by Porous Oxidation of Silicon (FIPOS), and Epitaxial Lateral Overgrowth (ELO). Each of these techniques has its own specific advantages and disadvantages, but thus far only two, SIMOX and BESOI, have shown the potential for being manufacturable technologies.

* Reference 111

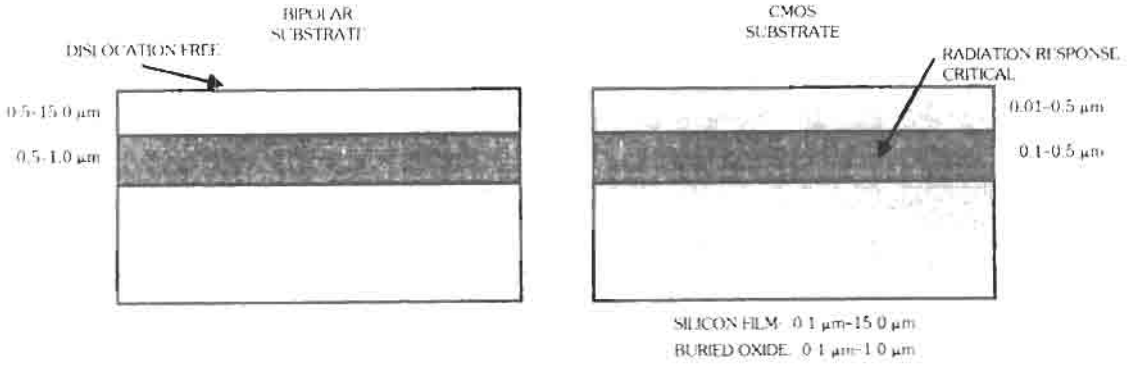

Fig. 89. Comparison of bipolar and CMOS substrates.

compatible with fabrication of generic wafers for both CMOS and bipolar large-area IC fabrication. This conclusion comes primarily from the fact that SIMOX has currently demonstrated the potential to produce both the very thin superficial layers needed for advanced performance CMOS device applications* and BESOI has been demonstrated to produce the thicker, dislocation-free layers needed for bipolar device applications.†

Device Structures Using SOI Materials

Devices built on SOI material have significant advantages to offer in the search for advances in IC technology. These include performance advantages, which add to the goal of increased circuit size and complexity, as well as yield advantages, which add to the ability to fabricate advanced large-area devices at acceptable cost. These advantages are applicable to both commercial and military IC's.

Among the performance advantages of SOI devices, the most significant are reduced susceptibility to "soft errors" from high-energy particles and upset from high-flux transient doses of X rays, elimination of latchup effects, high speed owing to reduced junction capacitance gained from the buried oxide, potential for very low standby power requirements, and reduced threshold lowering in short-channel transistors. In addition, and perhaps more significant for the short-term implementation of SOI in commercial manufacturing, SOI material offers advantages in higher packing density and lower "defect susceptible" area, both of which imply higher yield and lower final IC cost. As an added advantage, it is possible to integrate bipolar circuits into SOI substrates along with CMOS circuits, allowing the use of various device technologies on a single chip to optimize a broad range of performance parameters. This feature is particularly appropriate when applied to cases where devices may have significantly different voltage-level requirements, as may be needed for true "system-on-a-chip" alternatives—perhaps a key to future low-cost consumer markets and high-density, high-performance military systems.

The performance advantages of SOI ICs noted above are primarily a consequence of the unique construction allowed by the use of SOI substrates. These features can be noted by considering the typical structure of a CMOS/SOI transistor as shown in Fig. 90. Fig. 90A shows a surface view of the device; Fig. 90B shows a cross section through the gate; and Fig. 90C shows a cross section through the current flow channel. This device is constructed in a "mesa" format, where the individual transistors are built on separated single-crystal silicon islands formed on the buried oxide. This construction is uniquely allowed in SOI technology by the use of the insulated substrate to produce dielectric isolation between devices fabricated in the silicon islands. The first performance advantages noted above are reduced susceptibility to the effects of high-energy particles and resistance to high-dose X rays. These features are a direct consequence of the minimum charge collection volume available for an SOI device. This is apparent from Fig. 90, where only the volume bounded by the gate, buried oxide, and junction edges produces susceptibility to charge generation. This compares to the bulk case where there is a much larger depletion region, as well as the possibility of charge collection from the volume below the depleted area.

Since SOI transistors are completely dielectrically isolated, the advantages of no latchup and minimum parasitic capacitance are "built-in" for this construction. The advantage of no latchup is significant, particularly as smaller geometries are considered. Although various techniques are being considered to eliminate latchup in minimum-geometry bulk devices, in many

* Reference 142.
† Reference 143.

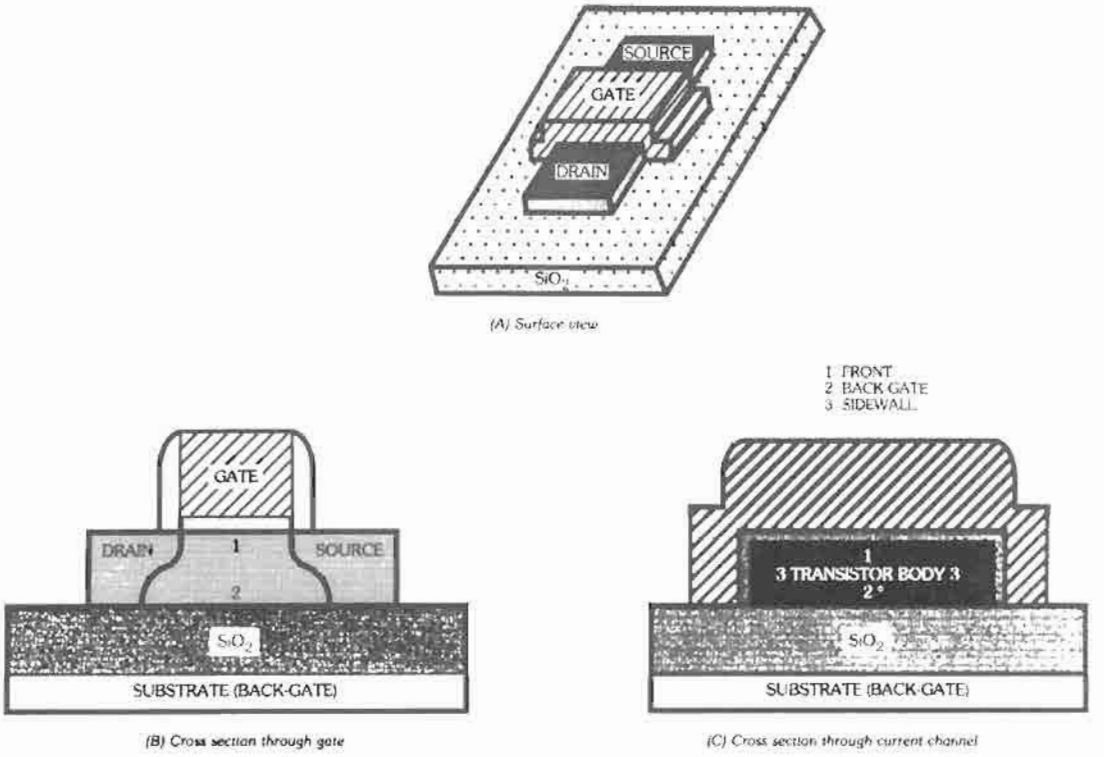

Fig. 90. Schematic of mesa-isolation SIMOX structure showing different channels present.

cases the techniques used impose significant added costs in area or other constraints on both device fabrication and performance.

The magnitude of the advantage to IC performance offered by reduction in capacitance resulting from the insulating substrate in SOI technology varies with device design and construction. Advantages obtained for sRAMs are typically calculated to be in the range of 10–20% reduction in access time. Advantages in propagation delay measured on CMOS dual-mode prescaler circuits have been shown to be more than a factor of 2.* The difference between these advantage factors is a function of the dominant source of capacitance in the circuit.

Perhaps the most significant potential performance advantage for VLSI applications offered by SOI is the possibility of making devices requiring very low standby power. In conventional bulk technology, a significant portion of the standby current can result from the leakage from junction areas that are not critical to transistor performance, such as the bottom of source-drain areas, which are used for contacts. As can be seen in Fig. 90, in the SOI transistor the leakage current associated with an "off" transistor is due only to the vertical area at the drain/channel junction. This area represents only a small fraction of the total source-drain area that could cause standby current in a bulk transistor of corresponding geometry.

The two fabrication advantages noted above, higher packing density and lower defect-susceptible area, can also be noted from Fig. 90. For the mesa-isolated device, separation between individual circuit elements is accomplished by producing individual silicon mesas. For this case, the minimum isolation width is determined by the minimum level of lithography available, rather than process limitations, such as are often found in LOCOS and trench isolation used for bulk devices.

The advantage of the lower defect-susceptible area noted above can also be seen from Fig. 90. As can be observed, the only "active area" of this device is the small cross section lying directly below the gate of the transistor. All of the remaining areas of the device are only effective in providing contact to the area beneath the gate, and these areas are entirely surrounded by insulation—either the buried oxide on the bottom or the isolation between the mesas. Even if a portion of the mesa is erroneously removed, or if a portion of the contact to the mesa is not opened, the liability is only a reduction in contact area, which in many cases will not

* Reference 144.

significantly impact the device performance. Compare this situation with the bulk silicon case. In this situation, the entire area beneath both of the junctions that comprise the source and drain are critical areas, and any defect in the silicon in this area, or lithography defect that erroneously opens these areas, will cause a fatal flaw in the resulting circuit. This difference in "active area" between the SOI device and the usual bulk technologies can be extremely significant in providing the ability to produce adequate yield on advanced large-area, high-performance structures.

Devices on SOI

The electrical performance of bipolar devices on SOI materials is similar to that of bipolar devices on bulk material, with the advantage of reduced capacitance and reduced susceptibility to latchup and upset by radiation sources. CMOS devices in SOI materials may be fabricated to operate in two different modes.* These are designated as "fully depleted" and "nonfully depleted" devices. From a physical standpoint, the difference between these two configurations is that in the nonfully depleted device the SOI film is doped in such a way that in operation a neutral region exists between the front and back gate depletion regions, thus eliminating coupling between the two parallel MOS devices making up the SOI transistor. In the fully depleted case, there is no neutral region between the two parallel devices, and direct coupling exists between the front gate and the back gate of the SOI device.

* Reference 145.

Nonfully Depleted Devices

The electrical characteristics of nonfully depleted CMOS/SOI devices are similar to those of bulk devices, with two distinct differences: the appearance of a "kink effect" and enhanced subthreshold slope. Both of these effects are directly related to the fact that the body of the SOI transistor is electrically "floating" between the source and drain junctions. The kink effect is a variation in the I_d versus V_d characteristics of n-channel MOSFETs caused by impact ionization near the drain. (This effect is not usually as significant for p-channel devices because of the low impact ionization cross section for holes.) This effect is illustrated in Fig. 91; the "kink" is clearly evident. Physically, this effect is one of impact ionization and accumulation of holes in the neutral body region of the device. As the drain bias is increased, impact ionization occurs near the drain junction owing to the high fields. In a bulk device, the holes generated from this mechanism flow into the substrate as substrate current, but in the SOI device this current path is cut off, so the holes accumulate in the neutral body. This raises the

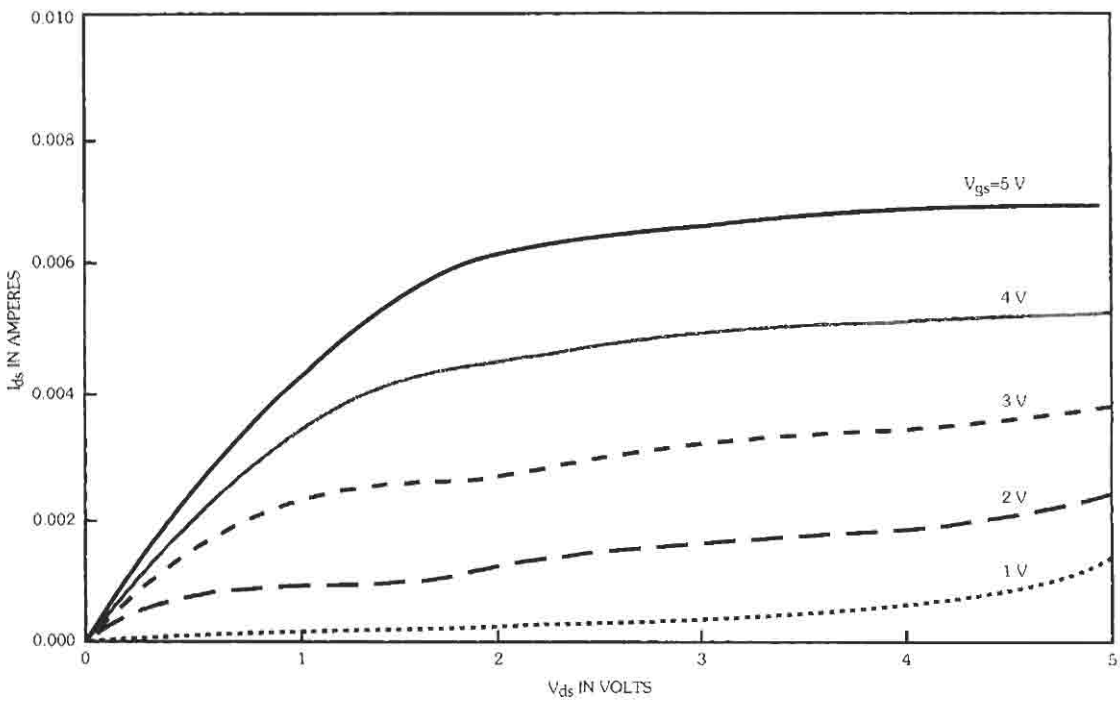

Fig. 91. I_{ds} vs V_{ds} curves for an n-channel MOSFET.

body potential, which in turn raises the drain current through an effective reduction in the threshold voltage and results in the "kink" in the I_{ds} versus V_{ds} curve. The kink effect is significantly affected by the body doping of the device—a higher body doping produces a more pronounced kink effect in SOI devices.

The subthreshold characteristics of MOS transistors on SOI materials can also be affected by the floating body effects. At high V_{ds}, the subthreshold current increases more rapidly with V_{gs} (giving a steeper subthreshold slope) because as V_{gs} increases, the weak inversion current causes ionization near the drain. The holes accumulated in the body from this impact ionization raise the body potential, resulting in a faster increase of the drain current with V_{gs} than would otherwise occur.

In many device structures the kink effect and enhanced subthreshold slope are not significant limitations. However, since these features become more pronounced for smaller geometries, significant efforts on "drain engineering" are used to minimize these effects.

Fully Depleted Devices

When the thickness of the silicon film is thinner than the combined depletion regions of the two parallel MOS transistors making up an SOI device, the V_t is not substantially influenced by the body potential, thus eliminating the kink effect. In addition, other advantages of the fully depleted configuration are higher drive current, reduced hot-carrier effects, and reduced short-channel characteristics.

High drive current in completely depleted SOI transistors is a result of lower channel doping, increased mobility due to lower vertical electric fields, and a more effective use of gate voltage to influence inversion charge. In a fully depleted device, a portion of the surface transistor gate voltage drop occurs across the active device film, and a portion of the drop is across the buried oxide and substrate. In this case, the vertical electric field is lower in the completely depleted device than it is in a comparable bulk device, which results in an increased mobility and increased current. In addition, in the presence of the buried oxide the changes in the gate voltage are more significantly reflected in the inversion charge than is the case for a bulk device. This results in an even greater increase in drive current. Calculations show that a 20% to 50% increase in drive current over comparable bulk devices is available with fully depleted technology.

The inverse subthreshold slope of fully depleted SOI transistors is typically smaller (resulting in faster turn-on) than that for comparable geometry bulk or nonfully depleted SOI devices. In bulk and nonfully depleted SOI devices, a change in the value of V_{gs} is reflected in a change in the voltage drop over the gate oxide and the depletion region in a ratio determined by the capacitive voltage divider between these two device components. In the usual construction of fully depleted devices, however, changes in V_{gs} occur mostly over the buried oxide, since there is no change in the depletion charge in the silicon film. This results in a much higher percentage of V_{gs} being reflected in changes in the surface potential of the device, and therefore a much smaller inverse subthreshold slope and faster turn-on characteristics. This rapid turn-on of completely depleted SOI devices, coupled with the availability of high current drive, makes this technology ideally suited for high-performance, low-voltage circuit applications.

SOI Circuits

A major drive for the initial development of SOI integrated circuits was applications in radiation hardened CMOS memory devices for defense applications. Prior to SOI, radiation hardened memory circuits were fabricated on silicon on sapphire substrates. These devices performed well in radiation environments, but the silicon on sapphire substrates typically had defect densities that were too high to use in fabrication of VLSI circuits, and they were too brittle to be run in standard silicon fabrication lines. The initial SOI VLSI devices were memories, produced to densities from 64 Kbits to 1 Mbit, fabricated on standard VLSI fabrication facilities with high yield and excellent radiation hardness.* These devices demonstrated the advantage of SOI over the prior silicon on sapphire technology.

The above-mentioned ICs were produced using nonfully depleted SOI technology. Various circuits have been fabricated using fully depleted transistors, and in all cases results superior to comparable bulk ICs have been achieved. A 16K sRAM fabricated as both a completely depleted SOI device and as a bulk device has shown a 40% increase in speed for the completely depleted structure. A high-speed CMOS prescaler circuit was built in completely depleted SIMOX and was found to operate 50% faster than a comparable bulk device. In addition, completely depleted devices with excellent short-channel characteristics at gate lengths below 0.5 μm have recently been discussed.†

SOI based devices received their first major commercial introduction in the year 2000 in the form of advanced microprocessors for IBM server applications. These systems provide a 20% performance advantage because of the use of SOI devices. The SOI device used is designated the AS400 processor. This device operates in the partially depleted SOI mode, and employs design features uniquely applicable to SOI circuits. This effort not only demonstrates that partially depleted SOI circuits can be fabricated in usual IC manufacturing environments, but it also shows examples where SOI unique features can be exploited for a larger performance gain than achievable through a simple bulk-to-SOI re-map. Several

other microprocessor manufacturers have announced plans to follow the IBM lead.

Three-Dimensional ICs

One of the most advanced applications proposed for SOI is in 3D ICs. In this application, SOI transistors are used as elementary building blocks for 3D ICs, as illustrated schematically in Fig. 92. Transistors in this format would require a succession of SOI process implementations and would allow for extensive "system-on-a-chip" type applications, particularly those requiring massive parallel processing. Several uses of this technology have been proposed, with applications ranging from image-data gathering and processing to neural network applications.*

Conclusion

The anticipated advantages of devices produced on SOI materials have been discussed for several years. These advantages include better performance due to higher drive current and lower capacitance, simpler isolation due to mesa structures, elimination of latchup due to completely oxide-isolated transistors, and extreme tolerance to both transient radiation and SER. Recent progress in fabrication and understanding of SOI materials has not only allowed the experimental verification of many of these advantages but has also resulted in the discovery of significant new effects and possibilities for new device structures. As SOI materials become more readily available in manufacturing quantities, it is anticipated that the advantages of SOI technology will be used extensively in the manufacture of high-performance commercial and military electronics.

21 Optoelectronics

Revised and Expanded by
Gregory E. Stillman

Optoelectronics is the technological marriage of the fields of optics and electronics. It includes the generation and evaluation of electromagnetic radiation in the optical wavelength range and its conversion into electrical current or signals, the interaction of light with matter, radiometry, and the characteristics of sources and detectors.

THE OPTICAL SPECTRUM

The optical spectrum is generally defined to encompass electromagnetic radiation with wavelengths in the range from 10 nm to 10^3 μm, or frequencies in the range from 300 GHz to 3000 THz (Fig. 1).

Other units are often used to describe the optical spectrum, as discussed below. For engineering calculations, three significant figures usually give sufficient accuracy. More precise values of the constants can be obtained from NBS/NIST data.

Wavelength λ*:*

$$1\ \mu\text{m} = 10^{-3}\ \text{mm} = 10^{3}\ \text{nm} = 10^{4}\ \text{Å}$$

Frequency (ν *or* f)*:*

$$1\ \text{cm}^{-1}\ \text{(wave number)} = 30\ \text{GHz} = 3 \times 10^{10}\ \text{Hz}$$

$$\nu\ (\text{or}\ f) = \frac{c}{\lambda} = \frac{3 \times 10^{14}}{\lambda\ (\mu\text{m})}\ \text{Hz}$$

$$\bar{\nu}\ (\text{wave number}) = \frac{\nu}{c} = \frac{1}{\lambda}\ (cm^{-1})$$

Photon energy (E)*:*

$$E = h\nu = \frac{hc}{\lambda} = \frac{1.24}{\lambda\ (\mu\text{m})}\ \text{eV},$$

where the velocity of light in free space is

$$c = 3 \times 10^{10}\ \text{cm/s}$$

and Planck's constant h is

$$h = 6.63 \times 10^{-34}\ \text{J·s}$$

The optical spectrum is divided into three major categories, as follows.

Ultraviolet: Wavelengths shorter than those in the visible spectrum and longer than for X rays are collectively designated ultraviolet (UV). Ultraviolet is classified according to wavelength as extreme (100–2000 Å), far (2000–3000 Å), or near (3000–3700 Å). Ultraviolet is also sometimes designated as short-wave or long-wave.

Visible: Those wavelengths in the approximate range 3700–7500 Å can be perceived by the human eye and are therefore collectively designated as visible light. Visible light is classified according to the various colors its wavelengths elicit in the mind of a standard observer. The major color categories are violet (3700–4550 Å), blue (4560–4920 Å), green (4930–5770 Å), yellow (5780–5970 Å), orange (5980–6220 Å), and red (6230–7500 Å).

Infrared: Those wavelengths longer than those in the visible spectrum and shorter than microwaves are collectively designated infrared (IR). Infrared is classified according to its wavelength as near (0.75–3 μm), middle (3–6 μm), far (6–15 μm), and extreme or submillimeter (15 μm–1 mm), although different authors often use slightly different wavelength ranges for these classifications.

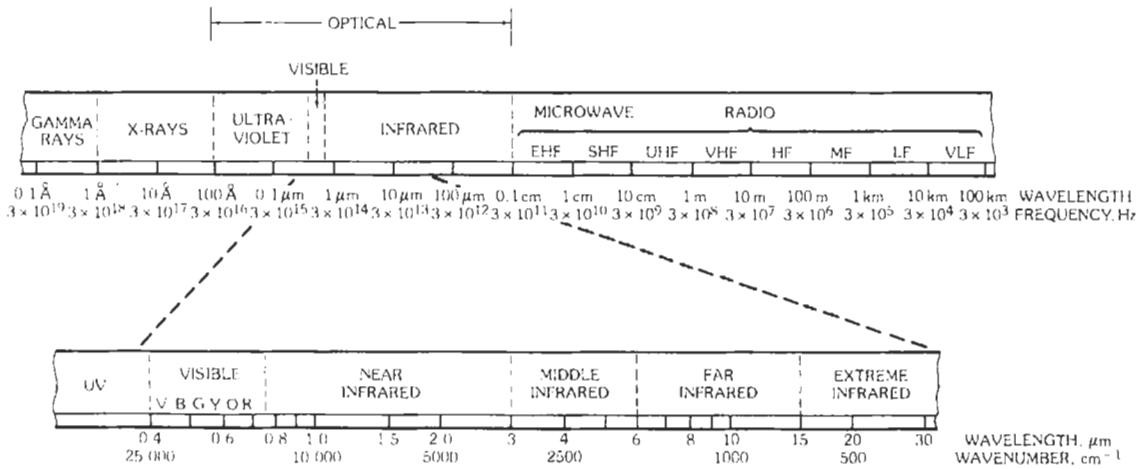

Fig. 1. The electromagnetic spectrum.

RADIOMETRY

Terms and Definitions

Radiometry is the science of measurement of optical radiation at any wavelength, based simply on physical measurements. Radiant energy cannot be measured quantitatively directly, but must always be converted into some other form such as thermal, electrical, or chemical. Radiometry applies over the entire electromagnetic spectrum, not just the optical region. The terms used to describe radiant power in radiometry are summarized in Table 1. All the terms used in radiometry are defined in terms of energy. When certain quantities are considered as a function of wavelength or frequency, the adjective "spectral" is used to modify the term, and the symbol for the quantity is followed by the appropriate spectral symbol, λ, ν, or $\bar{\nu}$, in parentheses. When the spectral concentration of a quantity is considered, it is also described by the adjective spectral, but in this case the symbol is subscripted with the appropriate spectral quantity; for example the spectral radiant excitance can be given as W_λ in units of $W \cdot m^{-2} \cdot \mu m^{-1}$.

Blackbody Radiation

Any surface of a body with a temperature greater than absolute zero ($T = 0$ K) is a source of radiation. The term "blackbody" applies to a thermal radiator that absorbs completely all incident electromagnetic radiation regardless of the wavelength, the direction of incidence, or the polarization. Such a radiator also has the maximum emission possible for any wavelength and in any direction for a thermal radiator in thermal equilibrium at a given temperature. Kirchhoff's law states that for any body (all materials) in an isothermal enclosure at temperature T, the ratio of the radiant excitance (emittance), W, to the absorptance, α, is equal to the radiant excitance of a blackbody, W_{bb}, at the same temperature:

$$W(T)/\alpha = W_{bb}(T)$$

Planck's law gives the blackbody spectral power for unpolarized radiation emitted at temperature T between the wavelengths λ and $\lambda + d\lambda$ as

$$W_\lambda(\lambda, T)d\lambda = 2\pi c^2 h \lambda^{-5} (e^{hc/\lambda kT} - 1)^{-1} \, d\lambda$$

$$= C_1 d\lambda / \lambda^5 (e^{C_2/\lambda T} - 1)$$

where,

$k = 1.38 \times 10^{-23}$ J·K^{-1} is Boltzmann's constant,
$C_1 = 2\pi c^2 h = 3.74 \times 10^4$ W·cm^{-2}·μm^4,
$C_2 = ch/k = 1.44 \times 10^4$ μm·K.

Fig. 2 shows the variation of $W_\lambda(\lambda, T)$ with λ for various values of T. The integral of $W_\lambda(\lambda, T)d\lambda$ over all wavelengths gives the Stefan-Boltzmann law for total blackbody radiant excitance $W_{bb}(T)$ in W/cm^2,

$$W_{bb}(T) = \int_0^\infty W_\lambda(\lambda, T)d\lambda = (2\pi^5 k^4 / 15c^2 h^3)T^4$$

$$= (\pi^4 C_1 / 15 C_2^4)T^4 = \sigma T^4$$

where $\sigma = 5.67 \times 10^{-12}$ W·cm^{-2}·K^{-4} is the Stefan-Boltzmann constant. The blackbody spectrum has a pronounced maximum at a particular wavelength λ_m for a given temperature T, and the relationship

$$\lambda_m T = C_2/4.9651 = 2897.8 \ \mu m \cdot K$$

is known as Wien's displacement law.

Planck's law can also be specified in terms of frequency or wave number instead of wavelength, and these relations result in slightly different forms of Wien's displacement law. For calculations it is often convenient to use the dimensionless quantity

$$x = hc/\lambda kT = h\nu/kT = C_2/\lambda T$$

for which Planck's law becomes

$$W_x(x, T)dx = (15\sigma T^4/\pi^4)[x^3 dx/(e^x - 1)]$$

The energy flux per unit area for wavelengths lying between x_1 and x_2 can easily be calculated using the series expansions below:

$$W_{0-\lambda_0}(T) = \int_0^{\lambda_0} W_\lambda(\lambda, T)d\lambda$$

$$= (15\sigma T^4/\pi^4) \int_{x_0}^\infty x^3 dx/(e^x - 1)$$

$$= (15\sigma T^4/\pi^4) \sum_{m=1}^{\infty} (e^{-mx_0}/m^4)$$

$$[(mx_0)^3 + 3(mx_0)^2$$

$$+ 6(mx_0) + 6]$$

where

$$x_0 = hc/\lambda_0 kT = C_2/\lambda_0 T$$

and the energy flux per unit area for wavelengths between λ_2 and λ_1 is given by

$$W_{\Delta\lambda} = (15\sigma T^4/\pi^4)$$

$$\sum_{n=1}^{\infty} (e^{-nx}/n^4)[(nx)^3 + 3(nx)^2 + 6nx + 6] \Big|_{x_2}^{x_1}$$

for $x_i \geq 2$.

TABLE 1. COMMON RADIOMETRIC TERMINOLOGY

Symbol	Term	Description	Units	Equation
U	Radiant energy	Energy transferred by electromagnetic waves	J	
u	Radiant energy density	Radiant energy per unit volume	$J \cdot cm^{-3}$	$u = dU/dV$
P	Radiant flux	Rate of transfer of radiant energy	W	$P = dU/dt$
W	Radiant emittance	Radiant flux emitted per unit area of a source	$W \cdot cm^{-2}$	$W = dP/dA$
Q	Radiant photon emittance	Number of photons emitted per second per unit area	$Photons \cdot s^{-1} \cdot cm^{-2}$	
J	Radiant intensity	Radiant flux per unit solid angle	$W \cdot sr^{-1}$	$J = dP/dQ$
N	Radiance	Radiant flux per unit solid angle per unit area	$W \cdot cm^{-2} \cdot sr^{-1}$	$N = W/\pi$
H	Irradiance	Radiant flux incident per unit area	$W \cdot cm^{-2}$	$H = dP/dA$
P_λ	Spectral radiant flux	Radiant flux per unit wavelength interval at a particular wavelength	$W \cdot \mu m^{-1}$	$P_\lambda = dP/d\lambda$
W_λ	Spectral radiant emittance	Radiant emittance per unit wavelength interval at a particular wavelength	$W \cdot cm^{-2} \cdot \mu m^{-1}$	$W_\lambda = dW/d\lambda$
Q_λ	Spectral radiant photon emittance	Radiant photon emittance per unit wavelength interval at a particular wavelength	$Photons \cdot s^{-1} \cdot cm^{-2} \cdot \mu m^{-1}$	$Q_\lambda = dQ/d\lambda$
J_λ	Spectral radiant intensity	Radiant intensity per unit wavelength interval at a particular wavelength	$W \cdot sr^{-1} \cdot \mu m^{-1}$	$J_\lambda = dJ/d\lambda$
N_λ	Spectral radiance	Radiance per unit wavelength interval at a particular wavelength	$W \cdot cm^{-2} \cdot sr^{-1} \cdot \mu m^{-1}$	$N_\lambda = dN/d\lambda$
H_λ	Spectral irradiance	Irradiance per unit wavelength interval at a particular wavelength	$W \cdot cm^{-2} \cdot \mu m^{-1}$	$H_\lambda = dH/d\lambda$
ϵ	(Radiant) emissivity	Ratio of radiant emittance of a source to that of a blackbody at the same temperature	(Numeric)	
α	(Radiant) absorptance	Ratio of absorbed radiant flux to incident radiant flux	(Numeric)	
θ	(Radiant) reflectance	Ratio of reflected radiant flux to incident radiant flux	(Numeric)	
τ	(Radiant) transmittance	Ratio of transmitted radiant flux to incident radiant flux	(Numeric)	

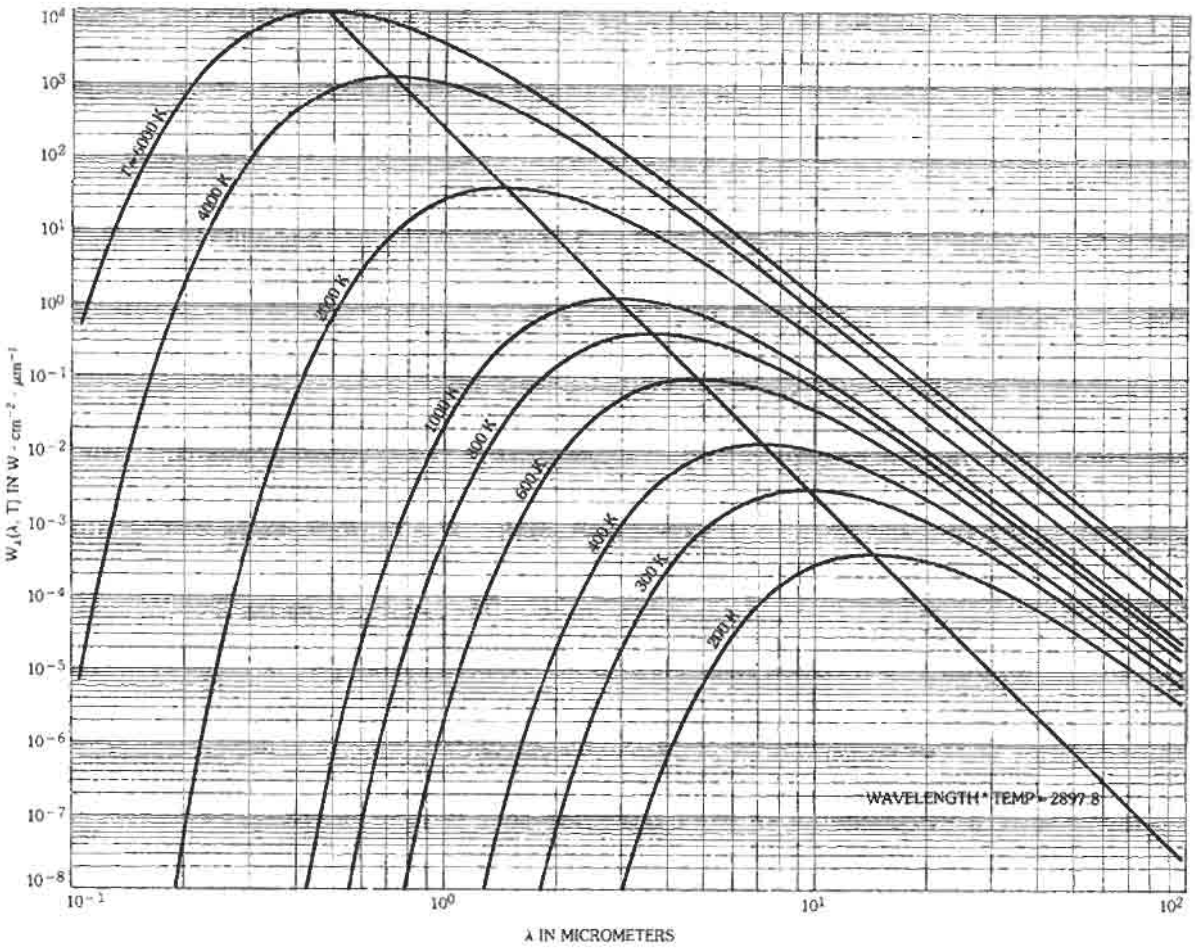

Fig. 2. Blackbody spectral radiant emittance, $W_\lambda(\lambda, T)$, for different blackbody temperatures.

A similar expression can be derived for values of $x_i < 2$ using

$$W_{0-\lambda_0}(T) = \sigma T^4 \{1 - (15/\pi^4)x_0^3 [1/3 - x_0/8 + x_0^2/60 - x_0^4/5\,040 + x_0^6/272\,160 - x_0^8/13\,305\,600 + \ldots]\}$$

which converges rapidly for $x_0 < 2$.

Similar relations for the number of quanta or photons emitted by a body at temperature T can be obtained by dividing $W_\lambda(\lambda, T)$ by the energy of the quanta at wavelength λ, hc/λ, as

$$Q_\lambda(\lambda, T)d\lambda = (C_3/\lambda^4)[d\lambda/(e^{c_2/\lambda T} - 1)]$$

where $C_3 = C_1/hc = 2\pi c$. The variation of $Q_\lambda(\lambda, T)$ with λ for several temperatures is shown in Fig. 3. The relation corresponding to Wien's displacement law relating the wavelength of maximum quanta emission λ'_m to the temperature is

$$\lambda'_m T = 3669.73\ \mu\text{m·K}$$

for λ'_m in micrometers, and the Stefan-Boltzmann law for the total number of photons emitted per unit area in blackbody radiation is

$$Q_{bb}(T) = \sigma T^4/2.75kT = \sigma' T^3$$

where $\sigma' = 1.49 \times 10^{11}$ s^{-1}·cm^{-2}·K^{-3}. These relations are summarized in Table 2.

Since the blackbody radiant emission and radiant photon emission are both functions of λT, it is possible to plot a single normalized curve of blackbody radiant emission as a function of λT that makes possible a simple determination of the fraction of the peak emission at any value of λT, as well as the fraction of the total radiant emittance below λT (i.e., for values of λ_0

TABLE 2. BASIC LAWS AND CONSTANTS OF BLACKBODY RADIATION

Stefan-Boltzmann Law	Wien's Displacement Law		Planck's Equation
$W_{bb}(T) = \sigma T^4$	$\lambda_m T = b$	$W_{\lambda m} = aT^5$	$W_\lambda(\lambda, T) = C_1\lambda^{-5}(e^{C_2/\lambda T} - 1)^{-1}$
$Q_{bb}(T) = \sigma' T^3$	$\lambda_m' T = b'$	$Q_{\lambda m} = a' T^4$	$Q_\lambda(\lambda, T) = C_3\lambda^{-4}(e^{C_2/\lambda T} - 1)^{-1}$

$W_{bb}(T)$ = Total blackbody radiant emittance, $W \cdot cm^{-2}$, for temperature T

$Q_{bb}(T)$ = Total blackbody photon emittance, photons $cm^{-2} \cdot s^{-1}$

σ = Stefan-Boltzmann constant

$= (5.67) \times 10^{-12}\ W \cdot cm^{-2} \cdot K^{-4}$

σ' = Photon Stefan-Boltzmann constant

$= 1.49 \times 10^{11}\ s^{-1} \cdot cm^{-2} \cdot K^{-3}$

λ_m = Wavelength of maximum radiant emittance

λ_m' = Wavelength of maximum radiant photon emittance

λ = Radiant wavelength

$a = 1.2862 \times 10^{-15}\ W \cdot cm^{-2} \cdot \mu m^{-1} \cdot K^{-5}$

$a' = 2.10098 \times 10^{7}\ s^{-1} \cdot cm^{-2} \cdot \mu m^{-1} \cdot K^{-4}$

$b = (2897.8 \pm 0.4)\ \mu m \cdot K$

$b' = (3669.7 \pm 0.4)\ \mu m \cdot K$

$h = (6.63) \times 10^{-34}\ W \cdot s$
Planck's constant

$W_\lambda(\lambda, T)$ = Blackbody spectral radiant emittance, $W \cdot cm^{-2} \cdot \mu m^{-1}$

$W_{\lambda m}$ = Maximum spectral radiant emittance, $W \cdot cm^{-2} \cdot \mu m^{-1}$

$Q_\lambda(\lambda, T)$ = Blackbody spectral photon emittance, photons $\cdot s^{-1} \cdot cm^{-2} \cdot \mu m^{-1}$

$Q_{\lambda m}$ = Maximum spectral radiant photon emittance, photon $\cdot s^{-1} \cdot cm^{-2} \cdot \mu m^{-1}$

$c = 3 \times 10^{10}\ cm \cdot s^{-1}$

$C_1 = 2\pi c^2 h = 3.74 \times 10^{4}\ W \cdot cm^{-2} \cdot \mu m^4$

$C_2 = ch/k = 1.44 \times 10^{4} \cdot \mu m \cdot K$

$C_3 = C_1/hc = 2\pi c$

$k = 1.38 \times 10^{-23}\ J \cdot K^{-1}$
Boltzmann's constant

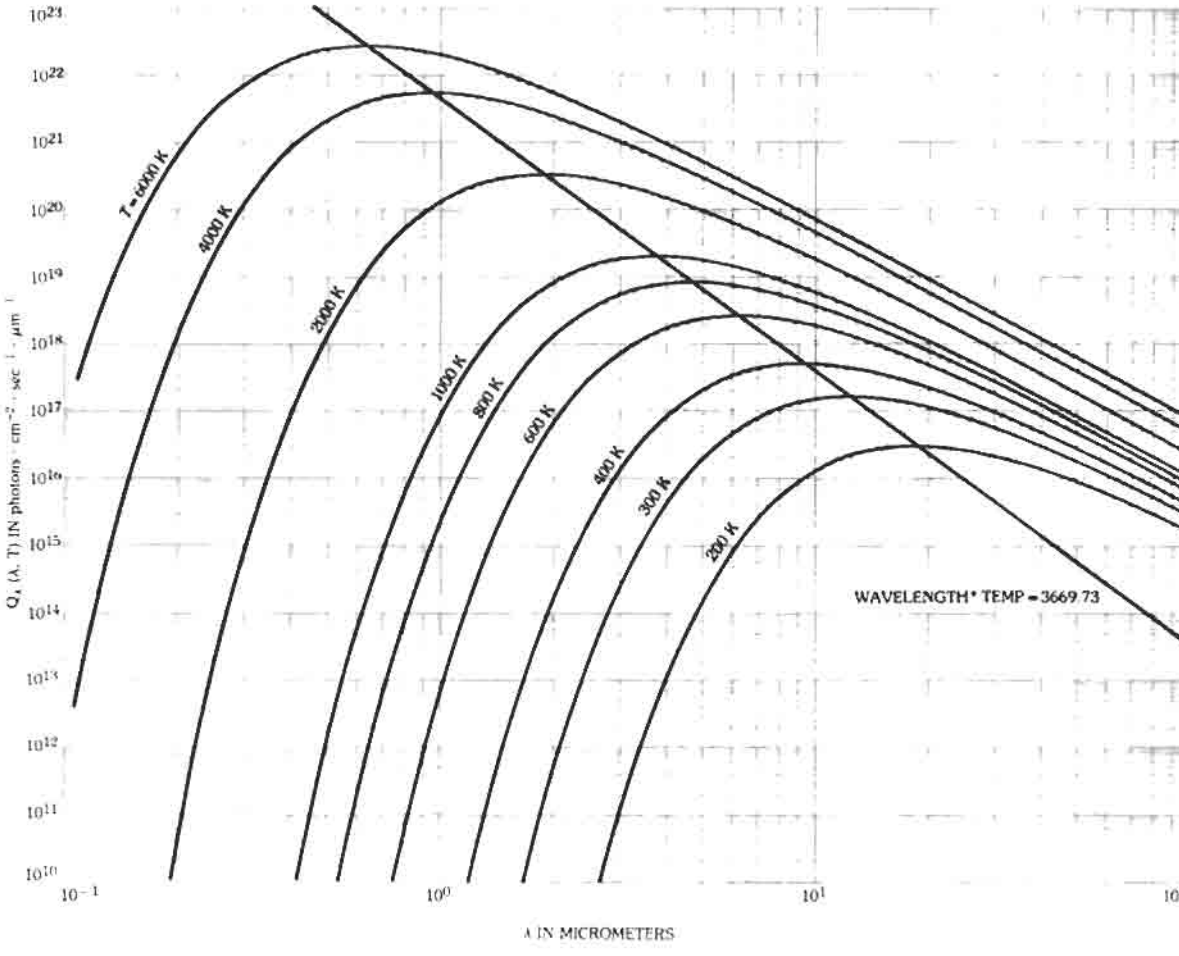

Fig. 3. Blackbody spectral radiant photon emittance, $Q_\lambda(\lambda, T)$, versus λ for different blackbody temperatures.

shorter than λ in λT). This type of plot is particularly useful in determining the effect of background radiation on the sensitivity of infrared detectors. A plot of this normalized photon emittance is given in Fig. 4. To use this curve, the product of the wavelength, λ, and the blackbody or background temperature in kelvins, T, is determined, and the photon emittance, in $cm^{-2} \cdot sec^{-1} \cdot \mu m^{-1}$ at the peak, given by

$$Q\lambda m = a' T^4$$

and the total photon emittance, in photons·cm^{-2} · sec^{-1}, for the blackbody or background at temperature T is determined from

$$Q(T) = b' T^5$$

as given in Table 2. Then, from values read from Fig. 4, the actual spectral emittance at wavelength λ for λT and the total photon emittance (photons·cm^{-2}·sec^{-1}) for wavelengths shorter than λ in λT can be directly calculated. The latter gives the total photon flux capable of exciting free carriers in photon detectors with a cutoff wavelength of $\lambda_c = \lambda$.

A more direct indication of the total photon emittance from the threshold wavelength to zero wavelength, i.e., the total photon emittance with energies greater than that determined by the wavelength λ_c, is given in Fig. 5 for blackbody temperature ranging from 250 K to 1500 K.

The results given above apply only to a blackbody. The emissivity of actual bodies can be accounted for by multiplying $W_\lambda d\lambda$, for example, by $\epsilon(\lambda, T)$, the variation of the emissivity of a particular material with a particular surface preparation or condition with wavelength and temperature. If $\epsilon(\lambda, T) = \epsilon(T) = \text{constant} < 1$, the body is referred to as a "graybody." The relationship between the emissivity and spectral radiant emittance is shown in Fig. 6.

INTERACTION OF OPTICAL WAVES WITH MATTER

An optical wave may interact with matter by being reflected, refracted, absorbed, or transmitted. The interaction normally involves two or more of these effects.

Reflectance

Some of the optical radiation impinging upon a surface is usually reflected from the surface. Reflectance varies according to the properties of the surface and the wavelength, and in real circumstances may range from more than 98% (smoked MgO at visible wavelengths) to less than 1% (lampblack at visible wavelengths). Reflection from a surface may be either diffuse, specular, or both. A diffuse reflector has a surface that is rough when compared to the wavelength of the impinging radiation. Lambert's law specifies a perfectly diffuse surface as one having a constant radiance independent of the viewing angle according to

$$N = W/\pi$$

where,

N is radiance ($W/m^2/sr$),
W is the radiant excitance (W/m^2).

In practice, the reflectance of real reflectors varies with the cosine of the viewing angle. A specular reflector has a surface that is smooth when compared to the wavelength of the impinging radiation. A perfect specular reflector will reflect an oncoming beam without altering the divergence of the beam. A narrow beam of optical radiation impinging upon a specular reflector obeys two rules:

1. The angle of reflection is equal to the angle of incidence.
2. The incident ray and the reflected ray lie in the same plane as a normal line extending perpendicularly from the surface.

Fig. 7 illustrates both diffuse and specular reflection.

Absorptance

Some of the optical radiation impinging upon any substance is absorbed by the substance. Absorptance varies according to the properties of the substance and the wavelength, and in real circumstances may range from a low of less than 2 dB/km for certain ultrapure fused silica glasses to more than 98% for lampblack.

Transmittance

Some of the optical radiation impinging upon a substance is transmitted into the substance. The penetration depth may be slight, in which case the transmittance is zero. Certain ultrapure silica glasses may have a transmittance of greater than 75% at certain wavelengths over a distance of 1 km. The reflectance, absorptance, and transmittance of a substance must satisfy

$$\rho + \alpha + \tau = 1$$

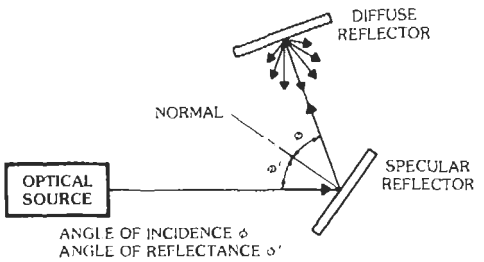

Fig. 7. Specular and diffuse (lambertian) reflectance. (*From Mims, F. M. III*, Optoelectronics. *Indianapolis: Howard W. Sams & Co., Inc., 1975, p. 19.*)

where,

ρ is reflectance,
α is absorptance,
τ is transmittance.

Refraction

A ray of optical radiation passing from one medium to another is bent at the interface of the two mediums if the angle of incidence is unequal to 90°. The index of refraction for a substance is the sine of the angle of incidence divided by the sine of the angle of refraction. Refractive index varies with wavelength and ranges from 1.002914 (air at 656 nm) to 2.7 (crystalline titanium oxide).

OPTICAL SOURCES

Important optoelectronic sources are tungsten lamps, fluorescent lamps, glow-discharge lamps, electroluminescent diodes, and lasers.

Tungsten Lamps*

Fig. 8 shows the spectral output of a tungsten lamp at a temperature of 2800 K. A typical tungsten lamp is an efficient optical source, but only about 5% of its radiant flux falls within the visible wavelengths. The addition of a halogen gas to a tungsten lamp can increase the life and efficiency of the lamp. At high operating temperature, the halogen (iodine or bromine) vaporizes and combines chemically with the evaporated tungsten on the quartz envelope and in the gas. The resulting tungsten-halogen gas migrates back to the filament, where the very high temperatures decompose it so that tungsten is redeposited on the filament and the halogen repeats the cycle. This permits uniform and constant output throughout the lamp life.

Fluorescent Lamps†

A typical fluorescent lamp is a sealed glass tube filled with argon gas and containing a small amount of mercury. When an electrical discharge is established in the tube, ultraviolet radiation is produced, which causes a phosphor coating on the inside wall of the tube to fluoresce with a bright white glow. Fluorescent lamps provide high efficiency.

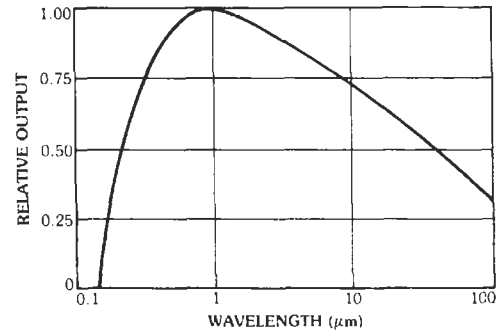

Fig. 8. Spectral output of a tungsten lamp at 2800 K.

Arc Lamps§

Arc lamps operate at considerably higher temperatures than other sources and, with the exception of certain lasers, are the most brilliant artificial sources. A representative arc lamp consists of a heavy-walled quartz envelope filled with gas (mercury, xenon, krypton, etc.) at a typical pressure of 20–40 atmospheres at operating temperature. The emission from a typical high-pressure arc lamp originates from the gaseous discharge, from the incandescence of the electrodes, and from the envelope.

Light-Emitting Diodes§

The operation of light-emitting diodes (LEDs) is dependent on the radiative recombination of electron-hole pairs at a forward-biased pn junction. The recombination of holes and electrons that occurs when current is injected into a pn junction results in the release of energy. This energy, which corresponds to the band gap, may be in the form of a photon (radiative recombination), a series of photons (lattice vibrations, nonradiative), or both. In some cases, the energy may be transferred to another electron. Light-emitting diodes are electroluminescent diodes in which radiative recombination is significant. Recombination radiation emitted by LEDs is peaked at or near the band-gap energy, and in practical devices ranges from 0.55 μm to 34 μm. The spectral emission width of a representative device may be 25–30 nm, and this provides sufficient monochromaticity for the production of discrete wavelength bands (including the visible colors green, yellow, orange, and red).

Direct band-gap semiconductors make more efficient LEDs than indirect band-gap semiconductors (those in which electron-hole recombination is accompanied by emission of a photon and phonons). Silicon and germa-

§ Saleh, B. E. A., and Teich, M. C. *Fundamentals of Photonics*. New York: John Wiley and Sons (Wiley Interscience), 1991.

nium, both indirect band-gap materials, produce far too little recombination radiation for practical use, but other direct and indirect band-gap materials or direct-indirect band-gap alloys, particularly GaAs, GaP, and solid solution alloys of GaAs and GaP, GaAs and AlAs, and InAs and GaP, can be tailored to produce relatively efficient radiative recombination.

Gallium arsenide (GaAs) LEDs and similar direct band-gap LEDs in other materials exhibit internal quantum efficiencies (ratio of emitted photons per injected electrons) very nearly unity. Due to such factors as internal absorption, contact shadows, and refractive-index-induced surface reflectance, the external quantum efficiency of practical LEDs is usually much lower (less than about 0.1). Both quantum efficiency and recombination radiation wavelength are affected by temperature, and the external quantum efficiency of specially fabricated LEDs may exceed 0.4 at 20 K. Wavelength is directly related to junction temperature and typically varies about 0.25 nm per degree Celsius. Therefore, changes in either the ambient temperature or junction heating will alter the emitted wavelength.

A wide range of economical long-lived plastic- and metal-packaged LEDs is commercially available. It is common practice to install the diode chip inside a miniature directional reflector and encapsulate the entire assembly in an index-matching epoxy to enhance the radiation extraction efficiency. This fabrication technique improves the external efficiency by a factor of 2 or more. Visible emitters suitable for use as visual indicators and other display roles include: GaP and GaP:N (green—550 nm); $GaAs_{0.25}P_{0.75}$:N (yellow—610 nm); $GaAs_{0.6}P_{0.4}$ (red—660 nm); $Al_{0.3}Ga_{0.7}As$ (red—675 nm); and GaP:Zn, O (red—690 nm). Several of these materials, particularly $GaAs_{0.6}P_{0.4}$, are in widespread use as display devices for digital clocks, watches, calculators, and electronic instruments. The most common infrared-emitting materials have been GaAs (905 nm) and GaAs:Si (940 nm). Until recently, these materials offered much higher efficiencies than visible emitters. They are useful in such applications as optical communications and ranging, position sensing, object detection, and electro-optical isolation. Ordinary GaAs LEDs are characterized by a reasonable power output (about 1.5 mW @ 100 mA I_F) and fast turn-on time (about 1 ns), whereas special GaAs diodes doped with Si are more efficient (about 10 mW @ 100 mA I_F) but slower (t_{on} of about 300 ns). Since the radiant emission from electroluminescent diodes is generally linear with respect to applied current below the saturation region, they can be easily and directly pulse or analog modulated by simply controlling the forward bias. Electroluminescent diodes of GaAs, GaAs:Si, GaAs-$Al_xGa_{1-x}As$, and related materials emitting in the near infrared (approximately 750–950 nm) have found wide use in fiber-optical communication applications, but because of lower fiber losses in the 1.3- to 1.6-μm wavelength range, InGaAsP and InGaAs LEDs are being rapidly developed for use at these longer wavelengths.

Electroluminescent diodes normally emit radiation in a relatively broad pattern and therefore cannot be coupled to optical waveguide fibers as efficiently as the laser sources described below. Nevertheless, reasonable coupling efficiency can be obtained by utilizing epoxy lenses or special structures such as the Burrus diode structure shown in Fig. 9. This structure has a typical emission area of 2×10^{-5} cm^2 and a radiance of 100 W/sr/cm^2 at a forward bias of 150 mA. The output wavelength can be peaked anywhere between 750 and 905 nm by adjusting the aluminum concentration in the $Al_xGa_{1-x}As$ alloy making up the diode. About 2 mW can be coupled into a suitable optical waveguide fiber when this structure is used. This and most other electroluminescent diodes exhibit operating lifetimes of more than 10^4 hours at the relatively high current densities required to obtain significant optical output.

High-Intensity Visible LEDs

A typical package commonly used for LEDs is shown in Fig. 10. This device is a Hewlett Packard Optoelectronic Division high-power LED fabricated from AlInGaP and packaged with an epoxy lens. This material has very high luminous efficiency, and AlInGaP devices are capable of producing high light output over a wide range of drive currents. The package shown incorporates an advanced optical design that produces an extremely high peak intensity in a viewing angle as narrow as three degrees. The emission of these AlInGaP LEDs occurs in a narrow spectral range and can be

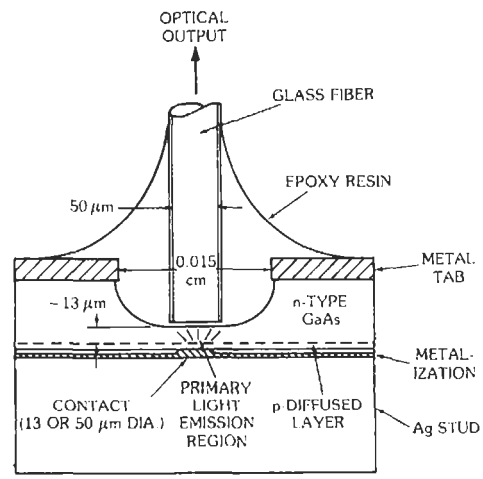

Fig. 9. GaAs electroluminescent diode specifically designed for direct coupling to an optical-fiber waveguide. (*After Burrus, C. A., and Dawson, R. W., "Small-Area High-Current-Density GaAs Electroluminescent Diodes and a Method of Operation for Improved Degradation Characteristics,"* Applied Physics Letters, *1 August 1970, pp. 97–99.*)

tuned to wavelengths in the range 590 nm to 620 nm by adjusting the AlInGaP alloy composition during growth as shown in Fig. 11. These lamps are suitable for applications in optical communications, as emitters in optical couplers, as LEDs in high ambient lighting conditions, as replacements for low-power laser diodes, and even as alternatives to incandescent lamps.

Superluminescent Diodes

Specially fabricated GaAs-$Al_xGa_{1-x}As$ double heterostructure and other electroluminescent diodes can be made to emit both spontaneous (quantum noise) and stimulated (amplified quantum noise) radiation. As in the case of a laser, stimulated emission implies a narrower spectral emission width and higher radiance than spontaneous emission. Fig. 12 shows the construction of a typical superluminescent diode (SLD). The structure of the device in the figure is virtually identical to that of a stripe-geometry injection laser with the major exception being an incomplete upper electrode. The incomplete electrode eliminates current injection near one of the mirrors, and this effectively isolates the mirror from the optical wave propagating along the plane of the junction and suppresses laser action. A similar effect can be had by angling one mirror of an injection laser a few degrees away from the normal or by coating one of the end mirrors of an injection laser with an antireflective film. The SLD is less efficient than most other electroluminescent sources, but its narrow spectral width and high radiance make it well suited for optical-waveguide links. Pulsed radiation of 50 mW has been coupled into an optical fiber from an SLD source.

Semiconductor Lasers*

Several fundamental modifications of the basic pn-junction electroluminescent diode exist, and chief among these is the semiconductor injection laser. In its simplest form, the injection laser is a direct band-gap LED having an exceptionally flat and uniform junction (the active region) bounded on facing sides by two parallel mirrors perpendicular to the plane of the junction, which provide a Fabry-Perot resonant cavity. The mirrors are usually produced by cleaving the semiconductor chip along parallel planes to produce perfectly parallel and flat surfaces. The remaining two sides of the chip perpendicular to the junction plane are intentionally roughened during the sawing process, which separates bars of material into individual chips. This surface roughening suppresses off-axis lasing

modes. The high index of refraction of the semiconductor provides sufficient reflectance at the semiconductor-air interface for the optical feedback necessary for laser action.

Below threshold, the injection laser behaves like a conventional LED, but as the current injection is increased, a threshold point occurs where the hole-electron population in the active region becomes inverted. Spontaneous recombination of holes and electrons then produces photons that stimulate in-phase recombination and photon emission by other holes and electrons, and lasing occurs as the optical gain in the active region overcomes absorption and other losses. The mirrors on either end of the active region provide the optical feedback necessary to sustain laser action, and a small fraction of the wave propagating between the mirrors emerges from each on each pass. One end facet on many commercial lasers is overcoated with a reflective gold film to cause all the radiation to emerge from only one end of the device and thus enhance collection efficiency.

The most common and best developed injection lasers utilize GaAs and AlGaAs (820–905 nm) and InGaAs and InP (1.3–1.55 μm) materials, though many other semiconductors have been used to produce wavelengths ranging from as short as 630 nm ($Al_xGa_{1-x}As$) to as long as 34 μm (PbSnSe). The high current density required to achieve lasing in broad-area homojunction injection lasers (8000 A/cm^2 or more) precludes continuous operation above temperatures greater than about 77 K. Room-temperature operation of a homojunction laser requires short current pulses (10–100 amperes for typical diodes) no more than 200 ns wide and with a duty cycle of 0.1%. Peak pulse power outputs at 300 K of up to 100 watts from single diodes and several kilowatts from diode arrays can be obtained from commercial devices. Injection lasers whose GaAs active region is sandwiched between two $Al_xGa_{1-x}As$ layers to produce a double heterojunction which confines both the recombination and the optical wave to a very thin layer have been fabricated with threshold current densities of less than 1000 A/cm^2. These devices are now commercially available and can be operated continuously at 300 K with appropriate heatsinking. Individual diodes may emit up to a few tens of milliwatts.

Injection-laser recombination radiation is characterized by a narrow spectral bandwidth, beam directionality, and moderate beam divergence. The beam directionality permits collection of up to 90% of the radiation by simple optics in most cases. The beam divergence, which may be 10–15° in the plane of the junction (half-power measurement) and 25–45° perpendicular to the plane of the junction, is a result of the very small emission region of the laser. Essentially a diffraction limited slit, the emission region and internal lasing modes both contribute to the various diffraction patterns and structures seen in the far-field pattern of the beam from most injection lasers.

Injection laser diodes at shorter wavelengths in the blue and green regions of the visible spectrum would be of considerable interest in many different applications. The wide band-gap II-VI compounds such as CdS, ZnSe, and ZnS have been studied extensively and have high luminescence efficiency when excited optically or with electron beams, but until 1991 injection lasers had not been obtained in wide band-gap II-VI semiconductors. In that year, however, heterostructure lasers utilizing the ZnSe-based single quantum well structure shown in Fig. 13 were reported.† The lattice matching of the different layers in heterostructure lasers is an important consideration for room-temperature semicon-

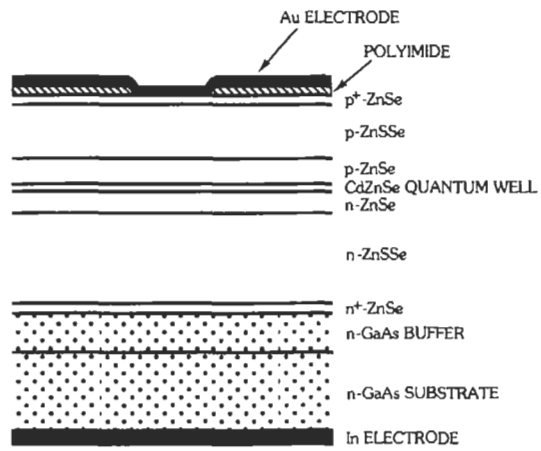

Fig. 13. Cross section of a blue-green laser diode.

ductor lasers, and the band-gap and lattice constant for important II-VI, III-V, and elemental semiconductors and semiconductor alloys are given in Fig. 14. The laser emission wavelength at 77 K was 490 nm, and this is the shortest wavelength ever generated by a semiconductor laser diode. More work will be required to optimize these devices and obtain room-temperature operation, but it is a very promising result.

OPTICAL DETECTORS

Detectors are designed to convert optical radiation into a current or voltage. Associated with both the "signal" radiation and the background radiation incident on the detector are fluctuations in the photon arrival rate, and these fluctuations induce fluctuations, or noise, referred to as signal noise and background noise, respectively, in the current or voltage produced by the detector. There are other sources of noise, such as thermal noise (Johnson or Nyquist noise), due to random thermal motion in any resistance in the circuit (including the detector itself), and generation-recombination noise in photoconductive detectors, due to random generation and recombination of free carriers, that can limit the sensitivity of an optical detector. There are several figures of merit used to evaluate the performance of detectors.

Terms and Figures of Merit

Noise equivalent power: (Abbreviated NEP.) The rms value of sinusoidally modulated radiant energy falling on the detector required to produce an rms-signal–to–rms-noise ratio of unity. The post-detection electrical bandwidth or noise bandwidth must be specified. Usually the NEP varies as the square root of the noise bandwidth, and the NEP is referenced to a 1-Hz bandwidth and expressed in units of $W/Hz^{1/2}$. The smaller the value of the NEP, the more sensitive is the detector. Noise equivalent power can be given for a particular wavelength (NEP_λ) or blackbody temperature NEP (T).

Detectivity: Because the NEP is smaller for higher sensitivity, it is common to define a figure of merit called the detectivity that is the reciprocal of the NEP reduced to a 1-Hz bandwidth, $D = 1/NEP$.

D^*: (Pronounced "dee star.") For some detector applications, especially those where the NEP and/or D is limited by background radiation, the NEP increases with the square root of the detector area, A, and to permit comparison of the performance of similar detectors with different areas, a normalized detectivity

$$D^* = A^{1/2}B^{1/2}/\text{NEP} \quad \text{cm Hz}^{1/2}\ \text{W}^{-1}$$

is defined, where B is the electrical noise bandwidth.

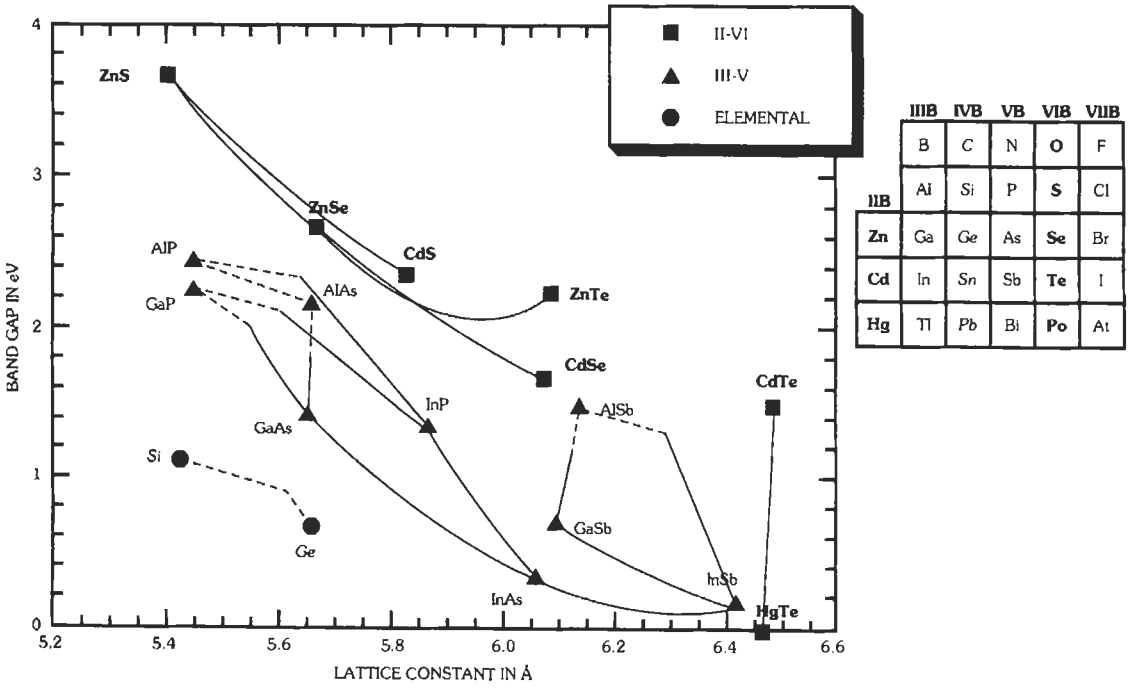

Fig. 14. Band gap and lattice constant of several II-VI, III-V, and elemental semiconductors and semiconductor alloys. (*Courtesy Photonics Research Laboratory, 3M.*)

Because of the way infrared detectors are characterized, it is common to specify the D^* as D^*_{bb} or D^*_λ to indicate measurement of the D^* with a blackbody or with a monochromatic source. Usually, D* is given as D^*_{bb} $(T, f, \Delta f)$ for a blackbody temperature T, chopping frequency f, and bandwidth Δf, and D^*_λ $(\lambda, f, \Delta f)$ for measurement or evaluation at wavelength λ, chopping frequency f, and bandwidth Δf.

D^{**}: (Pronounced "dee-double star.") The detectivity of a background-limited detector depends not only on the temperature of the background but, for cooled detectors, also on the field of view. As the field of view is decreased, the background radiation is reduced, and the detectivity is increased, so long as the detectivity is limited by the background radiation. The theoretical improvement factor in the detectivity as a function of the cone angle θ is shown in Fig. 15. To permit the comparison of different detectors of the same kind under different background conditions, a figure of merit is defined as

$$D^{**} = (\Omega/2\pi)^{1/2} D^*$$

where for circular geometry the solid angle Ω subtended by the background for a detector with an angle of view of θ is $\Omega = 2\pi \sin^2(\theta/2)$. Thus,

$$D^{**} = D^* \sin(\theta/2) \quad \text{cm Hz}^{1/2}\ \text{sr}^{1/2}\ \text{W}^{-1}$$

For $\theta/2 = \pi/2$ or $\theta = \pi$, and $\Omega = 2\pi$ sr,

$$D^{**} = D^*$$

This variation assumes that the thermal radiation from the cold shield which defines the field of view is negligible.

Responsivity: The responsivity is defined as the rms signal voltage or rms signal current per unit rms radiant power incident on the detector in units of volts/watt or amperes/watt. The voltage responsivity must be specified for a given load resistance or referenced to an open-circuit condition. The responsivity is also specified as R_{bb} or R_λ, denoting a blackbody responsivity or spectral responsivity at a particular wavelength λ as for D^*.

If R_λ is the responsivity in A/W for a detector at wavelength λ, then the signal current that results when an optical power $P_\lambda d\lambda$ at wavelength λ in interval $d\lambda$ is incident on the detector is

$$I_S = R_\lambda \cdot P_\lambda d\lambda \text{ amperes}$$

Quantum efficiency: The quantum efficiency η_λ of a photon or quantum detector is defined as

$$\eta_\lambda = \frac{\text{number of photoelectrons collected per second}}{\text{number of incident photons per second at wavelength } \lambda}$$

The number of photoelectrons collected per second is given by

$$I_S/q = R_\lambda P_\lambda d\lambda/q = q\eta_\lambda P_\lambda d\lambda/h\nu = \eta_\lambda P_\lambda d\lambda/(\eta c/\lambda)$$

where q is the charge of an electron and $h\nu$ and hc/λ are the photon energy at wavelength λ. Therefore, the quantum efficiency is given by

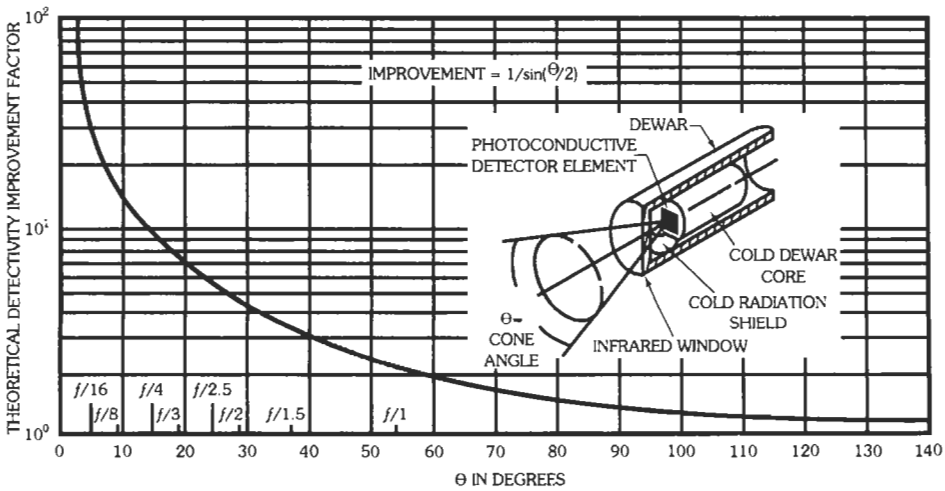

Fig. 15. Dependence of background-limited detectivity improvement on cooled-shield-limited field of view determined by cone angle θ or f number.

$$\eta_\lambda = R_\lambda hc/\lambda q$$

and $hc/q = 1.24 \times 10^{-6}$ W·mA^{-1}, so

$$\eta_\lambda = 1.24\, R_\lambda/\lambda \quad \text{for } \lambda \text{ in } \mu\text{m}$$

This relation permits a direct calculation of the quantum efficiency at wavelength λ from the measurement of the responsivity in A/W at the same wavelength. The term quantum efficiency usually refers to the interaction of the incident radiation with the detector, not including any gain mechanism in the device or in the electronic equipment used in the measurement of the signal current or voltage. Occasionally, however, external quantum efficiencies which include internal gain as in avalanche photodiodes are quoted, and in this case η can be significantly greater than unity.

Spectral response: The spectral responsivity variation for ideal photon detectors and thermal detectors is shown in Fig. 16. For photon detectors, the responsivity $R(\lambda)$, defined in terms of incident power, increases linearly with increasing wavelength up to the long-wavelength cutoff or the minimum energy for carrier excitation and then decreases abruptly to zero, whereas the responsivity for an ideal thermal detector is independent of wavelength. For photon detectors, a related figure of merit is the quantum efficiency η, the ratio of the number of electrons collected to the incident number of photons.

Response time: Another important measure of the performance of optical detectors is the response time. This is often specified in terms of a simple time constant, a rise time, or a cutoff modulation frequency.

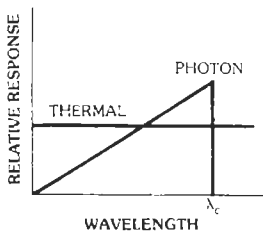
Characterization of Detectors

The characterization of detectors is important because the results of such measurements make it possible to select the best possible detector for a particular application. The determination of NEP, D, D^*, or D^{**} described above each requires measurements of the responsivity, or the rms signal for a given incident power, and the noise of the detector being characterized.

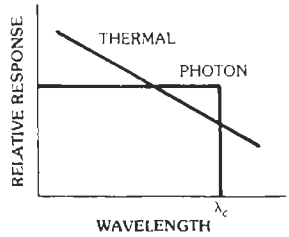
Responsivity—The power responsivity of a photon detector can be determined with the use of a blackbody source by the following procedure:

1. The relative spectral power responsivity is measured at all wavelengths to which the detector responds by using a monochromator source and thermal detector that is assumed to have a flat or constant spectral power responsivity.
2. The absolute spectral power responsivity is then determined by either: (A) measuring the absolute power responsivity at one or a few wavelengths by using a laser or calibrated source of known power output, or (B) measuring the blackbody responsivity of the detector and, from this result and the relative spectral responsivity, determining the responsivity at the peak of the relative spectral response curve by means of the technique described below.

Fig. 17 shows a schematic diagram of an experimental arrangement for the measurement of the relative spectral power responsivity. The monochromator provides a nearly monochromatic source of radiation that is modulated by the chopper at some suitable frequency (in the range from about 10 Hz to about 1000 Hz) depending on the type of detector being characterized. This chopped radiation is divided by a 50% beam splitter that is flat over the wavelength range of interest so that equal intensities of radiation fall on both the detector being characterized and a thermocouple or other reference detector that is assumed to be spectrally flat. Alternatively, the radiation can be switched back and forth from the detector being characterized and the reference detector at a low frequency (about 10 Hz) compatible with the thermal detector by means of mirrored chopper blades. The signal from the thermal detector is then detected synchronously with the mirrored chopper. The output signals from the detector being measured and the thermocouple detector are then ratioed by the ratiometer to give a reading proportional to the power responsivity of the test detector. By recording this signal as the wavelength of the output radiation of the monochromator is scanned over the desired range, the relative spectral response of the test detector, $r(\lambda)$, can be obtained. Automated computer



(A) Constant flux per unit wavelength interval.



(B) Constant photons per unit wavelength interval.

Fig. 16. Idealized spectral response curves for photon and thermal detectors. (*From Grum, F., and Becherer, R. J.* Optical Radiation Measurements, *Vol. 1,* Radiometry. *New York: Academic Press, Inc., 1979.*)

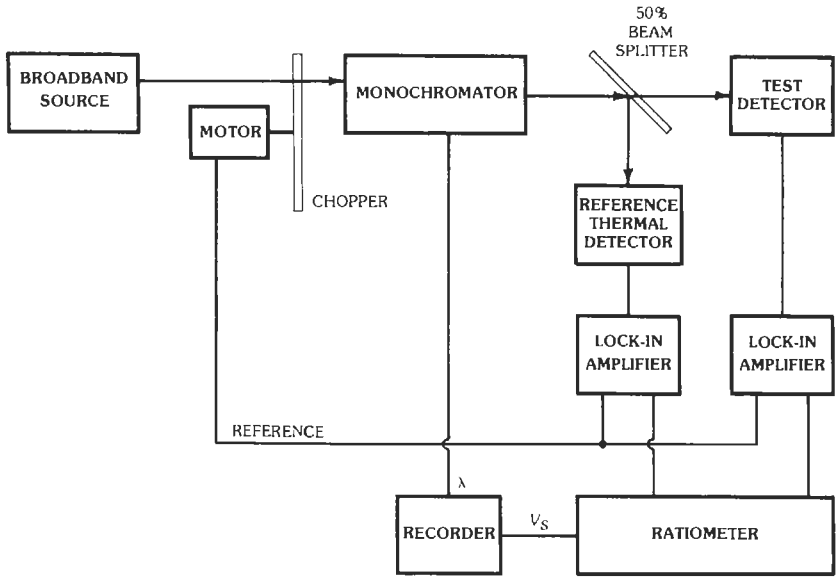


Fig. 17. Measurement of relative spectral power responsivity.

acquisition of data and calculated ratios can now often be used more easily than the analog ratiometer.

The absolute spectral responsivity of near-infrared detectors is usually determined by measuring the absolute responsivity at one or two wavelengths by using lasers with emission in the spectral range of interest and a calibrated output power. From these values of responsivity at specified wavelength, the relative spectral power responsivity curves can be made absolute.

For detectors in the wavelength range where calibrated lasers or reference detectors are not available, the spectral power responsivity is usually determined by using blackbody radiation. Fig. 18 shows an experimental arrangement for this process. The blackbody responsivity is

$$R_{bb}(f, T) = \frac{R_p \int_0^\infty r(\lambda)\, P_{\text{rms}}(\lambda, T)d\lambda}{P_{\text{rms}}(T)}$$

where,

R_p is the peak responsivity of the detector,
$r(\lambda)$ is the relative spectral power responsivity of the detector ($0 \leq r(\lambda) \leq 1$),
$P_{\text{rms}}(\lambda, T)$ is the rms value of the incident radiation at modulation frequency f and wavelength λ,
$P_{\text{rms}}(T)$ is the total rms blackbody radiation falling on the detector.

For a square-wave-modulated blackbody source of area A_1 at a distance d from the detector of area A_2, as in the diagram of Fig. 18,

$$R_{bb}(f, T) = \frac{[(0.45\, A_1A_2)R_P/\pi d^2] \int_0^\infty r(\lambda)W(\lambda, T)d\lambda}{[(0.45\, A_1A_2)/\pi d^2] \int_0^\infty W(\lambda, T)d\lambda}$$

$$= \frac{R_p \int_0^\infty r(\lambda)W(\lambda, T)d\lambda}{\sigma T^4}$$

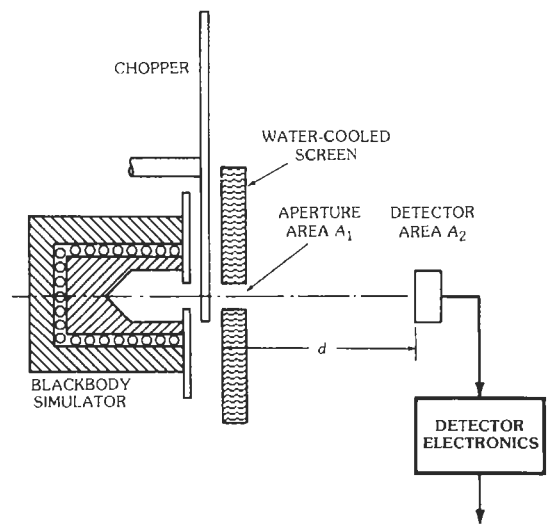

Fig. 18. Determination of spectral power responsivity with blackbody radiation.

But, the experimentally determined value of $R_{bb}(f, T)$ is

$$R_{bb}(f, T) = V_{rms}(f, T)/(0.45\, A_1 A_2/\pi d^2)\, \sigma T^4$$

where $V_{rms}(f, T)$ is the experimentally measured value of the rms voltage, for example, generated by the detector. The peak value of responsivity R_p is given in terms of the experimental blackbody responsivity $R_{bb}(f, T)$ by

$$R_p = \sigma T^4\, R_{bb}(f, T)/\int_0^\infty r(\lambda) W(\lambda, T) d\lambda$$

$$= R_{bb}(f, T)/\gamma(T)$$

where $\gamma(T)$ is called the effectiveness factor. For an ideal thermal detector, $r(\lambda) = 1$, $\gamma = 1$, and $R_p = R_{bb}(f, T)$. The units of R_p are amperes/watt or volts/watt.

Noise Measurements—In order to determine the NEP and related figures of merit for the detectors described above, it is necessary to measure the rms noise voltage or current characteristics of the detector being evaluated. The rms noise can be measured with rms-responding meters, lock-in amplifiers, spectrum analyzers with special noise-measuring capability, or tuned voltmeters with average-responding meters. When the latter are used, it should be noted that the meter reading for the rms value of a sinusoid must be multiplied by 1.128 in order to obtain the rms value of Gaussian noise. The NEP can then be calculated from the responsivity and the rms noise as $NEP_\lambda = V_n/R_\lambda$, where V_n is the rms noise voltage, for example. The D, D^*, etc., can be calculated similarly.

Ultimate Sensitivity of Detectors*

There are many noise sources that can limit the detection capability of any detection system. These noise sources can generally be categorized as noise in the detector, noise in the amplifier, and fluctuations in the radiating background and the signal itself. The noise in the detector comes from fluctuations in the concentration or motion of the current carriers. The amplifier noise consists of thermal noise as well as excess noise due to the same type of fluctuations as in the detector. The background noise or photon noise is due to the quasi-random absorption of photons from the surroundings of the detector; for thermal detectors it also comes from the quasi-random emission of photons from the detector. It is this background noise that limits the ultimate performance of infrared detectors.

Johnson, Nyquist, or Thermal Noise—This is the random fluctuation in the current or voltage at the electrical contacts of a resistor due to the random thermal motion of electrons in the resistor. The rms values of these fluctuations are given by

$$\overline{v_J^2}^{1/2} = (4kTBR_L)^{1/2}$$

$$= 1.287 \times 10^{-10}\, R_L^{1/2}\, (T/300)^{1/2}\, B \text{ volts}$$

and

$$\overline{i_J^2}^{1/2} = (4kTB/R_L)^{1/2}$$

$$= 1.287 \times 10^{-10}\, R_L^{-1/2}\, (T/300)^{1/2}\, B \text{ amperes}$$

where,

R_L is the resistance in ohms,
T is the absolute temperature,
B is the electrical bandwidth.

This noise source is independent of current for a given temperature.

For photovoltaic detectors, the diode terminal current for small voltages is linear with voltage and can be written as

$$I_t = -I_p + (1/R_o)\, V$$

where,

I_t is the diode terminal current,
I_p is the photogenerated current,
V is the open-circuit photovoltage,
$R_o \equiv (\partial V/\partial I)\,|_{V=0}$.

When the diode is operated as an open-circuited photovoltaic detector, $I_t = O$. Then,

$$V = I_p R_o = q\, \eta\, (P_\lambda/E_\lambda)\, R_o$$

where P_λ is the incident optical power at wavelength λ, E_λ is the photon energy at wavelength λ, and the rest of the parameters have meanings defined previously. For this case, the voltage responsivity $R_{V,\lambda}$ at the wavelength λ is given by

$$R_{V,\lambda} = V/P_\lambda = \eta q R_o/E_\lambda$$

The noise voltage for the unbiased open-circuit photovoltaic detector is just the Johnson noise of the incremental diode resistance,

$$\bar{v}^2 = 4kTR_o\Delta f$$

The NEP is given by the power P_λ required to give a signal/noise ratio of unity, and if the photovoltaic detector noise is only due to the Johnson noise of R_o,

* Vincent, John David. *Fundamentals of Infrared Detector Operation & Testing*. New York: John Wiley and Sons, 1990.

$$\text{NEP} = 2E_\lambda\,(kT)^{1/2}/nqR_o^{1/2}$$

and the detectivity D^*_λ is†

$$D^*_\lambda = A^{1/2}/\text{NEP} = \eta q(R_oA)^{1/2}/2E_\lambda(kT)^{1/2}$$

The variation of D^*_λ with R_o for a Johnson-noise limited open-circuit photon detector, i.e., under sufficiently low background conditions, is given in Fig. 19.

Shot Noise—Shot noise results whenever the fluctuation arises because of a series of independent events occurring at random, such as the emission of electrons by a temperature-limited thermionic cathode, or a photocathode, or the crossing of a junction by electrical carriers (electrons or holes) in a pn junction or transistor. Shot noise also results when transitions occur between two energy levels as for generation and recombination of carriers in a semiconductor or when photons are emitted by a laser. The root-mean-square current fluctuations for the process can be expressed in terms of the average dc current as

$$\overline{i_S^2}^{1/2} = (2qI_{dc}B)^{1/2}$$

$$= 5.657 \times 10^{-10}(I_{dc})^{1/2}B^{1/2} \text{ amperes}$$

where,

I_{dc} is the average dc current in amperes,
B is the electrical bandwidth in hertz.

Generation-Recombination Noise—Although the noise that results from fluctuations in the instantaneous values of the free carrier concentration in semiconductors can be described as shot noise for some cases, for photoconductive detectors it is more meaningful to describe this noise source in terms of the generation, recombination, and trapping processes that cause the fluctuations in the free carrier concentrations. The G-R noise for a homogeneous n-type extrinsic semiconductor is

$$\overline{i_{GR}^2}^{1/2} = \{(4I_{dc}^2/N_0)[\tau_0/(1 + \omega^2\tau_0^2)]B\}^{1/2}$$

amperes

where,

I_{dc} is the average dc current,
N_0 is the total number of free carriers in the semiconductor,
τ_0 is the carrier lifetime.

1/f Noise—There are several types of noise that increase as the frequency decreases. Because of the different, and not necessarily well understood, sources of this noise, there is no simple expression that describes $1/f$ noise accurately. However, empirical expressions like

$$\overline{i_{1/f}^2}^{1/2} = (KI_{dc}^{\alpha}B/f^{\beta})^{1/2}$$

† Melngailis, I., and Harmon, T. C. "Single-Crystal Lead-Tin Chalcogenides," in *Semiconductors and Semimetals*, Vol. 5. Academic Press, 1970, pp. 111–163.

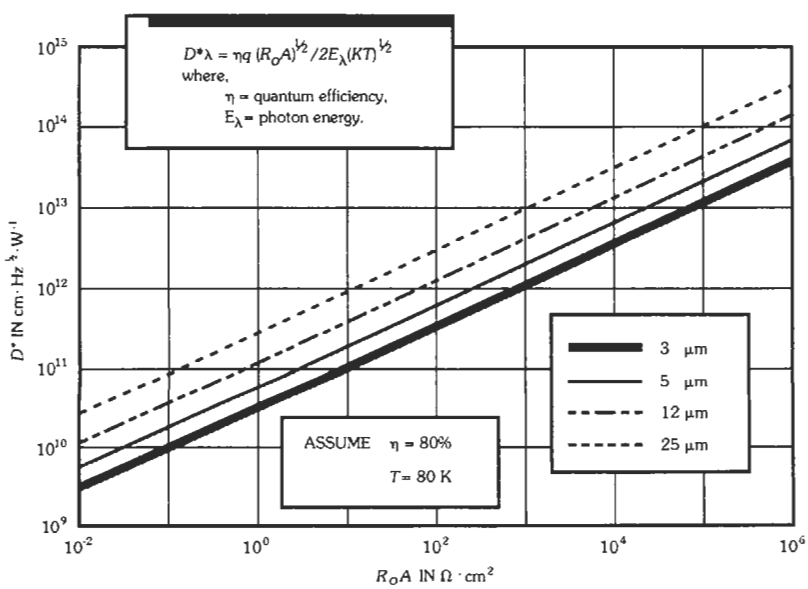

Fig. 19. D^*_λ for Johnson-noise-limited photon detectors where R_o is the differential resistance at zero bias.

where K is a proportionality factor, $\alpha \approx 2$, and $\beta \approx 1$ are frequently used. In this expression, I_{dc} is the average current, and B is the bandwidth.

Photon Noise—Also called radiation noise, photon noise results from fluctuations in the rate of absorption (and for thermal detectors, emission) of photons by the detector. For photons from a laser or nonblackbody source, this noise can be calculated accurately by the shot noise of the average current induced by the photon flux. For blackbody radiation, the noise is greater than that estimated by the shot-noise formula because blackbody photons, described by Bose-Einstein statistics, do not arrive randomly in time but, instead, are clustered together. Thus, the mean square fluctuation in the arrival rate of photons, which for independent events would simply be the average photon arrival rate, $\bar{n}$, is increased by the factor $e^{h\nu/kT}/(e^{h\nu/kT} - 1)$. For practical applications, this distinction is generally not important.

Temperature Noise—Temperature noise is the fluctuation in temperature of a thermal detector that is in contact with its surroundings by both conduction and radiation. If the detector is only in contact with its surroundings through radiation, the temperature noise reduces to blackbody photon noise due to both absorption and emission of photons.

Amplifier Noise—There is always the thermal Johnson noise of some equivalent load resistance associated with a detector circuit, but in addition, with real amplifiers there is some additional added noise called amplifier noise. This noise, as well as the Johnson noise of the load resistor, is usually referred to the input of the amplifier. The rms noise voltage referred to the amplifier input is described by the equation

$$\overline{v_a^2}^{1/2} = [4k(T_L + T_A)R_L B]^{1/2}$$

where,

T_L is the noise temperature of the equivalent load resistance, R_L,
T_A is the amplifier noise temperature,
B is the electrical bandwidth.

The noise figure, F, is another useful measure of amplifier performance and is the ratio of the signal-to-noise ratio at the amplifier input to the signal-to-noise ratio at the output for a room-temperature load resistor ($T_L = 290\ K$). In terms of T_A and T_L,

$$F = 1 + T_A/T_L$$

The noise figure is usually expressed as a logarithmic function,

$$\text{NF} = 10 \log_{10} F \quad \text{decibels}$$

In this notation,

$$\overline{v_a^2} = 4kFT_L R_L B$$

It should be noted that F for a given amplifier usually depends on both R_L and the frequency, f.

Ultimate Detector Sensitivity—The ultimate sensitivity of a detector is limited by the shot noise of the signal itself. For photon detectors this is given by

$$\text{NEP}_\lambda = 2hcB/\lambda\eta(\lambda)$$

where $\eta(\lambda)$ is the detector quantum efficiency at wavelength λ. In practice, this limit is seldom if ever achieved, because of the various noise sources described above. However, because of the large amount of background radiation present in much of the infrared spectral region, it is common for the sensitivity of good infrared detectors to be limited by the photon noise due to background radiation. The mean square noise power spectral density of the photon flux from blackbody radiation at temperature T incident on a thermal detector of area A is given by

$$S_p(f) = \int_0^\infty \frac{2A2\pi h^2 \nu^4}{c^2} \frac{e^{h\nu/kT} d\nu}{(e^{h\nu/kT} - 1)^2} = 8AkT\sigma T^4$$

and for a thermal detector, in equilibrium with and at the same temperature as the background (and with unity emissivity), this fluctuation must be doubled because of the fluctuations due to the photons emitted by the detector; so

$$S_p(T) = 16\, AkT\sigma T^4$$

Thus, the mean square noise power in a bandwidth B is

$$\overline{P_b^2} = 16AkT\sigma T^4 B$$

and the D^* for such a thermal detector is

$$D^* = A^{1/2}B^{1/2}/\overline{P_b^2}^{1/2} = 1/4(kT\sigma T^4)^{1/2}$$

$$= 5.5171 \times 10^{-11}\ (T/300^{5/2}\ \text{cm Hz}^{-1/2}\ \text{W}^{-1}$$

The D^* for an ideal photon detector with a long-wavelength cutoff of $\lambda_0 = c/\nu_0$ for a signal at ν_s within the spectral range of the detector is given by

$$D_\lambda{}^* = \frac{c\eta(\nu_s)}{2h\nu_s \pi^{1/2} \left[\int_{\nu_0}^\infty \frac{\eta(\nu)\nu^2 \exp(h\nu/kT)\, d\nu}{[\exp(h\nu/kT) - 1]^2}\right]^{1/2}}$$

and this can be readily evaluated for the peak detectivity of an ideal detector for ν_s and ν_0, assuming $\eta(n)$ is independent of wavelength, by using a computer or a programmable calculator and the series solution

$$D_{\lambda_0}{}^* = \frac{c[\eta(\nu_0)]^{1/2}}{2\pi^{1/2}h^{1/2}\nu_0{}^2(kT)^{1/2}} U$$

where U is

$$\left\{\sum_{m=1}^{\infty} \exp(-mhv_0/kT)\,[1 + 2kT/mhv_0 + 2(kT/mhv_0)^2]\right\}^{-1/2}$$

The background-limited $D^*_{\lambda 0}$ at the peak wavelength, λ_0, is shown in Fig. 20 for several values of the background temperature. This result applies to photoemission and photovoltaic detectors where only the background fluctuations contribute to the noise. For $T = 300\ K$, the minimum $D^*_{\lambda 0}$ occurs at about 14 μm. The rapid increase in $D^*_{\lambda 0}$ for detectors with short cutoff wavelengths occurs because these detectors respond to less of the photon noise of this background. The small increase in $D^*_{\lambda 0}$ for longer wavelength occurs because the increase in the photon noise received from the background is more than compensated by the increase in the number of photons per watt of signal. For photoconductive photon detectors, there is the additional fluctuation due to fluctuations in the recombination of carriers in addition to the excitation of free carriers, so for photoconductive detectors the photon noise is larger by $\sqrt{2}$ and the background-limited D^* is smaller by $\sqrt{2}$.

The various types of thermal and photon or quantum detectors are described briefly below.

Thermal Detectors

Thermal detectors respond to optical-radiation–induced temperature variations and are therefore well-suited for broadband detection throughout the optical spectrum. Thermal detectors include the bolometer, thermocouple, thermopile, thermopneumatic cell, and pyroelectric detector.

Bolometer—The bolometer changes its resistance in response to thermal energy resultant from impinging radiant energy. The most common bolometric detector is the thermistor.

Thermocouple—A thermocouple is a junction of two dissimilar metals that, upon absorbing thermal energy, produces an emf.

Thermopile—The thermopile is an array of thermocouples. Miniature thermopiles made with thick film deposition techniques are commonly used in infrared detection applications.

Thermopneumatic Cell—The thermopneumatic cell senses the presence of thermal energy by means of a sealed cell that expands or contracts in response to variations in applied radiant energy. The magnitude of the expansion can be detected by means of interferometric techniques.

Pyroelectric Detector—The pyroelectric detector is a temperature-sensitive current source. In a typical detector, a thin wafer of a ferroelectric crystal such as triglycine sulfate or lithium tantalate forms a capacitor whose capacitance is altered by thermal energy. Because of the ferroelectric effect, this detector will not detect constant unmodulated incident radiation.

Quantum Detectors

Quantum detectors respond to variations in the number of incident photons. Quantum detectors have a

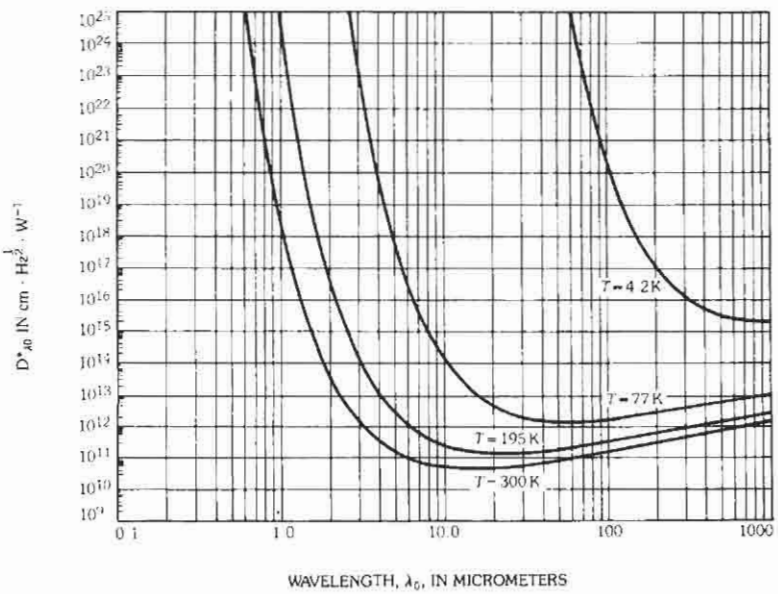

Fig. 20. Background-limited $D^*_{\lambda 0}$ at peak wavelength, λ_0, for ideal photon detection with threshold wavelength λ_0 and different background temperatures T.

more limited spectral sensitivity range than thermal detectors but are generally characterized by relatively fast response time and high sensitivity. Quantum detectors include photoemissive devices, photovoltaic cells, photoconductive cells, and photoelectromagnetic cells.

Photoemissive Devices—If photons with sufficient energy impinge on a photocathode, electrons are emitted. Such electrons are known as photoelectrons. For an input flux of fixed relative spectral distribution, the number of photoelectrons is proportional to the intensity of the input flux, whereas the energy of the photoelectrons is independent of this intensity. The maximum energy of emitted electrons expressed in volts, V, depends on the wavelength, λ, and the temperature. At absolute zero, according to Einstein's law

$$e(V + \phi) = hc/\lambda$$

where,

e = electron charge = 1.6×10^{-19} coulomb,
ϕ = work function in volts,
h = Planck's constant = 6.6×10^{-34} joule-second,
c = velocity of light in meters/second,
λ = wavelength in meters.

If a threshold wavelength, λ_0, is defined by

$$e\phi = hc/\lambda_0$$

then V is seen to be zero (except for thermal velocities) at the wavelength λ_0; for $\lambda > \lambda_0$, there is no photoelectric emission at absolute zero. At temperatures above absolute zero, there is always a finite probability of some photoemission at all wavelengths due to the thermalization of the electron distribution.

Photocathode Response to Monochromatic Radiation—The output current dI_λ in amperes, generated by a photocathode subjected to a monochromatic input flux dW_λ in watts, is given by

$$dI_\lambda = s_\lambda dW_\lambda$$

where s_λ is the monochromatic radiant responsivity of the photocathode in amperes/watt defined by this equation. Similarly, the number of electrons/second, dn_λ, generated by an input flux of dN_λ photons/second is given by

$$dn_\lambda = \eta_\lambda dN_\lambda$$

where η_λ is the monochromatic quantum efficiency of the photocathode in electrons/photon defined by this equation.

The monochromatic radiant responsivity, s_λ, in A/W, is related to the monochromatic quantum efficiency, η_λ, at wavelength λ, in μm, by

$$s_\lambda = e\lambda\eta_\lambda/hc = 0.81\lambda/\eta_\lambda$$

Typical values of the monochromatic radiant responsivity, s_λ, and corresponding monochromatic quantum efficiency, η_λ, as a function of wavelength, λ, are shown in Fig. 21 for some commonly used photocathodes, designated by their JEDEC registered "S numbers." Table 3 gives typical peak responsivities for the various surfaces, and Table 4 indicates the general composition and other properties of the common surfaces.

Vacuum Photodiodes—The combination of a photocathode and an anode electrode for collecting the emitted photocurrent in an evacuated envelope is called a vacuum photodiode. A positive anode potential sufficient to assure collection of all emitted photoelectrons (that is, to "saturate" the diode phototube) is normally required, the tube then acting as a constant-current generator (Fig. 22). The power-supply potential, V_B, must assure sufficient anode potential in the presence of a voltage drop in the load resistor, R_L.

Under these conditions the total anode output current, I_a, neglecting all noise fluctuations, is given by the equation

$$I_a = I_s + I_b + I_d + I_L$$

where,

I_s = emitted photocathode signal current,
I_b = emitted photocathode photocurrent due to stray background flux,
I_d = photocathode thermionic dark current,
I_L = residual dark current (leakage, etc.).

The instantaneous value of signal current I_s will follow the instantaneous signal flux input magnitude from direct current up to an upper frequency limit (commonly 0.2–2 GHz) set by the transit-time spread of the electrons crossing the gap between cathode and anode, and including induced displacement currents during transit.

For steady-state or slowly varying input flux rates, the total noise current output, i_n, from the diode and load resistor is given by

$$\overline{i_n^2} = 2qB(I_s + I_b + I_d) + (4kTB/R_L) + i_L^2$$

where,

q = the electron charge = 1.6×10^{-19} coulomb,
B = noise-current measurement bandwidth,
k = Boltzmann's constant = 1.38×10^{-23} joule per K,
T = absolute temperature of the load resistor (K),
R_L = load resistance (ohms),
i_L = residual dark noise current (from leakage, stray pickup, etc.).

To increase the absolute level of the noise voltage generated by noise current i_n so that tube noise predominates over the noise voltage of the subsequent amplifiers, and to suppress load-resistor noise relative to tube

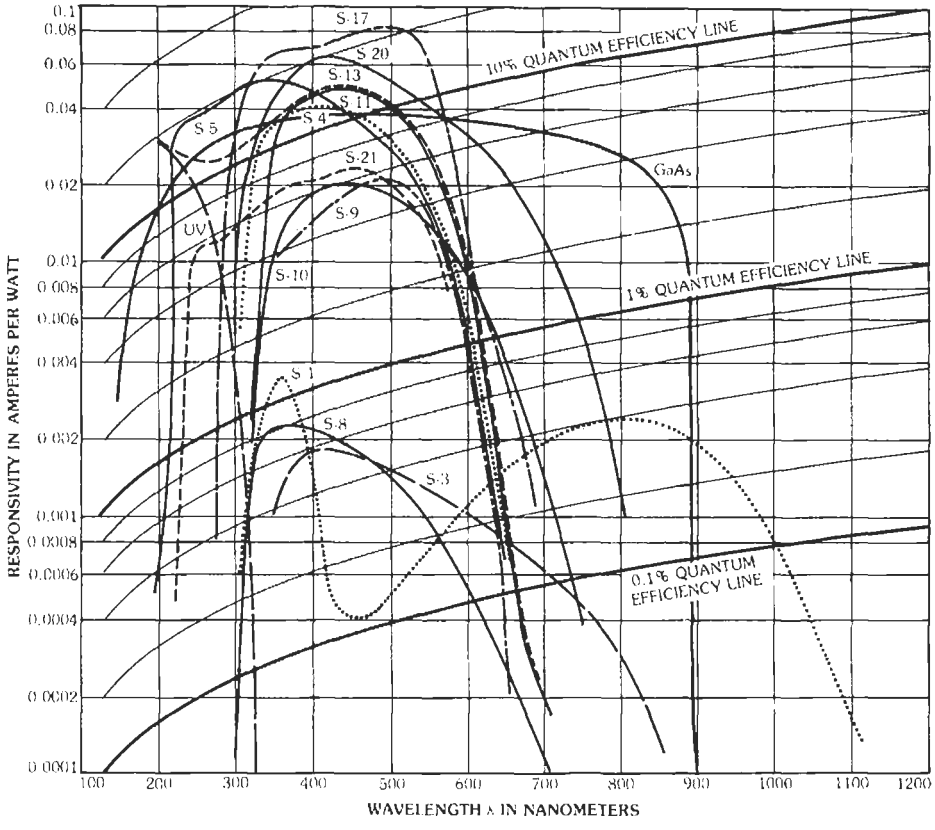

Fig. 21. Typical absolute spectral response characteristics of various photocathodes.

noise, large values of the load resistor (of the order of 10^7–10^9 ohms) are commonly used when response time is not a limitation.

TABLE 3. TYPICAL PEAK PHOTOCATHODE RESPONSIVITIES

S Number	Radiant Responsivity $s_{\lambda max}$ ($A \cdot W^{-1}$)	Radiant Responsivity λ_{max} (nanometers)	Quantum Efficiency $\eta_{\lambda max}$ (electron photon^{-1})	Quantum Efficiency λ_{max} (nanometers)

* Neglecting short wavelength peak

For a plane-parallel vacuum photodiode, the space-charge-limited output current, $I_{a(max)}$, in amperes for a given applied cathode-to-anode potential difference, V, in volts is given by

$$I_{a(max)} = 2.33 \times 10^{-6} AV^{3/2}/d^2$$

where,

A = uniformly emitting emission area (meters^2),
d = anode-cathode spacing (meters).

In practice, linear output currents up to approximately half of this maximum limit can be obtained.

For a plane-parallel vacuum phototube, the output anode current, I_A, as a function of time, t, for an ultrashort exciting light pulse is given by

$$I_A = (2QRC/T^2)[(t/RC) + \exp(-t/RC) - 1] \quad \text{for } 0 < t < T$$

$$I_A = (2QRC/T^2)[(T/RC) + \exp(-T/RC) - 1] \exp[-(t - T)/RC] \quad \text{for } t \geq T$$

and

Notes:

1. The S number is the designation of the spectral response characteristic of the device and includes the transmission of the device window material.
2. Principal components of the photocathode are listed without regard to order of processing or relative proportions.
3. When the supporting substrate is the entrance window, an intermediate semitransparent electrically conductive layer may be used.
4. Corresponding to the specific absolute response curves shown in Fig. 21 using a 2854 K color-temperature tungsten-lamp test source.
5. Specific dark current excludes direct-current leakage.
6. Lime glass and Kovar sealing borosilicate glass are commonly used for visible-light-transmitting glass.
7. The opaque material used as the supporting substrate for photocathodes in which the input radiation is incident on the same side as the emitted photoelectrons is usually metallic in nature.
8. An S number designation has not yet been assigned to this experimental "solar blind" photoemissive surface.

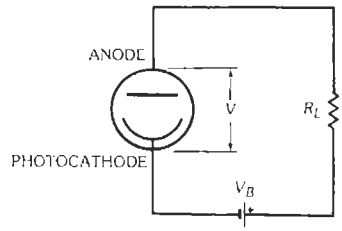

Fig. 22. Photodiode circuit.

$$T = d(2m/qV)^{1/2}$$

$$= (3.37 \times 10^{-6})d/(V)^{1/2} \text{ seconds}$$

where,

T = transit time of the charge from cathode to anode (seconds),
V = cathode-to-anode potential (volts),
C = total capacitance including external circuit capacitance,
R = load resistance,
Q = total charge,
m = electron mass.

Photomultipliers—The combination of a photocathode and a secondary-emission electron multiplier is called a photomultiplier. Emitted photoelectrons from the photocathode are directed under the influence of a suitable electrode, often called the "focus electrode," to the surface of a secondary-emitting electrode, the "first dynode." Subsequently emitted secondary electrons, increased in number by the effective secondary-emission ratio, σ_1, are then directed to the secondary emitting surface of a subsequent dynode by an appropriate electric field for further multiplication. Continuing this process for n successive dynodes and collecting the multiplier charge at an output electrode called the "anode" or "collector" leads to a charge or current amplification, G, given by

$$G = \sigma^n, \text{ for } \sigma_1 = \sigma_2 = \sigma_3 \ldots = \sigma$$

Gains as high as 10^5–10^9 are commonly achieved in 10-stage to 16-stage multipliers.

Disregarding all noise fluctuations of the output current, and assuming operation within the usual linear-response region, a photomultiplier acts as a constant-current source generating an output current, I_o, given by

$$I_o = I_s + I_b + I_d = G\epsilon I_{ks} + G\epsilon I_{kb} + G\epsilon I_{kd} + I_{ad}$$

where,

I_s = anode signal current due to an incident signal flux to be detected,
I_b = anode current due to any background flux simultaneously present on the photocathode,
I_d = anode dark current,
G = current gain of the electron multiplier,
ϵ = collection efficiency (ratio of current entering the electron multiplier to emitted photocathode current),
I_{ks} = photocathode signal current due to an incident signal flux to be detected,
I_{kb} = photocathode current generated by any background flux simultaneously present on the photocathode,
I_{kd} = photocathode dark current,
I_{ad} = component of anode dark current I_d not originating from the photocathode.

The output signal current, I_s, follows the instantaneous value of the input signal flux from direct current up to an upper frequency limit (typically 20–200 megahertz) established by the response time or "transit-time spread" (typically 1–10 nanoseconds).

Noise fluctuations of the output current in photomultipliers can be divided into two classes: dark noise, occurring in the absence of input flux, and noise-in-signal, including "quantum" noise resulting from the inherent quantum nature of the input flux as well as uncontrolled fluctuations of that flux. The presence of an appreciable, in fact often predominant, noise-in-signal current component in photomultipliers depending on the instantaneous signal current magnitude requires caution in applying noise concepts to photomultipliers and may lead to erroneous conclusions regarding photomultiplier behavior, particularly for a modulated flux input.

For a steady-state unmodulated flux input, the total noise current, i_n, in the load resistance, R, is given by

$$i_n^2 = 2eGK\Delta f(I_s + I_b + G\epsilon I_{kd}) + i_r^2 + (4k\,T\Delta f/R)$$

where,

e = electron charge,
K = photomultiplier noise factor,
Δf = noise bandwidth of the noise-current measuring circuits (Hz),
i_r = residual photomultiplier anode dark noise current, excluding dark-current emission from the photocathode (amperes),
$(4k\,T\Delta f/R)^{1/2}$ = Johnson-Nyquist noise current in load resistance R (amperes),
k = Boltzmann's constant, 1.38×10^{-23} joule/K,
T = absolute temperature of the load resistance (kelvins).

For photomultipliers with a constant gain per stage, σ, in the first few stages of the electron multiplier, the noise factor, K, may be estimated from

$$K = \sigma/(\sigma - 1)$$

Photomultipliers as Scintillation and Single-Electron Counters—In combination with suitable

scintillating material, typically thallium-activated NaI crystals, photomultipliers are extensively used to detect the single flashes of light generated by the scintillating material on bombardment by a single triggering particle, typically X rays or a gamma ray from a nuclear disintegration process. If the scintillating material generates an average of N photons per disintegration incident on the effective photocathode of peak quantum efficiency, Y_{max}, the resultant average charge pulse, Q_A, appearing in the anode circuit (disregarding all photons or electrons producing no output charge) will be given by the equation

$$Q_A = NY_{max}\alpha Ge$$

where α is a spectral matching factor describing the relative match between the scintillator spectral output and cathode sensitivity.

Because of the random statistical fluctuations of cathode quantum efficiency Y_{max} and electron-multiplier gain G, as well as in the number of effective photons, N, generated by the scintillator, the anode charge, Q_A, will vary in magnitude from pulse to pulse, introducing ambiguity in the determination of the average magnitude of N, which in turn is used to determine the energy of the triggering input particle, for example the gamma ray. The ratio of the spread of the amplitude of individually observed values of charge Q_A at half maximum to the most probable value $Q_{A(max)}$ is called the "energy resolution" of the photomultiplier-plus-scintillator combination and is commonly 7–10% minimum (see Fig. 23).

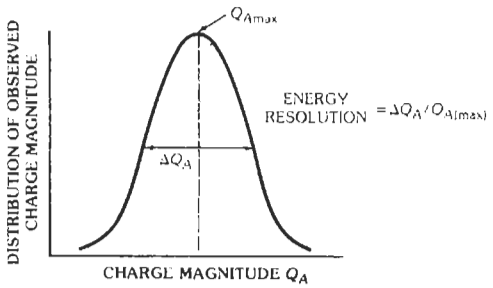

Fig. 23. Energy resolution of photomultiplier.

If the input flux has no time-coherent groups of photons, as it does in scintillation detection, photoelectrons are emitted singly at random emission times from the photocathode and also generate an average output charge, Q_A, given by

$$Q_A = Gq$$

where all photons or electrons generating no output pulse are disregarded in measuring G and computing Q_A. Assuming sufficiently large gain G and sufficiently low generation of dark pulses of similar charge amplitude, the individual anode pulses of charge amplitude Gq can be detected and counted individually, the photomultiplier then acting as a single-electron counter.

Photoconductivity—Photoconductivity is the increase in electrical conductivity of a material that takes place when the material is illuminated with infrared, visible, or ultraviolet light.

The absorption of light is a quantum process in which electrons are excited to higher energy levels. Ordinarily, the excited electrons are more mobile than unexcited

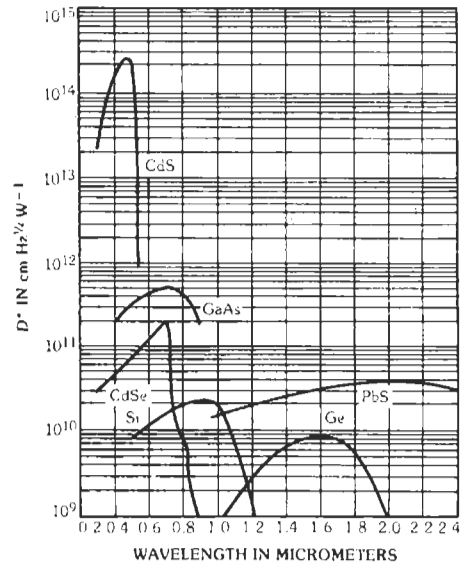

Fig. 24. Detectivity for some typical photoconductors at room temperature.

electrons. Photoconductivity is commonly analyzed in terms of the number and mobility of the excited electrons in an electron conduction band and of holes in a lower-energy valence band. To maintain a steady current, both types of current carriers must be generated in the volume of the material, or else charge carriers must enter the photoconductor at one of the electrodes. Many high-resistivity photoconductors make "ohmic" contacts with their electrodes. These serve as practically unlimited reservoirs of mobile electrons, free to enter the photoconductor volume. Even in these photoconductors, the steady dark current is usually limited to a low value by a build-up of a space-charge-potential barrier in the photoconductor.

At the same time that mobile photoelectrons are excited (thermally or optically) in the interelectrode volume, positive charges must also be generated; these

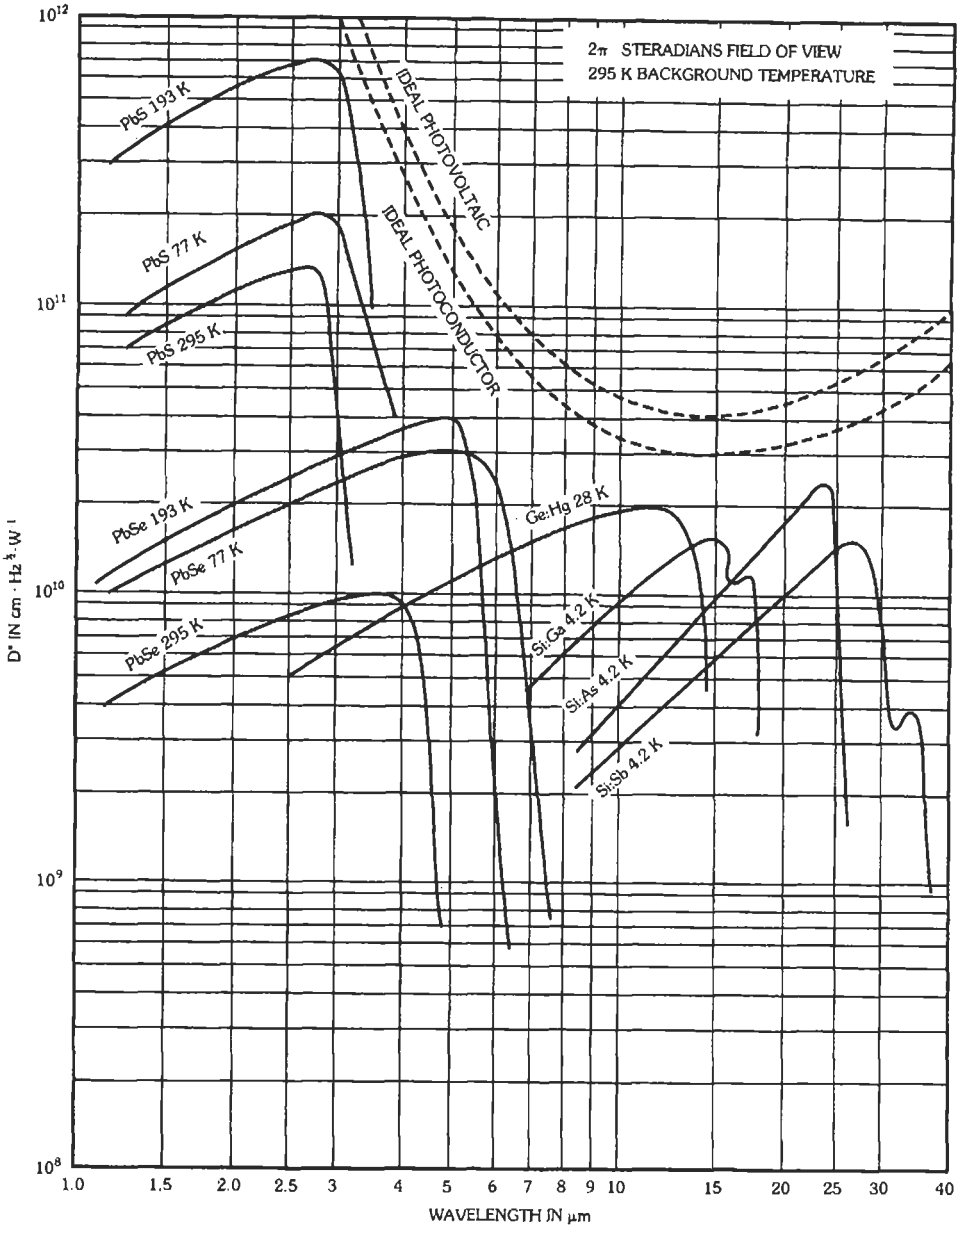

Fig. 25. Spectral detectivities of several thin-film and doped germanium and silicon extrinsic photoconductive detectors. (*From Santa Barbara Research Center.*)

compensate the charge of the photoelectrons in such a way that a "photocurrent" can be superimposed on the small space-charge-limited "dark" current originating at the electrode. If the positive charges are immobile, then long after the photoelectron has passed through the photoconductor into the anode, the immobile positive charges may remain to support a photocurrent of electrons, drawing on the reservoir of electrons at the cathode. This will continue until the immobile "holes" or impurity centers are neutralized by recombination with some of the mobile electrons. Since the recombination lifetime may be much longer than the electron transit time between electrodes, the number of "photoelectrons" transported across the photoconductor may be much larger than the rate of generation of photoelectrons in the photoconductor volume. This ratio of

photocurrent to generation rate is called the photoconductive gain.

The photoconductive gain of a pure material can often be greatly increased by addition of localized traps lying near the conducting band. Since these are in thermal equilibrium with the conducting band, they serve as an additional reservoir of the charge carriers. This can increase both the response time and the sensitivity by a large factor.

Practically all materials are photoconductors in the sense that light of the correct wavelengths will generate current carriers. However, in many materials the photoconductivity is not detectable by ordinary measurements, either because of very short carrier lifetimes or because of a large dark current. The useful photoconductors, characterized by comparatively long lifetimes and low dark currents, have most of their charge carriers immobile (in the dark). Light of the proper energy can excite these carriers through the forbidden energy regions into the conduction bands. The long-wavelength limit of photoconductivity at low temperatures is given approximately by

$$\lambda_{max} = hc/E_g$$

where,

E_g is the forbidden band gap,
h is Planck's constant,
c is the velocity of light.

For wavelengths longer than 5 micrometers, this equation gives a band gap smaller than ¼ electronvolt. Photoconductors with such small energy gaps are usually cooled to reduce the dark conductivity due to thermal excitation of carriers across the gap.

Values of D^*, a commonly used figure of merit for photoconductors, for several typical photoconductors at room temperature are shown in Fig. 24. The photoconductors with long-wavelength cutoffs will be considerably more sensitive if they are cooled below room temperature.

Photodiodes†—When photons irradiate a semiconductor having a band gap less than the energy of the photons, hole-electron pairs are produced. By forming a pn junction in a semiconductor, those hole-electron pairs can be collected. The resulting photodiode may have a quantum efficiency (ratio of collected photoelectrons to impinging photons) of from 0.2 to 0.7 or higher with antireflection coating.

Photodiodes have two primary operating modes, the photovoltaic mode and the reverse-biased mode that is often referred to incorrectly as the photoconductive mode. In the photovoltaic mode, the unbiased junction is illuminated to stimulate the production of hole-electron pairs. Charge separation then occurs in the field of the junction, and a current and/or voltage results. Since photovoltaic cells produce a short-circuit photocurrent that is linear with respect to the radiation incident upon the pn junction, they are well suited for low-level light detection and measurement. This is especially true for narrow-band-gap materials and devices where the leakage current of reverse-biased diodes is often high enough to contribute undesirable noise. In the figures where the D* limit for ideal photovoltaic detectors is shown, this refers to short-circuit photovoltaic detectors or reverse-biased photodiode detectors. If the photovoltaic detectors are operated in the open-circuit mode, the limiting D^*_λ is the same as that shown for ideal photoconductive detectors, since in this case the recombination of carriers in the open-circuit photovoltaic detector contributes noise just as in photoconduction.

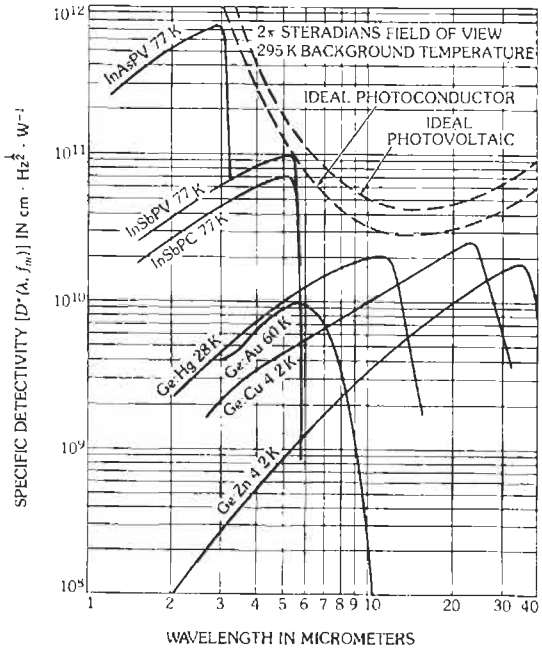

Fig. 26. Spectral detectivities of several semiconductor detectors. (*Santa Barbara Research Center data.*)

The major application for photovoltaic cells, however, is the conversion of solar radiation into electrical power. The operating specification of most interest in this application is the power conversion efficiency (ratio of the power produced by the cell to the power in the incident photon flux). Cell efficiency is affected by such factors as surface reflectance, absorption between the surface and the pn junction, and transmissivity of the junction region. Power efficiencies of commercial solar

† Stillman, G. E., and Wolfe, C. M., "Avalanche Photodiodes," in *Semiconductor and Semimetals*, Vol. 12 (New York: Academic Press, Inc., 1977; pp. 291–393).

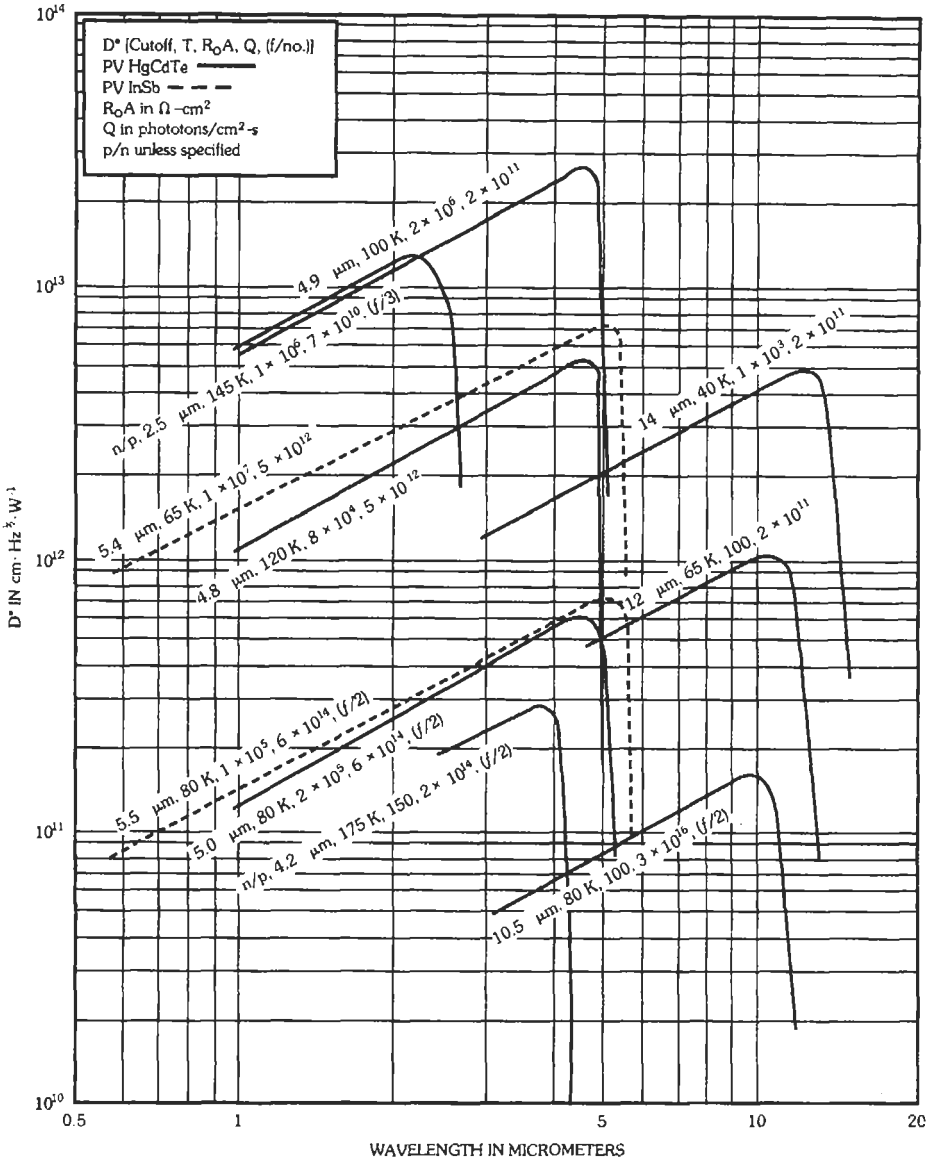

Fig. 27. Spectral response of detectors.

cells range from 5% to a maximum of about 15%. The best developed solar-cell material is silicon, but considerable work has been expended on gallium arsenide, indium phosphide, and cadmium sulfide. Fabrication advances now permit the production of long silicon ribbons, and this should eventually result in significant cost reductions for silicon solar-energy converters.

In the photoconductive mode, a photodiode (usually of special construction) is reverse biased and exposed to optical radiation. The resulting hole-electron pairs separate at the junction and establish a current that consists of a small and constant reverse leakage (the dark current) and the photocurrent (the signal). The photocurrent is linear with respect to the incident radiation. The dark current establishes a minimum noise level below which operation is impractical. An important advantage of photoconductive operation over the photovoltaic mode is response time. A photodiode resembles a parallel-plate capacitor. Unbiased operation is slowed by high junction capacitance, whereas reverse-biased operation reduces junction capacitance and enhances response time.

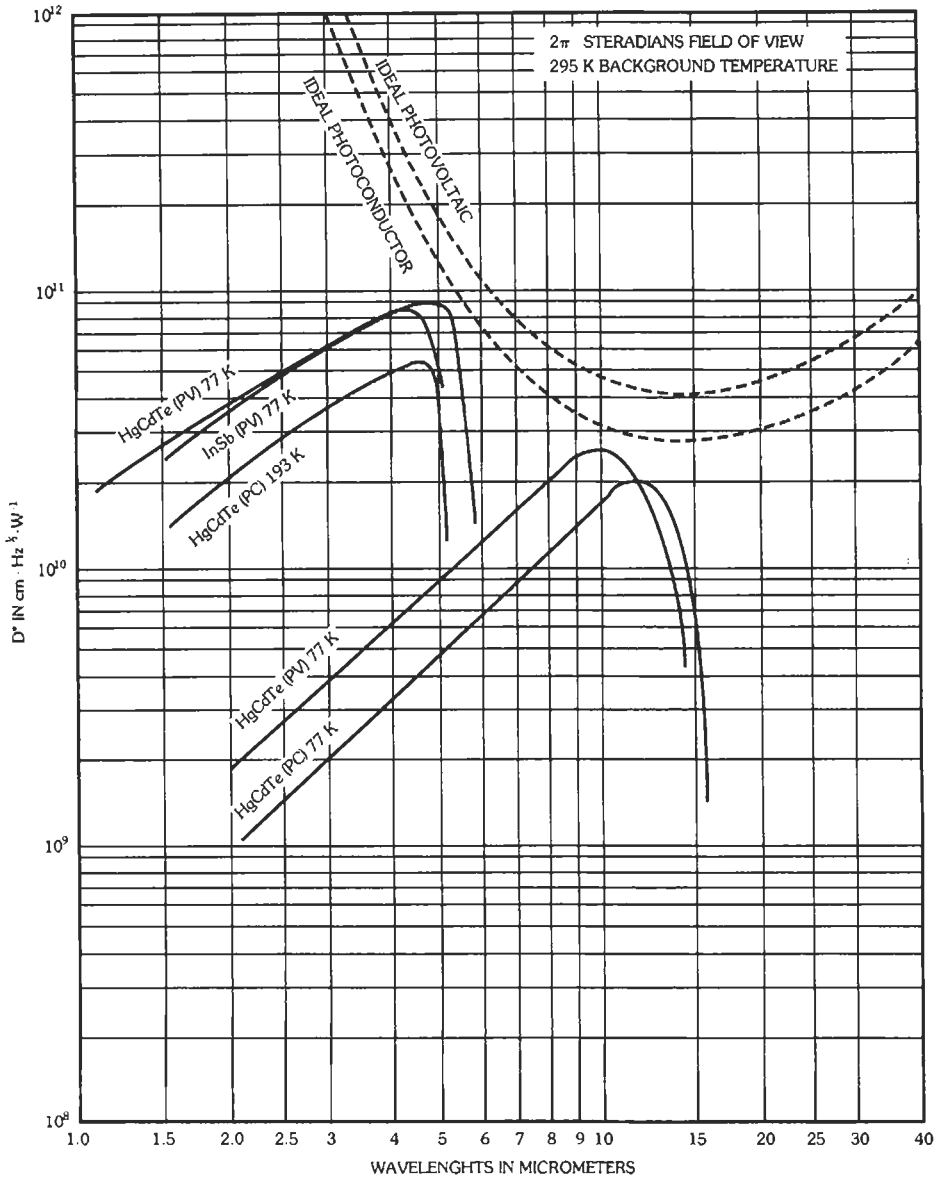

Fig. 28. Spectral response of detectors.

A photodiode of major importance is the avalanche photodiode. This device is a modified photodiode biased just below the avalanche breakdown region. Photons impinging upon the junction region create hole-electron pairs that initiate an avalanche multiplication of carriers across the junction. The resulting internal gain and response time make avalanche photodiodes suitable for operation in wide-bandwidth applications, where the s/n ratio is limited by the thermal noise of the load resistor and amplifier noise of wide-bandwidth amplifiers, formerly reserved for the photomultiplier tube.

Spectral Response of Semiconductor Detectors

A knowledge of detector spectral response and sensitivity or D^*_λ is essential in choosing a detector for a particular application. The spectral response of various detectors is summarized in Figs. 25 through 28. The operating temperatures can have a strong influence on the directivity of detectors, and the variation of D^* with temperature for several different detectors is shown in Fig. 29.

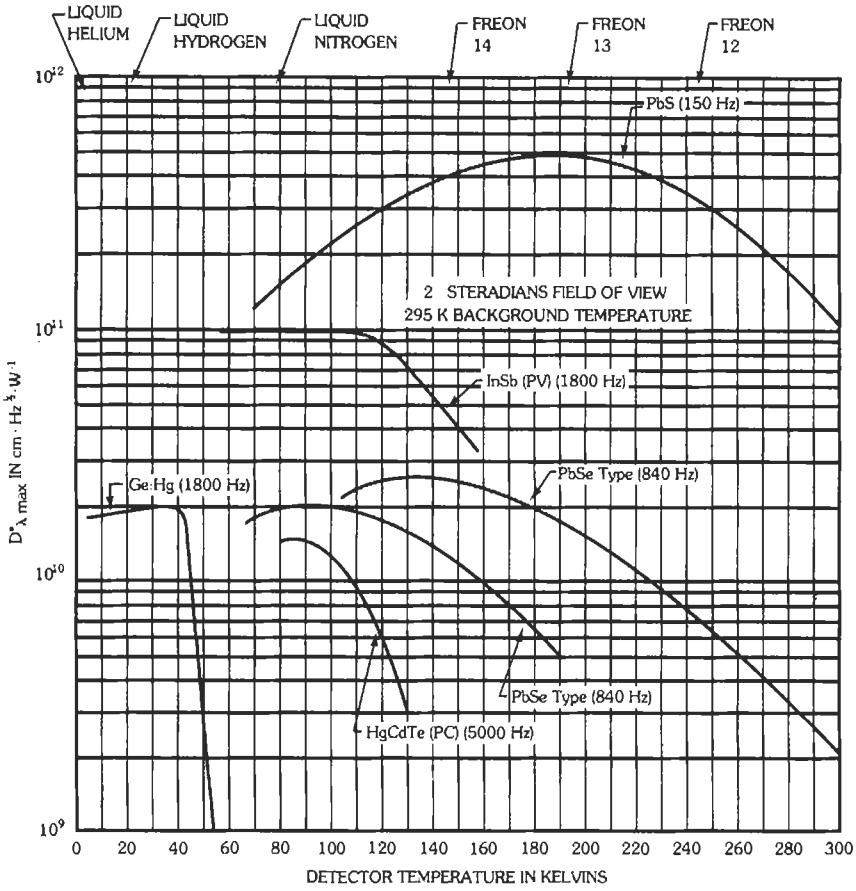

Fig. 29. Variation of $D^*_{\lambda max}$ for several different photoconductive and photovoltaic semiconductor detectors with operating temperature for a 295 K 2π steradians background condition. The chopping frequency used for the measurements is shown in parentheses.

22 Optical Communications

Chester S. Gardner and George Papen

In recent years, advances in device technology have significantly enhanced the capabilities of optical communication systems. High-data-rate systems have been constructed for space applications, and fiber-optic systems are finding wide use in telephone and data communications. In this chapter, the design of both fiber and free-space optical communication systems is discussed. Systems aspects are emphasized in this chapter. More detailed information on device technology can be found in Chapter 21 on Optoelectronics.

OPTICAL DETECTORS AND NOISE

Optical detectors can be classified into two general categories. Photomultiplier tubes (PMT) and vacuum photodiodes are photoemissive devices that emit electrons into a vacuum or gas. Avalanche photodiodes (APD), pin photodetectors, and phototransistors are solid-state devices in which the excited charge is transported in the solid by holes and electrons. Photomultiplier tubes, APDs, and pin photodetectors are the most widely used in optical communication systems.

Photomultiplier tubes are typically used when high sensitivity and bandwidth are required. Because their internal gain can be as high as 10^7, the output signal level is large compared to the thermal noise of the succeeding amplifiers. Receivers employing PMTs are, therefore, shot-noise limited. The disadvantages of PMTs are that they are relatively bulky and fragile compared to solid-state detectors and they require high-voltage power supplies. Solid-state detectors are small, reliable, and inexpensive, and they exhibit high quantum efficiency through the visible to near-infrared portions of the spectrum. Avalanche photodiodes are characterized by high gain and bandwidth.

Optical detectors are square-law devices because they respond to intensity rather than amplitude. The detection process involves the interaction of incident photons with the detector material. In the case of vacuum photodiodes and PMTs, the incident photons generate photoelectrons that are ejected from the photocathode and flow to the anode. Electron-hole pairs are created in the lattice structure of solid-state detectors by the incident photons. The quantum efficiency (η) of a detector is the fraction of incident photons that produce a photoelectron or electron-hole pair. The quantum efficiencies of photocathodes in PMTs range from a few tenths of a percent to about 30 percent. Silicon photodetectors can have quantum efficiencies exceeding 80 percent. In either case, each detected photon causes an impulse of current to flow in the detector load resistor. The photocurrent is equal to the number of electrons emitted per second times the electron charge ($e = 1.6 \times 10^{-19}$ C). Photodetector efficiency is sometimes expressed in terms of responsivity, which is defined as the photocurrent divided by the incident optical power. Responsivity (R) can be written in terms of the detector quantum efficiency, electron charge, and photon energy (hf)

$$R = \eta e/hf \qquad \text{(Eq. 1)}$$

where,

h is Planck's constant (6.63×10^{-34} J · s),
f is the optical frequency.

The detector output current can be modeled by using the following formula:

$$i(t) = \sum_{j=1}^{N(t)} G_j g(t - \tau_j) + i_{Th}(t) \qquad \text{(Eq. 2)}$$

where,

$N(t)$ = number of photons that have been detected during the time interval $(-\infty, t)$,
τ_j = arrival time of the jth photon,
G_j = detector gain for the jth photon,
$g(t)$ = detector impulse response,
$i_{Th}(t)$ = detector thermal noise current.

In the above expression, N is a random process whose statistics are related to the optical intensity. If the intensity is deterministic, N is Poisson distributed

$$\text{Prob}\ (N = k) = (\mu^k/k!)e^{-\mu} \qquad \text{(Eq. 3)}$$

where,

$$\mu = (\eta/hf) \int_{-\infty}^{t} P(\tau)\, d\tau, \qquad \text{(Eq. 4)}$$

$P(t)$ is the optical power.

The expected value and variance of N equal μ.

$$E(N) = \text{Var}(N) = (\eta/hf) \int_{-\infty}^{t} P(\tau)\, d\tau \qquad \text{(Eq. 5)}$$

The internal amplification processes of PMTs and APDs are noisy so that G is also random. This effect introduces additional noise into the detection process. Amplification noise is most significant in APDs and should be considered in analyzing receiver performance. However, if the gain is assumed to be constant, the mean and variance of the detector output current are given by Campbell's theorem

$$E[i(t)] = G(\eta/hf)g(t) * P(t) \qquad \text{(Eq. 6)}$$

$$\text{Var}[i(t)] = G^2(\eta/hf)g^2(t) * P(t) + \sigma^2_{Th} \qquad \text{(Eq. 7)}$$

The first term on the right-hand side of Eq. 7 is called shot noise. It is caused by the statistical nature of the

photon detection process. The term σ^2_{Th} is the thermal noise variance, which is given by

$$\sigma^2_{Th} = 4kT_LB/R_L \qquad \text{(Eq. 8)}$$

where,

R_L = detector load resistance,
k = Boltzmann's constant,
T_L = equivalent temperature of the detector load resistor (kelvins),
B = detector bandwidth.

Typically, the detector bandwidth will be larger than or equal to the bandwidth of $P(t)$. In this case, the convolutions in Eqs. 6 and 7 can be approximated by

$$g(t) * P(t) \cong P(t) \int_{-\infty}^{\infty} g(t)\, d\tau = eP(t) \qquad \text{(Eq. 9)}$$

$$g^2(t) * P(t) \cong P(t) \int_{-\infty}^{\infty} g^2(\tau)\, d\tau = 2e^2BP(t) \qquad \text{(Eq. 10)}$$

In deriving Eqs. 9 and 10, it was assumed that $g(t)$ is an ideal low-pass filter, with bandwidth B. Consequently, the mean and variance of the output current are given by

$$E[i(t)] = (\eta eG/hf)\,(P_s + P_b) \qquad \text{(Eq. 11)}$$

$$\text{Var}[i(t)] = (2\eta e^2G^2B/hf)\,(P_s + P_b) + 4kT_LB/R_L \qquad \text{(Eq. 12)}$$

where,

P_s is the signal power,
P_b is the optical background noise power.

For atmospheric systems operating during the daytime, P_b can be quite large. For fiber systems, P_b is negligible.

Eq. 12 is valid for PMTs and detectors with no internal gain ($G = 1$). For APDs, the random variation of the internal gain must be considered when calculating the variance of the output current. The details are complicated and need not be repeated here. The variance of the output current for an APD is given by*

$$\text{Var}[i(t)] = [2\eta e^2G^2F(G)B/hf]\,(P_s + P_b) + 4kT_LB/R_L \qquad \text{(Eq. 13)}$$

where,

$$F(G) = \rho G + (2 - 1/G)(1 - \rho), \qquad \text{(Eq. 14)}$$

G is the mean gain,
ρ is the ratio of hole collision ionization probability to electron collision ionization probability.

* Reference 1.

For silicon APDs, ρ is between 0.02 and 0.03, and G is typically less than 200. For noise-free avalanche gain, $F(G)$ would be equal to 1.

The current variance is proportional to the noise power at the detector output. The signal power is proportional to the square of the mean signal current. Therefore, the signal-to-noise power ratio (SNR) at the detector output is given by

$$\text{SNR} = \frac{[(\eta eG/hf)P_s]^2}{(2\ \eta e^2G^2B/hf)\,(P_s + P_b) + 4kT_LB/R_L} \qquad \text{(Eq. 15)}$$

Thermal-noise-limited detection occurs when the internal gain of the detector and the optical signal power are low. In this case, thermal noise dominates the detection process, and the SNR becomes

$$\text{SNR} = [(\eta eG/hf)P_s]^2/(4kT_LB/R_L) \quad \text{Thermal noise limited} \qquad \text{(Eq. 16)}$$

If the internal gain of the detector is high so that detection is shot-noise limited, the SNR can be written as

$$\text{SNR} = (\eta/2hfB)\,[P^2{}_s/(P_s + P_b)] \quad \text{Shot noise limited} \qquad \text{(Eq. 17)}$$

MODULATION TECHNIQUES

An optical carrier can be modulated with any of the conventional amplitude, phase, and frequency techniques employed at radio frequencies. However, intensity modulation and polarization modulation are the most widely used methods for optical systems. In digital communications, the polarization state of the optical carrier can be used to represent the value of a data bit. Bits can be represented as either right or left circular polarization or as any two orthogonal linear polarization states. Lithium niobate ($LiNbO_3$) and lithium tantalate ($LiTaO_3$) are two of the more commonly used electro-optic crystals for polarization modulators. Intensity modulation can be used for analog and digital signals. Analog signals are sometimes used to modulate RF subcarriers by conventional phase or frequency modulation. The optical intensity is then modulated by the RF subcarrier. Intensity modulation can be accomplished directly in laser diodes and LEDs by varying the diode forward current. External acousto-optic and electro-optic modulators can also be used to vary the optical intensity continuously.

Pulse-Position Modulation

Pulse-position modulation (PPM) is a very effective digital intensity-modulation technique. In M-ary PPM, each time slot is divided into M equal intervals. A single pulse of constant energy is transmitted during one of the M intervals. During a single time slot, one of M

different messages can be transmitted. If $M = 2^k$, this corresponds to a binary word of k bits. This modulation technique is a form of block coding. In general, the optimum detection strategy can be quite complicated. However, when the optical detector is shot-noise limited, the maximum-likelihood receiver reduces to a particularly simple form. For each time slot, the receiver counts the number of detected photons in each of the M intervals. The transmitted message is assumed to be the message corresponding to the interval with the largest count. The probability of word error (PWE) for this case is*

$$\text{PWE} = 1 - \{\exp[-(N_s + MN_b)]\}/M - \sum_{k=1}^{\infty} [(N_s + N_b)^k/k!] \exp[-(N_s + N_b)] \times \left[\sum_{j=1}^{k-1} (N_b^j/j!)\, e^{-N_b}\right]^{M-1} (1/aM)[(1 + a)^M - 1] \quad \text{(Eq. 18)}$$

where,

$$a = (N_b^k/k!)/\sum_{i=0}^{\infty} N^i{}_b/i! \quad \text{(Eq. 19)}$$

* Reference 3.

$$N_s = (\eta/hf)J_s \quad \text{(Eq. 20)}$$

$$N_b = (\eta/hf)J_b \quad \text{(Eq. 21)}$$

In these expressions, N_s is the expected signal photocount; N_b is the expected background noise count per pulse interval; and J_s and J_b are, respectively, the signal and background noise energies per pulse interval. In Fig. 1, PWE is plotted versus N_s for several values of M. The plots indicate that PWE increases as M increases. It is misleading to use these plots to compare M-ary systems at different values of M. As M increases, more bits are transmitted per pulse. Also, for a fixed time-slot width, the data rate increases with M. Comparisons of M-ary systems should be made only on a bit-error-rate basis for a fixed data rate. In Fig. 2, the equivalent probability of bit error (PBE) is plotted versus N_s for several values of M. Notice that for N_s sufficiently large, the PBE continually decreases with increasing M. When N_s is above the crossover point, there is a significant advantage to increasing M. However, it should be noted that the peak power of the optical transmitter and the bandwidths of the modulator and receiver must also increase.

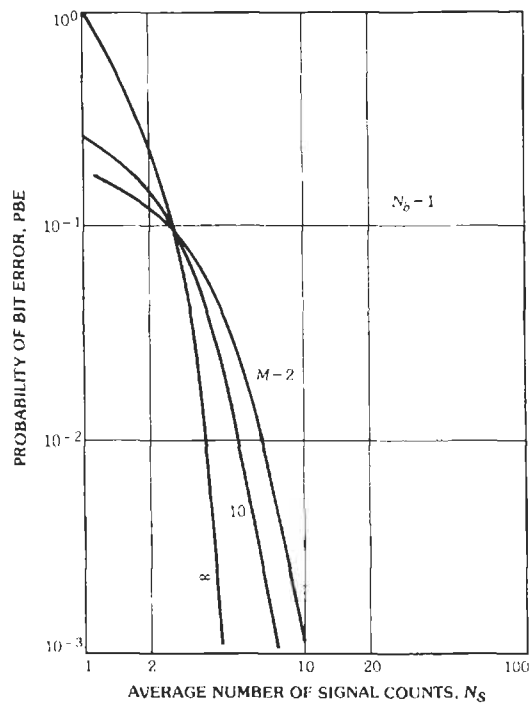

Fig. 2. Equivalent bit-error probability for block-coded pulse-position modulation. (*From Gagliardi, R., and Karp, S.* Optical Communications. *New York: John Wiley & Sons, Inc., 1976, p. 271.*)

Binary Orthogonal Signaling

When $M = 2$, we have binary modulation. In this case, the PBE is given by*

$$\text{PBE} = \tfrac{1}{2}\{1 + Q[\sqrt{2N_b}, \sqrt{2(N_s + N_b)}] - Q[\sqrt{2(N_s + N_b)}, \sqrt{2N_b}]\} \quad \text{(Eq. 22)}$$

where,

$$Q(a,b) = \int_b^\infty \exp[-(a^2 + x^2)/2]\, I_o(ax)\, x\, dx \quad \text{(Eq. 23)}$$

is Marcum's Q function. This expression for the PBE is also valid for other types of binary orthogonal signaling such as polarization modulation.† In Fig. 3, the PBE is plotted versus N_s for several values for N_b. For thermal-noise-limited detection, the PBE can be expressed in terms of the error function and the SNR:

$$\text{PBE} = \tfrac{1}{2}[1 - \text{erf}(\sqrt{\text{SNR}}/2)] \quad \text{(Eq. 24)}$$

where,

$$\text{SNR} = [G(eN_s/\tau_B)]^2/(4kT_L/R_L\tau_B) \quad \text{(Eq. 25)}$$

τ_B is the pulse interval width.

Eq. 25 was obtained from Eq. 16 by replacing the detector bandwidth by $1/\tau_B$ and P_s by N_s/τ_B. The PBE for the thermal-noise-limited detection is plotted in Fig. 4. In general, the signal levels required to realize a given PBE are much higher for thermal-noise-limited detection than for shot-noise-limited detection. This is expected because, by definition, the thermal noise power is much larger than the shot noise power in a thermal-noise-limited receiver.

OPTICAL TRANSMITTERS

When an incoherent source such as an LED is used in an optical communication system, the transmitting optics are designed to image the source onto the receiving telescope. For systems employing lasers, a beam expander is often used for the transmitting tele-

scope to decrease beam divergence. The transmitter and receiver can share the same telescope to reduce cost and weight. A variety of telescope configurations have been used in optical communication systems. The most common are the Cassegrain reflector and the simple refracting telescope. Because of the high cost of low-loss lens materials, reflecting optics are utilized almost exclusively in systems operating at the middle and far IR wavelengths. Both reflecting and refracting telescopes are used for near IR and visible systems.

Incoherent Sources

A simple imaging telescope for an LED source is diagrammed in Fig. 5. The objective lens is designed to project an image of the LED onto the receiver. The image intensity depends on the image magnification and the power radiated by the LED. The image magnification (m) is the ratio of the image distance (z) to the object distance (Z_o)

$$m = z/Z_o \qquad \text{(Eq. 26)}$$

The image and object distances are related through the lens-maker's equation

$$1/f_L = 1/z + 1/Z_o \qquad \text{(Eq. 27)}$$

where f_L is the lens focal length. By solving Eq. 27 for the object distance, we obtain

$$Z_o = f_L/(1 - f_L/z) \qquad \text{(Eq. 28)}$$

Usually, the image distance is large compared to the lens focal length so that $Z_o = f_L$ and $m = z/f_L$. The image diameter (d_i) is equal to the LED diameter (d_{LED}) multiplied by the magnification

$$d_i = (z/f_L)d_{\text{LED}} \qquad \text{(Eq. 29)}$$

The total optical power in the image is equal to the power collected by the transmitting telescope objective multiplied by the atmospheric transmittance. To compute the power collected by the objective, we need to know the radiation pattern of the LED. If the LED has no lens, the radiation is Lambertian and is proportional to the cosine of the angle between the observation point and the optical axis. Many LEDs are packaged with small lenses to collimate the radiation and reduce the beamwidth. In most cases, the radiation pattern can be fairly accurately modeled by the formula

$$P_L(\theta, \phi) = [(\xi + 1)/2\pi]P_L \cos^{\xi} \theta \qquad \text{(Eq. 30)}$$

where,

$$\xi = -\ln 2/\ln \cos(\theta_B/2) \qquad \text{(Eq. 31)}$$

θ and ϕ are the spherical coordinate angles,
P_L is the total power emitted by the LED into the hemisphere,
θ_B is the full-width at half-maximum (FWHM) beamwidth.

For a Lambertian source, $\theta_B = 120°$ and $\xi = 1$. For LEDs, θ_B can be as small as 10° and ξ can approach 200.

The power collected by the objective lens is calculated by integrating the LED radiation pattern over the solid angle of the lens.

$$P_T = \int_0^{2\pi} \int_0^{\tan^{-1}(d_L/2f_L)} \{(\xi + 1)/2\pi\} P_L \cos^{\xi} \theta \cdot \sin \theta \, d\theta \, d\phi$$

$$= P_L[1 - (1 + d_L^2/4f_L^2)^{-(\xi+1)/2}] \qquad \text{(Eq. 32)}$$

The quantity P_T is the total power transmitted by the telescope, and d_L is the diameter of the telescope objective lens. The maximum value of P_T is P_L, the total power emitted by the LED. The bracketed term is a factor describing the efficiency of the LED-telescope combination. The efficiency increases with decreasing beamwidth (increasing ξ) and decreasing $f/$ number (f_L/d_L) of the objective lens. This is illustrated in Fig. 6, where telescope efficiency is plotted versus the LED

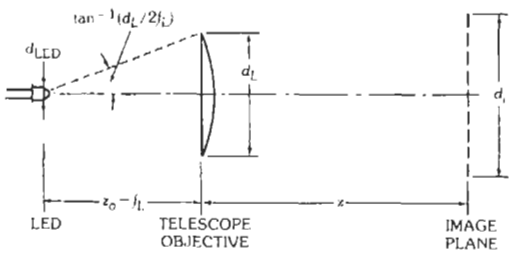

Fig. 5. Transmitting telescope for an LED source.

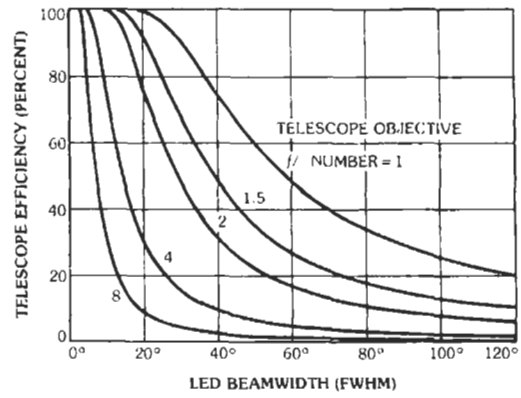

Fig. 6. Variation of the transmitting-telescope efficiency with LED beam width.

beamwidth for several values of the objective-lens *f*/ number. For a Lambertian source, Eq. 32 reduces to

$$P_T = P_L d_L^2/(d_L^2 + 4f_L^2) \qquad \text{(Eq. 33)}$$

If we assume that the image is uniformly bright, then the optical power density or signal intensity (I_s) in the receiver plane is equal to the total power in the image divided by the image area. For a circular LED source, the signal intensity is given by

$$I_s = (4f_L^2/\pi d^2_{\text{LED}})(T_a P_T/z^2) \qquad \text{(Eq. 34)}$$

where T_a is the atmospheric transmittance. As expected, the signal intensity decreases inversely with the square of the distance between the transmitter and receiver. Although the telescope efficiency decreases with increasing f_L, the f_L^2 dependence in Eq. 34 dominates so that I_s increases with increasing f_L. However, this does not always mean that it is better to have a large focal length. The magnification and image size decrease with increasing f_L. Smaller images require more precise pointing and tracking. The maximum permitted pointing error (θ_E) is approximately equal to the arctangent of the image radius divided by the image distance

$$\theta_E = \tan^{-1}(d_i/2z) = \tan^{-1}(d_{\text{LED}}/f_L) \qquad \text{(Eq. 35)}$$

This is the condition for the edge of the image to lie on the optical axis of the receiving telescope. The transmitting telescope must be pointed with an accuracy less than the angle given by Eq. 35. Small changes in the pointing angle can be obtained by moving the LED perpendicular to the optical axis of the transmitting telescope.

In direct analogy with conventions established in microwave-communication systems analysis, it is sometimes convenient to express the signal power density in terms of the transmitter or source power and an effective antenna gain. In this case, Eq. 34 is written as

$$I_S = (G_T/4\pi)(T_a P_L/z^2) \qquad \text{(Eq. 36)}$$

where,

$$G_T = (16f_L^2/d_{LED}^2)[1 - (1 + d_L^2/4f_L^2)^{-(\xi+1)/2}] \qquad \text{(Eq. 37)}$$

Coherent Sources

For spatially coherent laser sources, the transmitting telescope is usually a beam expander that is designed to reduce the beam divergence. The spatial mode structure of laser resonators has been discussed extensively in the literature.* The fundamental mode for a radially symmetric cavity has a Gaussian cross section

$$I_L(x,y,z) = [2P_L/\pi\omega^2(z)] \exp[-2(x^2 + y^2)/\omega^2(z)] \qquad \text{(Eq. 38)}$$

* Reference 6.

where,

I_L is the beam intensity,
P_L is the total power in the beam,
$\omega(z)$ is the beamwidth at the e^{-2} intensity point.

In Eq. 38, the optical axis of the laser is assumed to be the z axis. The laser is located at the origin, and the beam is propagating in the positive z direction. The factor $\omega(z)$ is a function of the beamwidth and phase-front curvature at the laser. If the receiver is in the far field, then $\omega(z)$ can be written as

$$\omega(z) = z \tan \theta_L \qquad \text{(Eq. 39)}$$

where θ_L is the beam divergence angle. Usually, θ_L is a few milliradians or less. The smallest beam is obtained whenever the laser radiation is focused onto the receiver plane. If the receiver is in the far field, this is equivalent to collimating the beam. For a collimated beam, $\omega(z)$ is given by

$$\omega(z) = \omega_0(1 + \lambda^2 z^2/\pi^2\omega_0^4)^{1/2} \qquad \text{(Eq. 40)}$$

or

$$\omega(z) = \omega_0[1 + (\lambda z/\pi\omega_0^2)^2]^{1/2}$$

where,

λ is the optical wavelength,
ω_0 is the beamwidth at the output of the beam expander.

The divergence angle for a collimated beam is

$$\theta_L = \lambda/\pi\omega_0 \qquad \text{(Eq. 41)}$$

In the far field, the on-axis signal intensity is calculated by substituting Eq. 40 into Eq. 38 and evaluating the result at $x = y = 0$:

$$I_S = (2\pi\omega_0^2/\lambda^2)(T_a P_L/z^2) \qquad \text{(Eq. 42)}$$

where T_a is the atmospheric transmittance. This expression is similar to Eq. 34 for incoherent sources. The beam divergence decreases and the on-axis intensity increases with increasing beamwidth, ω_0.

It is sometimes convenient to express the on-axis intensity in terms of an equivalent antenna gain:

$$I_S = (G_T/4\pi)(T_a P_L/z^2) \qquad \text{(Eq. 43)}$$

where,

$$G_T = 8\pi^2\omega_0^2/\lambda^2 \qquad \text{(Eq. 44)}$$

Because a Gaussian beam is infinite in extent, Eq. 44 is the maximum gain that would be obtained with an infinitely large beam expander. However, in practice, the beam will be truncated by the finite extent of the transmitting aperture. In addition, if a Cassegrain

reflecting telescope is used to expand the beam, the central obscuration caused by the secondary mirror will also reduce the effective gain. It is necessary to match the beamwidth to the telescope to minimize the gain loss.* This is illustrated in Fig. 7, where the relative far-field axial gain is plotted versus the ratio of the aperture radius to beamwidth for several values of obscuration ratio ($\gamma = b/a$). The radii of the primary and secondary mirrors are denoted, respectively, by a and b. The gain is plotted relative to the gain for an unobscured uniformly illuminated aperture, $4\pi^2a^2/\lambda^2$. A uniformly illuminated aperture has the maximum possible on-axis gain. Thus, the data in Fig. 7 represent the efficiency of the transmitting antenna. Truncation losses dominate when a/ω_0 is small, whereas obscuration losses dominate when a/ω_0 is large. Maximum efficiency is obtained whenever a/ω_0 satisfies the equality

$$a/\omega_0 = 1.12 - 1.30\gamma^2 + 2.12\gamma^4 \quad \text{(Eq. 45)}$$

The maximum efficiency is plotted versus obscuration ratio in Fig. 8. The loss in efficiency over an ideal uniformly illuminated aperture increases from approximately 1 dB to almost 5 dB as the obscuration ratio increases from 0 to 0.5. As a consequence, these effects must be taken into account, particularly for systems designed with a low gain margin. In some cases, the spider support structure for the secondary mirror can also have a measurable effect on the axial gain.* However, the effects are usually significant only when the obscuration ratio is small ($\gamma < 0.2$).

* Reference 7.

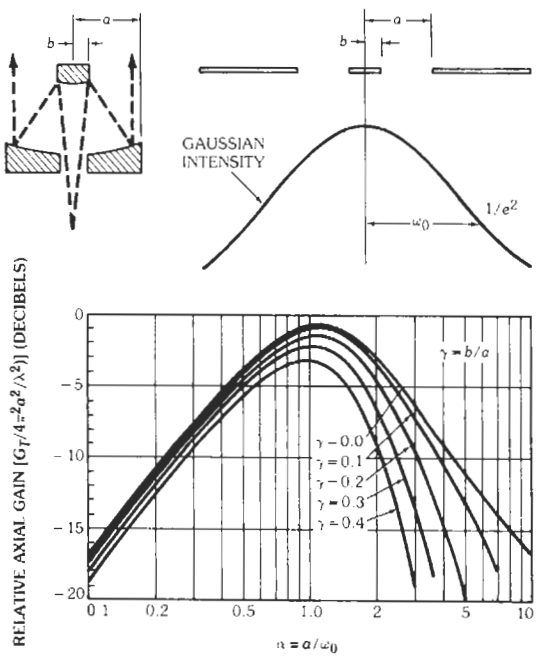

Fig. 7. Far-field axial gain of a centrally obscured transmitting telescope as a function of the ratio of the telescope radius to the laser beam width. (*From Klein, B. J., Degnan, J. J. "Optical Antenna Gain. 1. Transmitting Antennas,"* Appl. Opt., *13, September 1974, p. 2137.*)

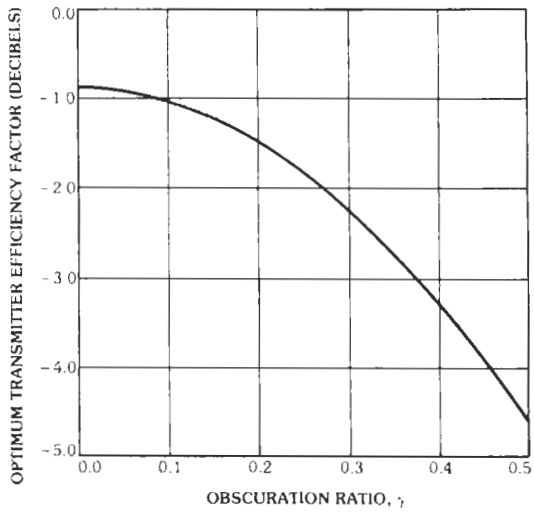

Fig. 8. Optimum telescope efficiency relative to an unobscured uniformly illuminated aperture ($4\pi^2a^2/\lambda^2$) as a function of obscuration ratio. (*From Klein, B. J., and Degnan, J. J. "Optical Antenna Gain. 1. Transmitting Antennas,"* Appl. Opt., *13, September 1974, p. 2139.*)

The pointing and tracking requirements become more severe as the beamwidth increases and beam divergence decreases. Small pointing errors can result in substantial loss of signal. This is illustrated in Fig. 9, where the loss due to transmitter pointing error is plotted versus pointing error for several values of the obscuration ratio. These curves correspond to the optimum antenna configuration where Eq. 45 is satisfied. The loss is approximately 10 dB when the pointing error is $\lambda/2a$ radians.

Because of the geometry of the emitting stripe in a semiconductor laser diode, the output beam has an elliptical cross section that is highly asymmetric. Therefore, the transmitting telescope must be designed to expand the minor axis of the beam more than the major axis to produce a symmetric cross section. This can be accomplished by using an anamorphic prism pair or cylindrical telescope.

OPTICAL RECEIVERS

Receiving telescopes are designed to focus the optical signal onto the photodetector and to reject as much of

* Reference 8.

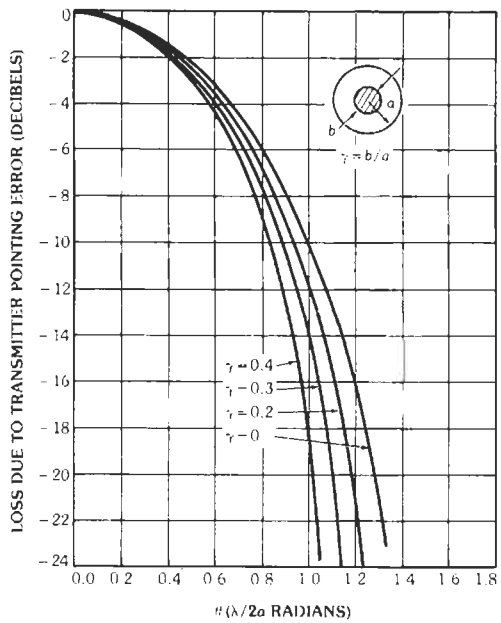

Fig. 9. The decibel loss due to transmitter pointing error as a function of the angular pointing error for optimum antenna configuration (maximum far-field gain) for several values of the obscuration ratio. (*From Klein, B. J. and Degnan, J. J. "Optical Antenna Gain. 1. Transmitting Antennas,"* Appl. Opt., *13, September 1974, p. 2139.*)

the background radiation as is practical. Interference filters are employed to eliminate background radiation that is not the same wavelength as the optical signal. Field stops are used to reject radiation that is not emitted from the region surrounding the transmitting telescope. Direct-detection receivers respond to the signal intensity and are the most widely used in communication systems. In heterodyne-detection receivers, the optical signal is combined with a local-oscillator beam, and then both signals are focused onto the same detector. Heterodyne-detection receivers respond to signal amplitude and are used primarily in the far infrared to overcome limitations imposed by poor detector sensitivity.

Direct-Detection Receivers

A simple direct-detection receiver is diagrammed in Fig. 10. Because of cost, the objective is usually a reflector such as a Cassegrain system whenever the aperture is greater than about 10 cm. The field-stop iris limits the field of view (FOV) of the telescope to a small region surrounding the transmitter. The FOV should be as small as possible to minimize background noise. However, because the pointing and tracking constraints are more severe with a smaller FOV, there is a trade-off. Even for point-to-point communication systems where the locations of the transmitter and receiver are fixed,

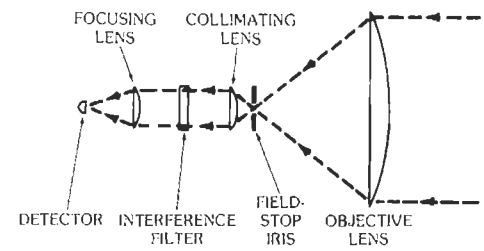

Fig. 10. Simple direct-detection receiver.

atmospheric turbulence and mechanical vibrations can cause the apparent position of the transmitter to change randomly. In these cases, the receiver FOV will have to be adjusted to prevent inadvertent loss of signal.

The planar (θ_R) and solid-angle (Ω_R) fields of view can be calculated from simple geometric considerations. If f_R and d_I denote, respectively, the focal length of the receiver objective and the field-stop iris diameter, then we have

$$\theta_R = \tan^{-1}(d_I/2f_R) \qquad \text{(Eq. 46)}$$

$$\Omega_R = 4\pi \sin^2(\theta_R/2) \qquad \text{(Eq. 47)}$$

These expressions for the FOV are useful for calculating the amount of background noise received by the telescope.

Interference filters are multilayered thin-film devices. They are constructed with dielectric and metallic layers and can have bandwidths as small as 1 Å. Usually, interference filters are designed to work with collimated light. If the optical signal is not adequately collimated, the peak transmission of the filter is reduced, and the center wavelength is shifted to a shorter wavelength. The center wavelength can also be shifted to shorter wavelengths by tilting the filter from normal to oblique incidence. For small angles, the shift is without distortion of the passband or reduction of the peak transmittance. Consequently, a receiver can be tuned over a limited wavelength range by tilting the filter. In terms of the angle of incidence, ϕ, the center wavelength at small angles of incidence ($\phi < 5°$) is given by the equation

$$\lambda = \lambda_{max}[1 - (n_o/n_e)^2 \sin^2 \phi]^{1/2} \qquad \text{(Eq. 48)}$$

where,

n_o is the refractive index of air,
n_e is the effective refractive index of the filter spacer.

Typical values for n_e range from about 1.4 to 2.1.

The center wavelength is also temperature dependent because the layer thicknesses and refractive indices change with temperature. The center wavelength shifts to longer wavelengths as the temperature increases. The thermal coefficient of wavelength shift is a function of

wavelength and filter construction. For visible and near IR wavelengths, the coefficient varies from approximately 0.1 to 0.3 Å/°C. To maintain proper tuning, it is usually necessary to mount the filter in a temperature-controlled oven for bandwidths below 10 Å FWHM. The peak transmittance of interference filters is a decreasing function of the bandwidth. Typical values range from over 70% for bandwidths on the order of 100 Å to less than 10% for bandwidths on the order of 1 Å.

The received signal power is calculated by multiplying the signal power density times the receiver area (A_R) and efficiency (η_R):

$$P_S = \eta_R A_R (G_T/4\pi)\,(T_a P_L/z^2) \qquad \text{(Eq. 49)}$$

where,

P_L is LED or laser power,
G_T is the transmitting antenna gain,
T_a is the atmospheric transmittance.

Efficiency η_R includes the effects of reflective and absorptive losses in the receiver optics including the interference filter. Low-loss optical materials and anti-reflection coatings can reduce losses to a few percent or less for each lens or mirror. Because losses are wavelength dependent, the optics should be coated for the specific wavelength of interest to obtain optimum performance.

Equation 49 can be expressed in terms of an equivalent receiving antenna gain (G_R):

$$P_S = (\lambda/4\pi z)^2 T_a \eta_T \eta_R G_T G_R P_L \qquad \text{(Eq. 50)}$$

where,

$$G_R = 4\pi A_R/\lambda^2 \qquad \text{(Eq. 51)}$$

A transmitting-antenna efficiency factor (η_T) has been included in Eq. 50 to account for losses in the transmitter optics. The transmitting antenna gain is given by Eq. 37 for LED sources and by Eq. 44 for laser sources with a Gaussian cross section. The factor $(\lambda/4\pi z)^2$ is called the free-space loss and represents the effect of path length on the signal strength. The SNR for a direct-detection receiver is calculated by substituting Eq. 50 into Eq. 15. The background noise power can be computed from the data presented in the section on background radiation.

Heterodyne-Detection Receivers

A simple heterodyne-detection receiver telescope is diagrammed in Fig. 11. The local oscillator (LO) beam is combined with the optical signal, and both are focused onto the same detector. Because the objective and collimating lenses demagnify the signal beam, the receiving telescope illustrated in Fig. 11 is optically equivalent to combining the signal and LO in front of

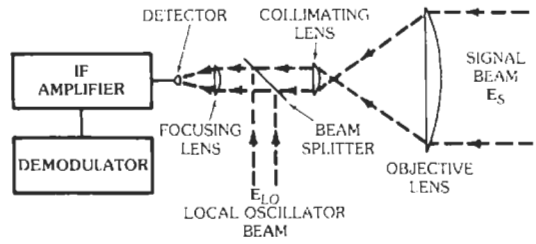

Fig. 11. Simple heterodyne-detection receiver.

the objective lens. Optical mixing of the signal and LO beams produces an intermediate-frequency (IF) signal in the detector output that is proportional to the signal amplitude. The IF is the difference between the signal and LO frequencies.

The electric field vectors for the signal ($\mathbf{E}_S$) and LO ($\mathbf{E}_{LO}$) can be written in the form

$$\mathbf{E}_S = \mathbf{A}_S \cos(2\pi f_s t + \phi_s) \qquad \text{(Eq. 52)}$$

$$\mathbf{E}_{LO} = \mathbf{A}_{LO} \cos(2\pi f_{LO} t + \phi_{LO}) \qquad \text{(Eq. 53)}$$

where,

$\mathbf{A}_S$ and $\mathbf{A}_{LO}$ are the vector amplitudes,
f_s and f_{LO} are the optical frequencies,
ϕ_S and ϕ_{LO} are the phases of the signal and LO, respectively.

The amplitudes and phases of both beams can depend on time and position. The detector responds to the total incident power, which is calculated by integrating over the receiver aperture the magnitude squared of the total field:

$$P_D = \int_{\text{Receiver Aperture}} \overline{|\mathbf{E}_S + \mathbf{E}_{LO}|^2}\, dxdy = P_S + P_{LO} + S_{IF} \qquad \text{(Eq. 54)}$$

The bar in Eq. 54 represents a time average over an interval that is short compared to the inverse of the detector bandwidth but is long compared to the optical periods of the signal and LO. Terms P_S and P_{LO} are, respectively, the total signal and LO powers focused onto the detector by the telescope. Term S_{IF} is the IF signal, which is given by

$$S_{IF} = \int_{\text{Receiver Aperture}} \mathbf{A}_S \cdot \mathbf{A}_{LO} \cos(2\pi f_{IF} t + \phi_S - \phi_{LO})\, dxdy \qquad \text{(Eq. 55)}$$

where,

$$f_{IF} = f_s - f_{LO} \qquad \text{(Eq. 56)}$$

The receiver sensitivity and S_{IF} are maximum when the polarization, amplitude distribution, and phase of the LO beam are matched to the signal beam.* If the receiver is in the far field and the effects of atmospheric turbulence are neglected, the signal beam can be approximated as a uniform plane wave. Then for uniform LO and signal beams, $\mathbf{A}_S$ and $\mathbf{A}_{LO}$ are constant throughout the receiver aperture and can be moved outside the integral sign in Eq. 55. To obtain maximum sensitivity, the signal and LO beams must be properly aligned. Small pointing errors can significantly reduce the IF signal strength. To illustrate, the phase fronts of the signal beam are assumed to be tilted with respect to the LO. The LO phase is constant, and the signal phase is

$$\phi_S = \phi_0 + (2\pi/\lambda)y \sin \theta_R \qquad \text{(Eq. 57)}$$

For simplicity, the coordinate system was chosen so that the tilt (θ_R) is with respect to the y-axis. Angle θ_R may be regarded as the angular pointing error of the receiver.

After substituting Eq. 57 into Eq. 55 and carrying out the integration for an unobscured circular aperture, we obtain

$$S_{IF} = \frac{2J_1[(2\pi a/\lambda) \sin \theta_R]}{(2\pi a/\lambda) \sin \theta_R} A_R \mathbf{A}_S \cdot \mathbf{A}_{LO} \cos(2\pi f_{IF} t + \phi_0 - \phi_{LO}) \qquad \text{(Eq. 58)}$$

where,

A_R is the receiver aperture area (πa^2),
a is the aperture radius,
J_1 is a Bessel function of the first RESET TO ADD ONE LINEkind.

The factor involving the Bessel function is a gain-reduction factor related to pointing error. When θ_R is zero (i.e., perfect LO and signal beam alignment), this factor is one. The IF signal is proportional to the LO amplitude. By increasing the LO power, the IF signal can be made much larger than the receiver thermal noise and the signal and background shot noises. Typically, the limiting noise for heterodyne detection is shot noise contributed by the LO. There is an IF signal contribution due to background noise. However, for typical IF filter bandwidths (B_{IF} less than approximately 1 GHz), this background-noise contribution is small compared to the IF laser signal and can be neglected.

The detector output is processed by an IF amplifier and filter and final demodulator. The expected current at the IF-amplifier output due to the optical signal is calculated by substituting Eq. 58 into Eq. 11 and is

$$E[i_{IF}(t)] = (\eta eG/hf) S_{IF} \qquad \text{(Eq. 59)}$$

* Reference 3.

If the polarization of the LO is matched to the signal, the IF signal power is given by

$$P_{IF} = 2(\eta eG/hf)^2 \left(\frac{2J_1(2\pi a/\lambda) \sin \theta_R}{(2\pi a/\lambda) \sin \theta_R} \right)^2 P_{LO} P_S \qquad \text{(Eq. 60)}$$

where,

$$P_S = A_R A_S^2/2 \qquad \text{(Eq. 61)}$$

$$P_{LO} = A_R A_{LO}^2/2 \qquad \text{(Eq. 62)}$$

The noise power is calculated from Eq. 12 with B replaced by the IF bandwidth (B_{IF}) and P_{LO} added to the signal and background shot-noise power. Therefore, when the pointing error is zero, the IF SNR is given by

$$\text{SNR}_{\text{IF}} = \frac{2(\eta eG/hf_s)^2 P_{LO} P_S}{(2\eta e^2 G^2 B_{IF}/hf_s)(P_s + P_{LO} + P_b) + 4k T_L B_{IF}/R_L} \qquad \text{(Eq. 63)}$$

If the LO power is large, the thermal noise power and the signal plus background shot-noise power will be negligible compared to the LO shot-noise power. In this case, the SNR reduces to

$$\text{SNR}_{\text{IF}} = \eta P_S/hf_s B_{IF} \qquad \text{(Eq. 64)}$$

The signal power can be calculated from Eq. 50, which was derived for a direct-detection receiver. The background noise power can be computed from the data presented in the section on background radiation.

The pointing error can have a significant effect on the IF SNR. This is illustrated in Fig. 12, where the IF SNR loss in decibels is plotted versus normalized pointing error for an unobscured circular aperture and uniform LO beam. To prevent significant loss, the pointing error must be very small. The condition for negligible loss is

$$\theta_R << \lambda/2\pi a \qquad \text{(Eq. 65)}$$

Equation 65 is the condition for pointing within the diffraction-limited FOV of the telescope. Signals that lie outside the diffraction-limited FOV will be rejected by the telescope. Consequently, the pointing and tracking requirements for heterodyne-detection receivers are quite severe.

In practice, atmospheric turbulence will cause the amplitude and phase of the signal beam to fluctuate randomly in space and time. The effect reduces the IF signal power, particularly when the receiving aperture is large. The IF signal strength is maximum when the LO and signal beams add coherently across the aperture.

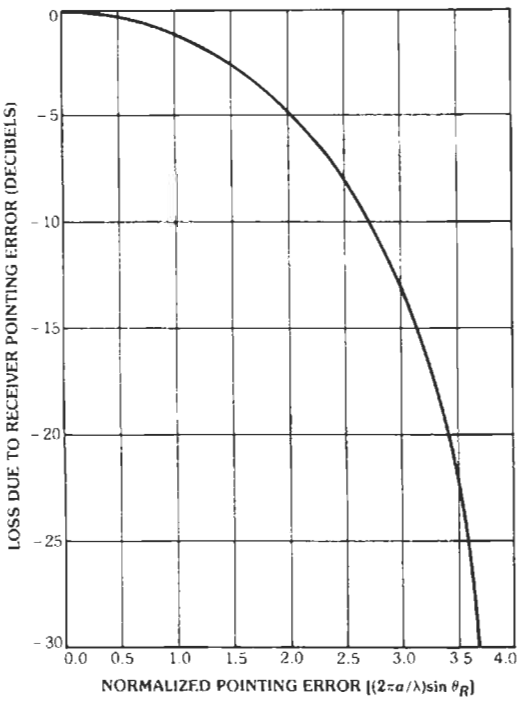

Fig. 12. Intermediate-frequency signal power loss due to receiver pointing error.

Turbulence reduces the spatial coherence of the signal beam and causes the signal phase to vary randomly across the aperture. As the diameter of the aperture increases, the additional signal may add incoherently or out of phase with the LO beam, resulting in either no increase or a reduction in the SNR. This phenomenon is discussed in more detail in the section on atmospheric effects.

BACKGROUND RADIATION

During the day, the dominant background-noise source is the sun, whereas at night, radiation from man-made sources, the moon, the stars, and the planets becomes important. Background radiation may enter the receiving telescope directly, when the source falls within the receiver FOV, or indirectly, when the radiation is reflected or scattered. The spectral distribution of the background radiation depends on many factors, including the spectral distribution of the source, absorption characteristics of the atmosphere, and reflection characteristics of the earth and objects near the transmitter. Uniform background sources are conveniently described by their spectral radiance, $N(\lambda)$, which is defined as the power radiated at wavelength λ per unit bandwidth into a unit solid angle per unit source area.* The total background noise power collected by the receiving telescope is

$$P_b = \begin{cases} N(\lambda)\,\Delta\lambda A_R\,\Omega_{FOV} & \text{if } \Omega_{FOV} \epsilon \Omega_S \\ N(\lambda)\,\Delta\lambda A_R\,\Omega_S & \text{if } \Omega_S \epsilon \Omega_{FOV} \end{cases} \quad \text{(Eq. 66)}$$

where,

$\Delta\lambda$ is the optical bandwidth of the receiver,
A_R is the receiver area,
Ω_{FOV} is the receiver solid-angle FOV,
Ω_S is the solid angle subtended by the source when viewed from the receiver.

When $\Omega_{FOV}\ \epsilon\Omega_S$, the source completely fills the receiver FOV, and only a fraction of the total power within the receiver optical bandwidth collected by the aperture is focused onto the detector. This is the case for sky background. When $\Omega_S\ \epsilon\Omega_{FOV}$, the complete image of the source is focused onto the detector. In this case, Ω_S must be known to evaluate Eq. 66. This is not particularly convenient for small sources such as stars and planets. Consequently, the radiation from point sources is usually described in terms of the spectral irradiance, $H(\lambda)$, which is the power per unit bandwidth per unit receiver area.* The spectral irradiance is related to spectral radiance by

$$H(\lambda) = \Omega_S N(\lambda) \quad \text{(Eq. 67)}$$

Expressed in terms of the spectral irradiance, the received background noise power is

$$P_b = H(\lambda)\,\Delta\lambda A_R \quad \text{(Eq. 68)}$$

Often the spectral radiance of a background source can be approximated by a blackbody curve

$$N(\lambda) = (2hc^2/\lambda^5)\,[\exp(hc/\lambda kT_b) - 1]^{-1} \quad \text{(Eq. 69)}$$

where,

h is Planck's constant (6.63×10^{-34} J · s),
k is Boltzmann's constant (1.38×10^{-23} J/K),
T_b is the source temperature,
c is the velocity of light.

Most earth objects have temperatures between 200 K and 300 K so that their spectral radiance peaks within the wavelength region 9 to 15 μm. The moon has an equivalent blackbody temperature of 373 K. Radiation from the sun and stars peaks at the near IR and visible wavelengths. The equivalent blackbody temperature of the sun is 5900 K.

* References 2 and 4.

Absorption in the atmosphere of the earth can significantly alter the spectral radiance of a background source. This is illustrated in Fig. 13, where the spectral irradiance of the sun outside the atmosphere of the earth and at sea level is plotted. Also noted in the figure are the atmospheric constituents that are responsible for some of the major absorption bands. Fig. 14 illustrates the measured spectral radiance of the clear daytime sky. (The zenith angle of the sun is 45°, and the visibility is excellent.) The radiance for sunlit clouds is approximately one order of magnitude larger. On a clear day, the color temperature of the sky is approximately 20 000 K to 25 000 K.

The spectral irradiances of planets and stars also approximate blackbody radiation curves. Fig. 15 shows the calculated spectral irradiances outside the atmosphere of the earth from the planets. It is likely that many stars of widely differing temperatures will be within the receiver FOV. The probable spectral irradiance from a one-square-degree star field near the galactic plane is plotted in Fig. 16.

If the background radiation is due to the reflection of the sun and sky, knowledge of the reflectance of the terrain surrounding the transmitter is required. In Fig. 17, the typical reflectances of water, snow, soil, and vegetation are plotted versus wavelength.

ATMOSPHERIC EFFECTS

Absorption, scattering, and turbulence affect any optical signal that propagates through the atmosphere of the earth. Absorption by minor constituents such as water vapor, carbon dioxide, and ozone can significantly attenuate the signal beam. Rayleigh scattering by air molecules and Mie scattering by larger particles such as aerosols, dust, and clouds also attenuate the signal. Turbulence is caused by small temperature fluctuations in the atmosphere that give rise to random variations in the refractive index. The optical signal is scattered by these refractive inhomogeneities. Portions of the signal that are scattered by different inhomogeneities interfere at the receiver aperture. The amplitude and phase of the total signal vary randomly in space and time. This loss of signal coherence results in reduced gain and fading in both direct-detection and heterodyne-detection receivers.

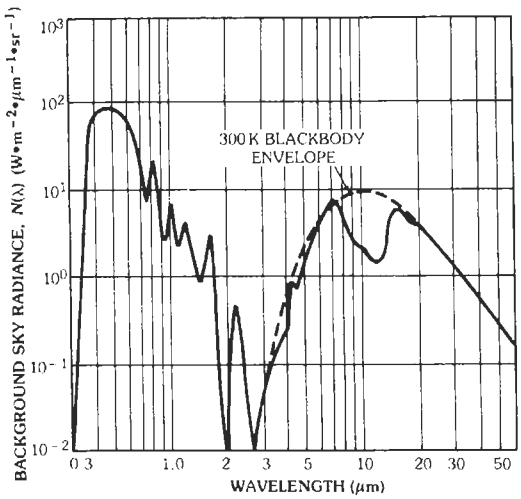

Fig. 14. Diffuse component of the typical background radiance from the sky viewed at sea level. (*From Pratt, W. K. Laser Communications Systems. New York: John Wiley & Sons, Inc., 1968, p. 121.*)

The transmittance of the atmosphere (T_a) over a path length z for radiation of wavelength λ is given by Bouguer's law (references 9 and 10)

$$T_a = \exp\left[-\int_0^z \alpha(\lambda,r)dr\right] \qquad \text{(Eq. 70)}$$

where $\alpha(\lambda,r)$ is the attenuation or extinction coefficient and the integral is taken over the propagation path. The attenuation coefficient has units of inverse meters. The integral of $\alpha(\lambda,r)$ in Eq. 70 is called the optical thickness of the propagation path. Optical thickness is dimensionless. Because the atmosphere attenuates through absorption and scattering by both gases and particles, the attenuation coefficient can be written as the sum of four terms

$$\alpha = \alpha_{g,a} + \alpha_{g,s} + \alpha_{p,a} + \alpha_{p,s} \qquad \text{(Eq. 71)}$$

where the subscripts g, p, a, and s denote, respectively, gases, particles, absorption, and scattering. Absorption by gases and scattering by particles are the most significant at optical wavelengths.

Absorption

The main absorbing gases in the atmosphere for ultraviolet, visible, and infrared wavelengths in order of importance are H_2O, CO_2, O_3, N_2O, CO, O_2, CH_4, and N_2. The variation of the molecular absorption coefficient is very complicated due to the presence of

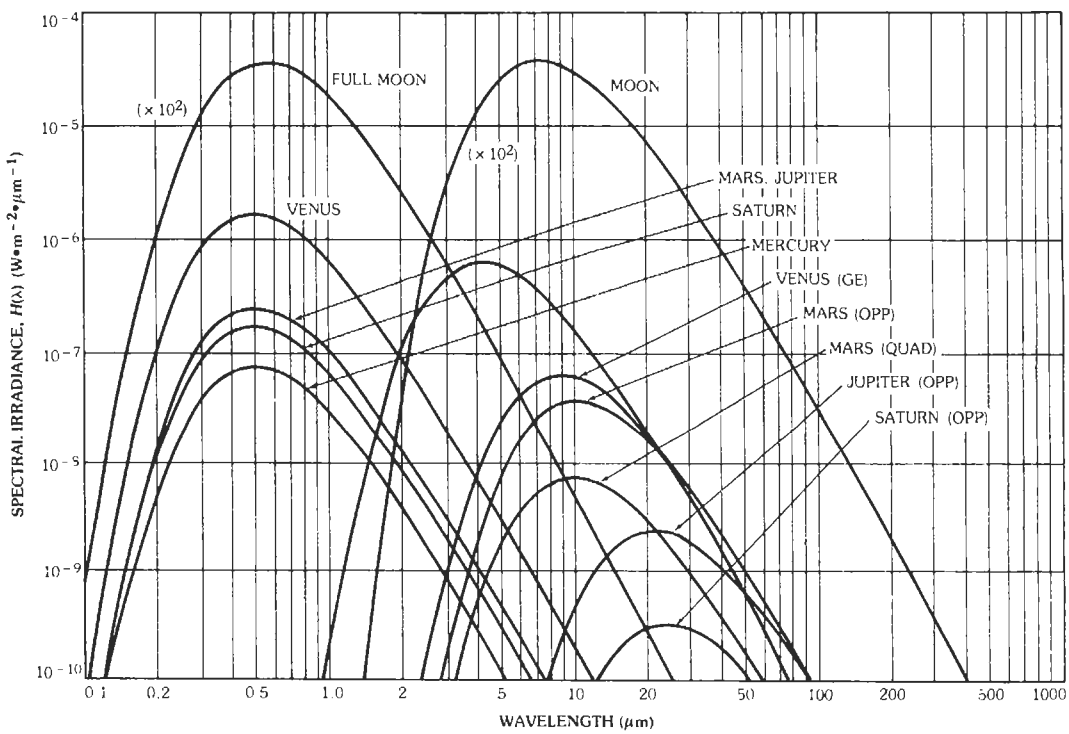

Fig. 15. Calculated planetary and lunar spectral irradiance outside the terrestrial atmosphere. (*From Pratt, W. K. Laser Communications Systems. New York: John Wiley & Sons, Inc., 1968, p. 123.*)

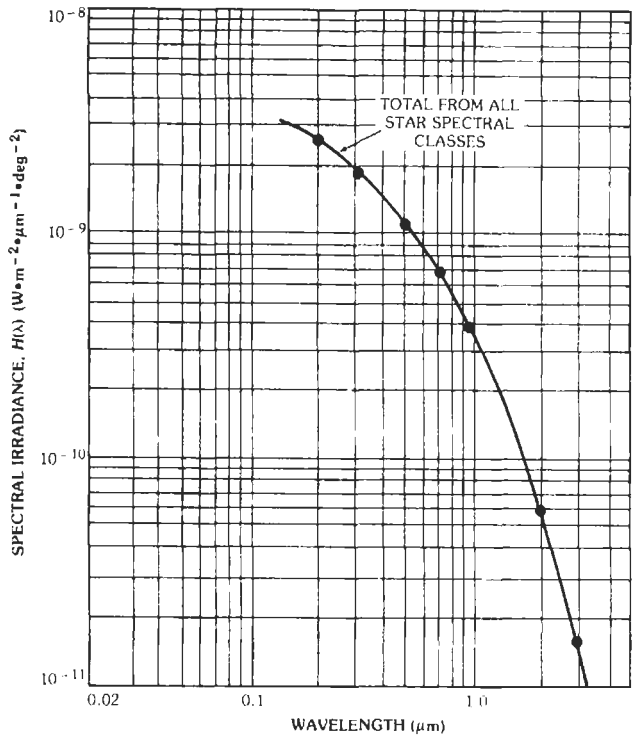

Fig. 16. Probable spectral irradiance from a one-square-degree star field near the galactic plane. (*From* RCA Electro-Optics Handbook. *RCA Commercial Engineering, 1974, p. 69.*)

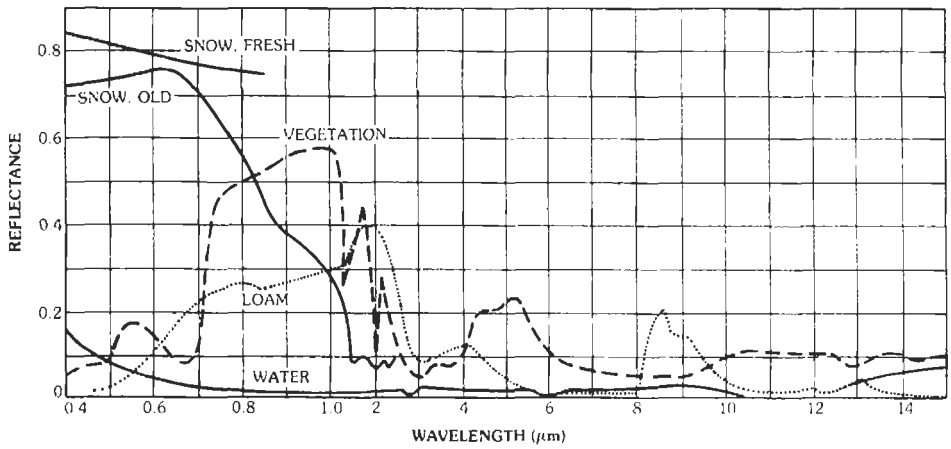

Fig. 17. Typical reflectance of water surface, snow, dry soil, and vegetation. (*From* Handbook of Optics. *New York: McGraw-Hill Book Co., 1978, pp. 14–54.*)

various absorption band complexes. Strong absorption lines occur most frequently at ultraviolet ($\lambda < 0.3$ μm) and infrared ($\lambda > 0.9$ μm) wavelengths, where they can severely limit the effective range of an optical communication system. Computer programs have been developed to calculate the detailed absorption spectrum for various atmospheric models.* Attenuation coefficients have also been tabulated for some of the more common laser wavelengths.† Fig. 18 shows the spectral transmittance

* Reference 11.
† Reference 12.

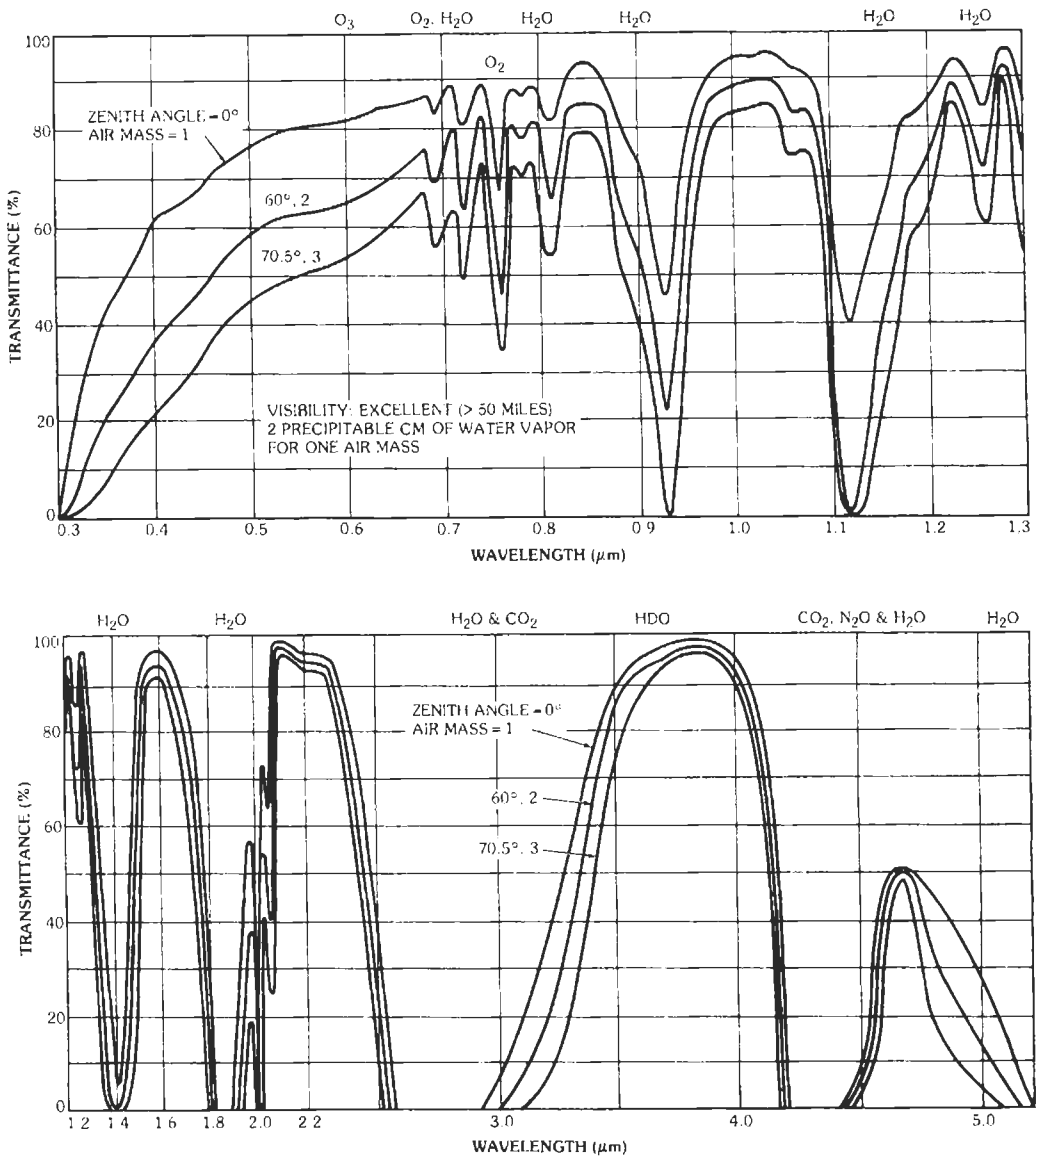

Fig. 18. Spectral transmittance from the atmosphere of the earth for varying optical air masses. (*From* RCA Electro-Optics Handbook. *RCA Commercial Engineering, 1974, p. 83.*)

through the entire atmosphere from sea level to space for several zenith angles. Fig. 19 shows the transmittance over a 1000-foot horizontal path at sea level between 0.5 μm and 25 μm. These figures illustrate the fact that certain wavelengths are strongly attenuated even for relatively short propagation path lengths.

Scattering

The attenuation coefficient due to scattering by gas molecules is dominated by the elastic component. Because the size of the gas molecules is small compared to the optical wavelength, the attenuation coefficient can be expressed in terms of the Rayleigh cross section σ_R

$$\alpha_{g,s} = N_g \sigma_R \qquad \text{(Eq. 72)}$$

where N_g is the number density of the gas molecules. For optical wavelengths, σ_R at altitudes below 100 km is given by*

* Reference 10.

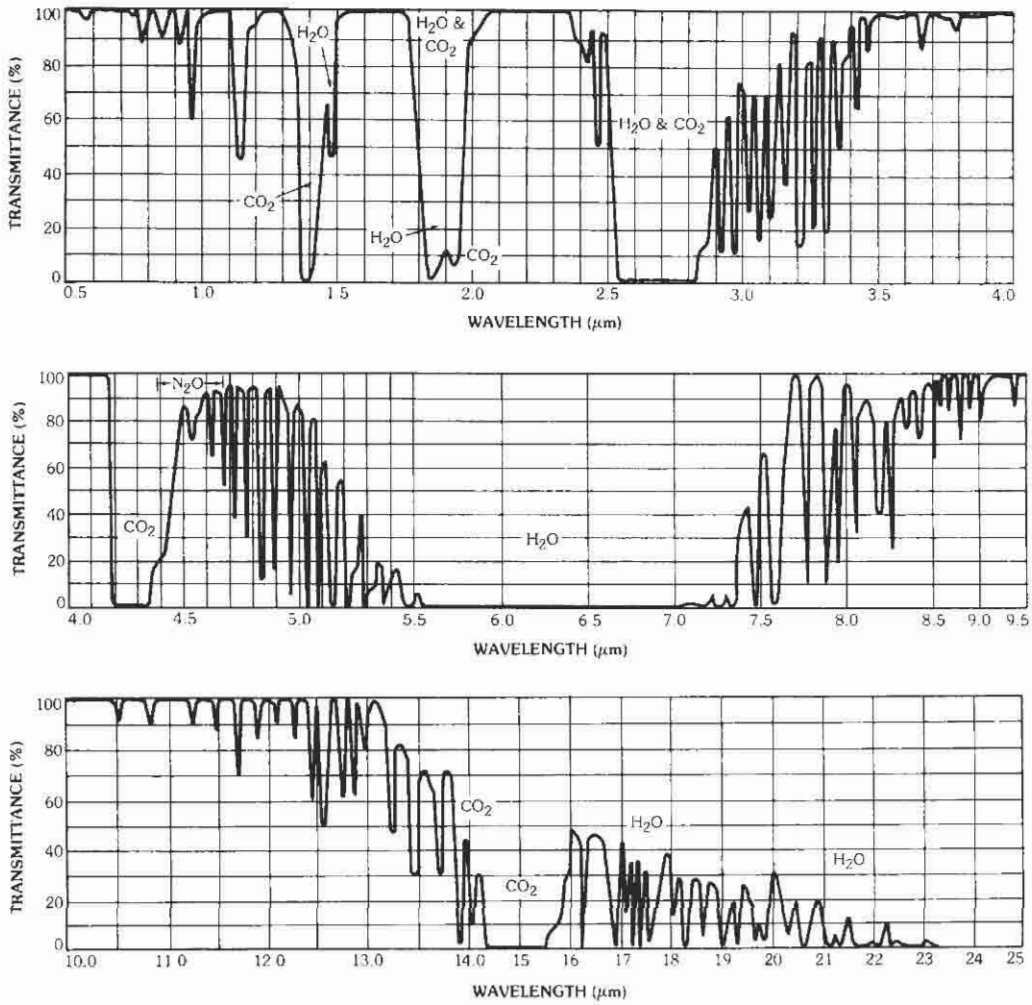

Fig. 19. Transmittance of 1000-ft horizontal air path at sea level containing 5.7 mm precipitable water at 79 °F. (*From* RCA Electro-Optics Handbook. *RCA Commercial Engineering, 1974, p. 84.*)

$$\sigma_R = 4.59[\lambda\ (\mu m)/0.55]^{-4} \times 10^{-27}\ cm^2 \qquad \text{(Eq. 73)}$$

Extensive tabulations of the Rayleigh attenuation coefficient based on several model atmospheres are included in reference 12.

Particulate and aerosol scattering depend on many factors, including the size distribution, shape, and composition (refractive index) of the scatterers. Fig. 20 shows the wavelength variation of the attenuation coefficient ($\alpha_{p,s}$) for various atmospheric conditions. At visible wavelengths, the attenuation coefficient is approximately*

$$\alpha(\lambda) \simeq (3.912/V_M)(0.55\ \mu m/\lambda)^{0.585\ V_M^{1/3}} \qquad \text{(Eq. 74)}$$

where V_M (km) is the meteorological visibility. Because precipitation particles are large compared to the optical wavelength, the corresponding attenuation coefficient does not depend on wavelength. Also, the dependence on the microstructure of the particles is negligible compared with the dependence on precipitation intensity. The attenuation coefficient for rains is approximately*

$$\alpha \cong 0.21\ r^{0.74}\ km^{-1} \qquad \text{(Eq. 75)}$$

where r is the rainfall rate (mm/hr).

Turbulence

Scattering by atmospheric turbulence reduces the spatial and temporal coherence of the signal beam. The

* Reference 10.

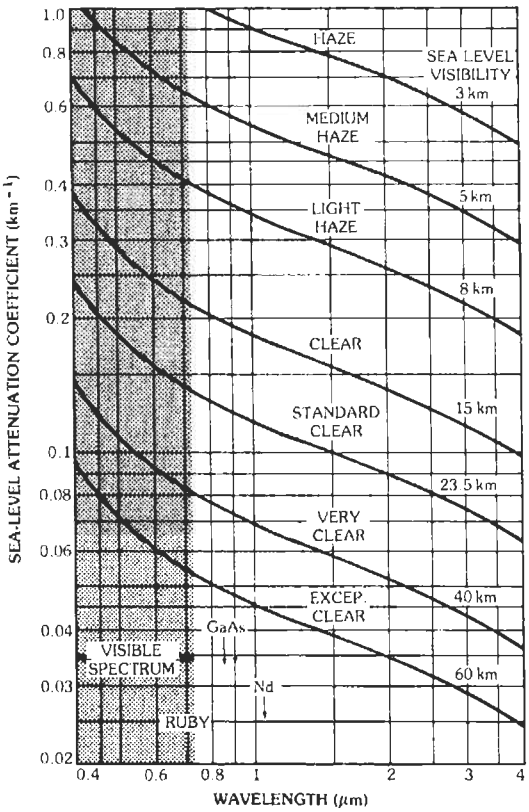

Fig. 20. Approximate variation of attenuation coefficient with wavelength at sea level for various atmospheric conditions. Absorption by water vapor and carbon dioxide is neglected. (*From* RCA Electro-Optics Handbook. *RCA Commercial Engineering, 1974, p. 89.*)

effect causes fading or scintillation in the signal power and a reduction in the SNR in heterodyne-detection receivers. In weak turbulence, the probability density of the intensity fluctuations is very nearly log-normal*

$$p(I) = [1/(2\pi)^{1/2} I\sigma] \exp\{-[\ln(I/\langle I\rangle) + (1/2)\,\sigma^2]^2/2\sigma^2\} \qquad \text{(Eq. 76)}$$

where,

$$\sigma^2 = \ln(1 + \sigma_I^2/\langle I\rangle^2) \qquad \text{(Eq. 77)}$$

σ_I^2 is the intensity variance,
$\langle I\rangle$ is the mean intensity.

In very strong turbulence, the intensity probability density approaches the exponential distribution

$$p(I) = (I/\langle I\rangle) \exp(-I/\langle I\rangle) \qquad \text{(Eq. 78)}$$

* Reference 13.

The intensity variance is a function of wavelength, path length, and turbulence strength. For weak turbulence, the intensity variance is given by

$$\sigma_I^2/\langle I\rangle^2 = \sigma_1^2 \qquad \text{(Eq. 79)}$$

where,

$$\sigma_1^2 = 1.23(2\pi/\lambda)^{7/6} C_n^2 z^{11/16} \qquad \text{(Eq. 80)}$$

C_n^2 is the refractive index structure parameter,
z is the path length.

The value of C_n^2 varies with altitude, meteorological conditions, and time of day. Typically, C_n^2 is maximum near noon, reaching values on the order of 10^{-14} to 10^{-13} $m^{-2/3}$. At night, the value ranges between 10^{-16} and 10^{-15} $m^{-2/3}$. Eq. 79 is valid for values of σ_1^2 up to approximately 0.3. In stronger turbulence, the normalized intensity variance is less than σ_1^2. For very strong turbulence, $\sigma_I^2/\langle I\rangle^2$ approaches a value near one.

Eqs. 76 through 79 describe the statistics of the signal-intensity fluctuations at a point. They can also be used to characterize the signal-power fluctuations for a direct-detection receiver if the aperture diameter is smaller than the intensity correlation length, ρ_c. The intensity correlation length is given approximately by

$$\rho_c \simeq \begin{cases} (\lambda z)^{1/2} & \sigma_1^2 \lesssim 0.3 \\ 0.36(\lambda z)^{1/2}/(\sigma_1^2)^{3/5} & \sigma_1^2 \gg 1 \end{cases} \qquad \text{(Eq. 81)}$$

Because of aperture averaging, power fluctuations are reduced in direct-detection receivers if the aperture area is large compared to the intensity coherence area ($\pi\rho_c^2$). This is illustrated in Fig. 21, where the ratio of the signal-power variance for a receiver of diameter $2a$

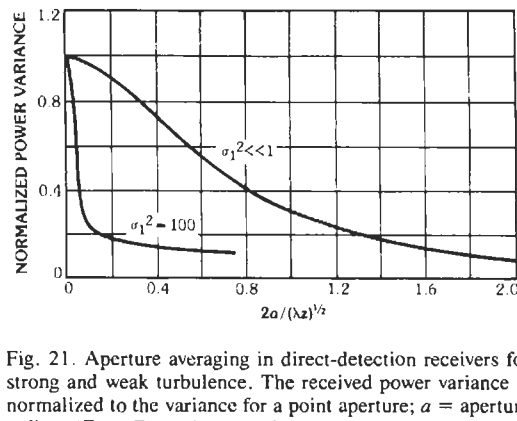

Fig. 21. Aperture averaging in direct-detection receivers for strong and weak turbulence. The received power variance is normalized to the variance for a point aperture; a = aperture radius. (*From Fante, R. L. "Electromagnetic Beam Propagation in Turbulent Media,"* Proc. IEEE, *63, December 1975, p. 1680.*)

to the variance for a point aperture is plotted versus aperture diameter. In both strong and weak turbulence, there is a significant reduction in the power fluctuations whenever the aperture diameter exceeds ρ_c.

Temporal fluctuations of signal intensity are caused by the movement and breakup of refractive inhomogeneities within the propagation path. The intensity temporal power spectrum has a cutoff frequency (f_c) that is related to the wind velocity normal to the propagation path ($V_\perp$) and the intensity correlation length:

$$f_c \simeq V_\perp/\rho_c \qquad \text{(Eq. 82)}$$

For weak turbulence, f_c is typically 10 to 100 Hz, whereas for strong turbulence, the cutoff frequency is approximately an order of magnitude higher. The inverse of f_c is the intensity coherence time and can be used to estimate the fade time.

Heterodyne-detection receivers are most affected by the signal phase fluctuations. Areas of the signal beam that are out of phase with the LO will add destructively at the detector and reduce the IF signal amplitude. This results in a reduction of the IF SNR. For plane-wave sources that are propagating horizontally, the phase correlation length (r_0) is given by the equation*

$$r_0 = [2.36\,(2\pi/\lambda)^2 C_n^2 z]^{-3/5} \qquad \text{(Eq. 83)}$$

The loss of phase coherence reduces the effective area of the receiver aperture. This is illustrated in Fig. 22, where the effective aperture area is plotted versus aperture diameter ($2a$). The effective area never exceeds the phase coherence area (πr_0^2). Because r_0 can be as small as 10 to 20 cm, this effect can severely limit receiver performance. Spatial diversity can be used to overcome some of these problems.†

FIBER WAVEGUIDE TRANSMISSION

In designing fiber-optic communication systems, there are two principle characteristics of optical fibers, attenuation and dispersion, that determine how much information can be sent and how far it can be sent. All current fiber-optic systems are either dispersion or attenuation limited. These characteristics, coupled with the transmitter and receiver characteristics, allow one to specify the type of fiber, transmitter, and receiver required for a particular application. Detailed design of fiber-optic systems is covered in specific fiber-optic handbooks. A representative sampling is given in the references.

Terminology

In order to specify the type of components required for a particular application, it is useful to be familiar with some of the important terminology and theory that is used in fiber optics.

There a two types of optical fiber predominately in use: single-mode step-index fiber and graded-index fiber. Single-mode step-index fiber is primarily used in high-bandwidth long-haul telecommunication systems. Graded-index fiber is primarily used in short-haul low-bandwidth systems such as local area networks (LANs).

The two types of fiber differ in how they guide the light. Single-mode step-index fiber has a small core region of a high-index glass (n_1) surrounded by a cladding region of lower index (n_2) (Fig. 23A). The normalized difference in the indices $\Delta = (n_1 - n_2)/n_1$* is usually small (0.001–0.02). The light is guided because it experiences total internal reflection at the core-cladding interface. (See "Snell's Law" below.)

Graded-index fiber differs from step-index fiber in that it has a continuously varying index-of-refraction profile from the center of the core to the cladding region (Fig. 23B). The functional form of the index profile is typically quadratic and is chosen to compensate for modal dispersion. In Fig. 23B, all the rays, regardless of the launch angle, take the same time to travel the length of the fiber.

Fig. 23C shows a multimode step-index fiber. Rays with different launch angles travel at different effective velocities, producing modal dispersion.

Snell's Law—For large core diameters, the light-guiding properties of optical fiber can be understood by the use of Snell's law and ray optics. Snell's law (refer to Fig. 24A) can be derived from the boundary conditions at the dielectric interface and is given by

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \qquad \text{(Eq. 84)}$$

* The choice of n_1 or n_2 in the denominator varies.

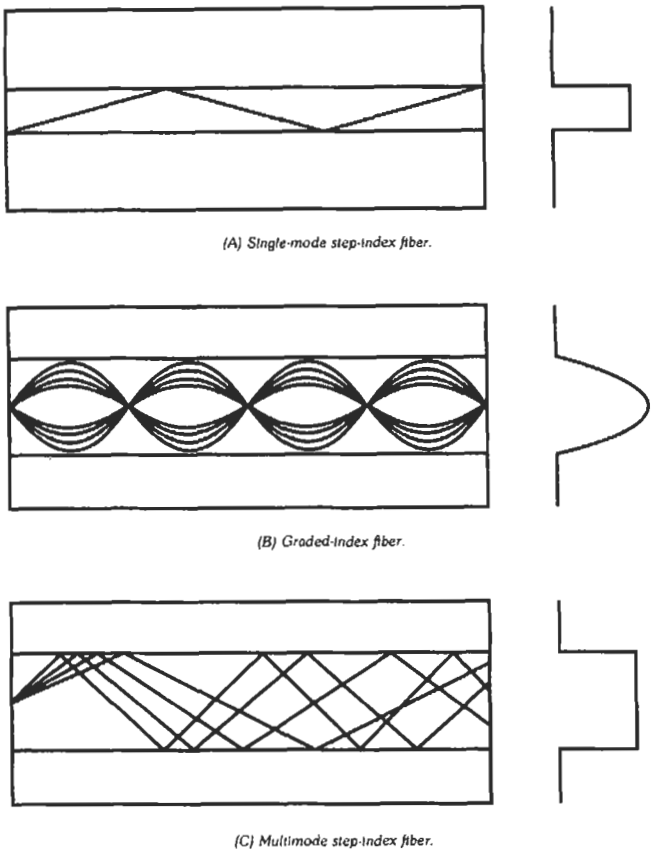

Fig. 23. Types of optical fiber. In each case, the index-of-refraction profile is shown on the right.

where the angles are measured from the normal to the interface. For light traveling from a higher-index material (n_1) to a lower-index material (n_2), the ray is refracted away from the normal. The critical angle θ_c is the incident angle where the refracted ray travels along the interface. When this occurs, $\sin \theta_2 = \sin(\pi/2) = 1$ (Fig. 24B), and Snell's Law yields

$$\theta_c = \sin^{-1}(n_2/n_1) \qquad \text{(Eq. 85)}$$

At angles greater than the critical angle, the ray is totally internally reflected (Fig. 24C) and is guided along the core.

Numerical Aperture—The numerical aperture of a fiber is a measure of the light-collecting ability of the fiber. For a large-core step-index fiber, it is the maximum angle θ_m that a ray can make with the axis of the fiber and still experience total internal reflection (Fig. 25). From the geometry in Fig. 25,

$$\sin \theta_m = \sqrt{n_1^2 - n_2^2} \approx n_1\sqrt{2\Delta} \quad \text{(Eq. 86a)}$$

$$\text{NA} = \sqrt{n_1^2 - n_2^2} \approx n_1\sqrt{2\Delta} \quad \text{(Eq. 86b)}$$

where $\Delta = (n_1 - n_2)/n_2$. The value of the numerical aperture changes slightly from the calculated values in Eqs. 86 for single-mode step-index fiber because a ray analysis is no longer strictly valid and diffractive effects have to be considered.

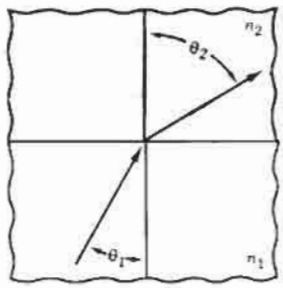
The numerical aperture of a graded-index fiber is defined slightly differently and is a function of the distance from the center of the core

$$\text{NA}(r) = \sqrt{n^2(r) - n_2^2} \qquad \text{(Eq. 87)}$$

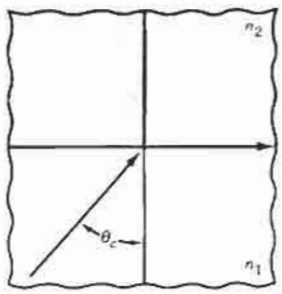
where $n(r)$ is the index profile (typically quadratic). The numerical aperture is now a function of r and is maximum for a thin beam along the axis. Values of the numerical aperture vary from ≈ 0.13 for single-mode step-index fiber to ≈ 0.3 for large-core graded-index fiber.

Group Index and Group Delay—The index of refraction n of a plane wave $\exp[-j(\omega t - \beta z)]$ in a medium is given by

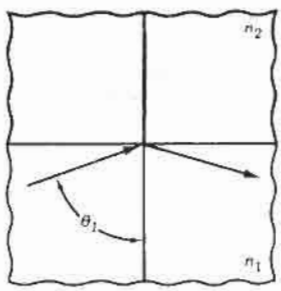
$$n = \beta/k \qquad \text{(Eq. 88)}$$



(A) Angle of incidence is **less than critical** angle



(B) Angle of incidence equals critical angle



(C) Total internal reflection; incident angle exceeds critical angle

Fig. 24. Snell's law of reflection.

where,

ω is the temporal frequency,
β is the propagation constant,
$k = \omega/c$,
c is the speed of light in free space.

The group index is the speed at which a pulse travels in a medium. For a pulse with a temporal width τ much less than the inverse of the optical frequency ($\tau << 1/\omega$), the group index N is given by

$$N = \partial\beta/\partial k = \partial(nk)/k = n + k(dn/dk) = n + \omega(dn/d\omega) = n\,[-\lambda(dn/d\lambda)] \qquad \text{(Eq. 89)}$$

The total time for a pulse to travel a distance L is given by

$$t = L/v_g = NL/c \qquad \text{(Eq. 90)}$$

and the differential delay δt of the pulse is given by

$$\delta t = L/v_g = (L/c)\,\delta N \qquad \text{(Eq. 91)}$$

These formulas are useful for dispersion calculations.

V-Number—Most commercial single-mode step-index fiber has a small index contrast Δ. Solutions to the wave equation for these "weakly guiding" geometries yield modes that are commonly referred to as LP modes. An important parameter that characterizes these solutions is the V number defined as

$$V = k \cdot a \cdot \mathrm{NA} \qquad \text{(Eq. 92)}$$

where,

$k = \omega/c$,
a is the core radius,
NA is the numerical aperture ($\mathrm{NA} = \sqrt{n_1^2 - n_2^2} = n_1\sqrt{2\Delta}$).

Note that V depends on λ through k. By using weakly guiding theory,* it can be shown that for $V < 2.40483$ (first zero of $J_0(x)$), only one mode will propagate. The dependence of β on V for the LP_{01} mode is shown in Fig. 26.

Losses

The dominant loss mechanisms in silica fiber are absorption (ultraviolet, infrared, and impurity) and

* Reference 16.

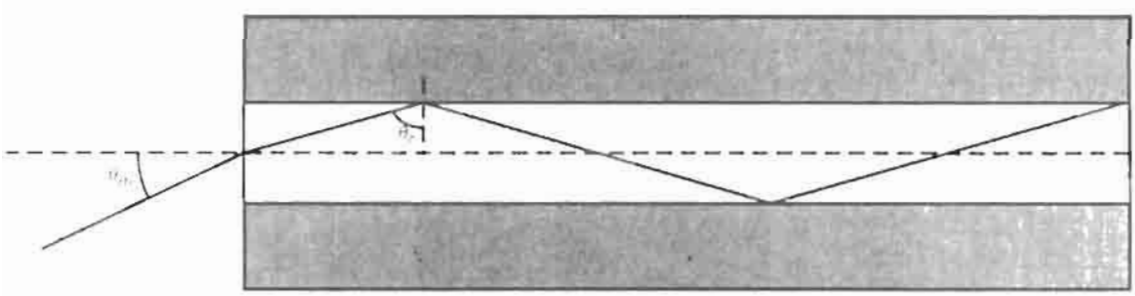


Fig. 25. Rays being reflected or refracted at the core-clad boundary.

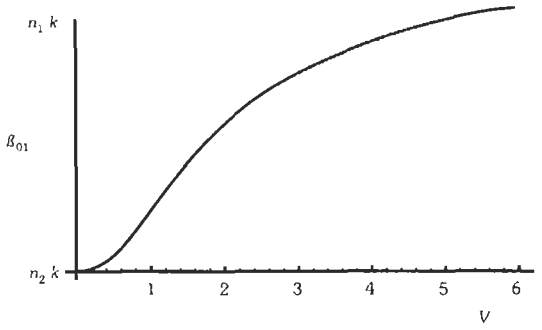

Fig. 26. The dependence of the propagation constant β on the V parameter for the LP_{01} mode in a single-mode fiber.

Rayleigh scattering. Ultraviolet absorption and Rayleigh scattering limit short-wavelength operation, and infrared absorption is dominant for wavelengths above about 1.6 μm. Impurity absorption from residual OH effects adds losses between 1.3 and 1.5 μm. For commercial fiber, it is Rayleigh scattering, which is proportional to $1/\lambda^4$, and infrared absorption that set the limits on losses within the wavelength regions of interest. Modern optical fiber operates at very close to these theoretical limits. The attenuation minimum for silica fiber occurs at about 1.55 μm and is < 0.2 dB/km. The attenuation minimum at 1.55 μm is the reason why this wavelength is used in long-haul systems. Typical absorption curves for various fibers are shown in Fig. 27.

Dispersion

Dispersion is the wavelength or modal dependence of propagation constant β. In fiber optic systems, one is generally interested in pulse propagation through the fiber. In general, the pulse can be decomposed into modes, and for each mode the pulse can be further decomposed into wavelength components. Each of the modes and each wavelength component within each mode will travel at a slightly different velocity. The result is that the pulse broadens as it travels down the fiber, and thus the amount of information that can be transmitted is reduced.

Modal Dispersion—The dependence of the propagation constant on the mode number is called modal dispersion. It can be eliminated by using single-mode step-index fiber. However, in graded-index fiber that supports many modes, an incident pulse will excite several modes. Each mode will travel at a different group velocity. It can be shown* that a quadratic index profile minimizes the modal dispersion and that the modal dispersion is given by

$$\delta t = (Ln_1/c)(\Delta^2/4) \qquad \text{(Eq. 93)}$$

where,

δt is the temporal spread of the pulse,
L is the total distance traveled,
$\Delta = (n_1 - n_2)/n_1$,
n_1 is the peak index at the center of the core.

Material Dispersion—Material dispersion is caused by the wavelength dependence of the index of refraction. It affects pulse broadening because each wavelength component of an initial pulse travels at a different group velocity.

If the initial pulse has a spectral width $\delta\lambda$, then if we use differentials $\delta\lambda/\delta N = d\lambda/dN$. The differential time δt for a pulse to travel a length L is $\delta t = \delta NL/c$. Using these relations, we can write the material response time as

$$\delta t = |D_\lambda|\ \delta\lambda\ L \qquad \text{(Eq. 94)}$$

where D_λ is the material dispersion coefficient given by

$$D_\lambda = (-\lambda/c)(d^2n/d\lambda^2) \qquad \text{(Eq. 95)}$$

The units of the material dispersion coefficient are usually ps/nm · km. For silica fiber, the term $d^2n/d\lambda^2$ crosses zero near $\lambda \approx 1.3$ μm. This is the zero material dispersion wavelength and is one of the reasons that 1.3-μm light is used in fiber optic systems.

As can be seen by examining Eq. 95, the effect of material dispersion can also be minimized by using a transmitter with a very narrow wavelength spectrum so that all of the wavelength components lie within a narrow band. This is one of the reasons why narrow-spectral-width lasers (typically distributed feedback lasers) are used in long-haul systems.

Waveguide Dispersion—In the absence of material and modal dispersion, there is still a dependence of the propagation constant β on the wavelength. This is called waveguide dispersion and can be understood by considering the distribution of the field within the core and cladding regions (Fig. 28). For a single mode, if the wavelength is such that the mode is well guided, then a large fraction of the energy is carried in the core region. As the wavelength changes and approaches cutoff for that mode, more and more energy is carried in the cladding region, and a different effective group index results.

Waveguide dispersion is determined by using the expression for the group index, Eq. 89

$$N = d\beta/dk = (d\beta/dV)(dV/dk) = (d\beta/dV)\ a \cdot \text{NA} \qquad \text{(Eq. 96)}$$

where $V = k \cdot a \cdot \text{NA}$ has been used. Now by using $\delta t = (dN/d\lambda)\ L/c\ \delta\lambda$ and changing variables from λ to V, the waveguide dispersion can be written as

$$\delta t = |D_w|\ \delta\lambda\ L \qquad \text{(Eq. 97)}$$

* Reference 17.

Fig. 28. Field distribution for the LP_{01} mode. The different distributions of the field within the core region yield different effective indices and produce waveguide dispersion.

where

$$D_w = -(1/2\pi c)\, V^2\, (d^2\beta/dV^2) \quad \text{(Eq. 98)}$$

The dependence of D_w on λ is through the dependence of V on λ. The units of D_w are the same as those for material dispersion.

Dispersion-Flattened and Dispersion-Shifted Fibers—The combined effect of material and waveguide dispersion is commonly called chromatic dispersion because both of these effects depend on the wavelength of the light.* The total chromatic dispersion is a function of both of D_λ and D_w. The material dispersion coefficient is generally fixed because most fiber is made of silica glass. However, the waveguide dispersion is a function of the geometry of the fiber. By changing the guiding properties of the fiber, the combined effect of the material and waveguide dispersion can be shifted from the material dispersion minimum of 1.3 μm to the attenuation minimum of 1.55 μm (see Fig. 29A). One can also produce two chromatic dispersion minimal results in a fiber than has a flat dispersion response between the two chromatic dispersion zeros (Figs. 29B and 29C).

Fiber Bandwidth

The bandwidth of a fiber is limited by dispersion; depending on the type of fiber, this may be modal or chromatic dispersion. For all the dispersive mechanisms, the amount of pulse spreading is a function of the distance L traveled. Thus, fiber bandwidth is generally specified as the product of the bandwidth times the distance (i.e., MHz · km or GHz · km).

Single-Mode Step-Index Fibers—The bandwidth of a single-mode step-index fiber is limited by material and waveguide dispersion. Modal dispersion is not present. However, both material and waveguide dispersion depend on the spectral width of the source. The data sheets of most manufacturers of single-mode step-index fiber will fit the total chromatic dispersion ps/nm · km to a polynomial within the wavelength range from about 1.3 to about 1.55 μm. They also list a range of values for the zero chromatic dispersion wavelength. From these values and the spectral width of the source, an overall bandwidth distance product (GHz · km) can be determined.

Graded-Index Fibers—The core diameter for graded-index fiber is much larger than for single-mode step-index fiber (50 and 62.5, 85 and 100 μm are standard core sizes) and allows for easier alignment and splicing. However, even with the quadratic index profile, modal dispersion is usually the dominant dispersive mechanism because of the difficulty in manufacturing an optimal index profile. In general, modal dispersion is only weakly dependent on the spectral width of the laser. Thus, in contrast to single-mode step-index fiber, the bandwidth distance product of graded-index fiber is specified independently of the spectral width of the source. The actual bandwidth of graded-index fiber varies from run to run because of the sensitivity of the bandwidth on the index profile. Typical available bandwidths and attenuation are given in Table 1. A frequency response curve of a 50-μm-core graded-index fiber at 1.3 μm is shown in Fig. 30.

Splicing

Whenever two sections of fiber are to be permanently joined, a splice is required. There are several types of splicing technology, with fusion splicing and mechanical splicing being two of the more common technologies. In fusion splicing, the ends of the fiber are permanently fused. In mechanical splicing, the fibers are aligned by using a mechanical sleeve, and then epoxy is applied to produce an index match between the two ends. A sample histogram of splice losses for a typical commercially available mechanical splice for a single-mode fiber is shown in Fig. 31. Losses for fusion splicing and other types (such as the AT&T rotary splice) are in the range 0.02–0.07 dB.

Connectors

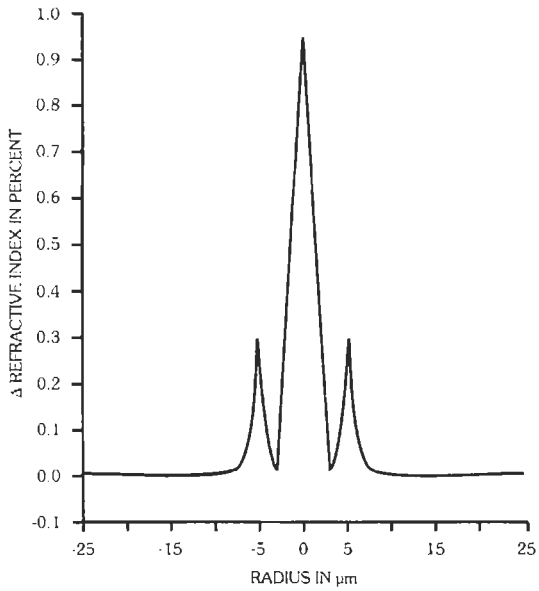
Connectors are used for temporary connections and whenever a system may need to be reconfigured. This is

* Other references restrict chromatic dispersion to refer only to material dispersion.

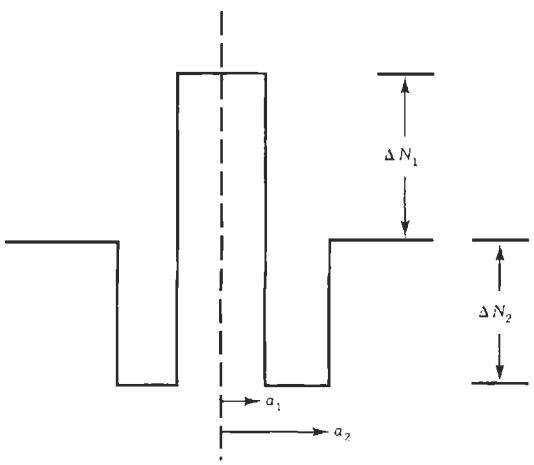
typically the case with fiber-optic LANs. There are many different kinds of connectors for both multimode and single-mode fiber. A typical loss histogram of two of the more common multimode fiber connectors (ST and SMA) is shown in Fig. 32.

Sample Calculation

If the frequency response of the fiber and the type of pulse for the data are known, the maximum data rate can be determined for graded-index fiber. This maximum data rate is approximately independent of the spectral width of the source.



(A) Index profile for commercial dispersion-shifted fiber. (Courtesy Corning, Inc.)



(B) Index profile for "W"-profile dispersion-flattened fiber.

For example, if the data is assumed to consist of Gaussian pulses of the form

$$f(t) = [1/(\sigma\sqrt{2\pi})] \exp(-t^2/2\sigma^2) \quad \text{(Eq. 99)}$$

then integrating Eq. 99 from -2σ to 2σ yields 95% of the total energy. If we define 4σ as the pulse interval, the pulse rate R_m is

$$R_m = 1/4\sigma \quad \text{(Eq. 100)}$$

The relationship between the optical 3-dB point (Fig. 30) and σ is given by*

$$\text{BW (3 dB opt.)} = 0.19/\sigma \quad \text{(Eq. 101)}$$

and is shown in Fig. 33. Note that while Eqs. 100 and 101 are strictly true only for a Gaussian pulse, Eq. 100 is approximately true if the rms values are used for the pulse width. (See sections 2.4.2 and 2.4.3 of reference 18.)

From Eqs. 100 and 101, the maximum pulse rate for the fiber shown in Fig. 30 is given by

$$R_m = 925/(0.19 \times 4) \approx 1.2 \text{ Gb/s} \cdot \text{km} \quad \text{(Eq. 102)}$$

at 1.3 μm. Thus for a 10-km link, the maximum data rate is roughly 120 Mb/s.

23 Analog Communications

Revised by
Michael B. Pursley

Modulation is a process whereby certain characteristics of a wave (often called a carrier) are varied or selected in accordance with a message signal. Modulation can be divided into continuous modulation, in which the modulated wave is always present, and pulsed modulation, in which no signal is present between pulses. Digital data modulation is discussed in Chapter 24.

PART 1—CONTINUOUS MODULATION

In continuous modulation* the modulated carrier can be given by the expression $s(t) = A(t)\cos\theta(t)$, where $A(t)$ is the *instantaneous amplitude* and $\theta(t)$ is the *instantaneous phase*. For a sinusoidal carrier of angular frequency ω_c, this expression reduces to $s(t) = A(t)\cos[\omega_c t + \phi(t)]$, where $\phi(t)$ is the carrier phase. When the instantaneous amplitude $A(t)$ is varied linearly by the message function and the carrier phase is constant, the process is called *amplitude modulation;* when the carrier phase angle $\phi(t)$ is modulated by the message function, the process is called *angular or phase modulation.*

The concept of a rotating vector can be used to represent a sinusoidal vector modulated in both amplitude and phase as shown in Fig. 1, where $s(t)$ is represented as the projection of a rotating vector on a fixed reference axis.

$$s(t) = A(t)\cos[\omega_c t + \phi(t)]$$

$$= \mathrm{Re}(A(t)\exp\{j[\omega_c t + \phi(t)]\})$$

In these expressions, $A(t)$ represents the envelope of the modulated carrier, and $\phi(t)$ is the modulated phase. The vector rotates with an instantaneous angular frequency $\omega_i(t)$ given by

$$\omega_i(t) = \omega_c + [d\phi(t)/dt]$$

In amplitude modulation, only the amplitude changes, and the general expression reduces to

$$s(t) = \mathrm{Re}[A(t)\exp(j\phi_0)\cdot\exp(j\omega_c t)]$$

* P. F. Panter, *Modulation, Noise, and Spectral Analysis* (New York: McGraw-Hill Book Co., 1965; Ch. 5 and 6).

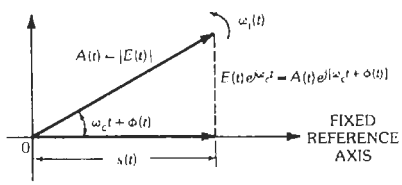

Fig. 1. Fixed-reference vector diagram. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 2-7, © 1965, McGraw-Hill Book Co.*)

In phase modulation, only the phase changes so that

$$s(t) = \mathrm{Re}\{A_c\exp[j\phi(t)]\cdot\exp(j\omega_c t)\}$$

where A_c is constant.

ANALYTIC SIGNAL REPRESENTATION OF MODULATED WAVEFORMS

A real signal

$$s(t) = A(t)\cos[\omega_c t + \phi(t)]$$

may be expressed either as

$$s(t) = \mathrm{Re}(A(t)\exp\{j[\omega_c t + \phi(t)]\})$$

or as

$$s(t) = \mathrm{Re}[\psi(t)]$$

where $\psi(t)$ is the analytic signal defined by

$$\psi(t) = s(t) + j\hat{s}(t)$$

The function $\hat{s}(t)$ is the Hilbert transform of $s(t)$, namely

$$\hat{s}(t) = \pi^{-1}\int_{-\infty}^{\infty}\frac{s(\tau)}{t-\tau}\,d\tau$$

Basically, the analytic signal $\psi(t)$ is a complex function of a real variable whose real and imaginary parts form a Hilbert pair. The analytic signal is simply a formalized version of the "rotating vector" discussed above. If $S(j\omega)$ is the Fourier transform of $s(t)$, then $\Psi(j\omega)$, the Fourier transform of $\psi(t)$, can be written in terms of $S(j\omega)$ as

$$\Psi(j\omega) = 2S(j\omega) \quad \omega > 0$$

$$= S(j\omega) \quad \omega = 0$$

$$= 0 \quad \omega < 0$$

Also, $\hat{S}(j\omega)$, the Fourier transform of $\hat{s}(t)$, is given by the equation

$$\hat{S}(j\omega) = -j(\mathrm{sgn}\omega)S(j\omega)$$

where

$$\mathrm{sgn}x = 1 \quad x > 0$$

$$= 0 \quad x = 0$$

$$= -1 \quad x < 0$$

and $\mathrm{sgn}x$ is the signum function.

AMPLITUDE MODULATION

In amplitude modulation, the frequency components of the modulating signal are translated to occupy a different position in the spectrum. It is essentially a multiplication process in which the time functions that describe the modulating signal and carrier are multiplied together. The following amplitude-modulation systems are discussed.

(A) Double-sideband suppressed carrier (DSB-SC), also called DSB
(B) Conventional amplitude modulation (AM)
(C) Vestigial sideband
(D) Single sideband (SSB)

Double Sideband (DSB)

In DSB modulation, the message signal $g(t)$, whose Fourier transform is $G(j\omega)$, is considered to have zero dc component. The product

$$e(t) = A_c g(t) \cos\omega_c t$$

represents a double-sideband suppressed-carrier signal, and A_c = amplitude of unmodulated carrier. The radio-frequency envelope follows the waveform of the modulating signal $g(t)$ as shown in Fig. 2. The spectral components of the DSB signal $e(t)$ are given by its Fourier transform

$$E(j\omega) = \tfrac{1}{2}G[j(\omega - \omega_c)] + \tfrac{1}{2}G[j(\omega + \omega_c)]$$

as shown in Fig. 3. Note that the upper and lower sidebands are translated symmetrically $\pm\omega_c$ about the origin.

Conventional Amplitude Modulation (AM)

In amplitude modulation, a dc term is added to the modulating signal $g(t)$. The resulting waveform, shown

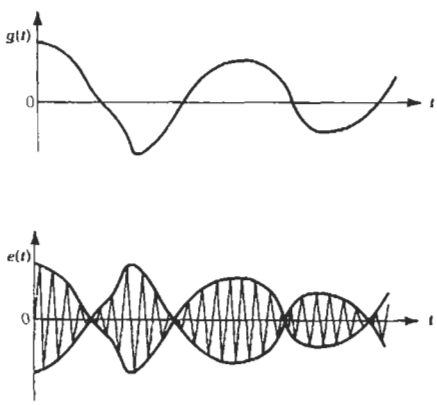

Fig. 2. Double-sideband waveforms. (*From P. F. Panter, Modulation, Noise, and Spectral Analysis, Fig. 5-3, © 1965, McGraw-Hill Book Co.*)

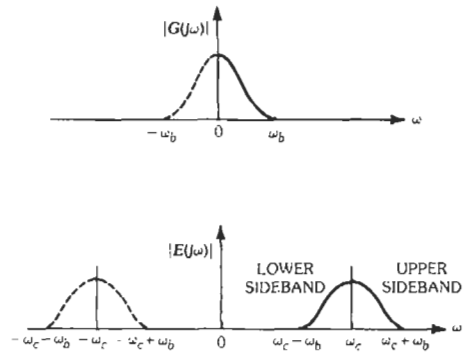

Fig. 3. Baseband signal and double-sideband spectra. (*From P. F. Panter, Modulation, Noise, and Spectral Analysis, Fig. 5-2, © 1965, McGraw-Hill Book Co.*)

in Fig. 4, is given by

$$e(t) = [A_0 + as(t)]\cos\omega_c t$$

$$= A_0\,[1 + m_a s(t)]\cos\omega_c t$$

where,

a = maximum amplitude of modulating function, $g(t) = as(t)$, $|s(t)| \leq 1$,
$m_a = a/A_0$ = modulation index or degree of modulation, $0 \leq m_a \leq 1$,
A_0 = amplitude of unmodulated carrier, $|m_a s(t)| \leq 1$, to ensure an undistorted envelope.

Vestigial Sideband

Vestigial-sideband modulation is derived from a DSB signal by passing the output of the product modulator through a filter whose transfer function is $H_v(j\omega)$, as shown in Fig. 5. The transfer function $H_v(j\omega)$ of the filter treats the two sidebands of the DSB signal in such a manner as to attenuate one sideband differently from the other. The process of vestigial-sideband modulation by the use of the filter network $H_v(j\omega)$ may be replaced by the equialent vestigial system shown in Fig. 6, where the transfer functions $H_i(j\omega)$ and $H_q(j\omega)$ are given by

$$H_i(j\omega) = \tfrac{1}{2}\{H_v[j(\omega - \omega_c)] + H_v[j(\omega + \omega_c)]\}$$

$$H_q(j\omega) = (1/2j)\{H_v[j(\omega - \omega_c)] - H_v[j(\omega + \omega_c)]\}$$

Single Sideband (SSB)

Single-sideband transmission may be produced in the same manner as vestigial sideband by using a high-pass filter $H_s(j\omega)$ which completely eliminates all signals on one side of the carrier frequency. The transfer function $H_s(j\omega)$ of the ideal high-pass filter is defined by

$$H_s(j\omega) =$$
$$[\tfrac{1}{2} + \tfrac{1}{2}\,\mathrm{sgn}(\omega - \omega_c)] + [\tfrac{1}{2} - \tfrac{1}{2}\,\mathrm{sgn}(\omega - \omega_c)]$$

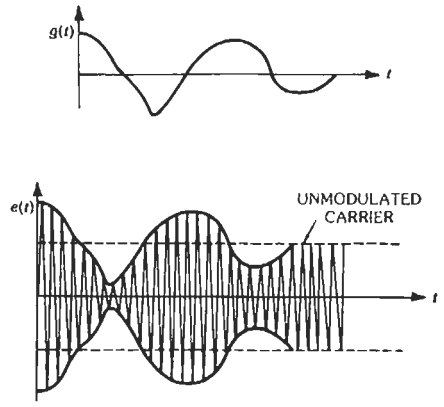

Fig. 4. Amplitude modulation. The modulating signal is at top and the modulated carrier at bottom. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 5-4,* © *1965, McGraw-Hill Book Co.*)

where sgnω is the signum function. The output spectrum $E_s(j\omega)$ is given by

$$E_s(j\omega) = H_s(j\omega)E(j\omega)$$

$$= \tfrac{1}{2}G[j(\omega - \omega_c)][\tfrac{1}{2} + \tfrac{1}{2}\,\mathrm{sgn}(\omega - \omega_c)]$$

$$+ \tfrac{1}{2}G[j(\omega + \omega_c)][\tfrac{1}{2} - \tfrac{1}{2}\,\mathrm{sgn}(\omega + \omega_c)]$$

The SSB signal can also be regarded as the resultant of quadrature modulation of a carrier by a pair of signals in phase quadrature. The modulated wave

$$e_s(t) = s(t)\cos\omega_c t - \sigma(t)\sin\omega_c t$$

represents an upper-sideband signal with no spectral components below the carrier angular frequency ω_c, where $s(t)$ is an arbitrary message function and $\sigma(t)$ its harmonic conjugate.

This equation can be written in the form

$$e_s(t) = [s^2(t) + \sigma^2(t)]^{1/2}$$

$$\cos\{\omega_c t + \tan^{-1}[\sigma(t)/s(t)]\}$$

$$= \alpha(t)\cos[\omega_c t + \phi(t)]$$

regarding the single-sideband signal as a hybrid amplitude-modulated and phase-modulated wave. The envelope $\alpha(t)$ and phase $\phi(t)$ are related by the analytic signal

$$\psi(t) = s(t) + j\sigma(t) = \alpha(t)\exp[j\phi(t)]$$

where $\sigma(t) = s(t)$, the Hilbert transform of $s(t)$. The amplitude and phase of the complex signal $\psi(t)$ are identical to the envelope and phase of the single-sideband wave. The Fourier transform of the analytic signal $\psi(t)$ is

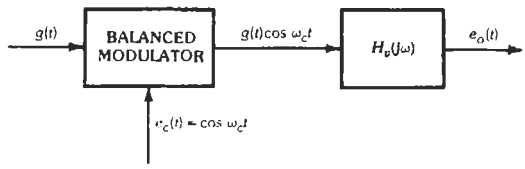

Fig. 5. Vestigial-sideband transmission system. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 5-7,* © *1965, McGraw-Hill Book Co.*)

$$\Psi(j\omega) = S(j\omega) + jS(j\omega)$$

$$= S(j\omega) + S(j\omega) = 2S(j\omega), \qquad \omega > 0$$

$$= S(j\omega) - S(j\omega) = 0, \qquad \omega < 0$$

Thus, a study of single sideband can be made through the analytic signal without reference to the arbitrary carrier frequency ω_c.

DEMODULATION, OR DETECTION, OF AMPLITUDE MODULATION

The process of separating the modulating signal from a modulated carrier is called demodulation or detection. In DSB or SSB detection, the detector must be supplied with a carrier wave that is synchronized with the wave used at the transmitter. This method of detection is called coherent or synchronous detection. In conventional amplitude-modulation systems, coherent detection is not necessary, and the modulating signal may be recovered by the use of envelope detection; e.g., the modulated carrier is applied to a half-wave rectifier whose output is then filtered to provide the desired modulating signal.

DSB Detection

In DSB reception, the incoming signal $e_r(t)$ is multiplied by a locally generated signal that is phase-synchronized with the carrier component of the received

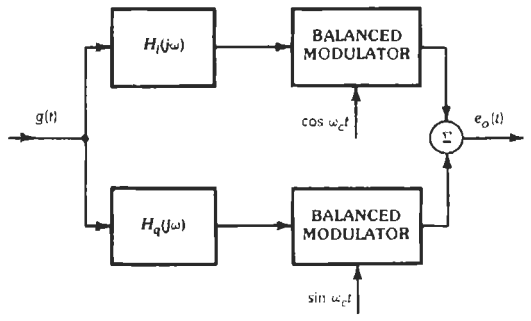

Fig. 6. Equivalent vestigial-sideband transmission system. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 5-8,* © *1965, McGraw-Hill Book Co.*)

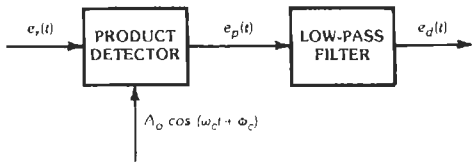

Fig. 7. Block diagram of double-sideband (DSB) receiver. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 6-1,* © *1965, McGraw-Hill Book Co.*)

signal $e_r(t)$, as shown in Fig. 7. The detected output after filtering is given by

$$e_d(t) = kg(t)\cos(\phi_c - \phi_0), \qquad k = \text{constant}$$

where $(\phi_c - \phi_0)$ represents the phase difference between the transmitted carrier and the locally generated oscillator. When the local carrier is in phase with the incoming carrier, the detected signal is maximum. The output signal-to-noise ratio $(S/N)_o$ is related to the input signal-to-noise ratio $(S/N)_i$ by the expression

$$\frac{(S/N)_o}{(S/N)_i} = 2\cos^2(\phi_c - \phi_0)$$

where the noise in each case is measured in a band occupied by the signal. This represents a maximum improvement of 3 decibels when the local oscillator is in phase with the incoming carrier.

AM Detection

Synchronous Detection:

$$\frac{(S/N)_o}{(S/N)_i} = \frac{2m_a^2 \langle g \rangle^2(t)\cos^2(\phi_c - \phi_0)}{1 + m_a^2 \langle g \rangle^2(t)}, \quad |g(t)| \leq 1$$

where $\langle g \rangle^2(t)$ equals the mean-square value of the message function, which is maximum for $m_a = 1$ and $\phi_c = \phi_0$.

Envelope Detection: In case of a carrier much stronger than the noise (high input carrier-to-noise ratio), we have

$$\frac{(S/N)_o}{(S/N)_i} = \frac{2m_a^2 \langle g \rangle^2(t)}{1 + m_a^2 \langle g \rangle^2(t)}$$

which is identical to the case of synchronous detection with $\phi_c = \phi_0$.

In case of poor input carrier-to-noise ratio, the message function $g(t)$ may be lost in the noise, which results in a threshold effect. This effect exists only in envelope detection and does not exist if synchronous or coherent detection is used.

SSB Detection

$$(S/N)_o/(S/N)_i = \cos^2(\phi_c - \phi_0)$$

where the signal component of the output is measured by the correlation of the detected output with the transmitted signal.

COMPARISON OF AMPLITUDE-MODULATION SYSTEMS

For equal power in the sidebands, the output signal-to-noise power ratios are identical.

For the same average total transmitted power, the following relations hold.

$$(S/N)_o(\text{DSB})/(S/N)_o(\text{AM}) = 1 + r^{-1}$$

where r equals the ratio of the mean-square power of the message function to its peak power, and

$$(S/N)_o(\text{DSB})/(S/N)_o(\text{SSB}) = 1$$

For equal peak power

$$(S/N)_o(\text{DSB})/(S/N)_o(\text{AM}) = 4$$

for any waveform of the modulating signal.

To compare the merits of SSB versus DSB and AM on the basis of the signal-to-noise ratio, the waveform of the modulating signal must be specified. This is illustrated in Fig. 8 for a modulating signal $\sin^\nu x$, $0 \leq \nu \leq 1$.

EXPONENTIAL MODULATION

In exponential or angular modulation, the carrier analytic signal $A_c\exp[j(\omega_c t + \phi_c)]$ is multiplied by the transformed message function $\exp[j\psi(t)]$ to produce an angle-modulated carrier analytic signal.

$$e(t) = \text{Re}\{A_c\exp[j(\omega_c t + \phi_c)] \cdot \exp[j\psi(t)]\}$$

$$= \text{Re}\{A_c\exp[j\psi(t)]\} \qquad (1)$$

where,

A_c = amplitude of unmodulated carrier,

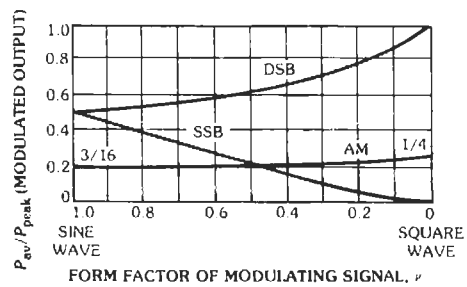

Fig. 8. Average-to-peak power relations as a function of modulating signal. (*After W. K. Squires and E. Bedrosian, "The Computation of Single-Sideband Peak Power,"* Proceedings of the IRE, *Vol. 48, p. 124, Fig. 2; January 1960.*)

ω_c = angular frequency of unmodulated carrier,
ϕ_c = carrier phase angle,
$\phi(t) = [\omega_c t + \phi_c + \psi(t)]$,
= instantaneous phase angle modulated by the message function, $g(t)$.

Expanding Eq. 1 in powers of $\psi(t)$, we have

$$e(t) = \text{Re}\{A_c \exp[j(\omega_c t + \phi_c)] \times [1 + j\psi(t) - (1/2!)\psi^2(t) - j(1/3!)\psi^3(t) + \cdots]\}$$

When $|\psi(t)|_{\max} >> 1$, we have nonlinear modulation, since the carrier is multiplied by higher powers of $\psi(t)$. In case $|\psi(t)|_{\max} << 1$, the exponential modulation is approximately linear and is given by

$$e(t) \cong \text{Re}\{A_c[1 + j\psi(t)]\exp[j(\omega_c t + \phi_c)]\}$$

Note that for amplitude modulation we have

$$e_{\text{AM}}(t) = \text{Re}\{A_c[1 + m_a g(t)]\exp[j(\omega_c t + \phi_c)]\}$$

Expressing Eq. 1 in the real form, we obtain

$$e(t) = A_c[\cos\omega_c t + \phi_c + \psi(t)]$$

where for phase modulation

$$\psi(t) = m_p g(t),\ m_p = \text{constant}$$

and for frequency modulation

$$\psi(t) = m_f \int_0^t g(\tau)d\tau,\ m_f = \text{constant}$$

The instantaneous frequency $\omega_i(t)$ is defined by

$$\omega_i(t) = \left[\frac{d\phi(t)}{dt}\right] = \left[\omega_c + \frac{d\psi(t)}{dt}\right]$$

In *phase modulation*, the instantaneous phase of the modulated signal varies proportionally with the modulating signal $g(t)$

$$e_{\text{PM}}(t) = A_c \cos[\omega_c t + m_p g(t)]$$

where ϕ_c has arbitrarily been set to zero.

For single-tone sinusoidal modulation, $g(t) = \cos\omega_m t$, we have

$$e_{\text{PM}}(t) = A_c \cos(\omega_c t + m_p \cos\omega_m t)$$

where $m_p = \Delta\theta$, and the peak phase deviation is independent of ω_m.

The instantaneous frequency

$$\omega_i(t) = d\phi(t)/dt$$

$$= \omega_c - m_p\omega_m \sin\omega_m t$$

and the peak frequency deviation $\Delta\omega = m_p\omega_m$ is proportional to the modulating frequency ω_m.

In *frequency modulation*, the instantaneous frequency of the modulated signal is proportional to $g(t)$

$$\omega_i(t) = \omega_c + m_f g(t)$$

or

$$e_{\text{FM}}(t) = A_c \cos\left[\omega_c t + m_f \int_0^t g(\tau)d\tau\right]$$

For single-tone sinusoidal modulation

$$\omega_i(t) = \omega_c + \Delta\omega\cos\omega_m t$$

$$e_{\text{FM}}(t) = A_c \cos[\omega_c t + (m_f/\omega_m)\sin\omega_m t]$$

The peak frequency deviation $\Delta\omega \equiv m_f$ is independent of ω_m, whereas the peak phase deviation $\Delta\theta = \Delta\omega/\omega_m$ is inversely proportional to ω_m; $\Delta\theta$ (in radians) is the modulation index, often denoted by β. For broad-band application, $\Delta\omega << \omega_c$ and $\beta >> 1$.

Frequency Spectrum of Single-Tone Angular Modulation

Small Phase Deviation (Narrow-Band PM):

$$e(t) = A_c \cos(\omega_c t + \beta \sin\omega_m t), \qquad \beta << 1$$

$$e(t) \cong A_c (\cos\omega_c t - \beta \sin\omega_m t)$$

$$= \underbrace{A_c \cos\omega_c t}_{\text{carrier}} - \underbrace{\tfrac{1}{2}(A_c\beta) \cos(\omega_c - \omega_m)t}_{\text{lower sideband}}$$

$$+ \underbrace{\tfrac{1}{2}(A_c\beta) \cos(\omega_c + \omega_m)t}_{\text{upper sideband}}$$

The corresponding equation for AM is

$$e_{\text{AM}}(t) = A_c \cos\omega_c t + \tfrac{1}{2}(A_c m_a) \cos(\omega_c - \omega_m)t + \tfrac{1}{2}(A_c m_a) \cos(\omega_c + \omega_m)t$$

Large Phase Deviation (Wideband PM):

$$e(t) = A_c \cos(\omega_c t + \beta \sin\omega_m t),\ \beta >> 1$$

$$= A_c[\cos\omega_c t \cos(\beta \sin\omega_m t) - \sin\omega_c t \sin(\beta \sin\omega_m t)]$$

$$= A_c[\cos\omega_c t \sum_{n=-\infty}^{\infty} J_n(\beta) \cos n\omega_m t - \sin\omega_c t \sum_{n=-\infty}^{\infty} J_n(\beta) \sin n\omega_m t]$$

The waveform for wideband modulation is given by the equation

$$e(t) = A_c\{J_0(\beta)\cos\omega_c t - J_1(\beta)[\cos(\omega_c - \omega_m)t - \cos(\omega_c + \omega_m)t] + J_2(\beta)[\cos(\omega_c - 2\omega_m)t + \cos(\omega_c + 2\omega_m)t] - J_3(\beta)[\cos(\omega_c - 3\omega_m)t - \cos(\omega_c + 3\omega_m)t] + \cdots\}$$

$$= A_c \sum_{n=-\infty}^{\infty} J_n(\beta)\cos(\omega_c + n\omega_m)t$$

as shown in Fig. 9.

In practical application, the required bandwidth is finite, for—beyond a certain frequency range from the carrier, depending on the magnitude of β—the sideband amplitudes, which are proportional to $J_n(\beta)$, are negligibly small (see Fig. 10). Note that at $\beta = 2.404$, $J_0(\beta) = 0$ and the carrier amplitude is zero.

The average power in an angle-modulated wave is constant

$$P = \tfrac{1}{2}(A_c^2)\sum_{-\infty}^{\infty} J_n^2(\beta)$$

$$= \tfrac{1}{2}(A_c^2)$$

Multitone Angle Modulation

For *two-tone angle modulation* with ω_1 *and* ω_2, the instantaneous frequency is given by

$$\omega_i(t) = \omega_c + \Delta\omega_{c1}t\cos\omega_1 t + \Delta\omega_{c2}\cos\omega_2 t$$

where $\Delta\omega_{c1}$ and $\Delta\omega_{c2}$ denote the corresponding frequency deviations of ω_c, and the FM signal is

$$e(t) = A_c\cos(\omega_c t + \beta_1\sin\omega_1 t + \beta_2\sin\omega_2 t)$$

where $\beta_1 = \Delta\omega_{c1}/\omega_1$ and $\beta_2 = \Delta\omega_{c2}/\omega_2$.

The spectral components are as follows.

(A) Carrier:

$$J_0(\beta_1)J_0(\beta_2)A_c\cos\omega_c t$$

(B) Sidebands due to ω_1:

$$J_n(\beta_1)J_0(\beta_2)A_c\cos(\omega_c \pm n\omega_1)t, \qquad n = 1, 2, 3$$

(C) Sidebands due to ω_2:

$$J_m(\beta_2)J_0(\beta_1)A_c\cos(\omega_c \pm m\omega_2)t, \qquad m = 1, 2, 3$$

(D) Beat frequencies at $\omega_c \pm n\omega_1 \pm m\omega_2$:

$$J_n(\beta_1)J_m(\beta_2)A_c\cos(\omega_c \pm nw_1 \pm m\omega_2)t$$

Spectral Distribution of an FM/FM Signal

Let ω_c = carrier angular frequency, ω_s = subcarrier, and ω_m = modulating angular frequency. The instantaneous frequency of the carrier wave is

$$\omega_i(t) = \omega_c + \Delta\omega\cos[\omega_s t + \phi_s + \beta_s\sin(\omega_m t + \phi_m)]$$

where,

$\Delta\omega$ = peak frequency deviation of carrier,
$\beta_s = \Delta\omega_s/\omega_m$ = peak phase deviation of subcarrier.

The spectral distribution is given by

$$e(t) = A_c \sum_{p=-\infty}^{\infty}\sum_{q=-\infty}^{\infty} J_p(\beta)J_q(p\beta_s) \times \cos[(\omega_c + p\omega_s + q\omega_m)t + \phi_c + p\phi_s + q\phi_m]$$

where $\beta = \Delta\omega/\omega_s$ = peak phase deviation of carrier.

Bandwidth Considerations in Multitone FM

An estimate of the IF bandwidth required for transmission of FM carrier by a complex modulating signal is given by

$$\beta_{IF} = 2(\Delta F + 2f_m) = 2\Delta F(1 + 2/\beta)$$

where,

ΔF = peak frequency deviation for the system,
f_m = highest baseband frequency (see Fig. 11).

Signal-to-Noise Improvement in FM Systems

The performance of a conventional FM receiver in the presence of random fluctuation noise is commonly judged on the basis of the variation of the output signal-to-noise $(S/N)_o$ power ratio as a function of the carrier-to-noise power ratio $(C/N)_i$ measured at the input to the limiter. This relationship is shown graphically in Fig. 12. The threshold of full improvement occurs when $(C/N)_i$ is about 12 decibels. For all values of the carrier greater than the threshold, the output $(S/N)_o$ is proportional to the input $(C/N)_i$. The signal-to-noise improvement ratio for a single-channel FM system is given by

$$(S/N)_o/(C/N)_i = (\Delta\Phi)^2, \text{ using a phase detector}$$

where $\Delta\Phi$ = peak phase deviation, and

$$(S/N)_o/(C/N)_i = 3(\Delta F/f_m)^2$$
$$= 3\beta^2, \text{ using a frequency discriminator}$$

where,

ΔF = peak frequency deviation,
f_m = highest modulating frequency.

The signal-to-noise improvement ratio for a particular channel of a multiplex system is given by

$$(S/N)_o/(C/N)_i = (B/B_c)(\Delta F_m/f_n)^2$$

where,

$2B$ = IF bandwidth,
B_c = channel bandwidth,

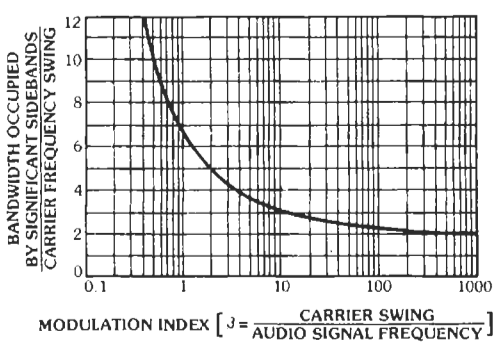

Fig. 11. Significant bandwidth (normalized) vs modulation index β. (*From C. E. Tibbs and G. G. Johnstone,* Frequency Modulation Engineering, *John Wiley & Sons, Inc., New York. Courtesy of Chapman & Hall, Ltd., London.*)

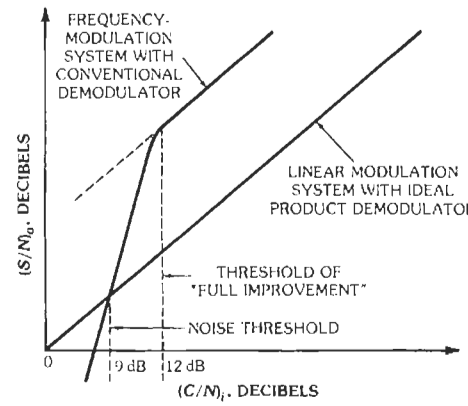

Fig. 12. Noise performance of conventional FM receiver. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 14-2, © 1965, McGraw-Hill Book Co.*)

ΔF_m = peak channel frequency deviation,
f_n = midband channel frequency in the nth channel.

In the nonlinear region, when the noise is larger than the carrier there exists a signal-suppression effect, the average amplitude of the discriminator output is reduced, and for $(C/N)_i \ll 1$ we have $(S/N)_o \propto (C/N)_i^2$.

Signal-to-Noise Improvement Through De-Emphasis

The $(S/N)_o$ ratio of the high frequency end of the baseband can be increased by passing the modulating signal (at the transmitting end) through a pre-emphasis network (Figs. 13A and B), which emphasizes the higher signal frequencies, and then passing the output of the discriminator through a de-emphasis network (Figs. 13C and D) to restore the original signal-power distribution. Typical pre-emphasis and de-emphasis circuit responses for general time constants τ are shown in Fig. 14.

The improvement factor ρ_{FM} is given by

$$\rho_{FM} = \frac{(2\pi f_m \tau)^3}{3(2\pi f_m \tau - \tan^{-1} 2\pi f_m \tau)}$$

where f_m denotes the highest baseband frequency.

For narrow-band FM

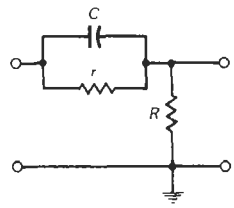
$$\rho_{FM} \rightarrow 1$$

For wideband FM, f_m is large, and

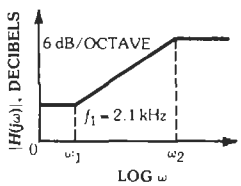
$$\rho_{FM} \rightarrow (2\pi f_m \tau)^2/3$$

The mean $(S/N)_o$ ratio for FM with pre-emphasis is given by

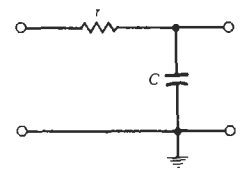
$$(S/N)_o = \rho_{FM} \cdot 3\beta^2 (C/N)_i$$



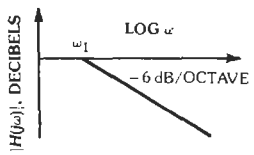
(A) Pre-emphasis network ($\tau >> R$, $rC = 75$ μs).



(B) Asymptotic response ($\omega_1 = 1/rC$, $\omega_2 \doteq 1/RC$).



(C) De-emphasis network ($rC = 75$ μs).



(D) Asymptotic response ($f_1 = 2.1$ kHz).

Fig. 13. Pre-emphasis and de-emphasis networks. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Figs. 14-6 and 14-7, © 1965, McGraw-Hill Book Co.*)

PART 2—PULSE MODULATION

In pulse-modulation systems, the unmodulated carrier is usually a series of regularly recurrent pulses; information is conveyed by modulating some parameter of the transmitted pulses such as the amplitude, duration, time of occurrence, or shape of pulse. This type of modulation is based on the "sampling principle," which states that a continuous message waveform that has a spectrum of finite width could be recovered from a set of discrete instantaneous samples whose rate is higher than twice the highest signal frequency. This discrete set of periodic samples of the message function is used to modulate some parameter of the carrier pulses. In *pulse-amplitude modulation* (PAM), the series of periodically recurring pulses is modulated in amplitude by the corresponding instantaneous samples of the message function. In *pulse-time modulation* (PTM), the instantaneous samples of the message function are used to vary the time of occurrence of

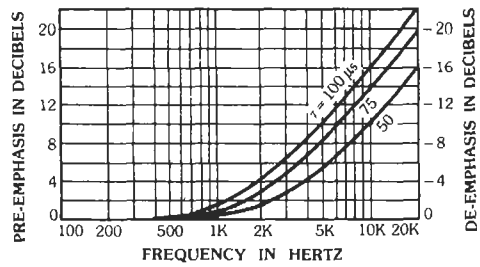


Fig. 14. Pre-emphasis and de-emphasis circuit response, for time constants of τ = 50, 75, and 100 μs. (*From C. E. Tibbs and G. G. Johnstone,* Frequency Modulation Engineering, *John Wiley & Sons, Inc., New York. Courtesy of Chapman & Hall, Ltd., London.*)

some parameter of the pulsed carrier. Pulse-duration, pulse-position, and pulse-frequency modulation are particular forms of pulse-time modulation. In *pulse-duration modulation* (PDM), the time of occurrence of either the leading or trailing edge of each pulse (or both) is varied from its unmodulated position by the samples of the modulating wave. This is also called *pulse-length* or *pulse-width modulation* (PWM). In *pulse-position* (or *phase*) *modulation* (PPM), the samples of the modulating wave are used to vary the position in time of a pulse, relative to its unmodulated time of occurrence. Pulse-position modulation is essentially the same as PDM, except that the variable edge is now replaced by a short pulse. In *pulse-frequency modulation* (PFM), the samples of the message function are used to modulate the frequency of the series of carrier pulses.

The pulse-modulation systems enumerated so far are examples of uncoded pulse systems. In *pulse-code modulation* (PCM), the modulating signal waveform is sampled at regular intervals as in conventional pulse modulation. However, in PCM, the samples are first quantized into discrete steps; i.e., within a specified range of expected sample values, only certain discrete levels are allowed, and these are transmitted over the system by means of a code pattern of a series of pulses.

Another example of a code-modulation system is *delta modulation*. As in PCM, the range of signal amplitudes is quantized, and binary pulses are produced at the sending end at regular intervals. However, in delta-modulation systems, instead of the absolute quantized signal amplitude being transmitted at each sampling, the transmitted pulses carry the information corresponding to the derivative of the amplitude of the modulating signal.

SAMPLING

Sampling in the Time Domain

If a signal $f(t)$ is sampled at regular intervals of time and at a rate higher than twice the highest significant signal frequency, then the samples contain all the information of the original signal. The function $f(t)$ may be reconstructed from these samples by the use of a low-pass filter. The reconstruction equation is

$$f(t) = \alpha \sum_{n=-\infty}^{\infty} f(n\alpha/2B) \frac{\sin 2\pi B\,(t - n\alpha/2B)}{2\pi B\,(t - n\alpha/2B)},$$

$$0 < \alpha \leq 1$$

where $f(t)$ is band-limited to B hertz, and the samples are taken at sampling intervals $\alpha/2B$ seconds apart.

Sampling in the Frequency Domain

A time-limited signal $f(t)$ that is zero outside the range $t_1 < t < t_2$ is completely determined by the values of the spectrum function $F(j\omega)$ at the angular-frequency sampling points given by

$$\omega_n = n[2/(t_2 - t_1)]$$

The function $f(t)$ expressed in terms of its sampling values in the frequency domain is given by the reconstruction equation

$$f(t) = \sum_{n=-\infty}^{\infty} (t_2 - t_1)^{-1} F\left(j \frac{2\pi n}{t_2 - t_1}\right) \times \exp\,[j2\pi nt/(t_2 - t_1)]$$

Sampling of a Bandpass Function (B_0, $B_0 + B$)

The reconstruction equation for $f(t)$ in terms of its sampled values is

$$f(t) = 2BT \sum_{n=-\infty}^{\infty} f(nT) \frac{\sin \pi B(t - nT)}{\pi B(t - nT)} \times \cos 2\pi B_c(t - nT)$$

where $B_c = B_0 + (B/2)$, the center frequency of the bandpass signal, and the permissible values of T are given by

$$m/2B_0 \leq T \leq [(m + 1)/2(B_0 + B)],\ m = 0, 1, 2, \cdots$$

provided $B_0 \neq 0$.

The minimum sampling frequency for a band-limited signal of width B is illustrated in Fig. 15.

PULSE-AMPLITUDE MODULATION (PAM)

In PAM, the samples of the message function are used to amplitude modulate the successive carrier pulses. When the modulated pulses follow the amplitude variation of the sampled time function during the sampling interval, the process is called *natural sampling*

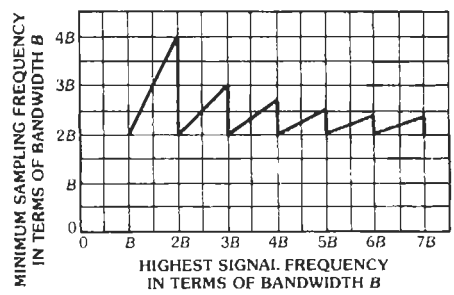

Fig. 15. Minimum sampling frequency for band of width B. (*From P. F. Panter*, Modulation, Noise, and Spectral Analysis, *Fig. 17-13, © 1965, McGraw-Hill Book Co.*)

or *top sampling*. In contrast with natural sampling is instantaneous or square-topped sampling, where the amplitude of the pulses is determined by the instantaneous value of the sampled time function corresponding to a single instant (i.e., center or edge) of the sampling time interval. Pulse-amplitude modulation can be instrumented by two distinct methods. The first produces a variation of the amplitude of a pulse sequence about a fixed nonzero value or pedestal and constitutes double-sideband amplitude modulation (Figs. 16A and B). In the second method, the pedestal is zero, and the output signal consists of double-polarity modulated pulses and constitutes double-sideband suppressed-carrier modulation (Figs. 16C and D).

Spectra of Amplitude-Modulated Pulses

Double-Polarity AM Pulses, Natural (or Top) Sampling—In the process of natural sampling (or exact scanning), the modulated pulses follow the sampled time function during the sampling interval. The unit sampling function (Fig. 16E) consists of a train of unmodulated periodic pulses of unit amplitude given by

$$p_T(t) = (\tau/T) \sum_{n=-\infty}^{\infty} \frac{\sin(n\pi\tau/T)}{n\pi\tau/T} \exp(jn\omega_0 t)$$

where,

$\omega_0 = 2\pi f_0 = 2\pi/T$ is the fundamental angular frequency of the pulse train,
τ is the duration of the pulse,
τ/T is the duty cycle.

Double-polarity AM pulses are obtained by multiplying the message signal $f(t)$ by the unit sampling function $p_T(t)$. In case of sinusoidal modulation, $f(t) = A\cos(\omega_m t + \phi)$, and the waveform of the AM pulses is given by

$$f_{s1}(t) = f(t)p_T(t)$$

$$= (\tau/T)A\cos(\omega_m t + \phi) + (\tau/T)A \sum_{n=1}^{\infty} \frac{\sin(n\pi\tau/T)}{n\pi\tau/T} \times \cos[(n\omega_0 \pm \omega_m)t \pm \phi]$$

In the general case, the message function $f(t)$ is band-limited, and its spectrum is $F(j\omega)$. The output spectrum is

$$F_{s1}(j\omega) = (\tau/T)F(j\omega) + (\tau/T) \sum_{n=1}^{\infty} \frac{\sin(n\pi\tau/T)}{n\pi\tau/T} \times \{F[j(\omega - n\omega_0)] + F[j(\omega + n\omega_0)]\}$$

$$= (\tau/T) \sum_{n=-\infty}^{\infty} \frac{\sin(n\omega_0\tau/2)}{n\omega_0\tau/2} F[j(\omega - n\omega_0)]$$

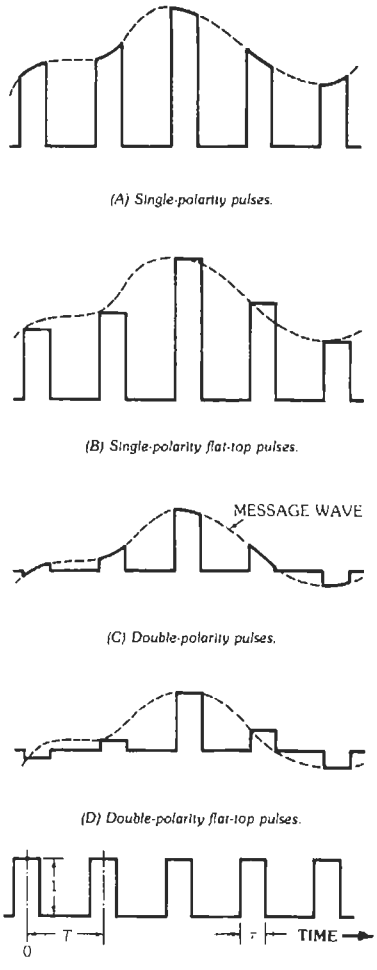

Fig. 16. Various shapes of amplitude-modulated pulses. (*From H. S. Black,* Modulation Theory. *Courtesy D. Van Nostrand Co., Inc., Princeton, N.J.*)

The spectrum of the double-polarity AM pulses consists of the original modulation spectrum and an infinite number of upper and lower sidebands around ω_0 and its harmonics.

Double-Polarity AM Pulses, Instantaneous (or Square-Top) Sampling—In case of sinusoidal modulation, the output waveform is given by

$$f_{s2}(t) = (\tau/T)A \sum_{n=-\infty}^{\infty} \frac{\sin[\pi(\tau/T)(n\omega_0 + \omega_m)/\omega_0]}{[\pi(\tau/T)(n\omega_0 + \omega_m)/\omega_0]} \times \cos[(n\omega_0 + \omega_m)(t - \tfrac{1}{2}\tau) + \phi]$$

In the general case, the output spectrum is

$$F_{s2}(j\omega) = (\tau/T)\frac{\sin(\omega\tau/2)}{\omega\tau/2} \sum_{n=-\infty}^{\infty} F[j(\omega - n\omega_0)]$$

Single-Polarity AM Pulses, Natural Sampling—For sinusoidal modulation

$$f_{s3}(t) = [1 + m_a \cos(\omega_m t + \phi)] \times (\tau/T) \sum_{n=-\infty}^{\infty} \frac{\sin(n\pi\tau/T)}{n\pi\tau/T} \exp(jn\omega_0 t)$$

$$= p_T(t) + f_{s1}(t)$$

where m_a is the modulation index. In the general case

$$F_{s3}(j\omega) = P(j\omega) + F_{s1}(j\omega)$$

where $P(j\omega)$ is the Fourier transform of $p_T(t)$.

Single-Polarity AM Pulses, Instantaneous Scanning—For sinusoidal modulation

$$f_{s4}(t) = p_T(t) + f_{s2}(t)$$

In the general case

$$F_{s4}(j\omega) = P(j\omega) + F_{s2}(j\omega)$$

Signal-to-Noise Ratio in PAM

The signal to noise ratio for PAM is

$$(S/N)_i = \tfrac{1}{2} m_a^2 \, P/N_0 B$$

where,

P = average power of unmodulated radio-frequency pulse train,
N_0 = noise-power density in watts/hertz,
B = channel (RF) bandwidth.

Also

$$(S/N)_o = \tfrac{1}{2} m_a^2 \, (\tau/T) \, P/N_0 f_m$$

where f_m = top frequency of message function. If the receiver is blocked between pulses to eliminate the noise in the interpulse period, the $(S/N)_o$ at the output of a low-pass filter is

$$(S/N)_o = \tfrac{1}{2} m_a^2 \, P/N_0 f_m$$

which is identical to the result obtained for conventional CW carrier amplitude modulation.

In practice, PAM provides a poorer signal-to-noise ratio than conventional AM, because the receiver is unblocked for rather longer than the pulse-duration time owing to the sloping sides of the pulse.

PULSE-TIME MODULATION (PTM)

The improvement in signal-to-noise ratio obtained by the use of time-modulated pulses of constant amplitude instead of amplitude-modulated pulses led to the development of systems using pulse-duration and pulse-position modulation. The sampling associated with pulse modulation may be either natural or uniform (periodic). Natural sampling may be defined as a process of sampling in which the time of sampling coincides with the time of appearance of the time-modulated pulse as shown in Fig. 17A. In the process of natural sampling, the pulse duration τ_n corresponds to the value of the modulating signal $M(t_n)$ at that instant, and consequently the sampling intervals t_n are not equal but depend on the modulation level. Uniform sampling may be defined as a process of sampling in which the variation in the parameter of the pulse is proportional to the modulating signal at uniformly spaced sampling times. This is illustrated in Fig. 17B, where the width of the pulses is proportional to the modulating values $M(t_n)$ which are sampled at equal intervals $t_n = nT_r$ and are independent of the modulation process.

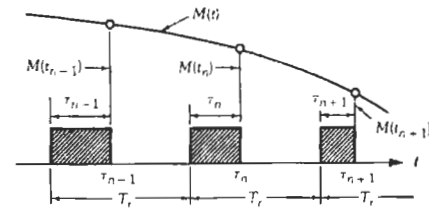
Spectra of Time-Modulated Pulses

The spectra of PTM pulses can be derived with reference to Fig. 18, where the two cosine waves, A and B, of angular frequency ω_r are displaced relative to each other by an amount τ, the width of the unmodulated pulse. The positive and negative steps that give rise to the pulse train are assumed to occur at the peaks of waveforms A and B, respectively. In the absence of modulation, the time of occurrence of the positive and negative steps is given by

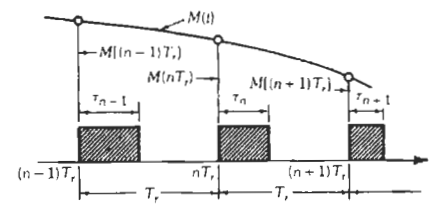
$$\omega_r(t + \tau/2) = 2n\pi$$

and

$$\omega_r(t - \tau/2) = 2n\pi$$



(A) Natural sampling.



(B) Uniform sampling.

Fig. 17. Pulse-duration modulation. (*From P. F. Panter, Modulation, Noise, and Spectral Analysis, Fig. 18-14, © 1965, McGraw-Hill Book Co.*)

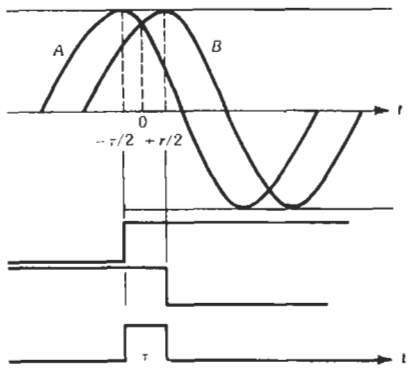


Fig. 18. Modulation process (modified). (*From P. F. Panter, Modulation, Noise, and Spectral Analysis, Fig. 17-14, © 1965, McGraw-Hill Book Co.*)

With natural modulation, the time of occurrence of the positive and negative steps is given by

$$\omega_r(t + \pi/2) + \beta \sin(\omega_m t + \phi) = 2n\pi$$

and

$$\omega_r(t - \pi/2) + \beta \sin(\omega_m t + \phi) = 2n\pi$$

Similarly, with uniform modulation, the time of occurrence or the position of the leading and trailing edges of the pulses is determined by

$$\omega_r(t + \pi/2) + \beta \sin(\omega_m t + \phi) = 2n\pi$$

$$\omega_r(t - \pi/2) + \beta \sin(\omega_m \overline{t - \tau} + \phi) = 2n\pi$$

where,

ω_m is the modulating frequency,
β is the modulation index.

Pulses whose moments of occurrence satisfy these equations are said to be time modulated. In pulse-frequency modulation, $\beta = \Delta\ \omega/\omega_m$, and in pulse-phase (or pulse-position) modulation, β is constant independent of the modulating frequency.

Pulse-Frequency Modulation, Natural Sampling—A useful expression for an infinite train of unmodulated pulses is in the form

$$p_T(t) = (A/2\pi j) \sum_{k=-\infty}^{\infty} k^{-1} \{\exp[jk\omega_r(\pi/2)] - \exp[-jk\omega_r(\pi/2)]\} \exp(jk\omega_r t)$$

where,

A is the amplitude of the pulses,
ω_r is the pulse repetition frequency.

Frequency modulation can be taken into account by substituting for $\omega_r\pi/2$ in the expressions for the leading and trailing edges in the last equation, the expressions

$$\tfrac{1}{2}(\omega_r\tau) + \beta \sin(\omega_m t + \phi)$$

and

$$\tfrac{1}{2}(\omega_r\tau) - \beta \sin(\omega_m t + \phi)$$

The frequency-modulated pulse train is then

$$p_m(t) = (A/2\pi j) \times \sum_{k=-\infty}^{\infty} k^{-1}(\exp\{j[k\omega_r(\pi/2) + k\beta \sin(\omega_m t + \phi)]\} - \exp\{-j[k\omega_r(\pi/2) - k\beta \sin(\omega_m t + \phi)]\}) \times \exp(jk\omega_r t)$$

$$= \frac{A\omega_r\tau}{2\pi} + \frac{A\omega_r\tau}{\pi} \sum_{k=1}^{\infty} \frac{\sin[k\omega_r(\pi/2)]}{k\omega_r(\pi/2)} \times (J_0(k\beta) \cos k\omega_r t + \sum_{n=1}^{\infty} J_n(k\beta) \times \{\cos[(k\omega_r + n\omega_m)t + n\phi] + (-1)^n \cos[(k\omega_r - n\omega_m)t - n\phi]\})$$

This expression may be compared with that for the spectrum of a frequency-modulated continuous wave given by

$$e_{FM}(t) = AJ_0(\beta) \cos\omega_r t + A \sum_{n=1}^{\infty} J_n(\beta) \{\cos[(\omega_r + n\omega_m)t + n\phi] + (-1)^n \cos[(\omega_r - n\omega_m)t - n\phi]\}$$

The conclusions reached are as follows.

(A) With pulse-frequency modulation using natural sampling, the direct-current component of the pulse spectrum has no sideband of the modulating frequency.
(B) The kth harmonic of the pulse-repetition frequency is frequency modulated, the modulation index being $k\beta$.

Pulse-Frequency Modulation, Uniform Sampling—In this type of modulation, the displacement of waveform B of Fig. 18 from its unmodulated position at any instant of time t will depend on the value of the modulating voltage at $(t - \tau)$. The expression for the modulated pulse train becomes

$$p_m(t) = (A/2\pi j)$$

$$\times \sum_{k=1}^{\infty} k^{-1} \left(\exp\{j[k\omega_r(\tau/2) + k\beta \sin(\omega_m t + \phi)]\}\right.$$

$$\left. - \exp\{-j[k\omega_r(\tau/2) - k\beta \sin(\omega_m t - \tau + \phi)]\}\right) \times \exp(jk\omega_r t)$$

$$= \frac{A\omega_r\tau}{2\pi} + A\left(\frac{\Delta\omega}{2\pi}\right)\tau \frac{\sin[\omega_m(\tau/2)]}{\omega_m(\tau/2)} \times \cos[\omega_m t + \phi - (\omega_m \tau/2)]$$

$$+ \frac{A\omega_r\tau}{\pi} \sum_{k=1}^{\infty} \left(J_0(k\beta) \frac{\sin[k\omega_r(\tau/2)]}{k\omega_r(\tau/2)} \right.$$

$$\times \cos k\omega_r t + \sum_{k=1}^{\infty} J_n(k\beta) \left\{ \frac{\sin(k\omega_r - n\omega_m)(\tau/2)}{k\omega_r(\tau/2)} \right.$$

$$\times \cos[(k\omega_r + n\omega_m)t + n\phi - n\omega_m(\tau/2)]$$

$$+ (-1)^n \frac{\sin(k\omega_r - n\omega_m)(\tau/2)}{k\omega_r(\tau/2)}$$

$$\left.\left. \times \cos[(k\omega_r - n\omega_m)t - n\phi + n\omega_m(\tau/2)] \right\} \right)$$

The conclusions reached are as follows.

(A) The direct-current component of the pulse spectrum has a sideband of the modulating frequency of amplitude

$$(A\Delta\omega\tau/2\pi)\{\sin[\omega_m(\tau/2)]/\omega_m(\tau/2)\}$$

Modulation can therefore be recovered by means of a low-pass filter.

(B) The upper and lower sidebands of the kth harmonic of the pulse-repetition frequency are not equal in amplitude, whereas in the case of natural sampling they are equal.

Pulse-Position (or Pulse-Phase) Modulation— The waveform of pulse-phase modulation can be directly derived from that for pulse-frequency modulation by substituting $\omega_r\tau_d$ for β, where $\omega_r\tau_d$ represents the peak phase deviation of waveforms A and B, which is constant independent of the modulation frequency ω_m. The resulting waveform is the following:

Natural sampling:

$$P_m(t) = \frac{A\omega_r\tau}{2\pi} + \frac{A\omega_r\tau}{\pi} \sum_{k=1}^{\infty} \frac{\sin[k\omega_r(\tau/2)]}{k\omega_r(\tau/2)}$$

$$\times (J_0(k\omega_r\tau_d)\cos k\omega_r t + \sum_{n=1}^{\infty} J_n(k\omega_r\tau_d)$$

$$\times \{\cos[(k\omega_r + n\omega_m)t + n\phi]$$

$$+ (-1)^n \cos[(k\omega_r - n\omega_m)t - n\phi]\})$$

Note that each pulse-repetition-frequency harmonic is phase-modulated, with peak deviation equal to $k\omega_r\tau_d$. Also, there is no sideband accompanying the direct-current component of the pulse spectrum, and hence modulation cannot be recovered by means of a low-pass filter.

Uniform sampling:

$$p_m(t) = \frac{A\omega_r\tau}{2\pi} + \frac{A\omega_r\omega_m\tau_d\tau}{2\pi} \frac{\sin[\omega_m(\tau/2)]}{\omega_m(\tau/2)}$$

$$\times \cos[\omega_m t + \phi - (\omega_m\tau/2)] + \frac{A\omega_r\tau}{\pi} \sum_{k=1}^{\infty} \left(J_0(k\omega_r\tau_d) \right.$$

$$\times \frac{\sin[(k\omega_r(\tau/2)]}{k\omega_r(\tau/2)} \cos k\omega_r t + \sum_{n=1}^{\infty} J_n(k\omega_r\tau_d)$$

$$\times \left\{ \frac{\sin(k\omega_r + n\omega_m)(\tau/2)}{k\omega_r(\tau/2)} \cos[(k\omega_r + n\omega_m)t \right.$$

$$+ n\phi - n\omega_m(\tau/2)] + (-1)^n \frac{\sin(k\omega_r - n\omega_m)(\tau/2)}{k\omega_r(\tau/2)}$$

$$\left.\left. \times \cos[(k\omega_r - n\omega_m)t - n\phi + n\omega_m(\tau/2)] \right\} \right)$$

This is an equation very similar to that for pulse-frequency modulation.

Signal-to-Noise Improvement Ratio in PTM

In PDM, the noise manifests itself as jitter in the leading and trailing edges of the recovered pulses, and the slopes of the pulse edges influence noise reduction. A PPM system is affected by noise in the same manner as a PDM system. For trapezoidal pulses (Figs. 19 and 20), the S/N power ratio at the demodulator output is

$$(S/N)_o = \tfrac{1}{2}(t_0/\tau_r)^2 (A_c/\sigma)^2$$

The peak pulse power to mean noise power ratio is

$$(C/N)_i = (A_c/\sigma)^2$$

Hence

$$(S/N)_o = \tfrac{1}{2}(t_0/\tau_r)^2 (C/N)_i$$

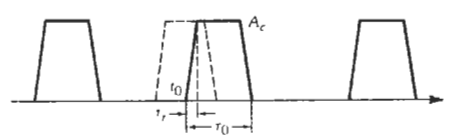

Fig. 19. Pulse-position modulation of trapezoidal pulses. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 18-26, © 1965, McGraw-Hill Book Co.*)

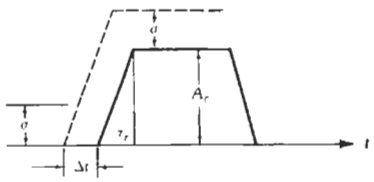

Fig. 20. Variation in pulse position due to the presence of noise or interference. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 18-27,* © *1965, McGraw-Hill Book Co.*)

The $(S/N)_0$ can be improved by decreasing the pulse rise τ_r or correspondingly by widening the transmission bandwidth. For $B \cong 1/\tau_r$

$$(S/N)_0 = \tfrac{1}{2}t_0^2B^2\ (C/N)_i$$

For $B \cong 1/2\tau_r$

$$(S/N)_0 = 2t_0^2B^2\ (C/N)_i$$

As in the case of FM, the $(S/N)_0$ ratio cannot be improved indefinitely by widening the bandwidth, because the noise power introduced at the receiver increases with bandwidth and eventually becomes comparable to the signal and "takes over" the system. A threshold level thus also exists just as in the FM case. This threshold level is usually taken as $A_c/\sigma = 2$, or $(C/N)_i = 4$ (6 dB).

PULSE-CODE MODULATION (PCM)

In PCM, several pulses are used as a code group to describe the quantized amplitude of a single sample. For example, a code group of n on-off pulses (binary code) can represent 2^n discrete amplitudes or levels, including zero level. In general, in an s-ary PCM system, the number of quantized amplitude levels the code group can express (including zero level) is given by

$$M = s^n$$

If a stands for 0 or 1, the binary notation with n digits, $a_1, a_2, \cdots, a_n$, represents the number

$$a_1 2^0 + a_2 2^1 + a_3 2^2 + \cdots + a_n 2^{n-1}$$

In the ternary number system, a stands for the pulse amplitude 0, 1, 2, and the code group of n digits represents the number

$$a_1 3^0 + a_2 3^1 + \cdots + a_n 3^{n-1}$$

Table 1 shows how the 64 numbers from 0 through 63 are represented in binary, quaternary, and octonary notation.

Quantization Noise in a PCM System

Representing the message signal by certain discrete allowed levels or steps is called quantizing. It inherently introduces an initial error in the amplitude of the samples, giving rise to quantization noise.

Uniform Spacing of Levels—In this case, the quantizing interval, or step, Δv is constant, and the quantizing noise power is given by

$$N_q = (\Delta v)^2/12$$

assuming that the quantization noise is uniformly distributed between $\pm\ \Delta v/2$. Assuming that the amplitudes of the samples are uniformly distributed, the signal power recovered from the quantized samples is

$$S_q = [(M^2 - 1)/12](\Delta v)^2$$

where M is the number of discrete levels assigned to the message signal. The ratio of the signal power to the quantizing noise power is

$$S_q/N_q = M^2 - 1 \cong M^2, \qquad M >> 1$$

Nonuniform Spacing of Levels—Quantization noise can be reduced by the use of nonuniform spacing of levels, to provide smaller steps for weaker signals and coarser quantization near the peak of large signals. Quantization noise can be minimized by an optimum level distribution that is a function of the probability density of the signal. The optimum level spacing Δv_k is given by

$$[p(v_k)]^{1/3}\ \Delta v_k = k/M, \qquad k = \text{constant}$$

With optimum level spacing, the total minimum error power is

$$(N_q)_{\min} = (2/3M^2)\left\{\int_0^v [p(v)]^{1/3} dv\right\}^3$$

where $p(v)$ is the probability density of the message signal, and the nonuniform levels are symmetrically disposed about zero level in the amplitude range $(-V, V)$.

In practice, nonuniform quantization is realized by compression, followed by uniform quantization as in Fig. 21. The logarithmic compression curve shown in Fig. 22 renders the distortion largely independent of the signal and is relatively easy to obtain in practice.

$$u = k \log[1 + (\mu v/V)]$$

where,

v = input voltage,
u = output voltage,
μ = compression parameter,
k = undetermined constant.

If the maximum values of the input and the compressed signals are adjusted to be equal, this gives

$$u = \frac{V \log(1 + \mu v/V)}{\log(1 + \mu)}, \qquad 0 \le v \le V$$

and

$$u = \frac{-V \log(1 - \mu v/V)}{\log(1 + \mu)}, \qquad -V \le v \le 0$$

The quantizing noise power with logarithmic compression is

$$N_q = (\alpha^2/12)(V^2 + \mu^2 S)$$

where

$$\alpha = \frac{2\log(1 + \mu)}{\mu M}$$

and

$$S = \int_{-V}^{V} v^2 p(v)\, dv = \text{average signal power}$$

False-Pulse Noise in a PCM System

In addition to quantization noise, a PCM system is characterized by *false-pulse noise*, which originates primarily at the receiving end of the system and is caused by noise spikes breaking through the threshold. This type of noise decreases rapidly as the signal power is increased above threshold. The effect of the false pulses introduced in the code group is to introduce an error in the decoded samples. The mean-square error introduced in the decoded signal is defined as the false-pulse noise. The output signal-to-noise ratio at the decoder is

$$(S/N)_o = (1/4pq) - 1$$

where,

p is the probability of sending out state one and receiving state zero and vice versa,
q is the probability that no transmission fault occurs $(p + q = 1)$.

The output signal-to-noise ratio drops from infinity with a noiseless channel $(p = 0, q = 1)$ to zero in the case of an infinitely large channel noise $(p = q = 1/2)$.

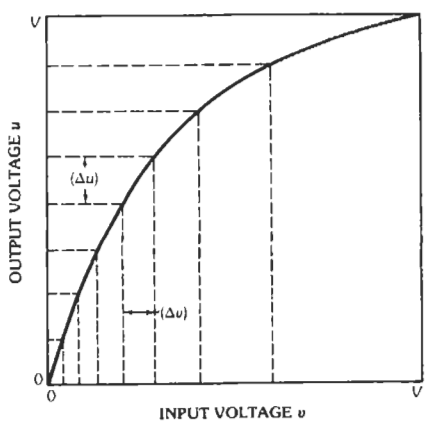

Fig. 21. Compression characteristic of "compressor." (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 20-10,* © *1965, McGraw-Hill Book Co.*)

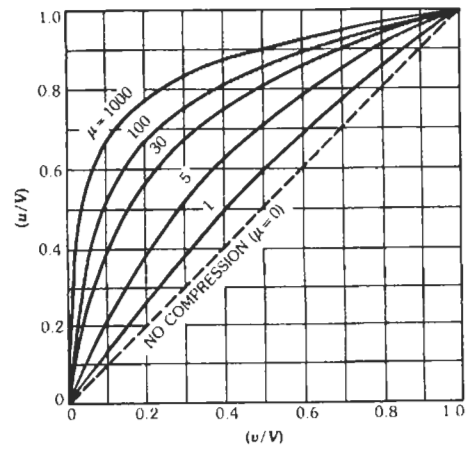

Fig. 22. Logarithmic compression characteristics. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 20-11,* © *1965, McGraw-Hill Book Co.*)

The output signal-to-noise ratio for K links in tandem is given by

$$(S/N)_{o,(K)} = \frac{(q - p)^{2K}}{1 - (q - p)^{2K}}$$

These expressions for the $(S/N)_o$ in a PCM system are given in terms of the probability of false pulses in the code group due to channel noise. The following expressions relate the output signal-to-noise ratio to the input carrier-to-noise ratio for one link.

$$(S/N)_o = (\pi/8)^{1/2} (V_0/2\sigma) \exp[\tfrac{1}{2}(V_0/2\sigma)^2]$$

For unipolar or on-off binary system

$$(S/N)_o = (\pi/16)^{1/2} [(C/N)_i]^{1/2} \exp[\tfrac{1}{4}(C/N)_i]$$

For bipolar binary system

$$(S/N)_o = (\pi/8)^{1/2} [(C/N)_i]^{1/2} \exp[\tfrac{1}{2}(C/N)_i]$$

For K links in tandem

$$(S/N)_{o(K)} = (\text{erf}x)^{2K}/[1 - (\text{erf}x)^{2K}]$$

where $x = V_0/2\sigma$. For high $(c/n)_i$, $x \gg 1$, and

$$\text{erf}x \cong 1 - (2/\pi)^{1/2} \frac{\exp(-x^2/2)}{x}$$

The rapid improvement in $(S/N)_o$ for small increases in $(C/N)_i$ is illustrated in Fig. 23 for various links in tandem.

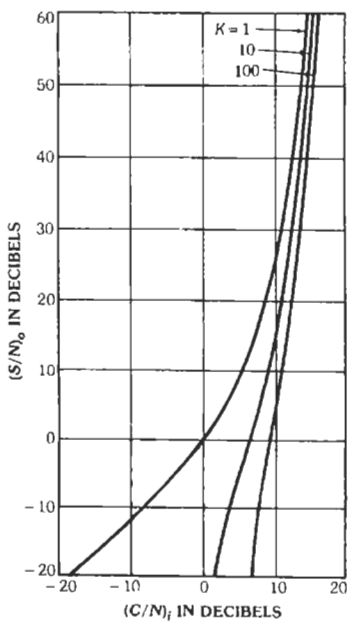

Fig. 23. Output signal-to-noise ratio for PCM. (*From H. F. Mayer, "Principles of Pulse Code Modulation,"* Advan. Electron., *Vol. 3, © 1951, Academic Press, Inc., New York.*)

DELTA MODULATION (DM)

In a DM system, instead of the absolute signal amplitude being transmitted at each sampling, only the changes in signal amplitude from sampling instant to sampling instant are transmitted. As shown in Fig. 24, the transmitted pulse train $e_2(t)$ of positive and negative pulses at the output of the encoder can be assumed to be generated at a constant clock rate. The transmitted pulses from the pulse generator are positive if the change in signal amplitude is positive; otherwise the transmitted pulses are negative. In the decoder, the delta-modulated pulse train $e_2(t)$ is integrated into the voltage $e_1(t)$, which consists of the original message function plus noise components due to sampling. These are eliminated by a low-pass filter so that the reconstructed signal of the final output is a close replica of the original modulating signal $e_0(t)$.

Signal-to-Noise Ratio in DM

The difference between the original and reconstructed signals gives rise to a "quantizing noise" that can be decreased by increasing the "sampling frequency," which in DM is made equal to the pulse frequency. The quantized noise power when single integration is used is given by

$$N_0 = \tfrac{2}{3}(f_m/f_s)(\Delta v)^2$$

where,

f_m = highest modulating frequency,
Δv = height of unit step in volts.

A DM system has no fixed maximum signal amplitude limitation but overloads when the slope of the

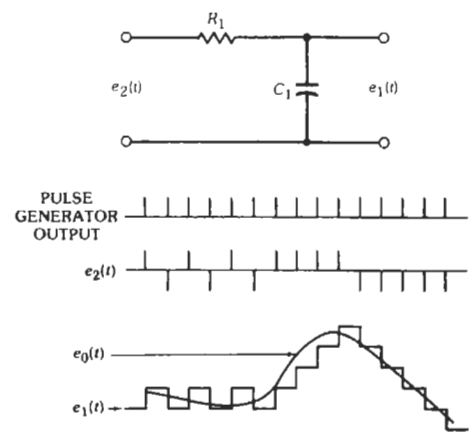

Fig. 24. Delta-modulation waveforms for single integration. (*From P. F. Panter,* Modulation, Noise, and Spectral Analysis, *Fig. 22-2, © 1965, McGraw-Hill Book Co.*)

signal is too large. The largest slope the system can reproduce is one that changes by one level or step every pulse interval, so that the maximum signal power depends on the type of signal. The signal power in the calculation of signal-to-noise ratio is taken as the power of the sinusoidal tone that is just below the overload point. The maximum amplitude of such a sinusoidal signal of frequency f that can be transmitted with single integration without overloading is

$$A = f_s\,(\Delta v)/2\pi f$$

The average signal power is

$$S_0 = f_s^2(\Delta v)^2/4\pi^2 f)^2$$

so that the signal-to-noise ratio for single integration is

$$(S/N)_0 = \tfrac{3}{2}r^3\,(f_m/\pi f)^2$$

where $r = f_s/2f_m$ = bandwidth expansion factor. The signal-to-noise ratio for double integration is

$$(S/N)_0 = \tfrac{3}{2}r^5\,(f_m/\pi f)^4$$

Thus, the improvement in signal-to-noise ratio varies with f_s^3 for the system with single integration, whereas it varies with f_s^5 for double integration.

24 Digital Communications

Michael B. Pursley

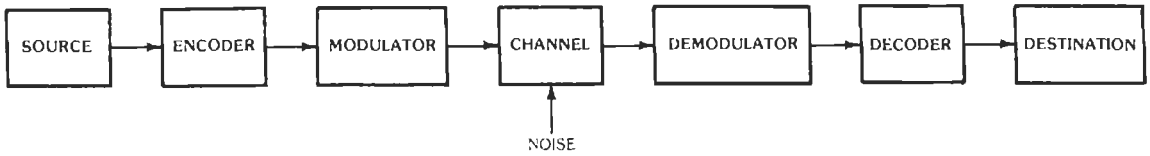

Fig. 1. General model for a communication system.

A general model for a digital communication system is illustrated in the block diagram of Fig. 1. The source, encoder, and modulator are part of the transmitter, and the demodulator, decoder, and destination are in the receiver. In this chapter, we are primarily concerned with the *digital data channel*, which consists of the modulator, channel, and demodulator; the encoder and decoder are discussed in Chapter 25. To focus attention on the digital data channel, consider the model of Fig. 2. In this model, the source and the encoder are combined into a single element called the message source, and the decoder is absorbed into the destination.

The information to be conveyed to the destination consists of a sequence of elements called *messages*. The *message set* is a set of M elements that are indexed by the integers $0, 1, \ldots, M-1$. The modulator produces signals that are used to represent these messages on the channel. During each transmission interval, the message source produces one of the M messages, and the corresponding waveform is transmitted over the channel to the receiver.

Rather than attempting to reproduce the transmitted waveform (as in an analog communication system), the goal of the demodulator in a digital communication system is to determine which of the M messages was sent. It accomplishes this by processing the received signal, which is a distorted, noisy version of the transmitted signal. The demodulator first produces a real number or vector called the *decision statistic*. This statistic is the input to a decision device (e.g., a threshold device), which bases its decision on a predetermined strategy referred to as a *decision rule*. Decision rules are selected according to various criteria such as average probability of error.

The set of allowable decisions can be different from the message set, such as when we permit the receiver to erase symbols. For example, the binary erasure channel has a message set $\{0,1\}$, but the set of allowable decisions is $\{0, 1, e\}$, where "e" denotes the erasure. This is in contrast to the binary "hard-decision" channel, which has the set $\{0,1\}$ as both the message set and the set of allowable decisions.

The number of waveforms available to represent the messages is typically reflected in the names of the elements associated with the communications system (including the system itself). For $M = 2$, the signal sets, modulation techniques, and communications systems are referred to as *binary;* for $M = 3$, they are called *ternary;* and for $M = 4$, they are called *quaternary*. In this chapter, the term *M-ary* refers to nonbinary signaling (i.e., it is implicit that $M > 2$).

All of the digital modulation schemes described here use time-limited waveforms. A waveform $v(t)$ is *time limited* if $v(t) = 0$ for values of t outside some finite interval, and we say it is of *duration* T if this interval is $[0,T]$. The energy is perhaps the most important parameter of the transmitted signal. In general, the *energy* E_v in the waveform $v(t)$ is

$$E_v = \int_{-\infty}^{\infty} v^2(t)\, dt$$

If $v(t)$ has duration T,

$$E_v = \int_0^T v^2(t)\, dt$$

BASEBAND SIGNAL SETS

A baseband signal set is a collection of M baseband signals $\{s_k : k = 0, 1, \ldots, M-1\}$, each of which is of duration T. The kth signal $s_k(t)$ represents the message

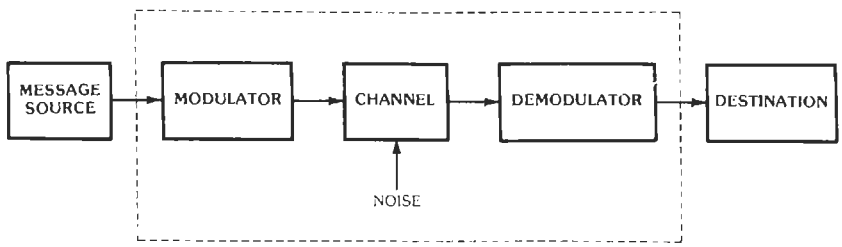

Fig. 2. Model for a digital data channel.

k, and a sequence of messages is sent to the receiver by transmitting the corresponding sequence of signals.

The energy in the kth signal is denoted by E_k. If all of the signals in the set have the same energy, the common value is denoted by E. Given two signals $s_k(t)$ and $s_j(t)$, their *inner product* (s_k,s_j) is defined by

$$(s_k, s_j) = \int_{-\infty}^{\infty} s_k(t)s_j(t)dt$$

Two types of signal sets are of particular interest: orthogonal signal sets and binary antipodal signal sets. In general, a signal set is said to be an *orthogonal* set if $(s_k,s_j) = 0$ for all $k \neq j$. A binary signal set is *antipodal* if $s_0(t) = -s_1(t)$ for all t in the interval $[0,T]$. Antipodal signals have equal energy E, and their inner product is $(s_0,s_1) = -E$.

Many of the baseband signal sets of interest can be defined in terms of a single waveform $v(t)$. To describe such sets, it is convenient to define a set of data variables $\{d_k : k = 0, 1, \ldots, M-1\}$ which are real numbers that represent the messages. Given a set of data variables and a pulse waveform $v(t)$ of duration T, a baseband signal set can then be defined as follows.

The kth signal in the set is given by

$$s_k(t) = Ad_kv(t)$$

where the constant A represents the signal amplitude due to amplification and attenuation (e.g., antenna gains and propagation losses). In many cases, A is the peak signal voltage at the receiver. Since $v(t)$ has duration T, each signal in the set $\{s_k:k = 0, 1, \ldots, M-1\}$ also has duration T. The energy in the kth signal is

$$E_k = A^2d_k^2E_v$$

Each antipodal signal set can be defined in this way with $M = 2$, $d_1 = -d_0$, and $E_1 = E_0$.

Four examples of binary baseband signal sets are illustrated in Fig. 3. Each of these signal sets can be obtained from a single waveform $v(t)$. For the signal sets shown in Figs. 3A and B, the waveform is a rectangular pulse of duration T. This waveform arises so frequently that it is convenient to give it a special notation. We denote the *rectangular pulse* of duration T by $p_T(t)$; it is defined by

$$p_T(t) = \begin{cases} 1 \text{ for } 0 \leq t < T \\ 0 \text{ otherwise} \end{cases}$$

Thus for the signal sets shown in Figs. 3A and B, $v(t) = p_T(t)$. The basic waveform for the baseband signals shown in Fig. 3C is the split-phase or Manchester-coded pulse. For the signal set shown in Fig. 3D, the basic waveform is the *sine pulse*, which is one-half of a full period of a sine wave. That is, $v(t) = \sin(\pi t/T)$ for $0 \leq t < T$.

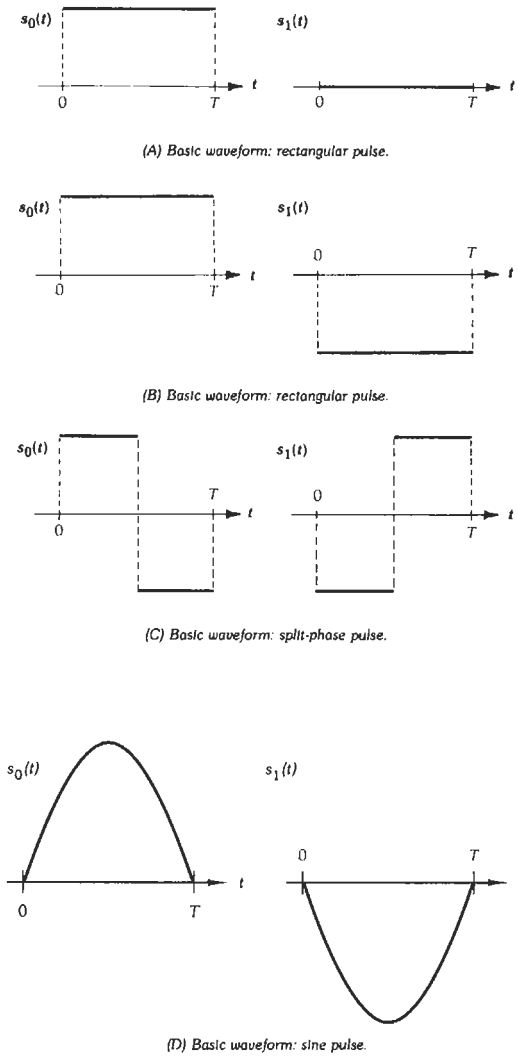

Fig. 3. Four examples of baseband signal sets.

The data symbols for the signal set of Fig. 3A are $d_0 = 1$ and $d_1 = 0$, so this is an orthogonal signal set. For the other three signal sets, $d_0 = +1$ and $d_1 = -1$; thus each of these is an antipodal signal set.

There are binary and M-ary baseband signal sets that cannot be described in terms of a single waveform of duration T. If M is a power of 2, for example, a set of M orthogonal signals can be obtained by letting the signals be sequences of pulses (each pulse is of duration T/M) with amplitudes determined by the rows of an M by M Hadamard matrix.* Other M-ary orthogonal signal sets of this type can be designed from maximal-length linear feedback shift-register sequences. A biorthogonal signal set* consists of the signals from an orthogonal set

* Reference 3.

together with all of their negatives. Two signals from a biorthogonal set are either orthogonal or antipodal.

Of course, the transmitter does not send a single message; it sends a sequence of messages. In order to send a sequence of messages, a corresponding sequence of signals must be transmitted. The message k is sent in the nth time interval by transmitting s_k during this interval. The baseband modulation process is described mathematically as follows. If m_n denotes the message produced by the source during the nth interval $[nT, (n + 1)T]$, the sequence of messages to be sent to the receiver is

$$(m_n) = \ldots, m_{-1}, m_0, m_1, m_2, \ldots$$

If the source output in the nth interval is k, $m_n = k$ and the transmitted signal $s(t)$ is equal to $s_k(t - nT)$ for $nT \leq t < (n + 1)T$. The signal $s(t)$ is actually a sequence of replicas of the basic waveforms, which suggests the representation

$$s(t) = \sum_{n=-\infty}^{\infty} s_{m_n}(t - nT)$$

Because the signals available for use in other intervals are simply replicas of those for $[0,T]$, most of the key features of a particular baseband modulation technique can be described and analyzed by considering only the signal set $\{s_k : k = 0, 1, \ldots, M - 1\}$, which is defined on the interval $[0,T]$.

For signal sets that are derived from a single waveform $v(t)$ on $[0,T]$, the above description can be simplified by taking advantage of the fact that for such signal sets

$$s_k(t) = Ad_k v(t)$$

The transmitted signal is defined as follows. First, the message sequence (m_n) is represented by the corresponding sequence (b_n) of data variables; the latter sequence is defined by $b_n = d_k$ if $m_n = k$. Next, the transmitted signal can be written as

$$s(t) = \sum_{n=-\infty}^{\infty} Ab_n v(t - nT)$$

It follows that the signal set can be described and analyzed by considering only the waveform $v(t)$ and the set of data variables $\{d_k : k = 0, 1, \ldots, M - 1\}$.

As an example, consider the waveform $v(t) = \sin(\pi t/T)$, which is shown in Fig. 3D. For binary communications, the message set is $\{0,1\}$. In order to use antipodal signals, we can let $d_0 = +1$ and $d_1 = -1$, so that a binary 0 is transmitted as a positive sine pulse and a binary 1 is transmitted as a negative sine pulse. Message sequences for which $m_0 = 0$, $m_1 = 1$, $m_2 = 1$, and $m_3 = 0$ correspond to data sequences with $b_0 = +1$, $b_1 = -1$, $b_2 = -1$, and $b_3 = +1$. The resulting signal $s(t)$ is shown in Fig. 4.

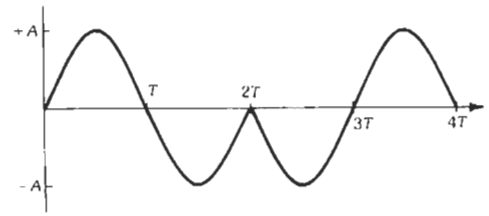

Fig. 4. Transmitted signal $s(t)$ for the message sequence 0110.

SIGNAL SETS FOR RF CHANNELS

The most general RF signals that are considered in this section are of the form

$$s(t) = A\, a(t) \cos[2\pi f_c t + \theta(t) + \phi]$$

where $a(t)$ and $\theta(t)$ are baseband signals of the type described in the preceding section. The signal $a(t)$ represents *amplitude modulation*, and $\theta(t)$ represents *phase modulation*. The variable A is a real number that represents the signal amplitude at the receiver. Physically, the parameter A may be the peak signal voltage, such as when $|a(t)| = 1$. The variable ϕ is the phase of the RF carrier at the time $t = 0$ in the absence of any phase modulation (i.e., $\theta(t) = 0$). This phase angle may or may not be known to the receiver.

A variety of RF signal sets can be obtained by employing the baseband waveforms of Fig. 3, or other elementary waveforms, as amplitude and phase modulation in the formulation given above. The most common RF signal sets that can be generated in this manner are described below.

The signal energy values given in the descriptions that follow are based on the assumption that either $2f_cT$ is an integer and both $|a(t)|$ and $\theta(t)$ are constant on $[0,T]$ (in which case the value is exact) or $f_cT >> 1$ (in which case the value is a good approximation). These conditions imply that the double-frequency component of the square of the signal is negligible. It is also assumed that the signals $a(t)$ and $\theta(t)$ use baseband waveforms of duration T. For such signals the *energy per data pulse* is defined as follows. If the kth message is being sent in the interval $[0,T]$, the energy is

$$E_k = \int_0^T s^2(t)\, dt$$

For several of the modulation schemes, $\theta(t)$ is equal to a constant θ_k for $0 \leq t < T$ if the kth message is sent during the interval $[0,T]$. In this case, the energy is

$$E_k = (A^2/2) \int_0^T a^2(t)\, dt$$

Because of the assumption concerning f_cT, the energy does not depend on the value of θ_k. It does depend on

the energy in the waveform $a(t)$, so E_k may depend on the message k that is being sent.

Amplitude-Shift Keying (ASK)

The signal structure for amplitude-shift keying (ASK) is

$$s(t) = A\, a(t) \cos(2\pi f_c t + \phi)$$

where $a(t)$ is a sequence of baseband pulses whose amplitudes are modulated to represent the messages. This type of signaling is also commonly referred to as digital AM or multiamplitude signaling. The baseband signal $a(t)$ can be written as

$$a(t) = \sum_{n=-\infty}^{\infty} b_n\, v(t - nT)$$

where $b_n = d_k$ if the kth message is being sent during the nth interval. The set $\{d_k : k = 0, 1, \ldots, M-1\}$ of data variables is the set of amplitudes for the sequence of pulses. The simplest case is binary ASK modulation with $d_0 = 1$ and $d_1 = 0$; this is known as *on-off keying* (*OOK*).

Another important special case results if $M = 2$, $v(t)$ is the rectangular pulse of duration T, $d_0 = +1$, and $d_1 = -1$. This is just the amplitude-modulation representation for BPSK (see next subsection).

In general, the energy per data pulse for ASK depends on the message being sent. For the kth message, the energy is

$$E_k = (A\, d_k)^2\, E_v/2$$

where E_v is the energy in the waveform $v(t)$, as defined at the beginning of this chapter.

A modification of ASK is *quadrature ASK* (*QASK*), which is also known as quadrature AM (QAM). The QASK signal is of the form

$$s(t) = A\,[a_1(t) \cos(2\pi f_c t + \phi] + a_2(t) \sin(2\pi f_c t + \phi)]$$

The baseband signals $a_1(t)$ and $a_2(t)$ are sequences of pulses of duration T_s with amplitudes from the set $\mathcal{D} = \{d_k : k = 0, 1, \ldots, M-1\}$. The QASK signal $s(t)$ can be written as

$$s(t) = s_I(t) + s_Q(t)$$

where

$$s_I(t) = A\, a_1(t) \cos(2\pi f_c t + \phi]$$

is the *in-phase* component of $s(t)$ and

$$s_Q(t) = A\, a_2(t) \sin(2\pi f_c t + \phi]$$

is the *quadrature* component. Each of these two components of the QASK signal is an ASK signal with pulse duration T_s.

The simplest, commonly used QASK signal set is 4-QASK in which the set $\mathcal{D}$ contains only the two values $+1$ and -1. The in-phase and quadrature signals for 4-QASK are each binary antipodal ASK signals. If $a_1(t)$ and $a_2(t)$ are sequences of binary pulses derived from a single binary source (e.g., odd-numbered bits go to the in-phase channel and even-numbered bits go to the quadrature channel), and if the source produces binary digits at the rate of one bit every T seconds, then $T_s = 2T$ for 4-QASK. The in-phase and quadrature binary ASK signals each have a data rate of $1/T_s$ bits per second, so the total data rate for the 4-QASK signal is $2/T_s = 1/T$ bits per second. A single binary ASK signal would have to use pulses of duration $T = T_s/2$ in order to provide the same data rate, but such a binary ASK signal would therefore require twice the bandwidth of the 4-QASK signal.

If each of these two signals $a_1(t)$ and $a_2(t)$ is allowed to take on more than two values, higher-order QASK signal sets are obtained. For example, letting $\mathcal{D} = \{-3, -1, +1, +3\}$ gives the 16-QASK signal set. The 16-QASK signal set is illustrated in Fig. 5, where points in signal space are determined by the amplitudes for the pulses in the in-phase and quadrature components of the signal. This signal set provides a data rate of $4/T_s$ bits per second, and so a binary ASK signal set requires four times the bandwidth of 16-QASK in order to provide the same data rate. Greater bandwidth savings relative to binary ASK can be achieved by letting $\mathcal{D}$ be larger, and this is now a standard approach for such applications as high-speed modems* for telephone lines. The application of trellis-coded modulation† has further improved the performance of such modems.

Binary Phase-Shift Keying (BPSK)

One of the most commonly used binary signal sets is obtained by shifting the phase of the RF carrier by $+\pi/2$ radians or $-\pi/2$ radians, depending on whether the data bit is a 0 or a 1. Binary phase-shift keying can be viewed as binary phase modulation or binary amplitude modulation; the only requirement is that, during each signaling interval, $s(t)$ is one of two sinusoidal signals that differ in phase by π radians.

Suppose that the binary digit k is to be sent during the nth time interval. Viewed as phase modulation, the corresponding BPSK signal is

$$A \cos[2\pi f_c t + d_k(\pi/2) + \phi]$$

for $nT \le t < (n+1)T$ where $|d_0 - d_1| = 2$. The two most common choices for d_k are $d_0 = 0$ and $d_1 = 2$ or

---

* Reference 19.

† References 18 and 23.

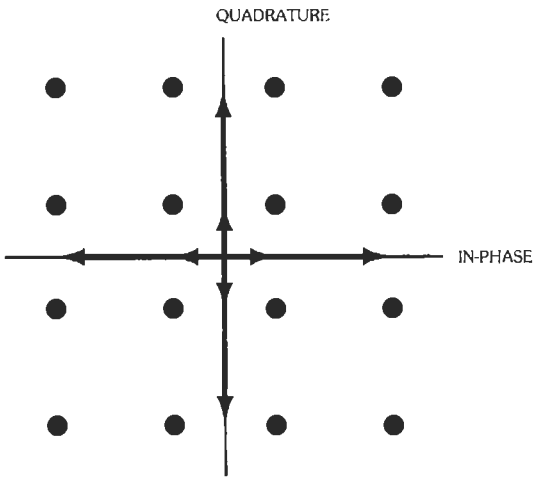

Fig. 5. A 16-QASK signal constellation.

$d_0 = +1$ and $d_1 = -1$. Based on the latter choice for d_k, the BPSK signal can be defined by

$$s(t) = A\, a(t) \cos[2\pi f_c t + \theta(t) + \phi]$$

where $a(t) = 1$ for all t and

$$\theta(t) = (\pi/2) \sum_{n=-\infty}^{\infty} b_n p_T(t - nT)$$

The data symbol b_k is d_k if k is to be sent in the nth time interval. This formulation corresponds to phase modulation by a sequence of rectangular pulses of duration T with amplitudes $(\pi/2)b_n$. The resulting signal $s(t)$ is illustrated in Fig. 6A for the data sequence $b_0 = -1$, $b_1 = +1$, and $b_2 = +1$. This illustration is for $f_c T = 2$ and $\phi = 0$.

Viewed as binary amplitude modulation, the BPSK signal can be expressed in a form that reveals its connection with binary ASK. Let $\theta(t) = 0$ for all t and use the amplitude to convey the information by defining

$$a(t) = \sum_{n=-\infty}^{\infty} b_n p_T(t - nT)$$

Thus, 0 is sent by transmitting

$$s(t) = A \cos[2\pi f_c t + \phi]$$

and 1 is sent by transmitting

$$s(t) = -A \cos[2\pi f_c t + \phi]$$

This formulation of binary PSK corresponds to amplitude modulation by a sequence of rectangular pulses of duration T with amplitudes $+1$ and -1. However, it is equivalent to phase modulation of the form

$$s(t) = A \cos[2\pi f_c t + d_k(\pi/2) + \phi]$$

with $d_0 = 0$ and $d_1 = 2$.

Although the modulator implementations suggested by these two formulations are quite different, the resulting signal sets are mathematically equivalent. In particular, it is clear from either of these formulations that the BPSK signals representing the binary digits 0 and 1 form an antipodal signal set. Notice also that for each of these representations the energy per data pulse is $E = A^2T/2$.

Quadriphase Shift Keying (QPSK)

Binary PSK can be generalized by allowing the phase waveform to take on more than two values. The QPSK signal is of the same basic form as BPSK, except that quaternary modulation is employed instead of binary modulation. Thus the transmitted signal for the interval $[nT, (n + 1)T]$ can be written as

$$s(t) = A \cos[2\pi f_c t + \theta_k + \phi]$$

where k denotes the message to be sent in the nth interval ($k = 0, 1, 2,$ or 3). The four different values for θ_k must be separated by $\pi/2$ radians. For example, we can let $\{\theta_k : k = 0, 1, 2, 3\}$ be the set $\{0, \pi/2, \pi, 3\pi/2\}$ or the set $\{\pi/4, 3\pi/4, 5\pi/4, 7\pi/4\}$. As with BPSK, the values themselves are unimportant, but the differences are constrained.

The QPSK signal can be expressed as

$$s(t) = A \cos[2\pi f_c t + \theta(t) + \phi]$$

The phase modulation $\theta(t)$ is a sequence of rectangular pulses of duration T and amplitudes $(\pi/2)b_n$ with $b_n = 0, 1, 2,$ or 3. This signal is illustrated in Fig. 6B for the data sequence $b_0 = 0$, $b_1 = 2$, and $b_2 = 3$. As in Fig. 6A, $f_c T = 2$ and $\phi = 0$.

The QPSK signal can also be viewed as quadrature amplitude modulation by writing

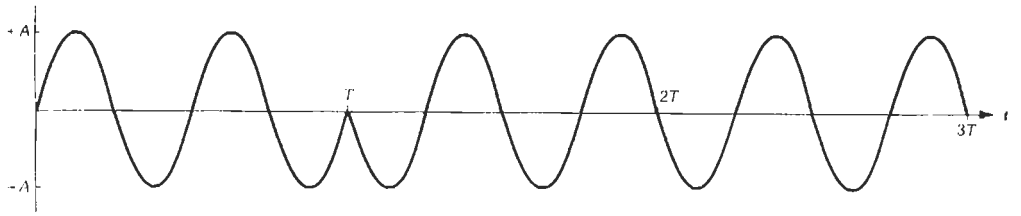
$$s(t) = A \cos[2\pi f_c t + \theta(t) + \phi]$$

as

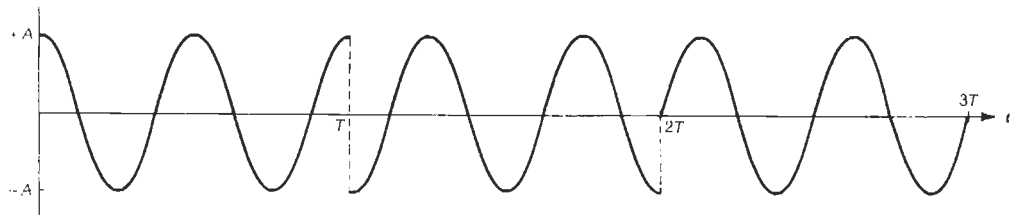
$$s(t) = A \{\cos[\theta(t)] \cos[2\pi f_c t + \phi] - \sin[\theta(t)] \sin[2\pi f_c t + \phi]\}$$

If $\theta(t)$ takes on values in the set $\{\pi/4, 3\pi/4, 5\pi/4, 7\pi/4\}$, then $\cos[\theta(t)]$ is either $+1/\sqrt{2}$ or $-1/\sqrt{2}$, and $\sin[\theta(t)]$ takes on the same two values. Thus $s(t)$ can be written as

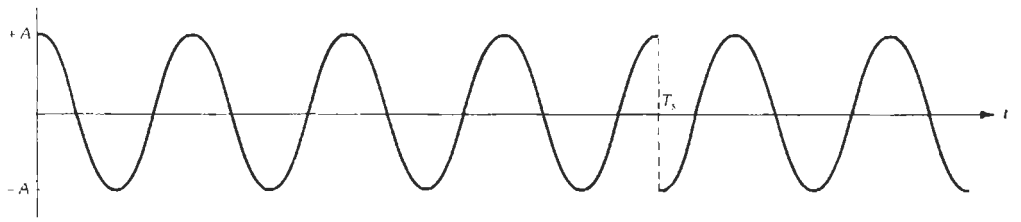
$$s(t) = (A/\sqrt{2}) \{a_1(t) \cos[2\pi f_c t + \phi] + a_2(t) \sin[2\pi f_c t + \phi]\}$$



(A) Binary PSK, data rate 1/T bits per second.



(B) Example of QPSK, data rate 2/T bits per second.



(C) Example of QPSK, data rate 1/T bits per second.

Fig. 6. Various forms of phase-shift keying.

where $a_1(t)$ and $a_2(t)$ are sequences of positive and negative unit-amplitude rectangular pulses of duration T. This formulation of QPSK clearly exhibits its relationship to QASK. If we define the *in-phase* and *quadrature* signals by

$$s_I(t) = (A/\sqrt{2})\, a_1(t) \cos[2\pi f_c t + \phi]$$

and

$$s_Q(t) = (A/\sqrt{2})\, a_2(t) \sin[2\pi f_c t + \phi]$$

respectively, the QPSK signal can be written as

$$s(t) = s_I(t) + s_Q(t)$$

Each of the signals $a_1(t)$ and $a_2(t)$ has the same number of pulses per unit of time as the signal $a(t)$ that appears in the amplitude-modulation formulation of BPSK. Consequently, QPSK signaling has twice the data rate of BPSK. This can also be observed from the original quaternary-phase-modulation formulation by noticing that each pulse of duration T takes on one of four values, and this gives $\log_2(4) = 2$ bits of data per pulse.

The quadrature-amplitude-modulation formulation of QPSK displays the signal as the sum of two quadrature binary ASK signals. A QPSK signal can also be viewed as two quadrature BPSK signals. For example, we can write the QPSK signal as

$$s(t) = (A/\sqrt{2}) \{\cos[2\pi f_c t + \theta_1(t) + \phi] + \sin[2\pi f_c t + \theta_2(t) + \phi]\}$$

where $\theta_1(t)$ and $\theta_2(t)$ take on the values 0 and π.

The power in the QPSK signal is $A^2/2$, just as for BPSK, and so the energy per pulse is $E = A^2T/2$. Since each pulse represents two bits of data, the energy per bit for QPSK is $E_b = A^2T/4$, which is one-half of the energy per bit for BPSK for the same pulse duration T. Because the pulse shape and duration are the same for BPSK and QPSK, the two signals have the same bandwidth.

For most purposes, it is better to compare BPSK and QPSK signals that have *the same energy per data bit and the same data rate* (rather than the same pulse duration as above). To do this, simply replace T by T_s in the QPSK expressions, and let $T_s = 2T$. That is, the signal $s(t)$ is given by

$$s(t) = A \cos[2\pi f_c t + \theta(t) + \phi]$$

as before, but now the phase modulation $\theta(t)$ is a sequence of rectangular pulses of duration $T_s = 2T$, rather than T. The amplitudes of these pulses are still given by $(\pi/2)b_n$ with $b_n = 0, 1, 2,$ or 3; however, the sequence (b_n) is now transmitted at the rate of one quaternary symbol every T_s seconds. This signal is illustrated in Fig. 6C for $b_0 = 0$ and $b_1 = 2$, with $f_c T = 2$ and $\phi = 0$.

Because a QPSK pulse of duration T_s provides two bits of data, the data rate of a QPSK signal that uses pulses of duration T_s is

$$R_{\text{QPSK}} = 2/T_s = 1/T$$

bits per second. If the digital data consists of a single sequence of binary digits, half of the data bits can be modulated onto the in-phase component and half onto the quadrature component.

Since $1/T$ is also the data rate for a BPSK signal with pulse duration T, these two forms of PSK modulation can now be compared on the basis of the same data rate. In this case, the energy per pulse for QPSK is given by

$$E = A^2 T_s/2$$

which is equivalent to an energy per bit of

$$E_b = A^2 T/2$$

the same as BPSK. The pulse shapes for QPSK and BPSK are the same, but the pulse duration for QPSK is $T_s = 2T$, twice that for BPSK. This means the QPSK signal has one-half the bandwidth of the BPSK signal.

In summary, if QPSK and BPSK are compared for the *same data rate*, BPSK requires twice the bandwidth of QPSK. If the two signals have the *same data rate* and *equal power*, they also have the same energy per data bit.

Offset Quadriphase Shift Keying (OQPSK)

The OQPSK signal can be defined by replacing $\theta_1(t)$ with $\theta_1(t + T)$ in the quadrature-phase-modulation formulation of QPSK. That is, OQPSK can be represented in terms of two quadrature BPSK signals as

$$s(t) = (A/\sqrt{2}) \{\cos[2\pi f_c t + \theta_1(t + T) + \phi] + \sin[2\pi f_c t + \theta_2(t) + \phi]\}$$

where $\theta_1(t)$ and $\theta_2(t)$ are sequences of pulses of duration $T_s = 2T$ as in the preceding subsection. Since the amount of the offset is one-half the pulse duration, the phase transitions of the in-phase and quadrature components of the OQPSK signal are separated in time by T seconds.

The OQPSK signal can be represented as quadrature amplitude modulation with the baseband signal of the in-phase component offset by T seconds relative to the baseband signal of the quadrature component. Thus, the amplitude-modulation representation of OQPSK is

$$s(t) = (A/\sqrt{2}) \{a_1(t + T) \cos[2\pi f_c t + \phi] + a_2(t) \sin[2\pi f_c t + \phi]\}$$

where $a_1(t)$ and $a_2(t)$ are as in the preceding subsection. Notice that the baseband signal for the in-phase component can change polarity at times nT for odd integers n only, but the transitions of the baseband signal for the quadrature component are at times nT for even values of n only. This is an important feature of OQPSK for band-limited channels with nonlinearities. A band-limited version of QPSK or BPSK has an envelope that may go to zero when the in-phase and quadrature signals switch polarity at the same time; the offset in OQPSK leads to a more nearly constant envelope for the band-limited signal.

If the OQPSK signal is expressed in the form

$$s(t) = A \cos[2\pi f_c t + \theta(t) + \phi]$$

the phase $\theta(t)$ can change every T seconds, whereas the phase shifts in QPSK occur only at $2T$-second intervals. However, for OQPSK the magnitudes of the phase shifts are limited to 0 or $\pi/2$ only. Phase shifts for QPSK can have magnitudes 0, $\pi/2$, or π.

Minimum-Shift Keying (MSK)

The MSK signal can be considered as a special case of offset quadrature amplitude modulation in which the baseband waveform is the sine pulse $v(t) = \sin(\pi t/2T)p_{2T}(t)$. Thus the MSK signal can be written as

$$s(t) = A \{a_1(t + T) \cos[2\pi f_c t + \phi] + a_2(t) \sin[2\pi f_c t + \phi]\}$$

where $a_1(t)$ and $a_2(t)$ are sequences of sine pulses of duration $2T$. That is, for each $i (i = 1$ or $i = 2)$

$$a_i(t) = \sum_{n=-\infty}^{\infty} b_{i,n} v(t - 2nT)$$

where $(b_i) = \ldots, b_{i,0}, b_{i,1}, b_{i,2}, \ldots$ is a binary data sequence. Minimum-shift keying can also be viewed as continuous-phase frequency-shift keying (discussed in a later subsection).

Binary Frequency-Shift Keying (FSK)

Binary FSK signals are of the form

$$s(t) = A \cos[2\pi f_c t + \theta(t)]$$

where the modulation $\theta(t)$ is defined as follows. If 0 is the bit to be transmitted in the nth interval,

$$\theta(t) = 2\pi f_d t + \phi_0$$

and if 1 is sent,

$$\theta(t) = -2\pi f_d t + \phi_1$$

Thus, the signal

$$s(t) = A\cos[2\pi(f_c + f_d)t + \phi_0]$$

represents a 0 for the nth interval, and the signal

$$s(t) = A\cos[2\pi(f_c - f_d)t + \phi_1]$$

represents a 1. The quantity f_d is called the *frequency deviation*, and the parameter $h = 2f_dT$ is called the *deviation ratio* or *modulation index* for the FSK signal set. The FSK signals may be generated by switching between two oscillators or by applying a binary baseband signal at the input of a voltage-controlled oscillator (VCO).

In general, the phase angles ϕ_k are arbitrary, and ϕ_0 need not be related to ϕ_1 in any way. If the FSK signals are obtained by switching between two oscillators, one at frequency $f_c + f_d$ and one at frequency $f_c - f_d$, the phase angles ϕ_0 and ϕ_1 represent the phases of these oscillators at time $t = 0$. Alternatively, the FSK signals may be generated by applying a baseband signal to a VCO (or another frequency-modulation circuit), in which case the phase angles ϕ_0 and ϕ_1 may be related.

The signals in FSK systems are often referred to as "tones," and the two signals are distinguished by calling one of them "*mark*" and the other "*space*." The convention followed here is to refer to the signal at frequency $f_c + f_d$ as the space and the signal at frequency $f_c - f_d$ as the mark (the binary digit 0 is transmitted as a space, and the binary digit 1 is transmitted as a mark).

If $2f_cT$ and $2f_dT$ are integers, the mark and space signals form an *orthogonal* signal set for *all* values of ϕ_0 and ϕ_1. It is often the case that $f_cT >> 1$. Under this condition, the signals are approximately orthogonal if $2fdT$ is an integer or if $f_dT >> 1$. If $2f_cT$ and $2f_dT$ are integers or if $(f_c - f_d)T >> 1$, the energy per data bit is $A^2T/2$.

For certain applications, it is necessary to generalize the above formulation of FSK by introducing a phase angle $\phi(n)$ that depends on the interval in which the signal is transmitted. To send a 0 in the nth interval, the transmitted signal for $nT \le t < (n + 1)T$ is

$$s(t) = A\cos[2\pi(f_c + f_d)t + \phi(n) + \phi_0]$$

and to send a 1 in this same interval, the signal is

$$s(t) = A\cos[2\pi(f_c - f_d)t + \phi(n) + \phi_1]$$

This generalization is required in order to characterize FSK signals in frequency-hopped spread-spectrum systems, for example, where the phase $\phi(n)$ represents a phase shift introduced by noncoherent frequency hopping.* This generalization is also required for the description of certain continuous-phase FSK modulation schemes.

Continuous-Phase Frequency-Shift Keying (CPFSK)

Continuous-phase FSK signals are of the form

$$s(t) = A\cos[2\pi f_c t + \theta(t)]$$

just as for other types of FSK signals. However, for CPFSK the phase modulation $\theta(t)$ is a continuous function of t. In order to describe CPFSK modulation, it is sufficient to consider only the case in which $\phi_0 = \phi_1 = 0$. This is because the phase angles ϕ_0 and ϕ_1 can always be absorbed in the phase modulation $\theta(t)$ for CPFSK signals.

The signal $\theta(t)$ is defined as follows. Suppose b_n is the data symbol to be sent in the nth interval, and b_n is either $+1$ or -1. The phase modulation is

$$\theta(t) = 2\pi b_n f_d t + \phi(n)$$

for $nt \le t < (n + 1)T$. The phase angles $\phi(n)$ are such that the phase is continuous from one interval to the next. In order to make the phase continuous at time nT, the phase angles $\phi(n)$ and $\phi(n - 1)$ must satisfy

$$2\pi b_n f_d nT + \phi(n) = 2\pi b_{n-1} f_d nT + \phi(n - 1)$$

which is equivalent to the condition

$$\phi(n) = 2\pi(b_{n-1} - b_n)f_d nT + \phi(n - 1)$$

In other words, $\phi(n) = \phi(n - 1)$ if the two successive data symbols b_{n-1} and b_n are the same, but $\phi(n)$ and $\phi(n - 1)$ differ by $4\pi f_d nT$ radians if these two data symbols are different.

The simplest CPFSK signal is obtained for the case in which the modulation index $h = 2f_dT$ is an integer. For this case, $4\pi f_d nT$ is an integer multiple of 2π, and $\phi(n) = \phi(n - 1)$ modulo 2π, regardless of whether the successive data symbols are the same or different. But phase angles that differ by integer multiples of 2π are the same for our purposes, so we can let $\phi(n) = \phi$, where ϕ is a constant phase (independent of n). No phase changes are required in order to make $\theta(t)$ continuous provided the modulation index is an integer.

Another modulation index of considerable interest for CPFSK is 1/2. For $h = 1/2$, the frequency deviation is $f_d = 1/4T$, and the condition for continuous phase is

$$\phi(n) = \pi n[(b_{n-1} - b_n)/2] + \phi(n - 1)$$

* Reference 29.

If the successive data bits b_{n-1} and b_n are the same, the phase angles $\phi(n-1)$ and $\phi(n)$ are also the same. If the successive data bits are different, $b_{n-1} - b_n$ is either $+2$ or -2, and so the phase angles must differ by an integer multiple of π radians. It follows that if $\phi(0) = 0$ and $2f_cT$ is an integer, or if $f_cT >> 1$, the mark and space signals are orthogonal. It is important to realize that orthogonality is obtained for $h = 1/2$ only if the phases in successive intervals are controlled.

From the relationship

$$\theta(t) = 2\pi b_n f_d t + \phi(n)$$

which holds for $nT \leq t < (n+1)T$, it follows that

$$\theta(nT) = 2\pi b_n f_d nT + \phi(n)$$

Making the substitution for $\phi(n)$ from the last equation into the expression for $\theta(t)$, we find that

$$\theta(t) = 2\pi b_n f_d (t - nT) + \theta(nT)$$

for $nT \leq t < (n+1)T$. This fact and the continuity condition imply

$$\theta((n+1)T) = 2\pi b_n f_d T + \theta(nT)$$

If we denote $\theta(kT)$ by θ_k and let $h = 1/2$ in this expression, it can be written as

$$\theta_{n+1} = (\pi/2) b_n + \theta_n$$

Similarly, the expression for $\theta(t)$ becomes

$$\theta(t) = (\pi/2T) b_n (t - nT) + \theta_n$$

which is valid for $nT \leq t < (n+1)T$.

The CPFSK signal is

$$s(t) = A\{\cos[\theta(t)]\cos[2\pi f_c t] - \sin[\theta(t)]\sin[2\pi f_c t]\}$$

The above relationships for $\theta(t)$, θ_n, and θ_{n+1} imply that if n is an even integer and $h = 1/2$,

$$-\sin\theta(t) = -\sin[\theta_{n+1}]\sin[\pi(t - nT)/2T]$$

for $nT \leq t < (n+2)T$. Similarly, if n is an odd integer and $h = 1/2$,

$$\cos\theta(t) = -\cos[\theta_{n+1}]\sin[\pi(t - nT)/2T]$$

for $nT < t < (n+2)T$. Define the data sequence (B_n) by

$$B_n = -\sin\theta_{n+1}$$

if n is an even integer and by

$$B_n = -\cos\theta_{n+1}$$

if n is an odd integer. The data sequence (B_n) is related to the original data sequence (b_n) by

$$b_n = -B_n \cos\theta_n$$

if n is an even integer and by

$$b_n = B_n \sin\theta_n$$

if n is an odd integer.

From the above development, we conclude that for $h = 1/2$ the CPFSK signal $s(t)$ is of the form

$$s(t) = A\{a_1(t+T)\cos[2\pi f_c t] + a_2(t)\sin[2\pi f_c t]\}$$

The baseband signals $a_1(t)$ and $a_2(t)$ are given by

$$a_1(t) = B_{2k-1}\sin[\pi(t - 2kT)/2T]$$

and

$$a_2(t) = B_{2k}\sin[\pi(t - 2kT)/2T]$$

for $2kT \leq t < 2(k+1)T$. A comparison of these last three equations with analogous equations in the subsection on minimum-shift keying shows that CPFSK with modulation index $h = 1/2$ is the same as MSK.

M-ary Signaling and Multiple Frequency Shift Keying (MFSK)

The general M-ary RF signal set has signals of the form

$$s_k(t) = A a_k(t)\cos[2\pi f_c t + \theta_k(t) + \phi_k]$$

for k = 0, 1, . . . , $M-1$. The signals $a_k(t)$ and $\theta_k(t)$ are baseband signals with bandwidths much smaller than the carrier frequency f_c. The messages are indexed by the integers 0, 1, . . . , $M-1$, and in order to send the kth message during the nth interval, the signal $s(t) = p_T(t - nT)\, s_k(t)$ is transmitted. (The rectangular pulse of duration T is defined by $p_T(u) = 1$ for $0 \leq u < T$ and $p_T(u) = 0$ otherwise.)

The RF signal set is characterized by the inner products

$$(s_k, s_j) = \int_0^T s_k(t)\, s_j(t)\, dt$$

Since the amplitude modulation $a_k(t)$ and phase modulation $\theta_k(t)$ are narrow-band signals, the inner products are (at least approximately) given by

$$(s_k, s_j) = A^2 \int_0^T a_k(t)\, a_j(t)\cos[\theta_{k,j}(t) + \phi_{k,j}]dt$$

where

$$\theta_{k,j}(t) = \theta_k(t) - \theta_j(t)$$

and

$$\phi_{k.j} = \phi_k - \phi_j$$

If $(s_k, s_j) = 0$ for all $j \neq k$, the signals form an *orthogonal* signal set. One type of orthogonal signal set is obtained by letting $\theta_k(t) = 0$ for all t and using a set of orthogonal baseband signals for the amplitude modulation $a_k(t)$.

Multiple frequency shift keying (*MFSK*), which is also known as M-ary frequency shift keying, is a direct extension of binary FSK to modulation with more than two frequency tones. It is also a special case of M-ary signaling in which $a_k(t) = 1$ and

$$\theta_k(t) = (f_k - f_c)t$$

The resulting signals are of the form

$$s_k(t) = A \cos[2\pi f_k t + \phi_k]$$

In order to send the kth message in the nth interval, the transmitted signal is

$$s(t) = Ap_T(t - nT) \cos[2\pi f_k t + \phi_k]$$

If the frequencies f_k are such that $f_k T = n_k$ for some integers $n_0, n_1, \ldots, n_{M-1}$, the M different signals are orthogonal on each interval $[nT, (n + 1)T]$. The signals are at least approximately orthogonal if $|f_k - f_j|T >> 1$ for each choice of $j \neq k$. The phases $\phi_0, \phi_1, \ldots, \phi_{M-1}$ are arbitrary and, in general, not related to each other in any way.

Spectra of PSK and MSK Signals

By introducing appropriate random time delays and phase angles, we can model the signal $s(t)$ as a wide-sense stationary random process. The Fourier transform of the autocorrelation function for this random process is called the *power spectral density*, or simply the *spectrum*. The spectrum of a signal gives a measure of the distribution of its power as a function of frequency. For example, the bandwidth of a signal is usually defined in terms of its spectrum (e.g., see reference 15). The four digital modulation techniques considered are three forms of phase-shift keying (PSK) and MSK. The three PSK schemes are BPSK, QPSK, and OQPSK. The data rate in each case is assumed to be $R = 1/T$ bits per second.

The spectrum of the BPSK signal is

$$S_1(f) = (A^2T/4)\{G_1[(f - f_c)T] + G_1[(f + f_c)T]\}$$

where the function G_1 is defined by

$$G_1(x) = [\text{sinc}(x)]^2 = [\sin(\pi x)/\pi x]^2$$

The spectrum of a QPSK signal with data rate $R = 1/T$ bits per second is given by

$$S_2(f) = (A^2T/4)\{G_2[(f - f_c)T] + G_2[(f + f_c)T]\}$$

where

$$G_2(x) = 2\ G_1(2x)$$

The spectrum of the OQPSK signal is the same as the spectrum of the QPSK signal. The spectrum of the MSK signal is

$$S_3(f) = (A^2T/4)\{G_3[(f - f_c)\ T] + G_3[(f + f_c)T]\}$$

where the function G_3 is defined by

$$G_3(x) = \{[(4/\pi)\cos(2\pi x)]/(1 - 16x^2)\}^2$$

The power in each of the PSK and MSK signals is $P = A^2/2$. Since the power is equal to the integral of the power spectral density,

$$\int_{-\infty}^{\infty} S_i(f)\, df = (A^2/2) \int_{-\infty}^{\infty} G_i(x)\, dx = P$$

for each i. The comparisons below of the spectra of PSK and MSK signals are made on the basis of equal power in the signals. It is also common to compare the signals on the basis of equal values of $S_i(f_c)$, the spectral density at the carrier frequency (e.g., reference 15), but in this case the signals have different power levels.

Notice that the spectra $S_1(f)$, $S_2(f)$, and $S_3(f)$ are given in the form

$$S_i(f) = (A^2T/4)\{G_i[(f - f_c)T] + G_i[(f + f_c)T]\}$$

so that comparisons of these spectra can be made by comparing the corresponding functions $G_1(x)$, $G_2(x)$, and $G_3(x)$. In fact, if $f_cT >> 1$ the two components of the spectrum do not overlap significantly; that is, for each integer i,

$$G_i[(f - f_c)T] >> G_i[(f + f_c)\ T]$$

for $f > 0$, and the reverse inequality holds for $f < 0$. It follows that $S_i(f)$ is approximately

$$S_i(f) = G_i[(f - f_c)T]$$

for $f > 0$ and

$$S_i(f) = G_i[(f + f_c)T]$$

for $f < 0$. Consequently, for $f_cT >> 1$, the shape of spectrum $S_i(f)$ for $f > f_c$ is just the shape of $G_i(x)$ for $x > 0$. Also notice that $G_i(x) = G_i(-x)$.

The spectra of BPSK, QPSK, OQPSK, and MSK are compared in Figs. 7 and 8. In Fig. 7, $G_i(x)$ is shown as a

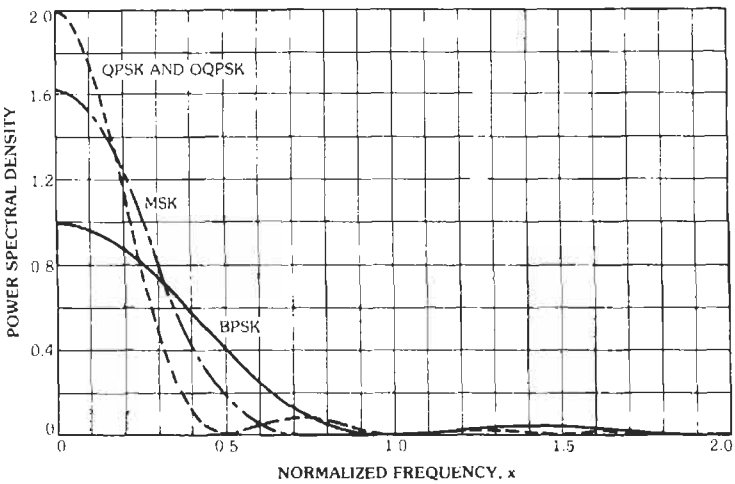


Fig. 7. Power spectral densities for PSK and MSK.

function of x for all three values of i. The parameter x can be thought of as *normalized frequency*, since it is frequency (in hertz) divided by the data rate R (in bits per second). Note that x is therefore a dimensionless parameter.

Specifications on signal spectra (e.g., bandwidths) are often given in terms of the power spectral densities in decibels (dB). Fig. 8 shows $G_i(x)$ in decibels as a function of x. Since $G_i(x)$ is a power density, the conversion is $10 \log_{10}[G_i(x)]$. The *3-dB bandwidth* of $S_i(f)$ is the width of a frequency band outside of which the power spectral density is at least 3 dB below $S_i(f_c)$, its value at the center of the band. Typically, bandwidths are normalized by dividing by R, which is equivalent to specifying the bandwidth in terms of the normalized frequency. Since $10 \log_{10}(0.5)$ is approximately -3 dB, the 3-dB bandwidth is also termed the *half-power bandwidth*. In terms of the function G_i, the 3-dB, or half-power, bandwidth is the largest value of y for which $G_i(y/2) = 0.5\ G_i(0)$.

Analogous definitions are given for other power-density levels (e.g., the 10-, 35-, or 50-dB bandwidths) in reference 15. The 3-dB bandwidths for the PSK and MSK signals are 0.88 for BPSK, 0.44 for QPSK and OQPSK, and 0.59 for MSK; and the 35-dB bandwidths are 35.12, 17.56, and 3.24, respectively.* The *null-to-*

* Reference 15.

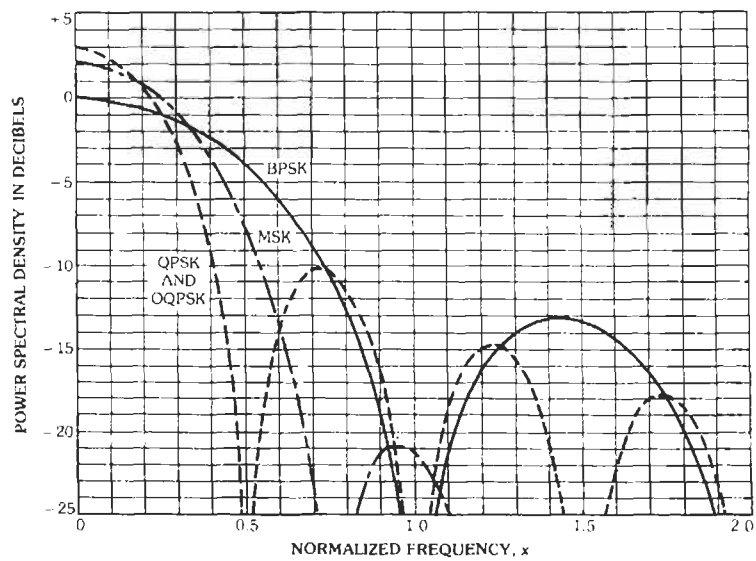

Fig. 8. Power spectral densities in decibels.

null bandwidth is the smallest value of y for which $G_i(y/2) = 0$. As can be seen in Figs. 7 and 8, the null-to-null bandwidths are 2.0 for BPSK, 1.0 for QPSK and OQPSK, and 1.5 for MSK. Notice that although MSK has lower side lobes and smaller 35-dB bandwidth than QPSK, QPSK has a narrower main lobe (i.e., smaller null-to-null bandwidth) and a smaller 3-dB bandwidth. These and related issues are discussed in greater detail in references 15 through 22.

OPTIMUM RECEIVERS FOR DIGITAL COMMUNICATIONS

Receivers for Binary Baseband Data Transmission

The general model for a binary baseband data transmission system with an additive Gaussian noise channel is shown in Fig. 9. The model of Fig. 9 is employed for coherent RF communications also, because it is the low-pass equivalent of a binary RF digital communications system with an additive Gaussian noise channel and a coherent receiver. The block diagram for the RF system is shown in Fig. 10. The input,

$$s(t) = \sqrt{2}s_k(t)\cos[2\pi f_c t + \phi]$$

for the RF channel corresponds to the input $s_k(t)$ for the baseband channel.

The principal elements of the channel are a binary signal set $\{s_0, s_1\}$, an additive Gaussian noise process $X(t)$, a linear filter with impulse response $h(t)$, a sampler, and a threshold device. The binary digit k is sent during the nth time interval by transmitting the signal $s_k(t - nT)$ for $nT < t < (n + 1)T$. For convenience, we consider the first time interval (i.e., $n = 0$) in all that follows. For this time interval, the channel output $Y(t)$ is the sum of the signal $s_k(t)$ plus the noise $X(t)$.

The channel output is the input to the linear time-invariant filter. The filter output $Z(t)$ is the sum of a filtered version of the signal, which is denoted by $\hat{s}_k(t)$, and a filtered version of the noise. The signal component of the filter output is given by

$$\hat{s}_k(t) = \int_{-\infty}^{\infty} s_k(u)\, h(t - u)\, du$$

the *convolution* of the functions s_k and h, which we denote by $\hat{s}_k = s_k * h$.

The output of the filter is sampled at time T_0 to give the decision statistic $Z(T_0)$. Our notational convention is to let s_0 denote the signal that produces the larger output at sampling time T_0; that is, we assume

$$\hat{s}_0(T_0) > \hat{s}_1(T_0)$$

In the threshold device, the decision statistic $Z(T_0)$ is compared with a threshold z, and the decision is that s_0 was transmitted if the statistic $Z(T_0)$ is greater than the threshold z. If $Z(T_0)$ is less than z, the decision is that the signal s_1 was transmitted. This system always makes the correct decision in the absence of noise provided that the threshold is in the range

$$\hat{s}_0(T_0) > z > \hat{s}_1(T_0)$$

The channel noise $X(t)$ is a wide-sense stationary random process with autocorrelation function given by

$$R_X(u) = E\{X(t)X(t + u)\}$$

where $E\{Y\}$ denotes the expected value of a random variable Y. Without loss of generality, the channel noise process can be assumed to have zero mean (the mean value can always be absorbed in the signal set). The autocorrelation function for the noise at the output of the filter is given by

$$R(u) = \int_{-\infty}^{\infty} R_X(v) f(u - v)\, dv$$

where the function f is defined by

$$f(t) = \int_{-\infty}^{\infty} h(v)h(v + t)\, dv$$

These two expressions are equivalent to $R = R_X * f$ and $f = h * g$, respectively, where the function g is defined by $g(t) = h(-t)$. That is, g is the time reverse of the impulse response of the filter. Since $f(t) = f(-t)$, $h(v + t)$ can be replaced by $h(v - t)$ in the definition of the function f, but the form given above is usually easier to evaluate.

Let $P_{e,k}$ denote the probability that an error is made by the receiver when the signal $s_k(t)$ is the input to the channel. The error probability $P_{e,k}$ can be thought of as a *conditional probability of error* given that $Y(t) = s_k(t) + X(t)$. That is, if H_k denotes the event that the signal $s_k(t)$ is transmitted, the probability $P_{e,k}$ is the conditional probability of error given H_k.

When the signal $s_0(t)$ is transmitted, the receiver makes an error if $Z(T_0)$ is less than the threshold z.

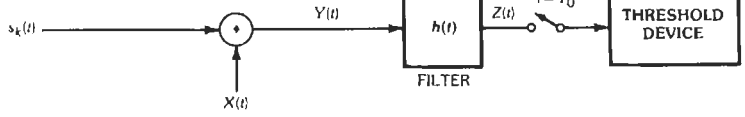

Fig. 9. Model of binary baseband data transmission system.

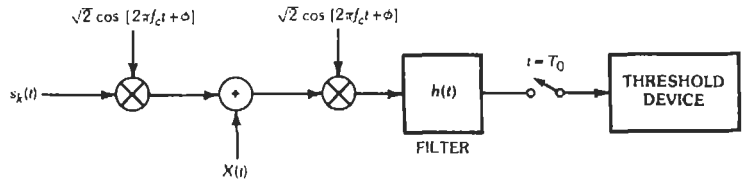

Fig. 10. Model of binary coherent RF communication system.

Thus,

$$P_{e,0} = P[Z(T_0) < z \mid H_0]$$

Given that $s_0(t)$ is the transmitted signal, $Z(T_0)$ is a Gaussian random variable that has mean $\hat{s}_0(T_0)$ and variance $\sigma^2 = R(0)$. Consequently,

$$P_{e,0} = Q[\{\hat{s}_0(T_0) - z\}/\sigma]$$

where the function Q is defined by

$$Q(x) = \int_x^\infty (2\pi)^{-1/2} \exp(-y^2/2)\, dy$$

The function $1 - Q(x)$ is the distribution function of a zero mean, unit variance, Gaussian random variable. A discussion of the function Q and its properties can be found in reference 11.

Similarly, if $s_1(t)$ is transmitted, $Z(T_0)$ is a Gaussian random variable with mean $\hat{s}_1(T_0)$ and variance $\sigma^2 = R(0)$, and an error occurs if $Z(T_0)$ is greater than the threshold z. Therefore, the error probability $P_{e,1}$ is

$$P_{e,1} = P[Z(T_0) > z|H_1]$$

$$= Q[\{z - \hat{s}_1(T_0)\}/\sigma]$$

Optimum Threshold for General Gaussian Noise—The choice of the threshold depends on the performance measure under consideration. One measure of performance that is often used is the maximum of the error probabilities,

$$P_{e,m} = \max\{P_{e,0}, P_{e,1}\}$$

The *minimax criterion* for selecting the threshold is to choose the threshold z to give the smallest possible value of $P_{e,m}$. The value of z that minimizes $P_{e,m}$ is given by

$$z_m = [\hat{s}_0(T_0) + \hat{s}_1(T_0)]/2$$

and this is referred to as the *minimax threshold*. Notice that the minimax threshold depends on the signal set $\{s_0, s_1\}$, the impulse response of the filter, and the sampling time T_0.

It is convenient to introduce the signal

$$s_d(t) = \{s_0(t) - s_1(t)\}/2$$

and let $\hat{s}_d(t)$ denote the output of the filter when $s_d(t)$ is the input (i.e., $\hat{s}_d = s_d * h$). If the minimax threshold is employed, the error probabilities $P_{e,0}$ and $P_{e,1}$ are given by

$$P_{e,0} = P_{e,1} = Q[\hat{s}_d(T_0)/\sigma]$$

Whenever these two probabilities are equal, we denote the common value by P_e.

As an example, consider an antipodal signal set (discussed earlier in this chapter). Since $s_0(t) = -s_1(t)$, the signal $s_d(t)$ is given by $s_d(t) = s_0(t)$. The error probability for the minimax threshold is

$$P_e = Q[\hat{s}_0(T_0)/\sigma]$$

There are other criteria for selecting the threshold z, but they typically require additional information about the data sequence that is to be transmitted. For instance, if the data sequence is modeled as a random process with a known probability distribution, the average probability of error can be employed as a criterion. If p_k denotes the *a priori probability* that the binary digit k is transmitted, the *average probability of error* is

$$P_{e,A} = P_{e,0}p_0 + P_{e,1}p_1$$

The threshold that minimizes $P_{e,A}$ is given by

$$z_A = z_m + 2\,\sigma^2[\hat{s}_d(T_0)]^{-1}\ln(p_1/p_0)$$

If the data bits 0 and 1 are equally probable (i.e., $p_0 = p_1$), the thresholds z_A and z_m are the same. Otherwise, the second term on the right-hand side of the expression for z_A is a nonzero term that biases the decision in favor of the data bit with the largest a priori probability.

For applications in which unequal costs are associated with the two types of errors and the a priori probabilities p_i are known, it may be desirable to select the threshold to minimize the average cost. This is the well-known *Bayes criterion*, which is discussed in references 4, 9, and 10.

The Matched Filter—A white Gaussian noise process $X(t)$ has spectral density $S_X(f) = N_0/2$ for all f. This is just the Fourier transform of a delta function that has area $N_0/2$. If the channel noise process has this flat spectral density, the autocorrelation function of the noise at the output of the filter is given by

$$R(u) = (N_0/2)f(u)$$

where $f = h^*g$, the convolution of the impulse response and its time-reverse. Letting $u = 0$, we find

$$\sigma^2 = R(0) = N_0 \|h\|^2/2$$

The norm of the function h is defined by

$$\|h\| = \{\int_{-\infty}^{\infty} h^2(t)\, dt\}^{1/2}$$

Consider first the minimax criterion. The optimum threshold depends on the filter impulse response $h(t)$, and for each choice of the filter impulse response, the corresponding minimax threshold gives the smallest possible value of $P_{e,m}$. Let P_e denote this minimum value of $P_{e,m}$ (recall that $P_e = P_{e,0} = P_{e,1}$ if the minimax threshold is used).

The value of P_e depends on the impulse response of the filter. For a system with an *additive white Gaussian noise channel*, the minimum possible value of P_e is achieved by the impulse response

$$h_M(t) = s_d(T_0 - t)$$

Multiplication of the filter impulse response by a positive constant c does not change the error probability if the corresponding minimax threshold is used, so $h_M(t)$ can be any positive constant multiple of $s_d(T_0 - t)$. A filter with this impulse response is called a *matched filter*.

Given a binary signal set $\{s_0, s_1\}$, let E_i denote the energy in the signal s_i, and define E_A by

$$E_A = [E_0 + E_1]/2$$

The signal correlation r' is the inner product

$$r' = (s_0, s_1) = \int_{-\infty}^{\infty} s_0(t)\, s_1(t)\, dt$$

and $r = r'/E_A$ is the correlation coefficient for the given signal set. The value of $|r|$ is never greater than one; moreover, $r = -1$ only for antipodal signals, and $r = +1$ only if $s_0(t) = s_1(t)$.

The norm of signal s_d is related to the energy by

$$\|s_d\|^2 = E_A(1 - r)/2$$

The matched filter impulse response $h_M(t) = cs_d(T_0 - t)$ has norm

$$\|h_M\|^2 = c^2 \|s_d\|^2$$

If this filter is employed in the receiver, the minimax threshold is $z_m = c(E_0 - E_1)/4$, and the signal $\hat{s}_d(T_0)$ is given by

$$\hat{s}_d(T_0) = \|s_d\| \|h_m\| = c \|s_d\|^2$$

It follows that the error probability for a receiver with a matched filter and minimax threshold is

$$P_e = Q\{[E_A(1 - r)/N_0]^{1/2}\}$$

This is the smallest error probability that can be achieved (if a single bit is transmitted) with *binary* baseband data transmission or *binary* coherent RF communications over an additive white Gaussian noise channel.

Two important points should be made concerning the above expression for the minimum error probability. First, the result does not depend on the sampling time T_0. This is because the matched filter automatically compensates for the sampling time by incorporating a delay in its impulse response. As a consequence of this, the sampling time can be selected for convenience of implementation. In particular, if the signal set $\{s_0, s_1\}$ is *time limited* to the interval $[0, T]$, the matched filter is causal for any choice of T_0 not less than T. For such a signal set, the customary choice for the sampling time is $T_0 = T$.

The second point is that the minimum probability of error depends on the three parameters E_A, N_0, and r. The energy E_A can be increased only by increasing the power in the received signal, and the noise density can be decreased only by lowering the noise level in the receiver. Both of these require increased cost and complexity in the communication system. However, the parameter r can be decreased by proper signal design. As previously mentioned, r can be no smaller than -1, and $r = -1$ if and only if the signals are antipodal. Antipodal signals have equal energy: $E_A = E_0 = E_1$. As a consequence, the subscripts on E can be omitted, and the error probability for antipodal signaling, an additive white Gaussian noise channel, and a matched-filter receiver is given by

$$P_e = Q\{[2E/N_0]^{1/2}\}$$

where E is the energy per data bit.

The Correlation Receiver—The matched-filter receiver is shown in Fig. 11. The decision statistic $Z(T_0)$ for this receiver can be expressed in terms of the channel output $Y(t)$ by

$$Z(T_0) = \int_{-\infty}^{\infty} Y(T_0 - u)\, h_M(u)\, du$$

The impulse response of the matched filter is defined in terms of the binary signal set $\{s_0, s_1\}$ by

$$h_M(t) = \{s_0(T_0 - t) - s_1(T_0 - t)\}/2$$

In terms of the signal

$$s_d(t) = \{s_0(t) - s_1(t)\}/2$$

the matched filter impulse response is

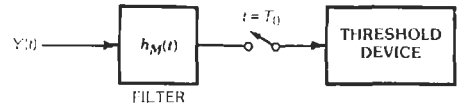

Fig. 11. Matched filter receiver.

$$h_M(t) = s_d(T_0 - t)$$

The statistic $Z(T_0)$ can therefore be expressed as

$$Z(T_0) = \int_{-\infty}^{\infty} Y(T_0 - u)\, s_d(T_0 - u)\, du$$

If the signals s_0 and s_1 are time limited to $[0, T]$ and the sampling time is $T_0 = T$, this expression reduces to

$$Z(T) = \int_0^T Y(t)\, s_d(t)\, dt$$

Thus, $Z(T)$ can be obtained by multiplying the channel output $Y(t)$ by the signal $s_d(t)$ and integrating from 0 to T, as shown in Fig. 12. The receiver that processes the channel output in this manner is known as the *correlation receiver*. The correlation receiver gives the same error probability as the matched-filter receiver.

Coherent Receivers for Binary and Quaternary RF Signals

For binary RF communications with signals of the form

$$s(t) = \sqrt{2}\, s_k(t) \cos[2\pi f_c t + \phi]$$

the matched-filter receiver for an additive white Gaussian noise channel is the receiver portion of the system shown in Fig. 10 with $h(t) = h_M(t)$. As in baseband systems, the correlation receiver can be substituted for the matched filter in coherent RF communication systems. The correlation receiver for coherent RF communications is shown in the diagram of Fig. 13.

Notice from Fig. 13 that the receiver must know the carrier phase ϕ. In practice, it suffices to have a good estimate of this phase, and there are many different kinds of tracking loops that can be employed in the receiver to provide such an estimate. A presentation of phase-tracking loops and related synchronization devices may be found in reference 5.

Binary phase shift keying (BPSK) employs binary RF signals with $s_d(t) = A/\sqrt{2}$ for $0 \le t < T$ (see subsection

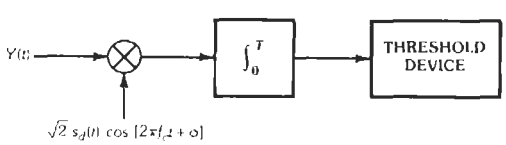

Fig. 13. Coherent correlation receiver for RF signals.

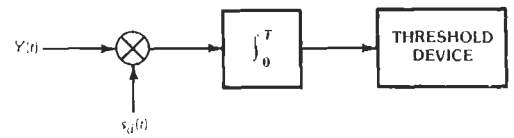

Fig. 12. Correlation receiver.

on BPSK). The optimum correlation receiver for coherent reception of BPSK is shown in Fig. 14. This is a special case of the receiver of Fig. 13. The square of the BPSK signal contains an unmodulated carrier at frequency $2f_c$ and phase 2ϕ, and this double-frequency carrier can be used to provide an estimate of the phase ϕ (this is the squaring loop*). This estimate is employed as the phase reference for coherent demodulation. An alternative method for coherent demodulation is to have the detection filter in the loop such as with a Costas loop or an I-Q loop.*

The coherent receivers for QPSK, OQPSK, and MSK are of the form shown in Fig. 15. These receivers consist of two branches, and each branch is a correlation receiver for an appropriate binary signal. The coherent references for the two branches differ in phase by $\pi/2$ radians, and in general there is a timing offset T' between the in-phase and quadrature branches. If the data rate is $R = 1/T$ bits per second in each case, then $T' = T$ for OQPSK and MSK, but $T' = 0$ for QPSK. The waveform $v(t)$ is the rectangular pulse $p_{2T}(t)$ for QPSK and OQPSK, and it is the sine pulse $\sin(\pi t/2T)$ $p_{2T}(t)$ for MSK.

Noncoherent Receivers

The signals employed in noncoherent communications are binary and M-ary signals of the type described in the subsections on FSK and MFSK. The signal set consists of M equal-energy signals of the form

$$s_k(t) = A a_k(t) \cos[2 f_c t + \theta_k(t) + \phi_k]$$

where $a_k(t)$ and $\theta_k(t)$ are baseband signals with bandwidths much smaller than the carrier frequency f_c.

For noncoherent demodulation, it is assumed that the receiver has no knowledge of the phase ϕ_k and that the phases for different signals are unrelated (e.g., ϕ_k and ϕ_j are statistically independent for $k \neq j$). Moreover, for some applications, a time-varying phase shift is introduced by the channel, so the phase of the received signal may change from one interval to the next.

* Reference 5.

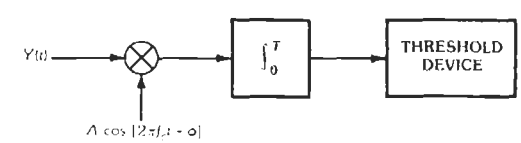

Fig. 14. Coherent correlation receiver for BPSK.

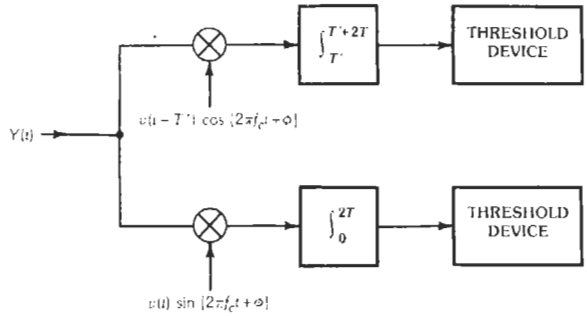

Fig. 15. Coherent receiver for quaternary RF signals.

The key component of the optimum noncoherent receiver for the signal set given above and an additive white Gaussian noise channel is the *noncoherent correlation detector (NCD)*, which is also referred to as an envelope correlation detector.* A block diagram of the noncoherent correlation detector for the signal $s_k(t)$ is shown in Fig. 16. This detector consists of in-phase and quadrature correlation receivers followed by squaring devices and a summing device. Thus the output of the noncoherent correlation detector is the square-law combination of the outputs of two correlation receivers whose phase references differ by $\pi/2$ radians. For convenience, let NCD/k denote the noncoherent correlation detector for the kth signal in the set.

Let $P_{e,k}$ denote the probability that an error is made by the receiver when the signal $s_k(t)$ is sent. Two performance measures of interest are the maximum probability of error

$$P_{e,m} = \max\{P_{e,k}: k = 0, 1, \ldots, M-1\}$$

and the average probability of error

$$P_{e,A} = P_{e,0}p_0 + P_{e,1}p_1 + \cdots + P_{e,M-1}p_{M-1}$$

In the expression for the average probability of error, p_k denotes the a priori probability that the signal $s_k(t)$ is sent. The receiver that gives the minimum possible value of $P_{e,m}$ also gives the minimum possible value of $P_{e,A}$ for equally probable signals (i.e., $p_k = 1/M$ for each k). The block diagram for this optimum receiver is shown in Fig. 17. The decision of the receiver is based on a comparison of the outputs of the noncoherent correlation detectors: the receiver decides the ith signal was sent if

$$Z_i = \max\{Z_k: k = 0, 1, \ldots, M-1\}$$

If the signals have unequal a priori probabilities, some additional processing of the outputs of the noncoherent correlation detectors is necessary in order to give the minimum average probability of error.* This is also necessary for signals with unequal energy.

Since MFSK is a special case of M-ary signaling, an optimum receiver for MFSK can be obtained from Figs. 16 and 17. The signals for MFSK are

$$s_k(t) = A\cos[2\pi f_k t + \phi_k]$$

so the noncoherent correlation detector for MFSK uses reference signals $\cos(2\pi f_k t)$ and $\sin(2\pi f_k t)$ as shown in Fig. 18. An optimum noncoherent receiver for MFSK is obtained by employing this noncoherent correlation detector in the system of Fig. 17. An optimum noncoherent receiver for binary FSK is this system with $M = 2$.

* Reference 10.

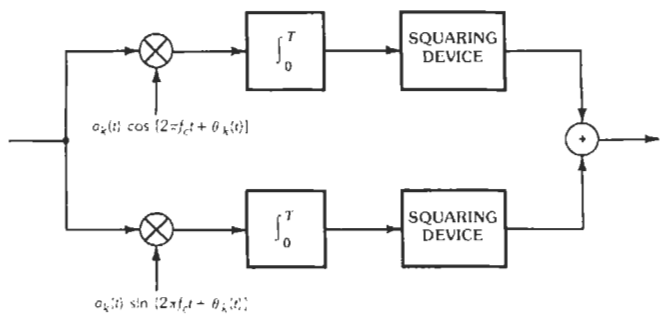

Fig. 16. Noncoherent correlation detector (NCD/k).

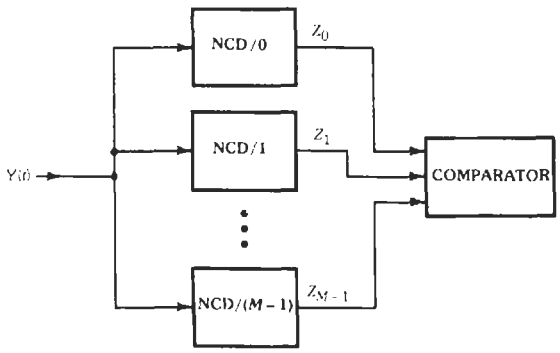

Fig. 17. Diagram of noncoherent receiver for M-ary communications.

If the channel noise is a band-limited white Gaussian noise process and the noise bandwidth is small compared to the tone frequencies f_k, there is an alternative implementation of the optimum noncoherent receiver that utilizes an *envelope detector*. In order to describe the response of the envelope detector to narrow-band inputs, define the signal

$$x_k(t) = v(t)\cos(2\pi f_k t) + w(t)\sin(2\pi f_k t)$$

in terms of baseband signals $v(t)$ and $w(t)$ that are narrow-band with respect to the frequency f_k. If $x_k(t)$ is the input to an envelope detector, the output is

$$e(t) = [v^2(t) + w^2(t)]^{1/2}$$

The signal $e(t)$ is called the *envelope* of the narrow-band signal $x_k(t)$.

Let $h_k(t)$ be the impulse response of a filter matched to the kth tone of the MFSK signal set; that is, let

$$h_k(t) = \cos(2\pi f_k t)$$

In contrast to the matched filters of the preceding subsection, this filter is *noncoherently matched* to the signal

$$s_k(t) = A\cos[2\pi f_k t + \phi_k]$$

since no phase information is utilized in $h_k(t)$. The output of the system of Fig. 19 at time T is equivalent to the output of the noncoherent correlation detector. Thus the matched filter/envelope detector can be substituted for the noncoherent correlation detector in the system of Fig. 17 to obtain an alternative form of the optimum receiver.

ERROR PROBABILITIES FOR DIGITAL COMMUNICATION SYSTEMS

In the preceding section, the optimal receivers are given for the most commonly used digital modulation techniques. Although there are a large number of different modulation techniques, many of them give the same performance. Throughout this section, performance will be measured by the *bit error probability* P_b as a function of the *bit energy to noise density ratio* E_b/N_0. Issues such as bandwidth and complexity of implementation will not be considered (see the subsection titled "Spectra of PSK and MSK Signals" for some comments on bandwidth of PSK and MSK signals).

Most binary communication systems of practical interest fall into two categories: coherent detection of antipodal signals and noncoherent detection of orthogonal signals. Moreover, certain quaternary signal sets such as QPSK, OQPSK, and MSK have the same bit error probability as binary antipodal signaling. For M-ary modulation, the primary case of interest is orthogonal signaling with noncoherent demodulation.

Coherent Systems With Additive White Gaussian Noise Channels

As discussed in the subsection titled "Receivers for Binary Baseband Data Transmission," binary coherent RF communication systems can be analyzed in terms of their low-pass equivalent systems. Thus, the results of that subsection give the error probabilities for optimum coherent demodulation of binary RF signaling over additive white Gaussian noise channels. If the channel noise has spectral density $N_0/2$, the error probability for

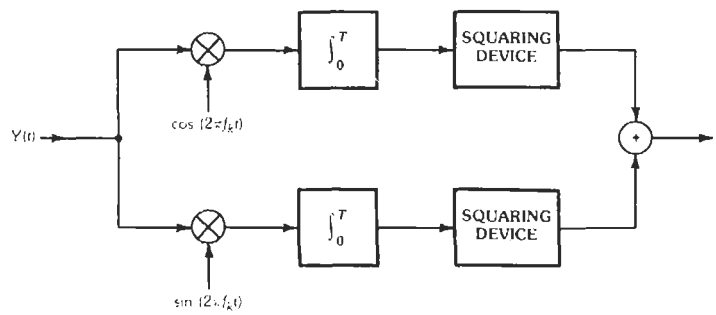

Fig. 18. Noncoherent correlation detector (NCD/k) for MFSK signal set.

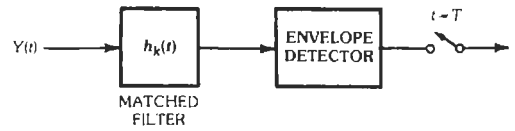

Fig. 19. Noncoherent matched filter/envelope detector.

binary signaling (baseband or RF) with an optimum receiver is

$$P_b = Q\{[E_A(1 - r)/N_0]^{1/2}\}$$

where,

r is the correlation coefficient for the binary signal set,

E_A is the average of the energies E_0 and E_1 for the two signals (see subsection cited above for formal definitions).

The binary signal sets of greatest interest are the *antipodal* ($r = -1$) and *orthogonal* ($r = 0$) equal-energy signals. If the two signals have equal energy, $E_A = E_0 = E_1$, and thus the *energy per bit* is E_A regardless of which bit is transmitted. For equal energy signals (binary or M-ary), it is customary to specify the performance in terms of the energy per bit, which is denoted by E_b.

It follows from the above comments that the bit error probability for optimum coherent detection of binary antipodal signals is

$$P_b = Q[(2E_b/N_0)^{1/2}]$$

For most applications, it is convenient to give the bit energy to noise density ratio in decibels. For this purpose, we define

$$(E_b/N_0)_{dB} = 10 \log_{10}(E_b/N_0)$$

A graph of P_b versus $(E_b/N_0)_{dB}$ for optimum demodulation and antipodal signaling is given in Fig. 20. Note that since binary PSK is just a special case of antipodal signaling, this curve applies to coherent detection of BPSK. Coherent detection of binary ASK with antipodal signals is another special case.

Many of the quaternary communication systems have the same bit error probability as binary antipodal signaling with an optimum receiver. The bit error probability for optimum coherent demodulation of QPSK, OQPSK, or MSK is given by

$$P_b = Q[(2E_b/N_0)^{1/2}]$$

exactly the same as for optimum coherent demodulation of BPSK. Consequently, the performance curve for QPSK, OQPSK, and MSK is the curve in Fig. 20 that corresponds to binary antipodal signaling.

Because the error probability $Q[(2E_b/N_0)^{1/2}]$ arises so frequently in the analysis of the performance of coherent communication systems, a short table of its values is given in Table 1. The table lists $(E_b/N_0)_{dB}$, E_b/N_0, and the error probability $Q[(2E_b/N_0)^{1/2}]$.

If the phase reference is not perfect, such as when it is estimated by some kind of tracking loop, the error probability for BPSK and related modulation schemes will be larger than given above. The *phase error* ϕ_e is the difference between the reference phase and the phase of the received signal. If ϕ_e is constant for the duration of the data bit, the bit error probability for BPSK is

$$P_b = Q[(2E_b/N_0)^{1/2} \cos(\phi_e)]$$

Coherent receivers for M-ary orthogonal signaling are of limited interest in applications. This is primarily because of the relative inefficiency of orthogonal signaling in a coherent system. For example, binary FSK requires twice the signal energy of BPSK to give the same bit error probability in a coherent system. This is true of any binary orthogonal signal set, since $r = 0$ implies

$$P_b = Q[(E_b/N_0)^{1/2}]$$

If a coherent receiver is to be employed, it makes sense to use a modulation scheme that is more efficient than orthogonal signaling.

The error probabilities for coherent demodulation of M-ary orthogonal signals are given in reference 5. The error probabilities for noncoherent demodulation of M-ary orthogonal signals are given in the next subsection. For large values of M, the performance of the coherent system is not much better than the performance of the noncoherent system (especially for low error probabilities). This is another reason there is little interest in implementing the more complex coherent receiver if M-ary orthogonal modulation is employed. For further discussion of this and related topics see reference 5.

Noncoherent Systems With Additive White Gaussian Noise Channels

The performance curve for binary FSK can be obtained by considering binary, orthogonal, equal-energy signals. For such signals, the bit error probability for optimum noncoherent detection is

$$P_b = 0.5 \exp(-E_b/2N_0)$$

which is also shown in Fig. 20.

Closely related to binary orthogonal signaling, although not always viewed as such, is *differential phase-shift keying* (*DPSK*). In DPSK, binary digits are transmitted at a rate of $1/T$ bits per second by phase transitions at the ends of successive T-second intervals. A phase change of 180 degrees can represent a binary 1,

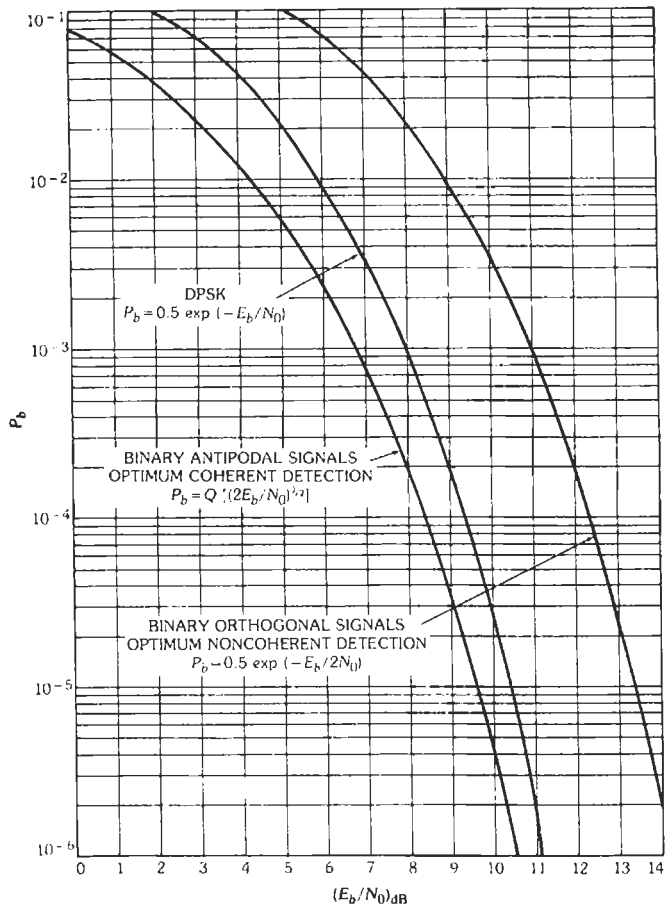

Fig. 20. Bit error probabilities.

and the absence of a phase change can represent a binary 0. This is simply differentially encoded PSK, and it can be demodulated either coherently or noncoherently.

The optimum noncoherent demodulator for DPSK is based on a noncoherent correlation detector (Fig. 16) in which the integration time is $2T$ seconds rather than T seconds. The optimality follows from the fact that

TABLE 1. VALUES OF ERROR PROBABILITY $Q[(2E_b/N_0)^{1/2}]$

$(E_b/N_0)_{dB}$	E_b/N_0	$Q[(2E_b/N_0)^{1/2}]$
5.0	3.16	5.95×10^{-3}
5.5	3.55	3.86×10^{-3}
6.0	3.98	2.39×10^{-3}
6.5	4.47	1.40×10^{-3}
7.0	5.01	7.73×10^{-4}
7.5	5.62	3.99×10^{-4}
8.0	6.31	1.91×10^{-4}
8.5	7.08	8.40×10^{-5}
9.0	7.94	3.36×10^{-5}
9.5	8.91	1.21×10^{-5}
10.0	10.00	3.88×10^{-6}
10.5	11.22	1.09×10^{-6}
11.0	12.59	2.62×10^{-7}
11.5	14.13	5.34×10^{-8}
12.0	15.85	9.03×10^{-9}

DPSK is a form of orthogonal signaling on the interval $[0,2T]$: the signal corresponding to a 180-degree phase change is orthogonal to the signal corresponding to no phase change. Since the integration time is $2T$, the effective signal energy is $2E_b$. For optimum noncoherent demodulation of orthogonal signals of energy $2E_b$, the error probability is

$$P_b = 0.5 \exp(-E_b/N_0)$$

which is shown in Fig. 20.

The noncoherent correlation detector structure can be simplified to provide the alternative implementation of the optimal noncoherent demodulator for DPSK that is shown in Fig. 21. For this receiver the decision is made as follows. If

$$W_c Z_c + W_s Z_s > 0$$

the decision is that 0 was sent, and if

$$W_c Z_c + W_s Z_s < 0$$

the decision is that 1 was sent.*

A suboptimal receiver that is commonly suggested for demodulation of DPSK involves delay and multiplication of the received continuous-time signal, as shown in Fig. 22. The delay-and-multiply receiver does not produce the same decision statistic as the receiver shown in Fig. 21, and its probability of error is larger than that obtained by the receiver of Fig. 21. For very large values of the signal-to-noise ratio, the performance difference between the two receivers is small.

* See reference 7 for details.

Additional information on DPSK reception is given in references 6, 7, and 8.

Next we consider M-ary signaling with equal-energy, orthogonal signals. That is, the signal set $\{s_k : k = 0, 1, \ldots, M-1\}$ is such that $\|s_k\|^2 = E_s$ for all k, and $(s_k, s_j) = 0$ whenever $k \neq j$. The energy in the signal s_k is called the *energy per symbol* (denoted by E_s). A symbol error occurs if the receiver decides that s_j was sent when in fact s_k was sent and $k \neq j$. For an additive white Gaussian noise channel and an optimum noncoherent receiver, the symbol error probability P_s is given by

$$P_s = M^{-1} \sum_{n=2}^{M} \binom{M}{n} (-1)^n \exp\{-[(n-1)/n] E_s/N_0\}$$

This can be evaluated on a digital computer for values of M up to 32, although double precision computation may be required for values of M larger than about 16. The symbol error probability can be computed for larger values of M by numerical integration of an alternative expression for P_s; for example, see equation (10-15) on p. 489 of reference 5.

If M-ary modulation is employed to transmit binary data, M should be a power of 2. If $M = 2^m$, each M-ary symbol can represent a unique sequence of m binary digits. The energy per bit is $E_b = E_s/m$. A symbol error can cause as few as one or as many as m bit errors. On the average, the number of bit errors per symbol error is $mM/2(M-1)$ for M-ary orthogonal signaling with optimum noncoherent demodulation. Thus the bit error probability P_b is related to the symbol error probability by $P_b = MP_s/2(M-1)$. Making the appropriate substitutions in the above expression for P_s, we find that the bit error probability is given in terms of the energy per bit by

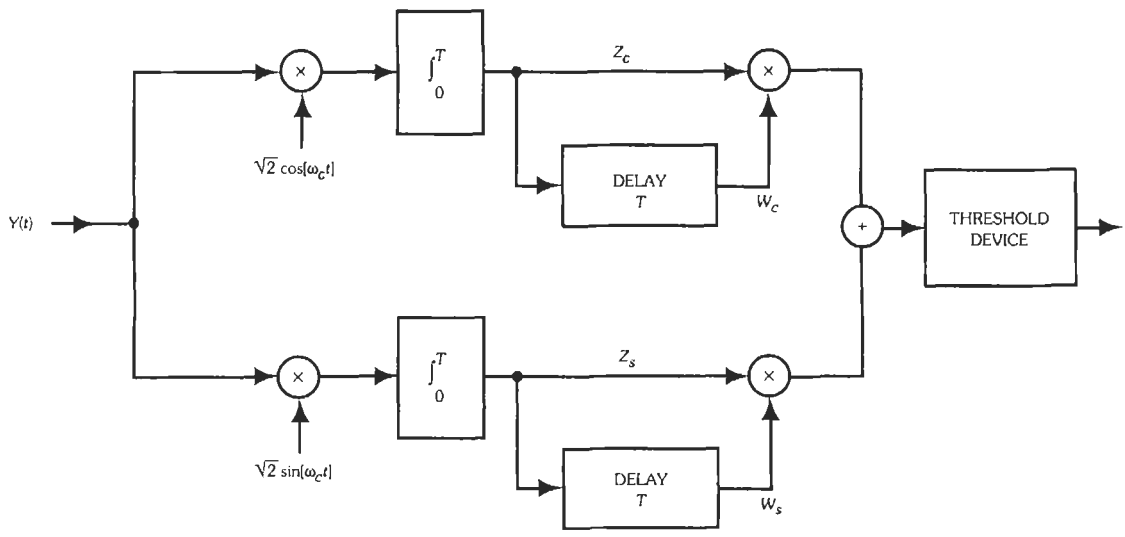

Fig. 21. Optimal noncoherent demodulator for DPSK.

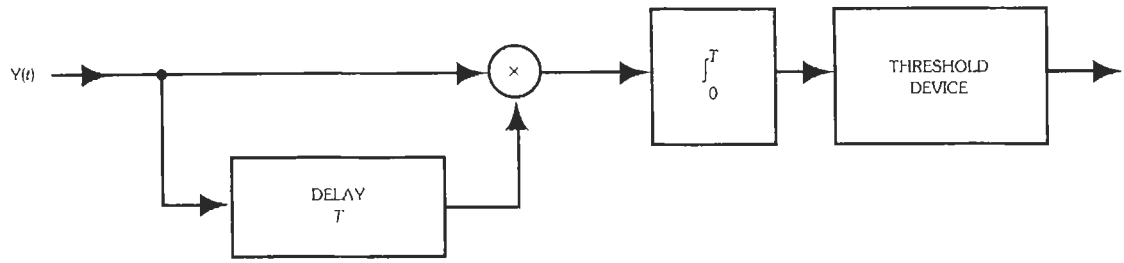

Fig. 22. The delay-and-multiply receiver—a suboptimal receiver for DPSK.

$$P_b = (2M - 2)^{-1}$$

$$\sum_{n=2}^{M} \binom{M}{n} (-1)^n \exp\{-[(n-1)/n] m E_b/N_0\}$$

A table of values of the symbol error probability is given in Table 2 for $M = 2$, 8, and 32. The bit error probabilities can be obtained from this table by multiplying the symbol error probabilities by $M/2(M - 1)$. Curves of the bit error probability versus the bit energy to noise density ratio are shown in Fig. 23 for $M = 2$, 4, 8, 16, and 32. It can be shown that $P_b \to 0$ as $M \to \infty$ provided that E_b/N_0 is greater than ln 2 (where ln denotes the natural logarithm).

Noncoherent Systems With Nonselective Fading Channels

In some communication channels, there are several propagation paths between the transmitter and the receiver. The signal components arriving at the receiver from different paths add destructively or constructively depending on the difference in the propagation times and on any phase shifts introduced by the medium (e.g., reflections from objects). Thus the signal strength depends on the relative phasing of the components of the received signal, and this gives rise to the condition known as *fading*.

If the differential propagation times for the paths are small compared with the data symbol duration, and the path strengths, propagation times, and phase shifts are nearly constant for the duration of the symbol, then there is no significant dispersion of the signal. In this case, the fading is referred to as *slow nonselective fading*. If the differential propagation times are large compared with the data symbol duration, signal dispersion will occur. Such channels are known as *time-dispersive* or *frequency-selective* fading channels. These channels may produce significant levels of intersymbol interference. A more complete discussion of fading and its effects on communication systems is given in reference 8, and the derivations of the results given in this section can be found in references 12, 13, and 14.

For *slow nonselective Rician fading*, the received signal is the sum of a nonfaded version of the transmitted signal and a slow nonselective Rayleigh faded version. The difference in propagation times for the two components is small enough that the channel is nonselective. The nonfaded component of the received signal is called the *specular component*, and the Rayleigh faded component is sometimes called the *random* or *scatter component*. The specular component may result from a direct path between the transmitter and receiver, and the faded component may arise from a large number of reflections.

Consider the transmission of a unit-amplitude RF signal over this Rician fading channel. The received signal is the sum of a deterministic component of amplitude A and a random component of amplitude V. The quantities A and V represent the gains associated

TABLE 2. SYMBOL ERROR PROBABILITIES FOR OPTIMUM NONCOHERENT DEMODULATION OF M-ARY ORTHOGONAL SIGNALING

$(E_b/N_0)_{dB}$	Symbol Error Probability, P_s

8.0	2.13×10^{-2}	2.53×10^{-4}	2.10×10^{-6}
9.0	9.42×10^{-3}	2.27×10^{-5}	3.64×10^{-8}
10.0	3.37×10^{-3}	1.06×10^{-6}	2.15×10^{-10}

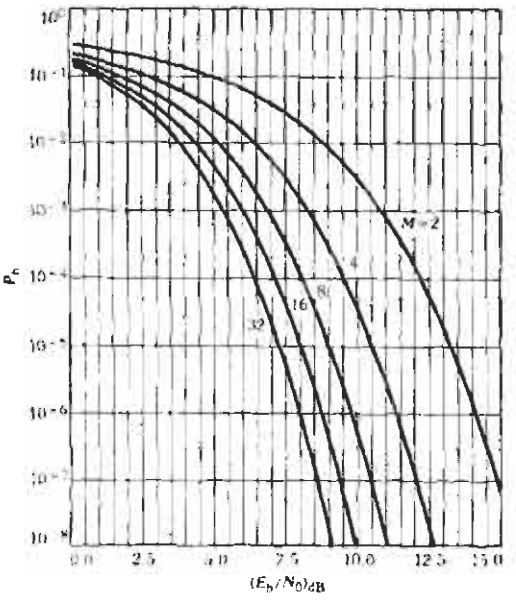

Fig. 23. Bit error probabilities for M-ary orthogonal signals and optimum noncoherent demodulation.

with the specular path and the scatter path, respectively. The random variable V has the *Rayleigh distribution*, and its probability density function is

$$f_V(v) = (2v/m_f) \exp\{-v^2/m_f\}$$

for $v > 0$, where m_f denotes the *second moment* or *mean-square value* of the amplitude of the faded component (i.e., $m_f = E\{V^2\}$). The phase between the two components is random and uniformly distributed on the interval $[0, 2\pi]$. The amplitude of the sum of the specular and faded components is a random variable Y which has a *Rician distribution*. The probability density function for the Rician distribution is

$$f_Y(y) = (2y/m_f) \exp\{(y^2 + A^2)/m_f\}\, I_0(2yA/m_f)$$

for $y > 0$, where I_0 is the zero-order modified Bessel function. The *second moment* for this distribution is $E\{Y^2\} = A^2 + m_f$. Notice that for $A = 0$ (no specular component), the Rician density reduces to the Rayleigh density, because $I_0(0) = 1$.

Let E' denote the transmitted energy per symbol in an M-ary noncoherent communication system. The energy per symbol in the received signal is Y^2E'. The average energy per symbol in the received signal is

$$E_r = E\{Y^2\}\, E' = (A^2 + m_f)\, E'$$

Let $e_1 = A^2E'/N_0$ and $e_2 = m_fE'/N_0$ be the symbol energy to noise density ratios for the specular and faded components, respectively. The conditional probability of symbol error given $Y = y$ is (see preceding subsection)

$$P_s(y) = M^{-1} \sum_{n=2}^{M} \binom{M}{n} (-1)^n \exp\{-[(n-1)/n]y^2E'/N_0\}$$

The *average probability of symbol error* is

$$P_s = \int_0^\infty P_s(y) f_Y(y)\, dy$$

$$= M^{-1} \sum_{n=2}^{M} \binom{M}{n} (-1)^n\, G[(n-1)/n, e_1, e_2]$$

where the function G is defined by

$$G(c, e_1, e_2) = (1 + ce_2)^{-1} \exp\{-ce_1/(1 + ce_2)\}$$

The *bit error probability* is obtained by multiplying the symbol error probability P_s by $M/2(M-1)$.

Two special cases are of interest. First, for the Rayleigh fading channel, $A = 0$ and $e_1 = 0$. It follows that $e_2 = E_s/N_0$. Moreover,

$$G(c, 0, e_2) = (1 + ce_2)^{-1}$$

so that the error probability for noncoherent reception of M-ary orthogonal signals with nonselective Rayleigh fading is given by

$$P_s = M^{-1} \sum_{n=2}^{M} \binom{M}{n} (-1)^n \{1 + [(n-1)/n]E_s/N_0\}^{-1}$$

The second important special case is the *nonfading* channel. If the received signal has no faded component, then $m_f = 0$, $e_2 = 0$, and $e_1 = E_s/N_0$. Since

$$G(c, e_1, 0) = \exp\{-ce_1\}$$

the error probability is

$$P_s = M^{-1} \sum_{n=2}^{M} \binom{M}{n} (-1)^n \exp\{-[(n-1)/n]E_s/N_0\}$$

as given in the preceding subsection.

For binary orthogonal signaling, each symbol represents one bit, so $P_s = P_b$. The resulting expression for the bit error probability in a Rician fading channel is

$$P_b = 0.5\, G(0.5, e_1, e_2)$$

$$= (2 + e_2)^{-1} \exp\{-e_1/(2 + e_2)\}$$

For Rayleigh fading, $e_1 = 0$ and $e_2 = E_s/N_0$. Since $E_b = E_s$ for binary signals, the bit error probability is

$$P_b = [2 + (E_b/N_0)]^{-1}$$

It is customary to present numerical data for the error probability in a Rician fading channel in terms of the

ratio of the power in the two components of the received signal. Let $g^2 = m_1/A^2$, so that $e_2 = g^2 e_1$. The signal-to-noise ratios e_1 and e_2 are related to E_s/N_0 by

$$e_1 = [1/(1 + g^2)] E_s/N_0$$

and

$$e_2 = g^2 e_1 = [g^2/(1 + g^2)] E_s/N_0$$

The Rician channel can be specified by giving either e_1 and e_2 or g^2 and E_s/N_0. In the latter specification, E_s/N_0 is a measure of the average signal-to-noise ratio at the receiver, and g^2 specifies how the signal power is distributed between its two components. Specifically, $1/(1 + g^2)$ is the fraction due to the specular component, and $g^2/(1 + g^2)$ is the fraction due to the faded component. A substitution for e_1 and e_2 in the expressions above gives expressions for the error probability in terms of g^2 and E_s/N_0.

Bit error probabilities for binary orthogonal modulation, noncoherent demodulation, and slow nonselective Rician fading are shown in Fig. 24 for five values of the parameter g^2. The curve for $g^2 = 0$ is the same as for the additive white Gaussian noise channel (Fig. 20), and the curve for $g^2 = 10$ is very nearly the same as the error probability for Rayleigh fading. Table 3 lists values of the bit error probability for a Rayleigh fading channel, a Rician fading channel with $g^2 = 0.1$, and a nonfading channel (Rician with $g^2 = 0$).

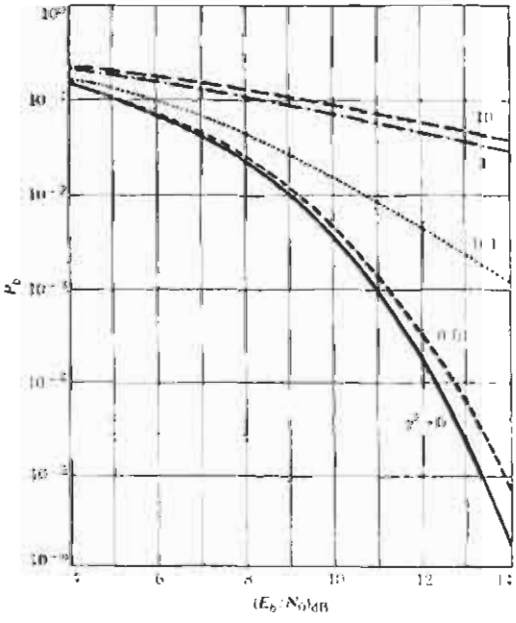

Fig. 24. Bit error probability for Rician fading.

SPREAD-SPECTRUM COMMUNICATIONS

A common trade-off in a communication system is performance versus bandwidth. That is, various aspects of communications performance can be improved at the expense of increased RF bandwidth. One example of this is the reduction of error probability in MFSK systems as the number of tones increases. More generally, the use of error-correcting coding gives lower error probabilities but requires a larger bandwidth than for uncoded signaling with the same information rate (see Chapter 25, Information Theory and Coding).

Spread-spectrum modulation is a very general method for improving other measures of system performance through the use of wideband signals. A properly designed spread-spectrum communication system can operate reliably in the presence of various types of radio-frequency interference (RFI) including multipath interference, multiple-access interference, and hostile jamming. In addition, when the signal power is spread over a large bandwidth, the signal has very small average power in any narrow-band slot. This means that the spread-spectrum system can share a frequency band with several narrow-band systems. It also means that it is difficult to detect the presence of the spread-spectrum signal by use of narrow-band equipment. The basic modulation formats and receiver structures are described below. Further details on the design and performance of spread-spectrum systems are given in references 24 through 40.

Direct-Sequence Spread-Spectrum Communications

The type of spread spectrum known as *binary direct-sequence spread spectrum* employs signals of the form

$$s(t) = A\, a_s(t)\, a_d(t) \cos[2\pi f_c t + \phi]$$

where,

$a_d(t)$ is a binary baseband data signal,
$a_s(t)$ is a baseband *spectral-spreading signal* with a bandwidth that is large compared to the data rate.

These binary baseband signals are of the form described in the section on baseband signal sets. Although only binary direct-sequence modulation is described here, there is a natural generalization to *quaternary direct sequence*, which is described in reference 24.

The data signal $a_d(t)$ consists of a sequence of positive and negative rectangular pulses; that is, it can be expressed as

$$a_d(t) = \sum_{n=-\infty}^{\infty} b_n p_T(t - nT)$$

TABLE 3. BIT ERROR PROBABILITIES FOR BINARY ORTHOGONAL SIGNALING, SLOW NONSELECTIVE FADING, AND NONCOHERENT DEMODULATION

$(E_b/N_0)_{dB}$	Bit Error Probability		
	Rayleigh	$g^2 = 0.1$	No Fading
4.0	2.22×10^{-1}	1.61×10^{-1}	1.42×10^{-1}
6.0	1.67×10^{-1}	9.15×10^{-2}	6.83×10^{-2}
8.0	1.20×10^{-1}	4.18×10^{-2}	2.13×10^{-2}
10.0	8.33×10^{-2}	1.51×10^{-2}	3.37×10^{-3}
12.0	5.60×10^{-2}	4.41×10^{-3}	1.81×10^{-4}
14.0	3.69×10^{-2}	1.13×10^{-3}	1.76×10^{-6}
20.0	9.80×10^{-3}	2.48×10^{-5}	9.64×10^{-23}

where,

$p_T(t)$ is the rectangular pulse duration T,
b_n is either $+1$ or -1, depending on the data bit to be sent in the nth interval.

Similarly, the spectral-spreading signal can be written as

$$a_s(t) = \sum_{j=-\infty}^{\infty} a_j v(t - jT_c)$$

where $v(t)$ is the *chip waveform*, a time-limited pulse of duration T_c. The parameter T_c is called the *chip duration*, and the sequence

$$(a_j) = \ldots, a_{-1}, a_0, a_1, a_2, \ldots$$

is called the *signature sequence*. For reasonable choices of signature sequence and chip waveform, $1/T_c$ is a rough estimate of the bandwidth of the spread-spectrum signal. For most direct-sequence systems, $T_c << T$, so the bandwidth of the spread-spectrum signal is much larger than that of the data signal.

Usually, the data pulse duration T is an integer multiple of the chip duration. If $T = NT_c$ for some integer N, there are N chips per data pulse, and the bandwidth of the spread-spectrum signal is roughly N times the data rate. Usually the signature sequence is periodic, and the period p is equal to N or else $p >> N$, depending on the nature of the application.

The optimum receiver for binary direct-sequence spread-spectrum modulation and an additive white Gaussian noise channel (i.e., thermal noise is the only interference) is the correlation receiver shown in Fig. 25 (cf. Fig. 14). The received signal $Y(t)$ is multiplied by

$$A\, a_s(t) \cos[2\pi f_c t + \phi]$$

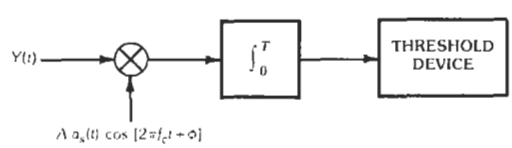

Fig. 25. Coherent correlation receiver for binary direct-sequence spread spectrum.

and the product is integrated over an appropriate interval of length T (this is illustrated for the interval $[0, T]$ in Fig. 25). Since the signals corresponding to $b_n = +1$ and $b_n = -1$ are antipodal, the bit error probability for binary direct-sequence spread-spectrum modulation and optimum coherent demodulation is

$$P_b = Q[(2E_b/N_0)^{1/2}]$$

the same as for binary BPSK with optimum coherent demodulation.

The motivation for considering direct-sequence spread spectrum is not performance improvement for channels in which the primary interference is thermal noise. Rather, it is the fact that the spectral-spreading signal can be selected to give the transmitted signal certain desirable properties and enable the receiver to discriminate against forms of interference other than thermal noise. For example, if the spread-spectrum signal is corrupted by additive RFI, and if we ignore the thermal noise for the moment, the received signal can be written as $Y(t) = s(t) + x(t)$, where $x(t)$ is an additive interference signal. The effects of this interference can be reduced by choosing the spectral-spreading signal to minimize

$$\int_0^T x(t)\, a_s(t) \cos[2\pi f_c t + \phi]\, dt$$

One application in which additive RFI is encountered is in a direct-sequence spread-spectrum *multiple-access* communication system.* In such a system, signals from the various transmitters have the same carrier frequency f_c. The spread-spectrum signals from other transmitters appear as additive RFI to a receiver that attempts to demodulate the signal $s(t)$. Let $s'(t)$ denote one of these other signals, and denote its spectral-spreading signal by $a'_s(t)$ and its signature sequence by (a'_j). Since the signal $s'(t)$ is from a different transmitter than $s(t)$, it arrives at the receiver with a different propagation delay and phase angle. If u denotes the propagation delay and

* Reference 24.

ϕ' denotes the phase for $s'(t)$, the quantity to be minimized is

$$\int_0^T a_s'(t - u)\, a_s(t)\, dt \cos(\phi - \phi')$$

Since this should be small for all values of the phase angles, it is necessary to minimize the magnitude of

$$\int_0^T a_s'(t - u)\, a_s(t)\, dt$$

for all values of u. The goal is to select the signature sequences to accomplish this minimization (see references 24 and 28).

Similar considerations arise for channels with specular multipath, narrow-band interference, hostile jamming, and other forms of RFI. For complete discussions of the problems of signature sequence selection see references 24, 27, and 28. The problems of obtaining phase and timing references for direct-sequence spread-spectrum communication systems are discussed in reference 26. The performance of direct-sequence spread spectrum with various forms of RFI is considered in references 24, 25, and 36 through 38.

Frequency-Hop Spread-Spectrum Communications

Signals with very large RF bandwidths can be generated by a method known as *frequency hopping* in which the carrier frequency of a digital communication signal is changed, or "hopped," over a wide range of frequencies. If the digital communication signal is

$$c(t) = A\, a(t) \cos[2\pi f_c t + \theta(t) + \phi]$$

the resulting *frequency-hopped* signal is

$$s(t) = A\, a(t) \cos[2\pi f(t) t + \theta(t) + \phi]$$

The function $f(t)$, which describes the carrier frequency as a function of time, is called the (frequency) *hopping pattern*. The hopping pattern is generated by applying a random or pseudorandom sequence of inputs to a frequency synthesizer. Typically, the available RF bandwidth is partitioned into q nonoverlapping frequency intervals called *slots*, and the q different frequencies generated by the frequency hopper are the center frequencies for these slots.

A frequency-hop (FH) spread-spectrum signal with hopping rate R_h hops per second is a signal that has the form of $s(t)$ above for which the frequency $f(t)$ can change every $1/R_h$ seconds. The frequency is constant on intervals of length $T_h = 1/R_h$. The parameter T_h is called the *frequency dwell time* or *hop interval*. In contrast to direct-sequence spread-spectrum signals, which occupy the full RF bandwidth at all times, FH spread-spectrum signals occupy only a small fraction of the RF bandwidth during a given hop interval.

Fast FH spread-spectrum systems have hopping rates that are larger than the data rate, and so the duration of a data pulse is larger than the hop interval. Since the transmission of a data pulse utilizes more than one of the q frequency slots, frequency diversity is obtained with fast FH spread-spectrum signaling. *Slow FH spread-spectrum systems* have hopping rates that are smaller than the data rate, and thus the hop interval is greater than the data symbol duration.

The total RF bandwidth of a slow FH spread-spectrum signal is approximately q times the bandwidth of the digital communication signal $c(t)$; it is virtually independent of the hopping rate. The total bandwidth of a fast FH spread-spectrum signal depends on the number of frequency slots and the hopping rate, but it does not depend very much on the data rate.

The multiple-access capability of frequency-hop spread spectrum is due to the fact that each signal occupies only the fraction $1/q$ of the bandwidth during each hop interval. Even for totally asynchronous operation of a large number of transmitters,* the hopping patterns can be designed such that the probability of interference between the signals from any two given transmitters during a given hop interval is no more than $2/q$. Since errors occur with high probability whenever the signals interfere, some form of error-control coding is necessary for typical multiple-access systems. In fact, error-control coding is virtually a requirement for frequency-hop spread-spectrum communication in the presence of any form of partial-band or pulsed interference. Convolutional codes and Reed-Solomon block codes (see Chapter 25) appear to be the most suitable error-correcting codes for use in frequency-hop spread-spectrum communication systems.

25 Information Theory and Coding

Richard E. Blahut

Information theory is a discipline centered around a common mathematical approach to the study of the collection and manipulation of information. It studies the theoretical basis of such activities as observation, measurement, data compression, data storage, communication, estimation, decision making, and pattern recognition. Many complex and expensive systems are built for automating or expanding these operations. Information theory attempts to guide the development of such systems based on a study of the possibilities and limitations inherent in mathematics and probability theory.

The communication problem, represented in Fig. 1, is the archetypal problem of information theory; much of the underlying structure and semantics of information theory is suggested by the communication channel. A source of information is to be connected to a user of information by a channel. A communication system is provided to prepare the source output for the channel and to prepare the channel output for the user. It consists of a device between the source and the channel called the encoder/modulator, and another device between the channel and the user called the demodulator/decoder.

It is conventional to partition the major functions of a modern communication system in the manner shown in the block diagram of Fig. 2. Data from the data source are first processed by a source encoder, whose purpose is to represent the source data more compactly. A block of source data is represented by a sequence of symbols, usually binary, called the "source codeword." The data then are processed by the channel encoder, which transforms the symbols from a sequence of source codewords into another sequence of symbols called the "channel codeword." The channel codeword is a new, longer sequence that has more redundancy than the source codeword. Each symbol in the channel codeword might be represented by a bit or a group of bits. Next, the modulator represents each symbol of the channel codeword by its corresponding analog signal from a finite set of possible analog symbols. The sequence of analog symbols, called a "waveform," is transmitted through the channel. Because the channel is subject to various types of noise, distortion, and interference, the channel output differs from the channel input. The demodulator converts the noisy received sequence of analog symbols, possibly mutually interfering, into a sequence of discrete symbols of the channel codeword alphabet (based on a best estimate of the transmitted signal). The demodulated sequence of symbols is called the "received word." Because of channel noise, the demodulator sometimes makes errors, so the symbols

Fig. 1. The communication problem.

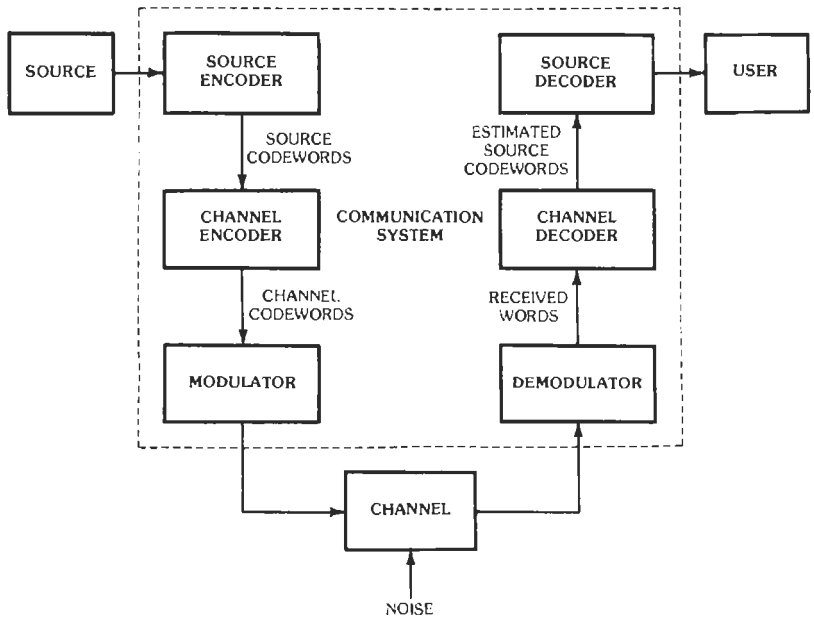

Fig. 2. Block diagram of a digital communication system.

of the received word do not always match those of the channel codeword.

The function of the channel decoder is to use the redundancy in a channel codeword to correct the errors in the received word, and then to produce an estimate of the source codeword from it. If all errors are corrected, the estimated source codeword matches the original source codeword. The source decoder performs the inverse operation of the source encoder and delivers its output to the user. The source encoder and decoder are studied under the terms "data compaction" and "data compression." The channel encoder and decoder are commonly split into two functions: implementing error control to negate the effects of channel noise, and preparing the sequence of transmitted symbols to be compatible with channel constraints. These are studied under the terms "error control codes" and "constrained channel codes." The modulator and the demodulator are studied under the term "modulation theory."

Although we use the terminology of communication theory, the model is general and applies to a great variety of situations. One can interpret many other information-handling systems, such as mass storage systems, in terms of this model. It only is necessary to identify the boundaries between the boxes. This is arbitrary and depends on the goals of a particular analysis. Usually, the source, channel, and user are identified with those parts of the system that are fixed, and the encoder/decoder and modulator/demodulator are identified with those parts of the system that are subject to design. Therefore, in different circumstances, the identification of these functions may be different.

The operation of the encoders and decoders is to map strings of symbols from one alphabet into strings of symbols from a second alphabet. The two alphabets are often the same, but they need not be. A *block code* breaks the input data stream into blocks of fixed length k and encodes each block into a codeword of fixed length n; these are concatenated to form the output data stream. A *variable-to-fixed-length block code* breaks the input data stream into blocks of variable length and encodes the blocks into codewords of fixed length n that are concatenated to form the output data stream. A *fixed-to-variable-length block code* breaks the input data stream into blocks of fixed length k and encodes these into codewords of variable length that are concatenated to form the output data stream. A *tree code* breaks the input data stream into frames of length k_0 that are encoded into codeword frames of length n_0 with the encoding map depending on the previous m input data frames. The codeword frames are concatenated to form the output data stream. A tree code is called a variable-to-fixed-length tree code or a fixed-to-variable-length tree code when the input or output frames, respectively, are of variable length. A tree code with a finite encoding memory of m frames is called a *sliding block code* if the encoding operation is time invariant, and it is called a *convolutional code* if the encoding operation is both linear and time invariant.

Introductory information-theory textbooks intended for engineers are listed as references 1 through 4 at the end of this chapter. Other books and papers devoted to special topics will be cited in the appropriate section only if the topic is not treated within the general textbooks of the field.

CODING FOR NOISELESS CHANNELS

A discrete channel is a system by means of which an arbitrarily long sequence of symbols, each chosen from a finite set of I symbols $\{a_0, \ldots, a_{I-1}\}$, can be transmitted from one point to another. The transmission of symbol a_i requires a certain time duration, t_i seconds, which is not necessarily the same for all i. A noiseless channel is one in which the output is completely determined by the input—errors do not occur. It is not always true that all possible sequences of symbols from the set $\{a_i\}$ can be transmitted through the channel. Some channels, called constrained channels, forbid certain sequences of symbols from being transmitted.

Teletypewriters and telegraphy are two simple examples of discrete channels that are historically important. In the teletypewriter case, there are 32 symbols, each of the same duration, and any sequence of the 32 symbols is allowed. Each symbol can be used to represent five bits of information. If the system transmits r symbols per second, it is natural to say that the channel has a capacity of $5r$ bits per second. This does not mean that the teletypewriter channel will always be transmitting information at this rate. Whether or not the actual rate reaches this maximum possible rate depends on how the source of information is connected to the channel.

For the telegraphy channel, convention has fixed the symbols as a dot, a dash, a letter space, and a word space. We formalize these symbols as follows: (1) a dot, consisting of line closed for one unit of time and then line open for one unit of time; (2) a dash, consisting of three time units of closure and one unit open; (3) a letter space, consisting of three time units of line open; (4) a word space, consisting of six time units of line open. We also impose the restrictions on allowable sequences that no space may directly follow another space. This we take as the formal definition of the telegraphy channel.

The Morse code is one system of encoding information for this channel. However, one may properly question the efficiency of the Morse code. Is there a limit on the information that can be conveyed through the telegraphy channel, and does the Morse code achieve this limit? These questions are answered by information theory.

Capacity of Discrete Noiseless Channels

The capacity, C (in units of bits/second), of a discrete noiseless channel is defined by

$$C = \lim_{T \to \infty} (1/T) \log_2 N(T)$$

where $N(T)$ is the number of allowed sequences of symbols of duration T.

The limit in the definition will exist and be finite in most cases of interest. From the definition, it is clear that about 2^{CT} different messages can be transmitted through the channel in T seconds for large enough T. We say that the channel can transmit C bits per second. It is easily seen that in the teletypewriter example this definition of capacity reduces to the previous result of $5r$ bits per second.

The evaluation of capacity is more difficult if the symbols are of different length, as in the telegraphy channel, or if certain sequences are forbidden, also as in the telegraphy channel. Suppose first that all sequences of the symbols $a_0, \ldots, a_{l-1}$ are allowed and these symbols have durations $t_0, \ldots, t_{l-1}$ that are integer multiples of one time unit. Let $N(t)$ represent the number of sequences of duration t. We can set up a recursive equation to find $N(t)$. A sequence of length t can be produced from a sequence of length $t - t_0$ by appending symbol a_0, or it can be produced from a sequence of length $t - t_1$ by appending symbol a_1, and so on. That is

$$N(t) = N(t - t_0) + N(t - t_1) + \ldots + N(t - t_{l-1})$$

According to a well-known result in the study of finite-difference equations, $N(t)$ is asymptotic for large t to λ^t, where λ is the largest real root of the characteristic equation:

$$x^{-t_0} + x^{-t_1} + \ldots + x^{-t_{l-1}} = 1$$

Then the capacity, C, is equal to $\log_2 \lambda$.

Even when there are restrictions on allowed sequences, we may still be able to write down a difference equation by inspection. In the case of the telegraphy channel:

$$N(t) = N(t - 2) + N(t - 4) + N(t - 5) + N(t - 7) + N(t - 8) + N(t - 10)$$

as we see by counting sequences of symbols according to the last or next-to-last symbol occurring. Hence, C equals $\log_2 \lambda$ where λ is the largest real zero of the polynomial $x^{-10} + x^{-8} + x^{-7} + x^{-5} + x^{-4} + x^{-2} = 1$. Solving this, we find $C = 0.539$ bit per unit of time. This is the maximum rate at which information can be conveyed by the telegraphy channel. One may devise many codes whose rates are close to the capacity of the channel, but never greater.

The Morse code shown in Table 1 is a widely used code for transmitting written text over the telegraphy channel. The Morse code combines both source encoding, described in the next section in terms of the *entropy* of the source, and channel encoding, described above. The Morse code does not exploit the Markov structure of natural language. We will evaluate the code for use with a memoryless source whose 27 output letters (including the space) occur with the same probabilities as in English text.

The entropy of this memoryless model of English is 4.03 bits per letter, and the telegraphy channel capacity is 0.539 bit per unit time. Hence, an optimum code uses an average of 7.48 units of signaling time per source output letter. The Morse code in Table 1 uses an average of 9.296 units of signaling time per source output letter, which is 124 percent of the time needed by the optimum code. This establishes the amount by which the Morse code could be improved for use with the memoryless model of English text. Of course, an optimum code may be too complex for an operator to learn. The Morse code is an excellent compromise between performance and simplicity.

State Diagrams and Trellises

A constrained channel is one that does not accept input sequences containing any of a certain collection of forbidden subsequences. Such a channel can be described by a state diagram. Each state, $s_0, s_1, \ldots, s_{m-1}$, corresponds to a recent past history of channel inputs. Loosely, we say that the channel is in one of these states, but we mean that its past history is described by that state. For each state, only certain symbols from the set $a_0, \ldots, a_{l-1}$ can be transmitted next. When one of these has been transmitted, the state changes to a new state depending both on the old state and on the particular symbol transmitted.

Sometimes the state diagram is augmented by a time axis so that one can see how the channel state changes with time. It is then called a *trellis*.

The telegraphy channel gives a simple illustration of a state diagram. There are two states. The state specifies whether or not a space was the last symbol transmitted. In state s_0, only a dot or a dash can be sent next, and the state always changes. In state s_1, any symbol can be transmitted, and the channel changes state if a space is sent; otherwise it remains in the same state. The conditions are indicated in the state diagram shown in Fig. 3.

The trellis diagram for the telegraphy channel is shown in Fig. 4. The Morse code is a collection of some of the paths through this trellis. An optimum code would use all of the paths, but the mapping from the set of source output sequences to the set of trellis paths might be a complicated one.

The digital magnetic-recording channel is another important example of a constrained channel. The channel input alphabet is binary, and a typical set of channel constraints, called run-length constraints, are that at least r zeros follow every one and that no more than s zeros occur in sequence. These constraints are imposed to minimize intersymbol interference and to facilitate clock recovery at the receiver.

In another kind of application, certain bit sequences

are used for higher-level protocols or punctuation in the communication system and so must be forbidden in the data. A code must be used to translate from the set of unconstrained binary sequences into the set of sequences that satisfy the constraints.

Fig. 5 is a state diagram for a channel with $r = 2$ and $s = 7$ run-length constraints. Fig. 6 is the trellis diagram for the same channel; the trellis is drawn with state s_2 as the initial state. The characteristic equation for this state diagram is found to be $x^8 - x^5 - x^4 - x^3 - x^2 - x - 1 = 0$. The capacity, C, of the channel, equal to the base-two logarithm of the largest zero of the characteristic polynomial, is 0.518 bit/bit. Codes exist that record 0.518 bit of information for each channel bit recorded, but no codes can do better. Practical codes in use fall a little short of the channel capacity. The Franaszek code* of Fig. 7 is a variable-to-variable-length code whose rate is 0.5. Hence, it achieves 96 percent of the channel capacity and yet is quite simple. A code that comes closer to channel capacity may be quite complex.

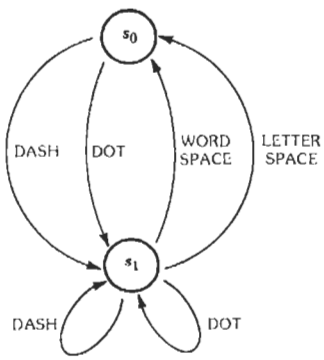

Fig. 3. State diagram for the telegraphy channel.

By inspection, one can see that any codeword of the Franaszek code followed by any other codeword satisfies the channel run-length constraints, and the codewords are uniquely decodable without punctuation. This last condition, known as the prefix condition, is due to the fact that no codeword looks like the beginning of any other codeword. This is an important requirement of a variable-length block code since the decoder must be able to break into codewords any concatenated string that is not punctuated.

Codes more elaborate than the Franaszek code are known, but they cannot be understood without develop-

ing more theory. The Adler-Hassner finite-state tree codes* encode a continuous bit sequence into a continuous bit sequence without word boundaries. Fig. 8 shows the encoder and decoder for an Adler-Hassner code for the $r = 1$, $s = 3$ run-length-limited channel. This channel has a channel capacity of 0.5515 bit/input. The rate one-half Adler-Hassner code implemented in Fig. 8 achieves 91 percent of the channel capacity. Binary symbols are clocked from the encoder into the channel and from the channel into the decoder at twice the source rate. Another Adler-Hassner code, say a rate 11/20 code, could achieve a larger fraction of a channel capacity, but the implementation would be much more complex.

* Reference 6.

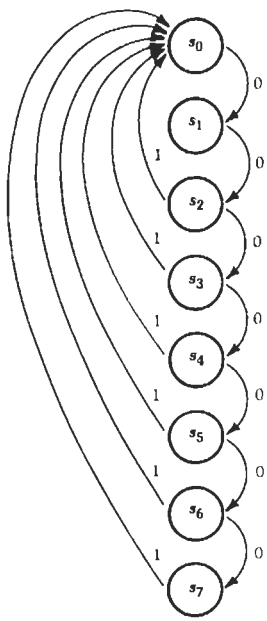

Fig. 5. State diagram of $r = 2$, $s = 7$ run-length-limited channel.

SOURCE COMPACTION CODES

Source compaction codes are used to represent the output of a data source more efficiently. Data sources such as facsimile, voice, digital recording, data tables, or word text can produce many millions or billions of bits. However, in their natural form, the data from these sources can be highly redundant. Practical data compaction codes are now available that can reduce considerably the number of bits needed to encode many such sources.

Source Models

An information source produces messages by generating a sequence of letters from a fixed alphabet of permitted symbols called the source alphabet. The alphabet may be finite, in which case the source is called a discrete source, or the source alphabet may be continuous, such as the set of real numbers, in which case the source is called a continuous source. A source might also put out continuous functions on the time axis. Sampling techniques are available to make this source into a time-discrete source.

The output of a discrete information source is a random sequence of symbols from a finite alphabet containing J symbols given by $\{a_0, a_1, \ldots, a_{J-1}\}$. The sequence is produced according to some probability rule. The sources that are the easiest to study mathematically are those known as ergodic sources. An *ergodic source* is one in which every sequence of symbols produced by the source is the same in statistical properties. If it is observed long enough, such a source will produce, with probability approaching one, a sequence of symbols that is "typical." In simple terms, this means that a sufficiently long sequence from the source will almost always produce the same frequency of occurrence of symbols and symbol combinations.

An information source is said to be *memoryless* if successive symbols generated by the source are statistically independent. That is, a source is memoryless if each symbol is selected without influence from all

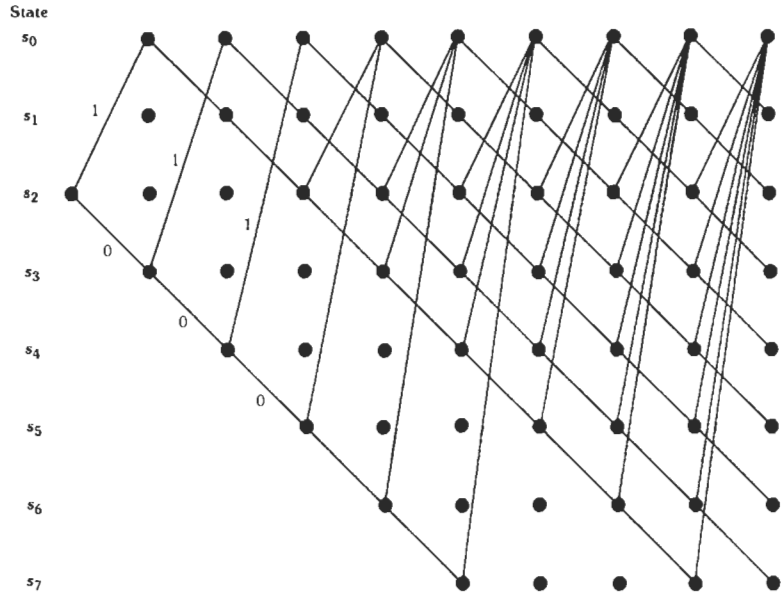

Fig. 6. Trellis diagram of $r = 2$, $s = 7$ run-length-limited channel.

previous symbols. If previously selected symbols influence the selection of a symbol, then the source is said to possess memory. If the selection of a symbol is influenced only by the immediately preceding symbol, the source is known as a *Markov source*. If the selection is influenced by the m previously selected symbols, the source is called an *mth-order Markov* source.

The Entropy Function

If a source output a_j occurs with probability $p(a_j)$, then the amount of information associated with the known occurrence of the event is defined to be

$$I(a_j) = -\log p(a_j)$$

In the definition, when logarithms are to the base 2, the information is measured in units of *bits*. When logarithms are taken to the base e, the information is measured in units of *nats* (a shortened form of natural units). Usually, the nat is more convenient for theoretical developments, and the bit is more convenient for the final result. The conversion factor is: one nat equals 1.443 bits.

INFORMATION WORDS	CODEWORDS
11	0100
10	1000
000	000100
010	001000
011	100100
0010	00001000
0011	00100100

Example:

1101010. . . ⟶ 01000010001000. . .

Fig. 7. The $r = 2$, $s = 7$ Franaszek rate one-half code.

If the probabilities of selecting the source symbols are $p(a_0)$, $p(a_1)$, . . . , $p(a_{J-1})$, respectively, then the information generated each time a symbol is selected is $-\log_2 p(a_j)$ bits. Since the symbol a_j will, on average, be selected $np(a_j)$ times in a total of n selections, the average amount of information obtained from n selections is

$$np(a_0) \log_2 p(a_0)^{-1} + \ldots + np(a_{J-1}) \log_2 p(a_{J-1})^{-1}$$

bits. Divide by n to obtain the average amount of information per symbol selection. This is known as the *average information*, the *uncertainty*, or the *entropy*, $H(p)$.

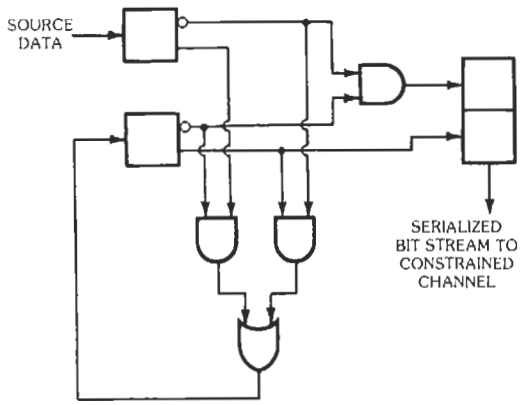
$$H(p) = -\sum_{j=0}^{J-1} p(a_j) \log_2 p(a_j) \text{ bits/symbol}$$

or

$$H(p) = -\sum_{j=0}^{J-1} p_j \log_2 p_j$$

where p_j is an abbreviation of $p(a_j)$.

The entropy associated with n selections from the statistically independent set is equal to n times the entropy per single selection. The term entropy is used



(A) Encoder.

since the function is the same as that derived in statistical mechanics for the thermodynamic quantity entropy.

For a first-order Markov source, the memory can be expressed by a conditional probability distribution. This conditional probability may be written as $p(a_j|a'_k)$ where a_j is any of the possible source symbols and a'_k is the source symbol emitted at the previous time instant.

The entropy is defined as an average

$$H(p) = -\sum_{k=0}^{J-1} p_k \sum_{j=0}^{J-1} p_{j|k} \log_2 p_{j|k}$$

where $p_{j|k}$ is an abbreviation of $p(a_j|a_k)$. This can also be rewritten

$$H(p) = -\sum_{k=0}^{J-1} \sum_{j=0}^{J-1} p_{jk} \log_2 p_{j|k}$$

where $p_{jk} = p_k p_{j|k}$.

The entropy function can be justified by its role in source compaction coding theorems, by its role in combinatorics, and by its intuitive properties as a measure of uncertainty. These properties are as follows:

1. The entropy function is continuous in p. This is a reasonable property, since it says that small changes in the probability distribution only make small changes in the uncertainty.
2. $H \geq 0$ and $H = 0$ if and only if all the p_j are zero except one which is unity. This a reasonable property of a measure of uncertainty, since if the outcome of a selection is sure, there is no uncertainty.
3. For a given n, $H(p) \leq \log n$ and is equal to $\log n$ if and only if the p_j are equal to $1/n$. This is a reasonable property which says that the more symbols available for selection without preference, the larger the uncertainty.

A binary source is one that contains only two symbols, a_0 and a_1; their probabilities are given by p and $1 - p$, respectively. The binary entropy function

$$H_b(p) = -p \log_2 p - (1 - p) \log_2 (1 - p)$$

is shown in Fig. 9.

The output of a binary source is a binary digit. The distinction between the bit used as a measure of information and the bit used as a binary output symbol

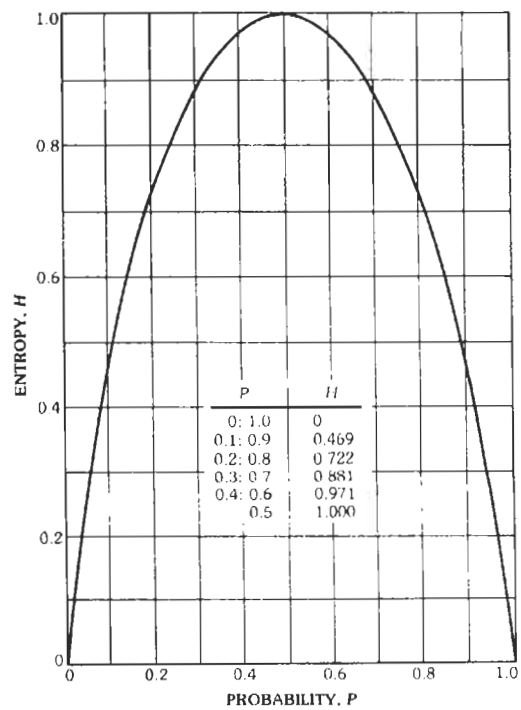

Fig. 9. The binary entropy function.

should be carefully noted. Fig. 9 shows that on average the amount of information provided by a binary source is always equal to or less than 1 bit/bit (one bit of information per data bit). The binary source provides one bit of information for each selected symbol only when the two symbols are equiprobable.

Source Encoding

The entropy function can be interpreted as the average amount of information necessary to specify which symbol has been produced by the source. If a source selects n symbols, where n is a very large number, then with high probability, it will select a sequence from the set of 2^{nH} different typical sequences each having a probability of occurrence of about $(1/2)^{nH}$. This is a direct physical interpretation of H. It means that, theoretically, a very long typical sequence of n q-ary symbols selected by the source can be encoded and retransmitted using only nH binary digits, each carrying one bit of information.

Usually, the binary codeword will be embedded in some longer binary text. Sometimes punctuation symbols are used and are not counted as part of the codeword. However, the more enlightened view is to incorporate the punctuation symbols into the code alphabet and devise an even more compact code. Then the code must be a self-punctuating code. Symbols to punctuate the code become implicit to the codeword.

Fixed-Length Block Codes

A fixed-length block code needs no punctuation. Compaction of a source with J symbols encodes n source output symbols into a codeword of length k bits, where n and k are fixed. There are J^n possible source output blocks the length n, so the blocklength of a binary code must be $\log_2 J^n$ bits if every possible output block is to be encoded. This requires $\log_2 J$ codeword bits per source output symbol. In general, this is much greater than the source entropy rate.

A fixed-length block code can encode at the entropy rate but then must allow the possibility of an error. A source compaction block code with rate a little above the entropy provides only $n(H(p) + \epsilon)$ bits, so $2^{n(H(p)+\epsilon)}$ codewords are assigned to the "typical" source output blocks—those blocks of greatest probability. By picking n large, the probability of a nontypical—hence noncodable—source output block can be made many orders of magnitude smaller than the probability of failure of the equipment. A fixed-length block code for source compaction must rely on this kind of reliability argument in order to encode at a rate near the entropy.

Variable-Length Block Codes

A variable-length block code encodes n source output symbols into k channel symbols, where either n or k is variable. The Huffman codes constitute the most common example. For them, k is variable and depends on the particular block of n symbols observed, while n is fixed.

The variable-length codewords of a Huffman code are constructed from knowledge of the probabilities of each of the J^n source output blocks of length n. We will construct a simple example using $n = 1$. The construction, illustrated in Fig. 10, proceeds as follows.

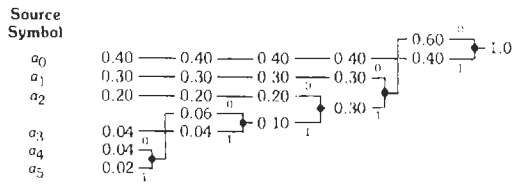
For convenience, the symbols are listed in order of decreasing probability. The two symbols of lowest probability are merged into a single symbol whose probability is the sum of the two constituent probabilities. At each step, this same procedure is repeated, merging two symbols into one symbol and adding their probabilities. The process stops when one symbol remains. Finally, read the tree from right to left, labeling the branches that leave each node either with a zero or with a one. The codeword is the string of labels from the rightmost node back to the original symbol.

A Huffman code can be formed just as easily for blocks of length n. Simply replace the source symbols in the construction with blocks of source symbols, and replace the symbol probabilities with probabilities of blocks. By choosing a large enough n—usually an n quite small will do—the average codeword length can be made as close to the source entropy as desired, and so a nearly optimal Huffman code can be constructed.

A Huffman code is a prefix code, sometimes said to be self-punctuating. It needs no explicit punctuation. Successive n blocks of source symbols can be encoded one after the other and concatenated. By decoding the codewords in a first-in, first-out fashion, the source symbols are uniquely recovered.

Variable-Length Tree Codes

A variable-length tree code for source compaction encodes indefinitely long strings of source output symbols into indefinitely long strings of code symbols. The encoding operation has a sliding structure whereby, as a



Source Symbol	Codeword
a_0	1
a_1	00
a_2	010
a_3	0111
a_4	01100
a_5	01101

Average codeword length = 2.06 binary digits/symbol.
The entropy of the source = 1.999 bits/symbol.

Fig. 10. Example of Huffman encoding.

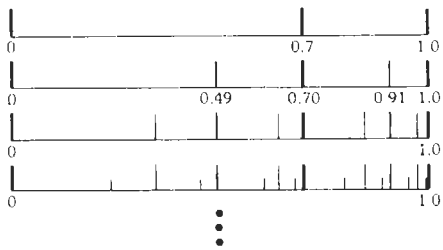
few source symbols enter the encoder, a few codeword bits leave the encoder. The relationship between the number of symbols entering the encoder and the number of bits leaving it is variable, depending on the particular source symbols to be encoded.

One of the earliest variable-length tree codes for source encoding is the Elias code. Because of its simplicity, it is an excellent tutorial example. We describe an Elias code for a binary source with binary source alphabet $\{a_0, a_1\}$ and probability distribution $p = \{0.7, 0.3\}$. The entropy of this source is 0.88 bit. Imagine that the semi-infinite sequence of source output bits is a binary representation of a real number, r, in the interval [0, 1]. Refer to Fig. 11. The first symbol tells whether r is in the interval [0, 0.7] or in the interval [0.7, 1]. This interval is itself subdivided in the same proportion, and the next source bit selects one of these two intervals. At each iteration, the process repeats, and, in this way, the process continues indefinitely.

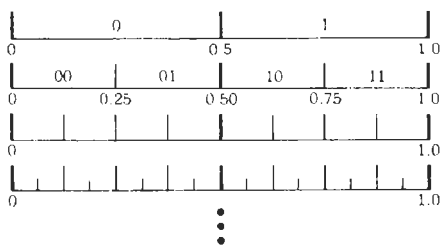
The codeword, on the other hand, is a conventional binary representation of point r. As soon as enough source symbols are received to determine whether r is in the interval [0, 0.5) or the interval [0.5, 1], a codeword bit can be transmitted. The encoding is variable length since the number of source symbols needed to produce one codeword bit is random.

The decoder can begin its task after receiving only a few codeword bits. For example, if the binary sequence starts with 011 . . . , the point represented must lie between 0.375 and 0.50; hence the first symbol from the source must be a_0. If the binary sequence starts with 0110, the point represented must lie between 0.375 and 0.4375; hence the first three symbols from the source must be $a_0a_0a_1$.

The Elias code is not practical because of precision problems. Errors in early calculations, no matter how small, will eventually cause encoding and decoding errors. A practical variable-length tree code, due to Pasco and Rissanen,* is available, but the description is more difficult.



(A) Description of r by sourceword.



(B) Description of r by codeword.

Fig. 11. Construction of an Elias code.

Universal Codes

A source compaction code usually requires a probabilistic model of the source in order to attain its best performance. The encoder will encode to near the entropy of the source only if it is given a satisfactory model of the source. Some source compaction codes, called *universal source codes*, implicitly construct their own model of the source as they go along (assuming that past source sequences are representative of future sequences) and so encode near the entropy of whatever source they are given.

The Lempel-Ziv code is a universal variable-to-fixed-length source-compaction block code that does not require an externally constructed source model. The technique, illustrated in Fig. 12, is to break up the string of source output symbols into substrings of variable length but not longer than a largest allowed length. The encoder has a buffered copy of the raw data that has already been encoded. At each iteration, it searches for a prefix of the data yet waiting to be encoded within the data already encoded. The longest prefix of which a copy can be found among the symbols recently encoded, together with one more innovation symbol, becomes the next substring.

A substring is encoded in three parts: a binary-encoded pointer telling where a copy of the substring begins within recently encoded data; a binary-encoded number giving the length of the substring; and the value of the innovation symbol. By including an innovation symbol, the encoder cannot degenerate into an unencodable situation.

The Lempel-Ziv decoder must keep a copy of recently decoded data in which it looks to recreate subsequent substrings that it must decode. The decoder contains a finite-length buffer equal in length to the encoder finite-length buffer. In decoding a substring, the decoder buffer contains the same symbols that the encoder buffer contained when that substring was encoded. Hence, the decoder can use the pointer and the substring length to reconstruct the next substring.

CODING FOR DISCRETE NOISY CHANNELS

The deep-space Gaussian noise channel and the noisy binary channel are two important examples of noisy channels. The first example is a continuous-time, continuous-amplitude channel that is usually made into a

* Reference 5.

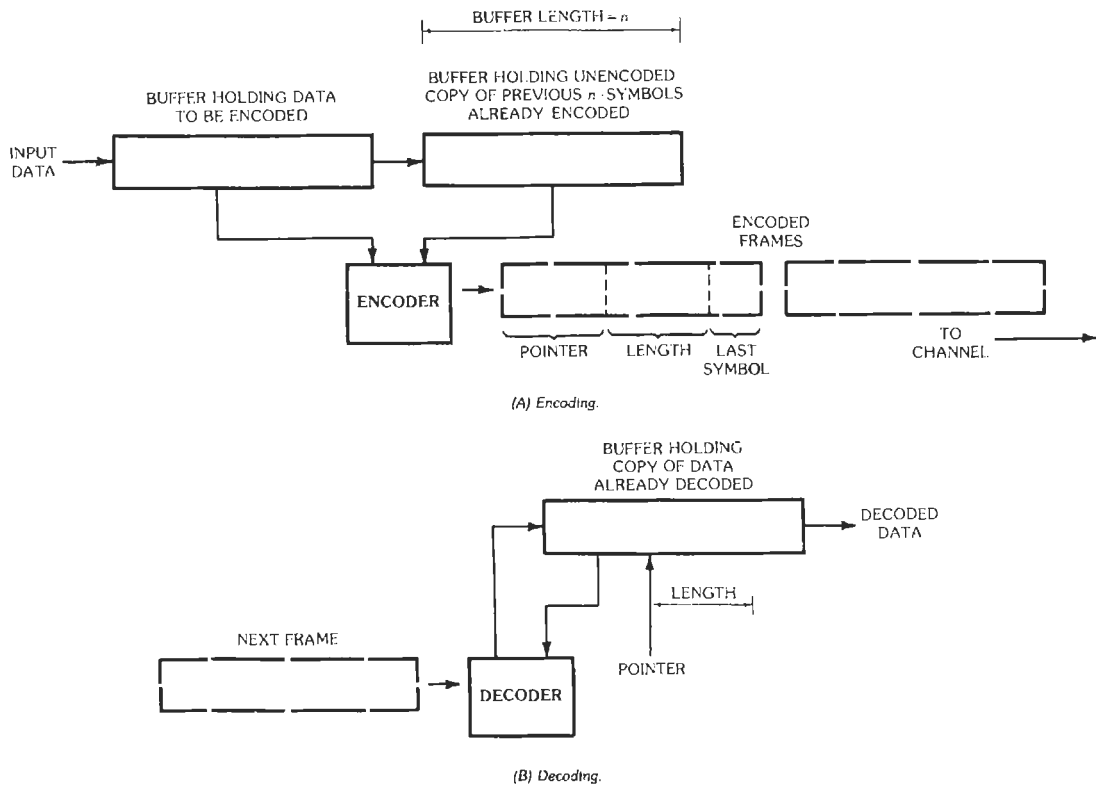


Fig. 12. Lempel-Ziv encoder and decoder.

discrete channel by the modulator/demodulator; the second is a discrete channel.

A *discrete channel* is a system in which a sequence of letters chosen from a finite set of symbols $\{a_0 \ldots a_{I-1}\}$ can be transmitted from one point to another. A *noisy channel* is one for which the output symbol is not completely determined by the input symbol; only some probability distribution on the set of output symbols is determined by the input symbol. If the probability distribution is independent of previous inputs or outputs from the channel, the channel is called *memoryless*. Let $\{b_0, \ldots, b_{J-1}\}$ be the set of channel output symbols; possibly $J \neq I$. Let $Q(b_j|a_i)$, abbreviated $Q_{j|i}$, be the probability that symbol b_j is received given that a_i was sent. It is called the *channel transition probability*, and the J by I matrix $\{Q_{j|i}\}$ is called the *transition matrix* of the channel. Some simple channels are shown in Fig. 13.

Information can be sent reliably through a discrete noisy channel by the use of elaborate crosschecking techniques known as error control codes. A noisy channel (such as a magnetic tape) may also have constraints. For such a channel, common practice is to treat the translation code that satisfies the constraints separately from the error control, and then use the two codes in series as shown in Fig. 14. Single codes that combine both functions neatly have not yet been discovered. An inner encoder/decoder matches its input symbols to the channel. When the channel makes an error, the inner decoder makes an error. The outer encoder/decoder has no constraints on the input sequence.

Mutual Information

Let $p(a_i)$, abbreviated p_i, be the probability that input symbol a_i is sent through the channel. The probability, $q(b_j)$, abbreviated q_j, of symbol b_j being the channel output is

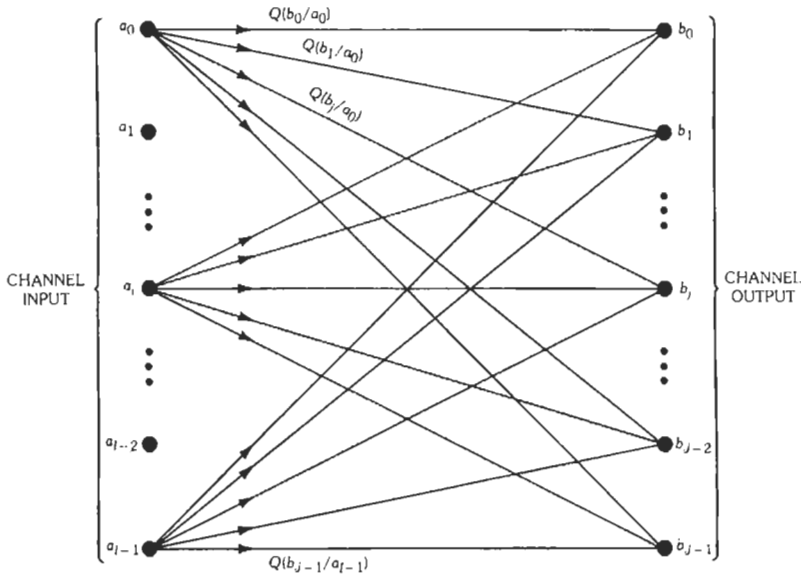
$$q_j = \sum_{i=0}^{I-1} p_i Q_{j|i}$$

Given output b_j, the probability, $P(a_i|b_j)$, abbreviated $P_{i|j}$, that symbol a_i was transmitted is given by the Bayes rule

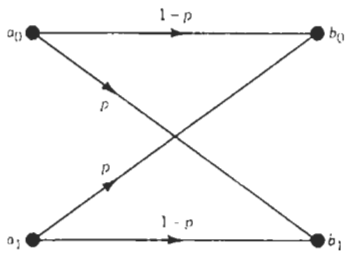
$$P_{i|j} = \frac{P_i Q_{j|i}}{\sum_i p_i Q_{j|i}}$$

The I by J matrix $\{P_{i|j}\}$ is called the *backward transition matrix* of the channel.

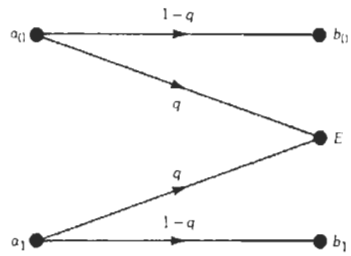
The average information per symbol carried by the input random variable, X, which takes value a_i with a probability $p(a_i)$, is the entropy.



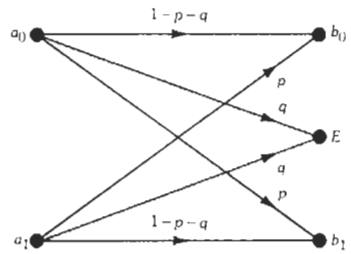
(A) The general case.



(B) Binary symmetric channel.



(C) Binary erasure channel.



(D) Errors and erasures channel.

Fig. 13. Some discrete memoryless channels.

$$H(X) = -\sum_{i=0}^{I-1} p_i \log_2 p_i$$

Conditional on b_j being received, the average information per symbol carried by input random variable X is

$$H(X|b_j) = -\sum_{i=0}^{I-1} P_{i|j} \log_2 P_{i|j}$$

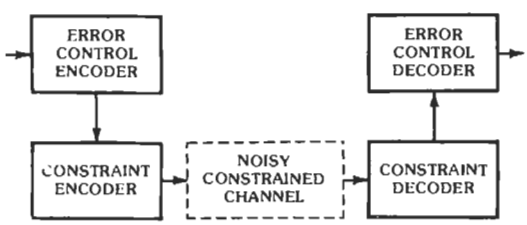


Fig. 14. Channel coding for noisy constrained channels.

The conditional input entropy, or *equivocation*, is then defined as an expectation

$$H(X|Y) = -\sum_{j=0}^{J-1} q_j \sum_{i=0}^{I-1} P_{i|j} \log P_{i|j}$$

bits/symbol. On average, this is the remaining uncertainty in the channel input after the channel output has been observed.

The difference between the average uncertainty in channel input X before and after channel output Y is received is called the *average mutual information* of the channel.

$$I(X; Y) = H(X) - H(X|Y)$$

$$= -\sum_{i=0}^{I-1} p_i \log p_i + \sum_{j=0}^{J-1} \sum_{i=0}^{I-1} q_j P_{i|j} \log P_{i|j}$$

By the Bayes formula, this becomes

$$I(X; Y) = \sum_{i=0}^{I-1} \sum_{j=0}^{J-1} p_i Q_{j|i} \log \frac{Q_{j|i}}{\sum_i p_i Q_{j|i}}$$

The average mutual information is a measure of the average amount of information about the channel input that can be received by the user by observing the symbol at the output of the channel.

The average mutual information has a number of important and satisfying properties:

1. Average mutual information is nonnegative and is strictly positive unless the channel output is independent of the channel input.
2. If $I = J$ and the channel is noiseless (i.e., $Q_{j|i} = 1$ if $j = i$), then $I(X; Y) = H(X)$, and the average mutual information between the output and the input of the channel is equal to the average information into the channel.
3. Average mutual information is symmetric in X and Y. That is $I(X; Y) = I(Y; X)$ where

$$I(Y; X) = \sum_{j=0}^{J-1} \sum_{i=0}^{I-1} q_j P_{i|j} \log \frac{P_{i|j}}{\sum_j q_j P_{i|j}}$$

Channel Capacity

The *channel capacity*, C, is defined to be the maximum rate at which information can be transmitted through a channel. The *fundamental theorem of information theory* says that at any rate below channel capacity, an error control code can be designed whose probability of error is arbitrarily small. Intuitively, in a well-designed message, an isolated channel input symbol a_i should occur with a probability p_i such that the average mutual information is maximized.

For the noisy channel, with transition matrix Q, the channel capacity, C, is expressed mathematically by

$$C = \max_p \sum_{i=0}^{I-1} \sum_{j=0}^{J-1} p_i Q_{j|i} \log \frac{Q_{j|i}}{\sum_i p_i Q_{j|i}}$$

where the maximum is over all probability distributions on the input alphabet. For simple channels, the capacity can be evaluated by finding the maximum analytically. For more difficult channels, efficient computational algorithms exist.

The capacity of the binary symmetric channel with transition matrix

$$\begin{bmatrix} 1-p & p \\ p & 1-p \end{bmatrix}$$

is

$$C = 1 + p \log_2 p + (1 - p) \log_2 (1 - p)$$

bits per input symbol. The capacity of the binary erasure channel with erasure probability q is

$$C = 1 - q$$

bits per input symbol. This is somewhat surprising, since it says that the erasures cause a loss in capacity exactly equal to the fraction of symbols erased despite the fact that the encoder does not know which nq symbols will be erased. The capacities of these two simple channels are shown in Fig. 15.

Error-Control Codes

Powerful codes are now available for use with q-ary symmetric channels whenever q is a prime or a prime power. Codes in use can achieve extremely small probability of symbol error, but the known codes are not good enough to achieve code rate near the channel capacity. Error control codes are routinely used for many purposes: to reduce required link signal-to-noise ratio; to protect against various forms of pulsed and other interference; to protect against hostile interference in military systems; to protect against noise and media defects in magnetic recording systems; and so forth.

Error-control codes in common use work with a code alphabet of size 2^m where m is a positive integer. For m equal to eight, the code alphabet consists of the set of all eight-bit bytes. It is common to use byte-organized codes because errors in practical systems tend to occur in bursts and because the hardware is simpler.

Error-control codes can be used for error detection or error correction. When they are used for error detection, a request for retransmission (called *automatic repeat request* (*ARQ*)) is fed back to the transmitter. When they are used for error correction (called *forward error correction* (*FEC*)), the link operates without interruption, and the error control is transparent to other levels of the system. Forward error correction can operate with noisy links and low transmitted power, whereas ARQ cannot; ARQ will play a reduced role in future systems.

English-language textbooks on error-control codes include Berlekamp (reference 8), Blahut (reference 9), Clark and Cain (reference 10), Lin and Costello (reference 11), and Peterson and Weldon (reference 12).

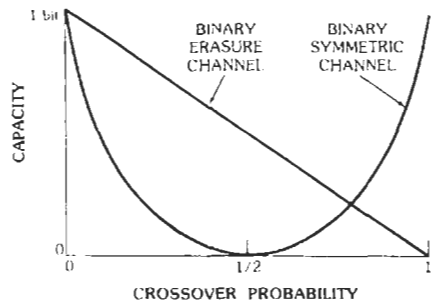

Fig. 15. Capacity of binary symmetric and binary erasure channels.

Block Codes

An (n, k) block code for error control encodes a block of k information symbols into a block of n codeword symbols. Each symbol is an m-bit byte. The rate, R, of the code is equal to k/n.

The rules for constructing good block codes for error control make use of the arithmetic of Galois fields. A Galois field with 2^m elements, denoted $GF(2^m)$, is an arithmetic system containing the operations of addition, subtraction, multiplication, and division defined in such a way that most arithmetic and algebraic procedures are valid. The arithmetic operations themselves are unconventional but have the enormous advantage that there is no overflow nor round-off error. Since the error control code is used to process bit packages but not to do real computations, it does not matter that the arithmetic rules are unconventional. Chart 1 shows addition and multiplication tables for several simple Galois fields. Notice that $GF(2)$ and $GF(3)$ are modulo 2 and modulo 3 arithmetic, respectively, but $GF(4)$ is *not* modulo 4 arithmetic. Modulo 4 arithmetic cannot form a field because $2 \cdot 1 = 2 \cdot 3 (\text{mod } 4)$, so division by 2 does not behave properly. Large fields such as $GF(256)$ are very important in practice, but the multiplication tables are too large to show here.

Chart 2 shows the set of codewords of the Hamming (7, 4) code, a binary code—symbols in $GF(2)$—that can correct a single bit error. This simple code has sixteen codewords. Chart 2 also shows some of the codewords of the Reed-Solomon (7, 5) code, an octal code—symbols are in $GF(8)$—that can correct a single octal symbol in error. This code has 8^5, or 32 768, codewords. This second example is actually a very small code although the number of codewords is already too great to enumerate. This is why it is important to use the computational structure of a Galois field to construct the encoders and decoders. Reed-Solomon codes as large as a (256 224) code over $GF(2^8)$ are now quite practical. This code consists of 224 information symbols followed by 32 parity symbols and can correct 16 symbol errors; a symbol error is a symbol that is wrong in any possible way. A symbol in $GF(2^8)$ may be used to represent eight bits by the user, yet on the channel may be represented by a 256-ary symbol.

The most important block codes in practice are those known as the *BCH codes* and the *Reed-Solomon codes*. They are important because efficient decoding algorithms exist for them. These decoders are based either on the *Berlekamp-Massey algorithm* or on the *Euclidean algorithm*, and they have a hardware cost proportional to nt where n is the blocklength and t is the number of errors to be corrected.

Convolutional Codes

A convolutional code encodes a stream of information symbols into a stream of codeword symbols. The duration of the stream is so long that it is effectively infinite and does not enter into the design of the encoder and decoder. An information sequence is shifted into the encoder beginning at time zero and continuing indefinitely into the future. The stream of incoming information symbols is broken into segments of k_0 symbols called information frames, which often may be as short as one symbol in practice. The encoder can store m frames. During each frame time, a new information frame is shifted into the encoder, and the oldest information frame is shifted out and discarded. At the end of any frame time, the encoder has stored the most recent m frames, a total of mk_0 information symbols. At the beginning of a frame, from the new incoming information frame and the m previously stored information frames, the encoder computes a single codeword frame of length n_0 symbols. This codeword frame is shifted out of the encoder as the next information frame is shifted in. Hence, the channel must transmit n_0 codeword symbols for each k_0 information symbols. The rate, R, of the convolutional code is defined as $R = k_0/n_0$.

The *constraint length*, v, of a convolutional code is defined as the number of memory stages in a minimum encoder. The complexity of a decoder is often q^v. Binary convolutional codes used in practice may have a constraint length in the range of about seven to forty. Fig. 16 shows an encoder for a much simpler convolutional code, one of constraint length 2 with $k_0 = 1$ and $n_0 = 2$. A trellis description of the code is shown in Fig. 17. The convolutional code is the set of all semi-infinite binary words that may be read off any path through the trellis. A "zero" information bit entering the encoder at any node is encoded into the upward path out of that node, and a "one" information bit is encoded into the lower path. This convolutional code is able to correct any number of error events each containing two bit

errors provided the error events are spaced far enough apart for the decoder to clear one error event before it sees the next.

Convolutional codes in use have a larger constraint length. The most important decoders for convolutional codes either use the *Viterbi algorithm* or use *sequential* decoding. The Viterbi algorithm has a hardware cost proportional to 2^v and so is practical only for small v. Sequential decoding, using either the *Fano algorithm* or the *stack algorithm*, has a hardware cost that grows only slowly with v, but has a random decoding delay and will occasionally overflow any finite-sized decoding buffer.

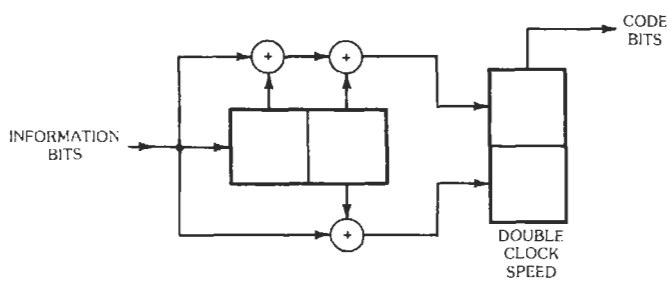

Fig. 16. Encoder for a convolutional code with constraint length 2.

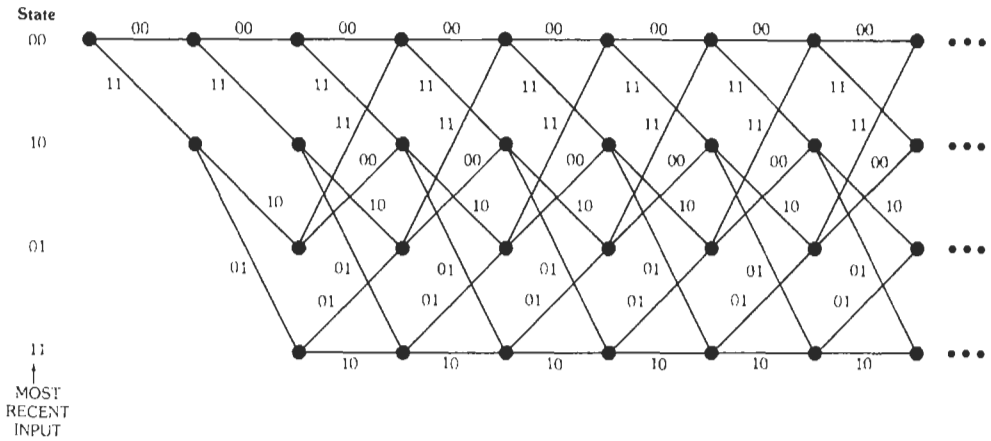

Fig. 17. Trellis diagram for a convolutional code with constraint length 2.

CONTINUOUS CHANNELS AND SOURCES

A discrete information source generates information at a finite rate; the entropy rate, which measures the information generated, is finite. A continuous information source can assume any one of an infinite number of amplitude values and so requires an infinite number of binary digits for its exact specification. The entropy rate is infinite. An immediate consequence of this is that in order to transmit the output of a continuous information source and recover it exactly, a channel of infinite capacity is required. Since, in practice, every continuous channel is perturbed by noise and therefore has a finite capacity, it is not possible to transmit the output of a continuous source over a channel and recover it exactly; there is always some distortion.

We distinguish among a discrete source or channel, a continuous source or channel defined on discrete time instants, and a waveform source or channel defined on a continuum of time points.

A waveform channel can be made into a discrete channel by choosing a finite set of modulation waveforms for the channel. The relationship between waveform design and information theory is discussed in Wozencraft and Jacobs.* A waveform source can be made into a continuous source by sampling, provided the bandwidth is finite, and into a discrete source by sampling and quantization provided a small amount of distortion can be introduced.

The Sampling Theorem

The sampling theorem is an important aid in the design and analysis of communication systems involving the use of continuous time functions of finite bandwidth. The theorem states that, if a function of time, $f(t)$, contains no frequencies of W hertz or higher, then it is completely determined by giving the value of the function at a series of points spaced $(2W)^{-1}$ seconds apart. The sampling rate of $2W$ samples per second is called the *Nyquist rate*.

If $f(t)$ contains no frequencies of W hertz or higher, then it can be recovered from its samples by the Nyquist-Shannon interpolation formula:

$$f(t) = \sum_{n=-\infty}^{+\infty} f(n/2W)\ \{[\sin\ \pi(2Wt-n)]/\pi(2Wt-n)\}$$

The sampling theorem makes no mention of the time origin of the samples; it is only the spacing of the samples that matters.

If function $f(t)$ is negligible in magnitude outside a time interval T and has negligible energy at frequencies higher than W hertz, it can be specified by $2TW$ ordinates. If a Gaussian noise process with rectangular spectrum is sampled at the Nyquist rate, the samples are independent.

Differential Entropy

The differential entropy of a continuous random variable, X, with probability density function $p(x)$ is defined as

$$H(X) = -\int_{-\infty}^{+\infty} p(x)\ \log_2 p(x)dx$$

The differential entropy is *not* the limiting case of the entropy; the entropy of a continuous distribution is infinite. The differential entropy is not invariant under coordinate transformations. By itself, it has no fundamental physical meaning, but it occurs often enough to have a name.

* Reference 13.

The Gaussian probability distribution

$$p(x) = [1/(\sqrt{2\pi}\,\sigma)]\exp(-x^2/2\sigma^2)$$

plays a major role in information problems. Of all probability distributions with variance σ^2, the Gaussian distribution has the largest differential entropy, given by

$$H(X) = \tfrac{1}{2}\log_2(2\pi e\sigma^2)$$

The differential entropy of a vector of length n whose components are independent identically distributed Gaussian random variables is

$$H(X) = \tfrac{1}{2}n\log_2(2\pi e\sigma^2)$$

Consequently, if a Gaussian noise process of ideal rectangular spectrum is sampled at the Nyquist rate of $2W$ samples per second, we say the differential entropy rate of the source is $W\log_2(2\pi e\sigma^2)$. A Gaussian noise process whose spectrum is constant for frequencies below W hertz and is zero for larger frequencies is called *band-limited white noise*.

Entropy Power

The *entropy power* of a random signal is defined to be the power of band-limited white noise having the same differential entropy rate and bandwidth as the original noise.

If a random signal has an entropy H(bits), the power of band-limited white noise having the same entropy rate is given by

$$N_e = (1/2\pi e)2^{2H}$$

The power N_e is the entropy power of the random signal.

It should be noted that since white noise has the maximum differential entropy for a given power, the entropy power of any random signal is less than or equal to its actual power.

Capacity of a Continuous Channel

The average mutual information between two continuous random variables X and Y with joint probability density function $P(x, y)$ is

$$I(X;Y) = H(X) - H(X|Y) = H(Y) - H(Y|X)$$

$$= H(X) + H(Y) - H(X, Y)$$

$$= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} P(x, y)\log_2[P(x, y)/p(x)p(y)]\,dy\,dx$$

$$= \int_{-\infty}^{\infty} p(x)\int_{-\infty}^{\infty} Q(y|x)\log_2\frac{Q(y|x)}{\int_{-\infty}^{\infty} p(x)\,Q(y|x)\,dx}\,dy\,dx$$

bits. Even though the differential entropy terms appearing here are not invariant under a coordinate transformation, their difference is. The mutual information has a fundamental significance.

A continuous channel usually has some constraint on the input probability distribution; an average power constraint or a peak power constraint is the most common. Therefore, $p(x)$ must satisfy one or more constraint equations of the form

$$\int_{-\infty}^{\infty} e(x)p(x)dx \leq S$$

where $e(x)$ is some nonnegative function. The average power constraint is

$$\int_{-\infty}^{\infty} x^2p(x)dx \leq S$$

The capacity of the continuous channel is the maximum value of the average mutual information

$$C = \max_{p(x)} I(X;Y)$$

where the maximum is taken over the set of probability distributions that satisfy the constraints.

The Additive Gaussian Noise Channel

Calculation of the capacity can be a difficult task requiring a computer, but the important case of an additive Gaussian noise channel subject to an average power constraint can be solved analytically.

The channel output, Y, is given by $Y = X + Z$ where X is the channel input and Z is the noise. Since X and Z are independent, $H(Y|X) = H(Z)$, and $I(X;Y) = H(Y) - H(Z)$. For Gaussian noise, $H(Z) = \frac{1}{2}\log_2 2\pi eN$ where N is the noise power. Then

$$C = \max_{p(x)} 2W[H(Y) - \tfrac{1}{2}\log_2 2\pi eN]$$

Factor $2W$ converts the units of capacity to bits/second. Output Y has variance $S + N$ where S is the average power constraint. Entropy $H(Y)$ is largest if Y is Gaussian, which will be true if X is Gaussian of variance S. Then

$$C = W\log_2 2\pi e(S + N) - W\log_2 2\pi eN$$

$$= W\log_2(1 + S/N)$$

This is Shannon's formula for the capacity of the additive Gaussian noise channel with an average power

constraint. The channel input signal that achieves channel capacity has an amplitude distribution described by the Gaussian function.

If a channel has additive but non-Gaussian noise and a power constraint, then the capacity may be difficult to calculate exactly. However, upper and lower bounds on the capacity are easy to obtain. At average transmitted power S, the capacity, C, in bits/second, is bounded by the inequalities

$$W \log_2 [(S + N)/N_e] \geq C \geq W \log_2 [(S + N)/N]$$

where,

W is the bandwidth,
N is the average noise power,
N_e is the entropy power of the noise.

Waveform Channels

An additive Gaussian noise waveform channel with a general transfer function is shown in Fig. 18. The capacity of the waveform channel under Gaussian noise is equal to the capacity one would obtain if the transfer function were approximated by many thin ideal rectangular transfer functions of different amplitudes. The capacity is given by the so-called "water-pouring" formulas, written parametrically in terms of θ.

$$C(S, \theta) = \frac{1}{2} \int_{-\infty}^{\infty} \max[0, \log \frac{\theta}{N(f)/|H(f)|^2}] df$$

$$S(\theta) = \int_{-\infty}^{\infty} \max[0, \theta - N(f)/|H(f)|^2] df$$

The reason these are called the water-pouring formulas can be understood from Fig. 19. The input information is imagined as "poured" into a vessel whose shape is defined by $H(f)$ and $N(f)$. This produces the optimum spectral shape of input waveform $S(f) = \max[0, \theta - N(f)/|H(f)|^2]$ that achieves the channel capacity. The important lesson given by the water-pouring principle is that optimum waveforms put most of their energy in the spectral region where the channel is good and little or no energy in the spectral region where the channel is poor. The optimum strategy is exactly the opposite of an often-used equalization strategy that "boosts" the skirts of the channel by adding extra gain there.

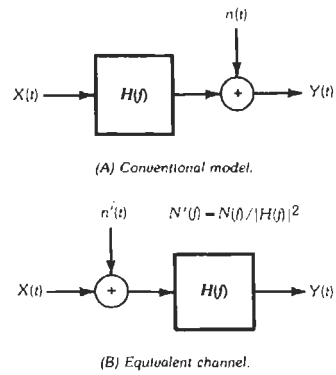

Fig. 18. Gaussian-noise waveform channel.

Bit Energy and Bit Error Rate

The performance of a digital communication system is measured by the probability of bit error, also called the *bit error rate* (BER). On an additive Gaussian noise channel, the bit error rate can always be reduced by increasing transmitted power, but it is by the performance at low transmitted power that one judges the quality of a digital communication system. The better of two systems, otherwise the same, is the one that can achieve a desired bit error rate with the lower transmitted power.

Given a message, $s(t)$, of duration T containing K information bits, the bit energy, E_b, is given by

$$E_b = E_m/K$$

where

$$E_m = \int_0^T s(t)^2 \, dt$$

is the message energy.

Bit energy E_b is calculated from the message energy and the number of information bits at the input to the encoder/modulator. At the input to the channel, one may find a message structure in which he perceives a larger number of bits. The extra symbols may be parity symbols for error control, or symbols for frame synchronization or channel protocol. These symbols do not represent transmitted information, and their energy must be amortized over information bits. Only information bits are used in calculating E_b.

For an infinite-length message of rate R information bits/second, E_b is defined by

$$E_b = S/R$$

where S is the message average power.

In addition to the message energy, the receiver also sees a white noise signal of one-sided spectral density N_o watts/hertz. Only the ratio E_m/N_o or E_b/N_o affects the bit error rate because the reception of the signal cannot be affected if both the signal and the noise are doubled. Signaling schemes are compared by comparing their respective graphs of BER versus required E_b/N_o.

It is possible to make precise statements about values of E_b/N_o for which good waveforms exist; these are a

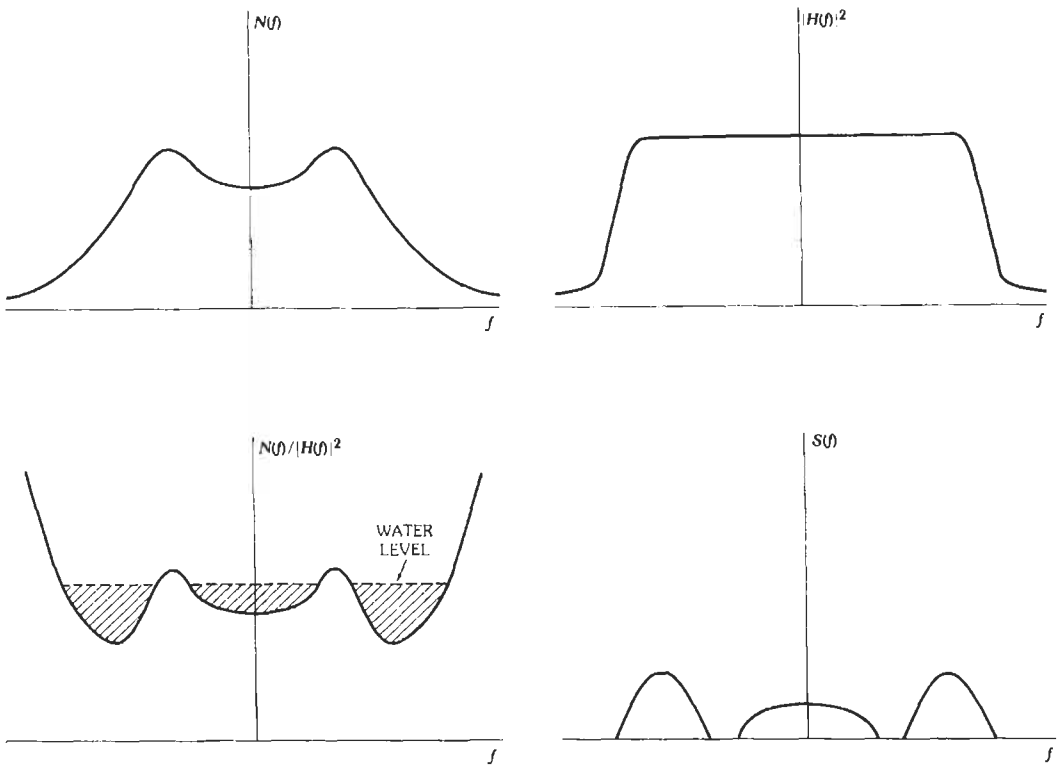

Fig. 19. Water pouring.

consequence of the channel capacity formula for the ideal rectangular bandpass channel in additive Gaussian noise. Let the signal power be $S = E_bR$ and the noise power be $N = N_oW$. Then

$$C/W = \log_2 (1 + RE_b/N_oW)$$

Define the spectral bit rate, r (measured in bits per second per hertz), by

$$r = R/W$$

The spectral bit rate, r, and E_b/N_o are the two most important figures of merit of a digital communication system.

Since the rate, R, is less than but can be made arbitrarily close to the capacity, C, the capacity formula becomes

$$E_b/N_o > (2^r - 1)/r$$

but E_b/N_o can be arbitrarily close to the bound by designing a sufficiently sophisticated digital communication system. This inequality, shown in Fig. 20, tells us that increasing the bit rate per unit bandwidth increases the required energy per bit. This is the basis of the energy/bandwidth trade of digital communication theory where increasing bandwidth at a fixed information rate can reduce power requirements.

Every communication system can be described by a point lying below the curve of Fig. 20. Any communication system that attempts to operate above the curve will lose enough data through errors so that its actual data rate will lie below the curve. By the fundamental theorem of information theory, for any point below the curve one can design a communication system that has as small a bit error rate as one desires. The history of digital communications can be described in part as a series of attempts to move ever closer to this limiting curve with systems that have very low bit error rate. Such systems employ both modem techniques and error-control techniques.

If bandwidth W is a plentiful resource but energy is scarce, then one should let W go to infinity, or r to zero. Then we have

$$E_b/N_o \geq \log_e 2 = 0.69$$

This is a fundamental limit. Ratio E_b/N_o is never less than -1.6 dB, and by a sufficiently expensive system one can communicate with any E_b/N_o larger than -1.6 dB.

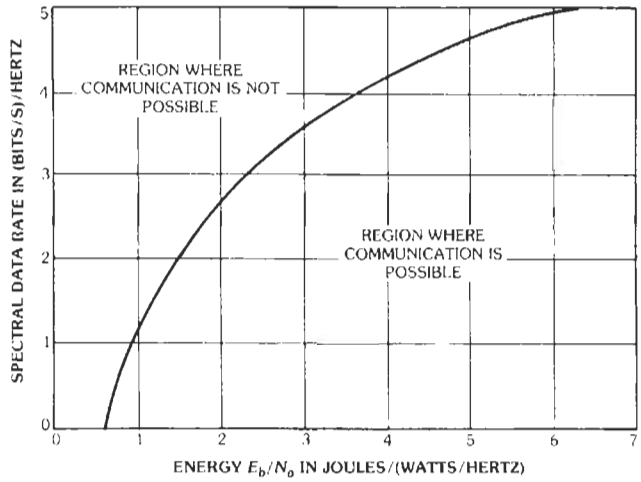

Fig. 20. Capacity of baseband Gaussian noise channel.

Signaling Without Bandwidth Constraints

If the bandwidth is much larger than the data rate, then in principle one can signal arbitrarily closely to channel capacity by using an M-ary signaling alphabet. An M-ary signaling alphabet is a collection of M sufficiently distinct waveforms. Usually M is chosen equal to 2^k for some k. The modulator maps each k-bit word from the channel encoder into one of the 2^k waveforms in the signaling alphabet. The demodulator compares the received signal in each signaling time interval with each of the 2^k possible transmitted waveforms and chooses the most likely.

There are a great many sets of M-ary signal alphabets that can be used. Those with the best performance known are a type known as *simplex waveforms*, but orthogonal waveforms are almost as good and are usually used in practice. The advantage of M-ary signaling can be understood as the resultant of two opposing forces. Since the modulator puts k bits into one waveform, it has k times as much energy as it would for a binary waveform. Since the demodulator must make a 2^k-way decision rather than a binary decision, it needs more energy in the waveform to preserve a small error probability. However, the additional energy needed grows with k more slowly than the additional energy available. The net effect is a system that can operate at a very low E_b/N_0; however, the waveforms occupy a bandwidth much greater than the bit rate. Fig. 21 shows the performance of a 2^k-ary family of orthogonal waveforms. The figure shows that E_b/N_0 of -1.6 dB is attainable for large k. Practical systems are usually limited to a k of about six. In the figure, E_b is the energy per data bit delivered; because some of these data bits will be incorrect, the energy per information bit is larger.

Signaling With a Bandwidth Constraint

When bandwidth is expensive, one no longer attempts to transmit with very small E_b/N_0. Now it becomes important to transmit with large spectral bit

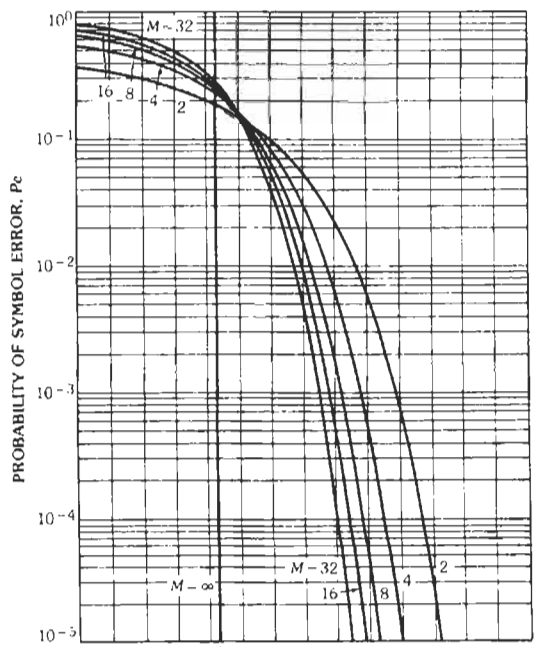

Fig. 21. Performance of M-ary signaling.

rate, r (bits/second)/hertz. Good performance can be achieved by careful combination of modulation and error control.

The Ungerboeck convolutional codes are a class of convolutional codes that provide good combinations of spectral bit rate and E_b/N_o. The rate 2/3 codes are designed to work with a set of eight fixed complex numbers, called a signaling constellation, which represent phase/amplitude modulation patterns. Two such signaling constellations are shown in Fig. 22. An encoder for the constraint-length-four Ungerboeck code for the PSK signaling constellation is shown in Fig. 23. This code can be used as a plug-in replacement for the popular uncoded four-phase PSK modulator. The information rate is still two bits per symbol. There is no change in the channel symbol rate, so the coded system has the same bandwidth as the uncoded system and transmits the same number of information bits per symbol. Hence, the user of the system is unaware of the presence of the code. However, the system now can run at a lower E_b/N_o or signal-to-noise ratio; the constraint-length-four code has a coding gain of 5.7 decibels.

DECISION THEORY AND ESTIMATION THEORY

Decision theory is concerned with the problem of deciding between a set of hypotheses when given a collection of imperfect measurements. Estimation theory is concerned with the problem of selecting the best value of a parameter from a continuum of possible values when given a collection of imperfect measurements. Estimation theory is also concerned with the selection of a best waveform from a collection of waveforms when given a collection of imperfect measurements.

General discussion of decision theory and estimation theory can be found in Davenport and Root* and Van Trees.†

Hypothesis Testing

The simplest problem of decision theory, called hypothesis testing or detection, is to decide between two mutually exclusive hypotheses. In the case of a radar,

* Reference 14.
† Reference 15.

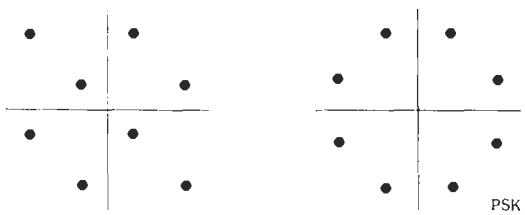

Fig. 22. Two 8-ary signaling constellations.

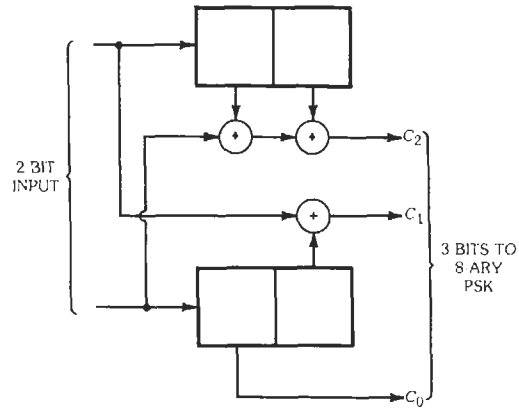

Fig. 23. Diagram of encoder for a constraint-length-four Ungerboeck code.

the hypotheses are *target present* or *target absent*. In the case of signal acquisition, the hypotheses are *signal present* or *signal absent*. In the general case, the hypotheses are called the *null hypothesis*, H_0, and the *alternate hypothesis*, H_1. The problem is to decide which hypothesis is correct by collecting data and processing them. The data are randomly distributed with a probability distribution that depends on the true hypothesis. The set of data may actually be quite extensive, but it is enough to think of it as a simple measurement whose outcome can only be an element of a finite set of K elements called the measurement space, and indexed by k. The theory applies to arbitrary data sets simply by replacing the scalar measurement by an appropriate vector measurement.

Associated with each hypothesis is a probability distribution on the measurement space. If H_0 is true, then q_{0k} gives the probability that k will be the measurement outcome; if H_1 is true, then q_{1k} gives this probability. A simple measurement consists of an observation of a realization of the random variable. A measurement is observed, and the problem is to decide whether hypothesis H_0 or hypothesis H_1 is true. A hypothesis testing rule is a partition of the measurement space into two disjoint sets $\mathbf{U}_0$ and $\mathbf{U}_1 = \mathbf{U}_0^c$. If the measurement is an element of $\mathbf{U}_0$, we decide that H_0 is true; if it is an element of $\mathbf{U}_1$, we decide that H_1 is true. Each hypothesis testing rule can be described as such a partition.

Accepting hypothesis H_0 when H_1 actually is true is called a type-one error, and the probability of this event is denoted by α. Accepting hypothesis H_1 when H_0 actually is true is called a type-two error, and the probability of this event is denoted by β. Obviously,

$$\alpha = \sum_{k \in \mathbf{U}_0} q_{1k} \qquad \beta = \sum_{k \in \mathbf{U}_1} q_{0k}$$

A method for finding the optimum decision regions is given by the Neyman-Pearson theorem. This theorem

expresses the decision regions in terms of a parameter, T, called the threshold, and a function called the log-likelihood ratio given by

$$l(k) = \log (q_{0k}/q_{1k})$$

The Neyman-Pearson theorem says that the sets parameterized by T,

$$\mathcal{U}_0(T) = \{k | l(k) \geq T\}$$

$$\mathcal{U}_1(T) = \{k | l(k) < T\}$$

are an optimum family of decision rules in the sense that no decision rule can have both type-one error and type-two error better than any of these rules. The type-one and type-two error probabilities can be traded by varying the threshold, T.

The log-likelihood ratio for a block $v = (k_1, \ldots, k_n)$ of independent identically distributed measurements of length n can be written as a sum of per-letter log-likelihood ratios

$$l(v) = \log [q_0(v)/q_1(v)] = \sum_{l=1}^{n} \log [q_{0k_l}/q_{1k_l}]$$

because the probability distributions on v are products of the single letter probability distributions

$$q_0(v) = \prod_{l=1}^{n} q_{0k_l} \qquad q_1(v) = \prod_{l=1}^{n} q_{1k_l}$$

The Neyman-Pearson decision regions for the block measurement are expressed in terms of $l(v)$ by the inequalities $l(v) < T$ and $l(v) \geq T$.

The same description applies even when the measurements are not independent or identically distributed. However, the log-likelihood ratio, $l(v)$, then cannot be written as the sum of per-letter log-likelihood ratios.

The expected value of the log-likelihood ratio with respect to q_0 is the function known as the *discrimination*.

$$L(q_0, q_1) = \sum_{k=0}^{K-1} q_{0k} \log (q_{0k}/q_{1k})$$

The discrimination is closely related to the entropy and the average mutual information. It is useful for forming bounds on the probability of error.

Estimation Theory

Estimation theory is concerned with the problem of finding a best value for an unknown parameter when only imperfect data are available. The estimation of the unknown parameter depends on measurements that are random variables. The quality of the estimate is limited by the quality of the measurements. These limitations can be expressed by means of information-theoretic bounds; one such bound is known as the Cramer-Rao inequality.

The simplest estimation problem involves an unknown real parameter, θ, to be determined, and a random variable, X. Understanding this problem leads to understanding of the more general problems: the estimation of several parameters based on the observation of a finite number of random variables; the estimation of several parameters based on observing a sample waveform of a stochastic process; and the estimation of a function on an interval based on observing a sample waveform of a stochastic process.

The random variable has a continuous probability distribution, $q(x|\theta)$, conditional on the parameter θ. The unknown θ must be estimated based upon an observation of X. The estimate of θ given the measurement X is a function $\hat{\theta}(x)$. The estimate, $\hat{\theta}$, is a random variable, since it is a function of the random variable X. Estimation theory studies various criteria for making good estimates, that is, for selecting the function $\hat{\theta}(x)$.

The quality of an estimator is judged by its bias

$$\bar{\theta} = E[\hat{\theta}(x)]$$

and by its variance

$$\sigma_{\hat{\theta}}^2 = E\{[\hat{\theta}(x) - \bar{\theta}]^2\}$$

Intuitively, one hopes to choose the estimator, $\hat{\theta}(x)$, so that its bias is zero and the variance is as small as possible. Such an estimator is called a *minimum-variance unbiased estimator*. Sometimes, however, the minimum-variance unbiased estimator does not exist, or another estimator has some advantage, and so another estimator is used.

The Cramer-Rao bound is a lower bound on the variance of any estimator. For an unbiased estimator of a single parameter θ, the most common form of the bound is

$$\sigma_{\hat{\theta}}^2 \geq \{E[(\partial/\partial\theta) \log q(x|\theta)]^2\}^{-1}$$

The same bound holds even if X is a vector of measurements. The Cramer-Rao bound can also be expressed in terms of the discrimination

$$\sigma_{\hat{\theta}}^2 \geq \left\{ \lim_{\theta' \to \theta_j} \frac{L(q_\theta; q_{\theta'})}{(\theta - \theta')^2} \right\}^{-1}$$

where,

$$L(q_\theta; q_{\theta'}) = \int q(x|\theta) \log [q(x|\theta)/q(x|\theta')]\, dx$$

The Matched-Filter Estimator

Suppose that a known waveform, $s(t)$, has spectrum $S(f)$ and that additive Gaussian noise has spectral

density $N(f)$. The received noisy signal with an unknown time of arrival τ is

$$v(t) = s(t - \tau) + n(t)$$

The Cramer-Rao bound says that any estimator of the time of arrival satisfies

$$\sigma_\tau^2 \geq \left[\int_{-\infty}^{\infty} \frac{|2\pi f S(f)|^2}{N(f)}\, df\right]^{-1}$$

The optimal estimator, if the noise is white and the signal-to-noise ratio is sufficiently high, is the matched-filter estimator. It achieves the Cramer-Rao bound. The matched-filter estimator passes $v(t)$ through a filter with impulse response $s^*(-t)$ (with some fixed delay to make it realizable) and estimates τ from the peak of the filter output. If the signal-to-noise ratio is not sufficiently high, then the optimal estimator is not known.

Similar remarks apply to the problem of estimating the frequency offset, ϕ, of an otherwise known bandpass waveform

$$v(t) = s(t) \cos [2\pi(f_0 + \phi)t + \theta]$$

$$+ n_R(t) \cos 2\pi f_0 t - n_I(t) \sin 2\pi f_0 t$$

where $s(t)$ has spectrum $S(f)$ and is a known and finite energy waveform whose bandwidth is much less than the known carrier frequency, f_0. A small offset in frequency ϕ is to be estimated, and $n_R(t)$, $n_I(t)$ are independent covariance stationary Gaussian processes with identical power density spectrum $N(f)$, which is known. The Cramer-Rao bound says that any estimator of frequency ϕ has an error variance satisfying

$$\sigma_\phi^2 \geq \left[\int_{-\infty}^{\infty} \frac{|S'(f)|^2}{N(f)}\, df\right]^{-1}$$

where $S'(f)$ is the derivative of $S(f)$. The matched-filter estimator of frequency consists of a bank of matched filters. Each filter has impulse response of the form $s^*(-t) \cos 2\pi(f_0 + \Delta)t$ for Δ in a range of interest. The Δ of the filter with the largest output provides the estimate of ϕ. If the noise is white, and the signal-to-noise ratio is sufficiently high, the matched-filter estimator achieves the Cramer-Rao bound, and so is optimal. This matched-filter estimator of frequency offset often can be approximated by a phase-locked loop. If the signal-to-noise ratio is not sufficiently high, the optimal estimator of frequency is not known.

Maximum Entropy and Minimum Discrimination

The *Jaynes maximum entropy principle* of data reduction says that when reducing a set of data into the form of an underlying model, one should be maximally noncommittal with respect to missing data. If one must estimate a probability distribution subject to constraints on it, then one should choose the probability distribution of maximum entropy consistent with the constraints. For example, if $q(x)$ is a probability density function of a single variable, x, and the mean and variance of $q(x)$ are known and otherwise $q(x)$ is unknown, then one should estimate that $q(x)$ is a Gaussian probability density function with the given mean and variance.

The *Kullback principle of minimum discrimination* is a more general principle that applies when one is given a distribution, $p(x)$, that is a prior estimate of $q(x)$ and a set of constraints on $q(x)$. The principle states that, of the distributions that satisfy the constraints, one should choose as the new estimate that $q(x)$ that minimizes the discrimination

$$L(q,p) = \int q(x) \log [q(x)/p(x)]\, dx$$

If the probability distribution is discrete and $p(x)$ is a uniform distribution, then this reduces to the maximum entropy principle.

Spectral Estimation

Spectral estimation is the problem of estimating the power spectrum of a stochastic process given partial data, usually only a finite number of samples of the autocorrelation function of limited accuracy. Most spectral estimation methods in use ignore the noise on the autocorrelation samples and treat only the problem of dealing with the missing autocorrelation samples.

The simplest and most popular spectral estimation procedure is to choose as the estimated spectrum the Fourier transform of the known values of the autocorrelation function, possibly tapering the known values of the autocorrelation function or padding them with some zero components. The Fourier transform techniques implicitly augment the measured components of the autocorrelation function with artificial components: either a periodic continuation of the known values or some zero components.

The Jaynes maximum entropy principle applied to spectral estimation yields an alternative procedure known as *maximum-entropy spectral estimation*. If the correlation samples are given at a set of equispaced lags, then the maximum entropy estimate of the stochastic process turns out to be

$$v_i = -\sum_{j=1}^{L} h_j v_{i-j} + n_i$$

which is the output of an *autoregressive filter* excited by discrete-time white noise. The filter coefficients are chosen so that the correlation coefficients of this process agree with the known correlation coefficients. Hence the filter coefficients are the solution of the matrix equation

$$\sum_{j=1}^{L} h_j R_{i-j} = -R_i$$

where the correlation coefficients, R_i, for $i = -L, \ldots, L$, are known and R_{-i} equals R_i. An efficient algorithm for solving this set of equations is the *Levinson algorithm.*

SOURCE COMPRESSION CODES

The average amount of information required to describe a source output symbol is equal to the entropy of the source. Sometimes it is not convenient or practical to retain all this information. It then is no longer possible to maintain an exact reproduction of the source. An analog source has infinite entropy, so distortion must always be present when the source output is passed through a channel of finite capacity.

Data compression is the practice of intentionally reducing the information content of a data record. This should be done in such a way that the least-distorted reproduction is obtained. Information theory finds the performance of the optimum compression of a random source of data; a naive encoder will have greater distortion.

The output of a discrete information source is a random sequence of symbols from a finite alphabet containing J symbols given by $\{a_0, a_1, \ldots, a_{J-1}\}$. A memoryless source produces the jth letter with probability p_j where p_j is strictly positive. The source output is to be reproduced in terms of a second alphabet called the reproducing alphabet, often identical to the source alphabet, but not always so. For example, the reproducing alphabet might consist of the union of the source alphabet and a single new element denoting "data erased."

A distortion matrix is a J by K matrix with nonnegative elements ρ_{jk} for $j = 0, \ldots, J-1$ and $k = 0, \ldots, K-1$ that specifies the distortion associated with reproducing the jth source letter by the kth reproducing letter. Without loss of generality, it can be assumed that for each source letter a_j there is at least one reproducing letter b_k such that the resulting distortion ρ_{jk} equals zero. Usually the distortion in a block is defined as the arithmetic average of the distortions of each letter of the block. This is called a per-letter fidelity criterion.

An important distortion matrix is the probability-of-error distortion matrix. For this case the alphabets are identical. For example, take $J = K = 4$ and

$$\rho = \begin{bmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{bmatrix}$$

This distortion matrix says that each error is counted as one unit of distortion. A different data-compression problem with the same source alphabet and reproducing alphabet is obtained if one takes the distortion matrix

$$\rho = \begin{bmatrix} 0 & 1 & 2 & 1 \\ 1 & 0 & 1 & 2 \\ 2 & 1 & 0 & 1 \\ 1 & 2 & 1 & 0 \end{bmatrix}$$

This distortion matrix says that, modulo four, an error of two units is counted as two units of distortion.

A source compression block code of blocklength n and size M is a set consisting of M sequences of reproducing letters, each sequence of length n. The source compression code is used as follows. Each source output block of length n is mapped to that one of the M codewords that results in the least distortion.

The entropy of the output of the data compressor is less than that of the original source and therefore can be encoded into a smaller number of bits.

The Distortion-Rate Function

Data compression is a deterministic process. The same block of source symbols always produces the same block of reproducing letters. Nevertheless, if attention is restricted to a single source output symbol without knowledge of the previous or subsequent symbols, then the reproducing letter is not predetermined. The letter, b_k, into which source letter a_j is encoded becomes a random variable even though the block encoding is deterministic. This random variable can be described by a transition matrix, $Q_{k|j}$. Heuristically, we think of $Q_{k|j}$ as describing an artificial channel that approximates the data compression. Each time the source produces letter a_j, it is reproduced by letter b_k with probability $Q_{k|j}$.

To obtain the greatest possible compression, it seems that this conditional probability should, on average, result in the smallest possible mutual information between the source and the reproduction provided that the average distortion is less than the allowable average distortion. This heuristic discussion motivates the following definition.

The distortion-rate function, $D(R)$, is given by

$$D(R) = \min \Sigma_j \Sigma_k p_j Q_{k|j} \rho_{jk}$$

where the minimum is over all probability transition matrices Q connecting the source alphabet and the reproducing alphabet that satisfy $I(p;Q) \leq R$. The definition is justified by the source compression theorems of information theory. Intuitively, if rate R bits per source letter is specified, then any compression must provide a distortion of at least $D(R)$. Conversely, compression to a level arbitrarily close to $D(R)$ is possible by appropriate selection of the compression scheme.

The distortion-rate function can be evaluated analytically for simple sources and distortion matrices. Fig. 24

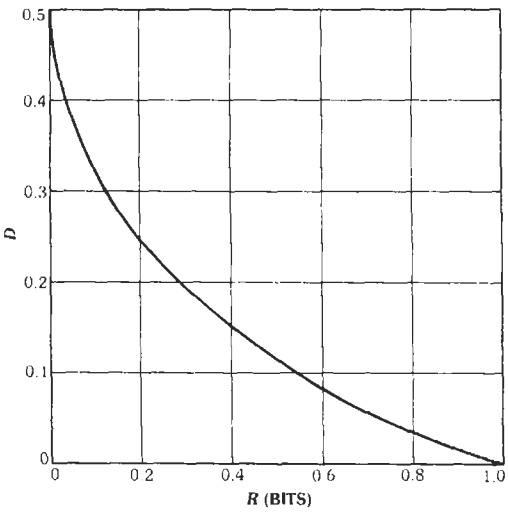

Fig. 24. Distortion-rate function for a binary symmetric source.

shows $D(R)$ for the simplest example, a binary memoryless source with equiprobable zeros and ones, and a probability-of-error distortion matrix. This figure shows that if only one-half bit per bit is used to represent the output of a binary equiprobable source, then at least 11 percent of the reproduced bits must be in error. Fig. 25 shows $D(R)$ for Gaussian sources with mean-square distortion measure. This figure shows that

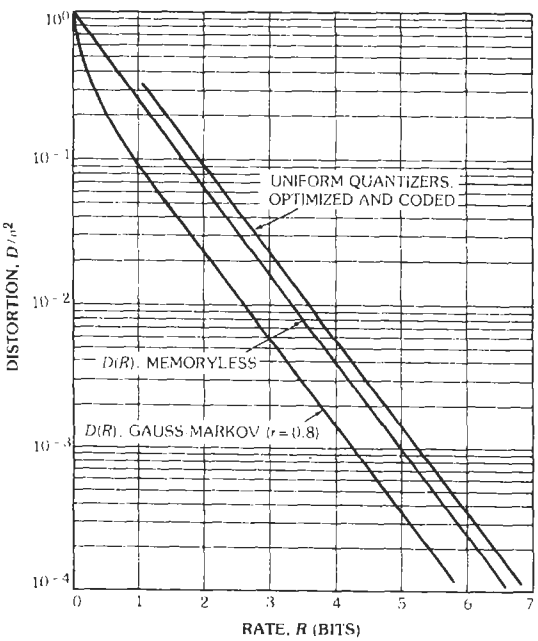

Fig. 25. $D(R)$ for Gaussian sources.

the conventional equispaced quantizer is not optimal, but the performance loss is quite small. Source compression codes are discussed further in Berger.*

MULTITERMINAL INFORMATION NETWORKS

Information networks involving several sources or several channels can have conflicting requirements imposed by the several users. An efficient system tries to satisfy several goals at once, perhaps to interlock several independent messages into one efficient waveform, perhaps to share a multiple-access channel with several users, or perhaps to break a message into two distorted replicas that together contain enough information to reconstruct the original message without distortion. Problems of these kinds are not efficiently implemented in today's communication technology. Multiterminal information theory studies how to solve such problems efficiently. Most such problems are only partially solved. Further discussion of multiterminal information theory can be found in the survey articles by van der Meulen,† Berger,§ and El Gamal and Cover.**

Two-Way Channels

A two-way channel has two terminals, as shown in Fig. 26. Each terminal attempts to get a message across to the other terminal through the two-way channel, but the transmission in one direction interferes with the transmission in the other direction. The problem is to design the terminals to achieve high data rates in both directions simultaneously.

Many practical channels are intrinsically two-way channels, but the designer elects to break them into two one-way channels using a technique such as time division or frequency division. This is a simple and workable solution, but one wishes to know if there is a performance penalty. What is the two-way capacity region, and what sort of communication scheme is optimal? This problem, one of the most difficult ones in multiterminal information theory, has been open for twenty years. Some highly simplified models have been solved or partially solved. These solutions show that time division and frequency division are not optimal.

Broadcast Channels

A broadcast channel consists of a single transmitter and multiple receivers as shown in Fig. 27. If the same message is to be sent to all receivers, then the task of designing the communication waveform is no different than when there is a single receiver. However, if a

* Reference 16.
† Reference 17.
§ Reference 18.
** Reference 19.

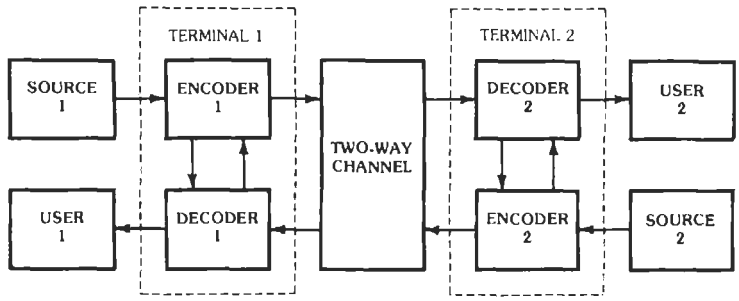

Fig. 26. The two-way channel.

different message is to be sent to each receiver, the problem is more complex. Conventionally, the channel is divided according to the needs of the receivers, using time-division or frequency-division signaling techniques. Optimum techniques are more tightly interlocked and do better. Time-division or frequency-division multiaccess signaling cannot achieve the capacity region of a broadcast channel.

Degraded Diversity Systems

A *diversity system* sends the same information to a user twice through two channels so that if one channel is broken, the message will still arrive. A *degraded diversity system* is more subtle. It sends half the message through each of two channels but in such a way that either half suffices to reconstruct a degraded copy of the message. A high-fidelity reproduction is obtained if both channels are intact; a low-fidelity reproduction is obtained if only one channel is intact. The simplest model of a degraded diversity system is shown in Fig. 28. The theory shows that the data can be encoded so that either side channel can reconstruct the data from the half-rate code with a probability of error of 20.7 percent, and no better encoding exists.

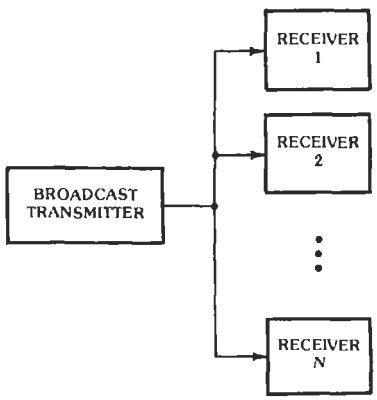

Fig. 27. Broadcast channel.

Remote Compaction of Dependent Data

A fundamental multiterminal source coding problem is shown in Fig. 29. Data sources X and Y are dependent. The data are to be sent to a common site at rates R_x and R_y, but the encoders do not communicate with each other. The admissible rate region is shown in Fig. 30. Encoder/decoders can be built with rate pairs corresponding to any point in the upper-right region. It is quite remarkable that this region would not be any larger even if the two encoders could each see the output of both sources.

THE COMMUNICATION GAMES

The communication problem is given a new dimension of complexity and becomes a two-person game when an adversary is introduced. The theory that is then developed has its roots in both information theory and game theory. The transmitter and receiver together constitute one player, or team, and the adversary is the second player. The adversary may have a variety of purposes. It may be his goal to interrupt communication, in which case he is called a jammer or a spoofer; it may be his goal to determine the specific message transmitted, in which case he is called a wiretapper or eavesdropper; it may be his goal simply to detect the existence of communication, in which case he is called a monitor; or it may be his goal to determine the location of the transmitter, in which case he is called a locator.

The Jammer Saddle Point

The jamming game is a game played by the jammer and the transmitter. The jammer selects the noise or interference properties of the channel. That is, the jammer selects a probability transition matrix, Q, connecting the input and output alphabets. The transmitter designs a communication waveform without knowledge of which channel noise was selected by the jammer. Variations are possible wherein the jammer

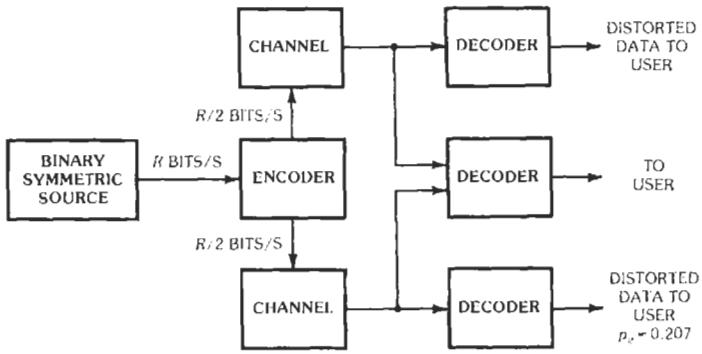

Fig. 28. A degraded diversity system.

has partial knowledge about the transmitted signal, but these variations will not be considered here. The jammer and the transmitter each must operate within certain constraints. The most important case is one in which the jammer and transmitter are each limited in average power, and this is the case we discuss.

The set of channels that the jammer can use is restricted in that he has a limited average transmitter power. Let Q_N denote the set of channel noise distributions that satisfy power constraints on the jammer,

$$Q_N = \{Q: \int z^2 Q(z)\, dz \leq N\}$$

and let P_S denote the set of probability distributions on the channel input that satisfy average power constraints on the transmitter.

$$P_S = \{p: \int x^2 p(x)\, dx \leq S\}$$

The *jammed capacity* is given by:

$$C(S, N) = \max_{p \in P_S} \min_{Q \in Q_N} I(p; Q)$$

$$= \min_{Q \in Q_N} \max_{p \in P_S} I(p; Q)$$

The first expression gives the capacity of the channel if the jammer must first choose the channel noise statistics before the transmitted waveform is designed. The second expression gives the capacity if the transmitted waveform is designed before the jammer chooses the channel noise. The well-known minimax theorem of game theory says that the two expressions are equal.

For the discrete-time, continuous-amplitude channel with transmitter and jammer both limited in average power, the minimax jammer strategy is to transmit Gaussian noise, and the minimax transmitter strategy is to encode assuming Gaussian noise. From the point of view of the jammer, the jammed capacity is the data rate to which the jammer can hold the transmitter. From the point of view of the transmitter, the jammed capacity is the data rate that the transmitter can achieve in the presence of the jammer.

The most important application is the band-limited waveform channel in which the transmitter and the jammer are each limited in average power. The jammer saddle point is

$$C(S, N) = W \log (1 + S/N)$$

This expression is linear in the bandwidth, W. If the signal power, S, and the jammer power, N, are fixed, the capacity can be increased by increasing W. This is the basis for the practice of spectrum spreading discussed below. If the spectral power density, N_o (watts/hertz), is fixed rather than N, then

$$C(S, N_o) = W \log (1 + S/WN_o)$$

The capacity is bounded as W increases. Spectrum

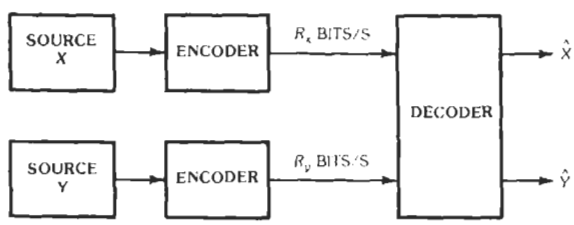

Fig. 29. Remote compaction of dependent data.

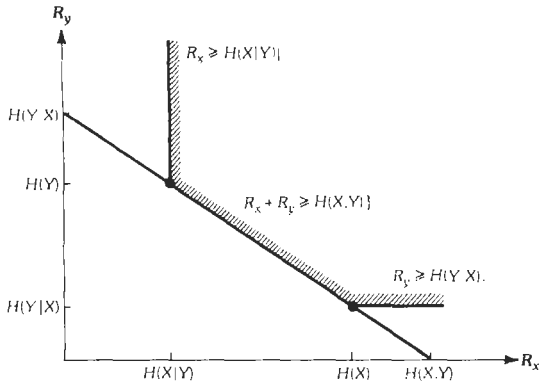

Fig. 30. The Slepian-Wolf admissible rate region.

spreading is useful only when the jammer's total power is limited. It is worthless if his spectral power density is limited instead. Spectrum spreading does not improve performance against broad-band white noise.

Spectrum Spreading

A *spread-spectrum* system is one that takes a signal of small bandwidth, say γW, where γ is much smaller than one, and converts it into a signal of high bandwidth, W. This is done as shown in Fig. 31 by modulating the information waveform with a wideband waveform that is not known to the jammer. The wideband waveform may be noise-like (hence called pseudo-noise, or PN), or a time-varying carrier frequency (called frequency hopping). The wideband signal is transmitted through the channel, received, and then compressed back into the original low-bandwidth signal by demodulating the information waveform from the wideband waveform. This scheme requires that the transmitter and receiver share knowledge of the bandspreading waveform through a secure channel. If the jammer knows nothing about the wideband waveform, his "best" strategy is to use wideband noise of bandwidth W. After the signal spectrum is compressed, the jammer signal will still have bandwidth W, but the signal will have bandwidth γW. A bandpass filter will reduce the jammer noise power by the factor γ. The reciprocal of the factor γ is called the processing gain of the spread-spectrum system.

A spread-spectrum system does not make optimum use of the wide bandwidth. This can be seen by looking at the channel capacity. The channel capacity of the available wideband channel of bandwidth W and jammer power N is

$$C = W \log (1 + S/N)$$

However, the channel capacity of the spread-spectrum channel of compressed bandwidth γW and processed jammer power γN is

$$C_{SS}(\gamma) = \gamma W \log (1 + S/\gamma N)$$

whereas if only the narrow bandwidth, γW, is used, there is no reduction of jammer power, and the channel capacity is

$$C_{NB}(\gamma) = \gamma W \log (1 + S/N)$$

If the channel must transmit R bits per second, the wideband channel requires a signal-to-noise ratio of at least

$$S/N = 2^{(R/W)} - 1$$

while the spread-spectrum channel requires a signal-to-noise ratio of

$$S/N = \gamma(2^{(R/\gamma W)} - 1)$$

which can be considerably larger than what is needed in the wide bandwidth but is smaller than

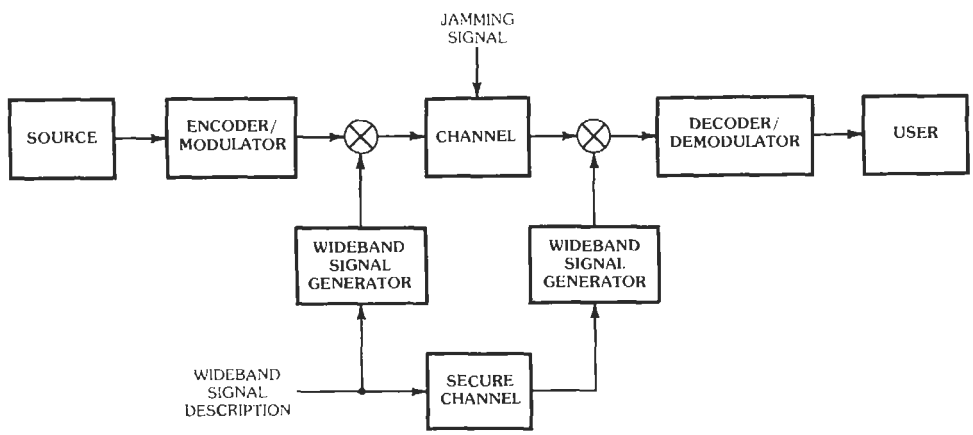

Fig. 31. Spread-spectrum signaling.

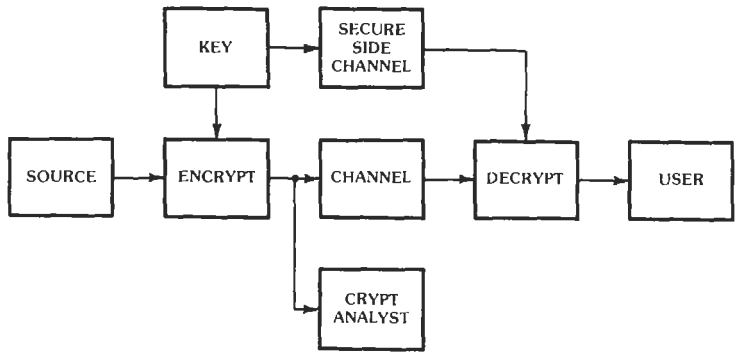
$$S/N = 2^{(R/\gamma W)} - 1$$

which is required if there is no spectrum spreading at all. Spread-spectrum by itself improves performance, but much better improvement is theoretically possible using the wide bandwidth.

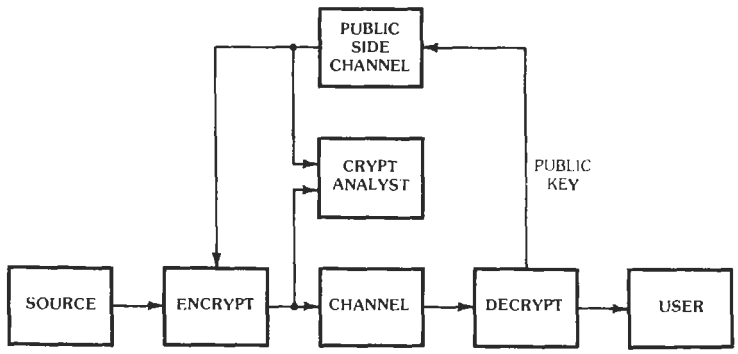
The use of M-ary orthogonal signaling, spread-spectrum, and error-control codes in combination will make better use of the wide bandwidth. In addition, error-control codes are necessary in a spread-spectrum system to protect against partial-time or partial-band jamming tactics. A well-designed spread-spectrum system will use an error-control code and a modulation waveform that operate at a small E_b/N_o and then spread the spectrum of this waveform to fill out the available frequency band.

Cryptography

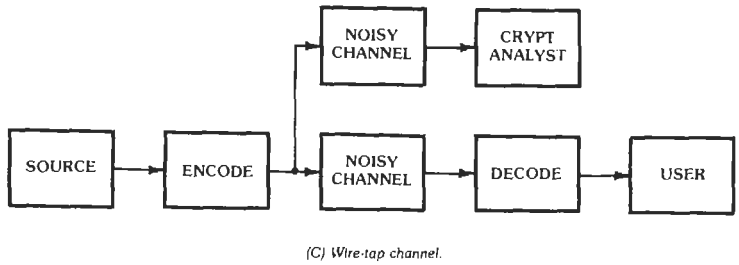
Three major kinds of cryptosystem are shown in Fig. 32. The first two kinds require some type of key; the third kind relies on noise in the channel to hide the message. While at first it may seem that the wire-tap channel (Fig. 32C) is not a true cryptosystem, in fact it would be misleading to ignore it. All cryptosystems have internal compartments where the message or the



(A) Conventional cryptosystem.



(B) Public-key cryptosystem.



(C) Wire-tap channel.

Fig. 32. Types of cryptosystem.

key exists in the clear. The designer relies on the fact that any portion that leaks out will be buried in the ambient noise. Hence the wire-tap channel is present in every cryptosystem. A secure side channel for transmitting a key is of this type.

A conventional cryptosystem (Fig. 32A) is secure from a direct attack by the cryptanalyst if the key is nearly as long as the message. A so-called "one-time pad" has one random bit in the key for each bit of the message, and it is not reused. The one-time pad can be penetrated only by an attack on the secure side channel. Since it is difficult to transmit and store long keys, most cryptosystems have short keys. Then there is redundancy in the encrypted message that the cryptanalyst can exploit.

A public-key cryptosystem (Fig. 32B) differs from a conventional cryptosystem in that it relies on one-to-one functions, $f(x)$, whose inverses, $f^{-1}(x)$, are very difficult—even computationally intractable—to deduce. These are sometimes called one-way functions. Hence, the user randomly makes up an $f^{-1}(x)$, finds $f(x)$, and publicly announces that he can decrypt messages that are encrypted with $f(x)$. The cryptanalyst always knows the encoding key, but is unable to convert this into a decoding key.

26 Computer Communications Networks

Fouad A. Tobagi and Mario Gerla

About two decades ago, a great challenge to many computer system designers was to enhance the processing power of computers and make them available to a large number of users on a time-sharing basis. The design of fast arithmetic and control units as well as the design of complex operating systems were identified among the key tasks needed to accomplish this objective. As time-sharing progressed, it was soon realized that such large resources would not be effectively utilized unless the problem of connecting remote user terminals to the central computing facility was adequately solved, thus allowing a large population of users to share the facility. With this problem, the field of computer communications came into existence. The early communications systems were merely *terminal access networks*. The next stage in the evolution consisted of the creation of the so-called distributed *resource-sharing networks*. The goal here is to interconnect computers and their users at various geographically distributed sites in order to allow the sharing of hardware and software resources developed at all sites by all users connected to the network. Today the term *computer communications* has a much broader meaning. Not only does it refer to communications among computers and their users, but it also refers to all kinds of communications applications (among humans and among machines) that make use of the computer as a tool. Examples of such applications are voice communications, electronic mail, facsimile, image transfer, process control, etc. The goals are also somewhat more diverse. Instead of communications per se, the driving force may very well be that of cost or reliability of computing power. High reliability may be achieved by having alternative sources of computing made available via a communications network. Lower cost may be achieved via distributed computing architectures that are simpler to design, cheaper to build, and easier to maintain, and of which communication is an intrinsic part. Thus, while in the seventies one might have characterized the computer communications field as having been in its research and development phase, the eighties and beyond will be marked by the wide use of this relatively new technology for a large repertoire of applications.

In the following, the structure of computer communications networks is examined and their building blocks identified. First, the various types of networks in existence and the switching techniques in use are described. Then the general functions of a network needed in establishing a communications path among remote users are described, and the organization of these functions into a standard layered architecture called the *Open Systems Interconnection reference model* is discussed. Using this reference model as a guide, we then examine in more detail the functions in each of the layers and highlight standards whenever applicable. Finally, we introduce a class of network architectures which has emerged in the past few years, namely, the class of high-speed networks. The OSI model also applies, with some modifications, to this class, but the requirements, characteristics, and applications of high-speed networks are so different from those of conventional networks that a separate treatment at the end of this chapter is justified. Two sections are dedicated to this subject, namely, high-speed local area networks and high-speed wide area networks.

THE STRUCTURE OF COMPUTER NETWORKS

A computer-communication network typically comprises a collection of computing resources called *hosts*, a collection of users, some of which are associated with the hosts, and a so-called *communication subnet* that connects them (Fig. 1.) The communication subnet consists of two basic components: the communication channels and the switching elements (or switching nodes). Depending on (1) the physical medium used for the communication channels, (2) the subnet topology according to which the communication channels and the switching elements are interconnected to form a network, and (3) the switching technique used in providing a physical path among two or more communicating parties, several computer network types may be identified.

Switching Techniques

There are two basic types of switching techniques: *circuit switching* and *message switching*. In circuit switching, a total path of connected lines is set up from the origin to the destination at the time the call is made, and the path remains allocated to the source-destination pair (whether used or not) until it is released by the communicating parties. The switches, called circuit switches (or office exchange in telephone jargon), have no capability of storing or manipulating users' data on their way to the destination. The circuit is set up by a special signaling message that finds its way through the network, seizing channels in the path as it proceeds. Once the path is established, a return signal informs the source to begin transmission. Direct transmission of data from source to destination can then take place without any intervention on the part of the subnet.

In message switching, the transmission unit is a well defined block of data called a *message*. In addition to the text to be transmitted, a message comprises a *header* and a *checksum*. The header contains information regarding the source and destination addresses as well as other control information; the *checksum* is used for error control purposes. The switching element is a computer referred to as a *message processor*, with processing and storage capabilities. Messages travel independently and asynchronously, finding their own way from source to destination. First the message is transmitted from the host to the message processor to which it is attached. Once the message is entirely received, the message processor examines its header, and accordingly decides on the next outgoing channel on which to transmit it. If this selected channel is busy,

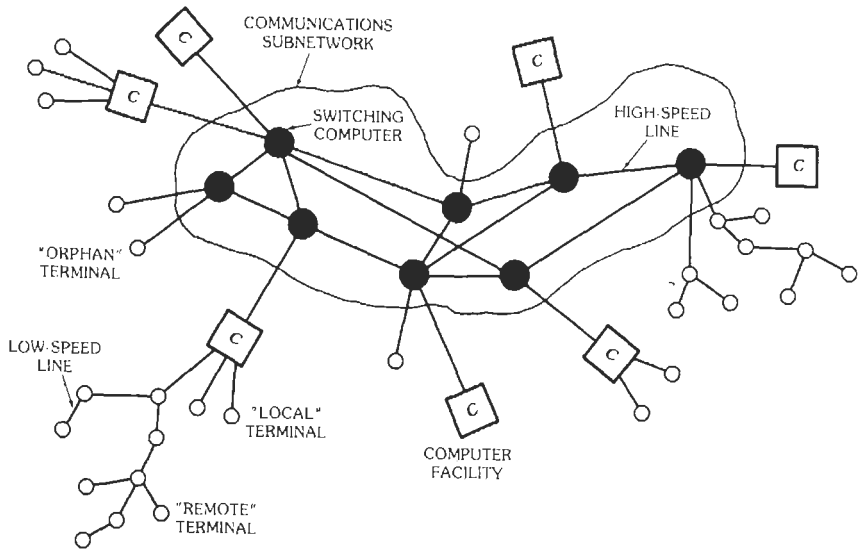

Fig. 1. The structure of a computer-communication network. (*From Leonard Kleinrock,* Computer Applications, *Vol. II of* Queueing Systems, © *1976 by John Wiley & Sons, Inc., New York.*)

the message waits in a queue until the channel becomes free, at which time transmission begins. At the next message processor, the message is again received, stored, examined, and transmitted on some outgoing channel, and the same process continues until the message is delivered to its destination. This transmission technique is also referred to as the *store-and-forward transmission* technique.

A variation of message switching is *packet switching*. Here the message is broken up into several pieces of a given maximum length, called *packets*. As with message switching, each packet contains a header and a checksum. Packets are transmitted independently in a store-and-forward manner.

With circuit switching, there is always an initial connection cost incurred in setting up the circuit. It is cost-effective only in those situations where once the circuit is set up there is a guaranteed steady flow of information transfer to amortize the initial cost. This is certainly the case with voice communication in the traditional way, and indeed circuit switching is the technique used in the telephone system. Communication among computers, however, is characterized as *bursty*. Burstiness is a result of the high degree of randomness encountered in the message-generation process and the message size, and of the low delay constraint required by the user. The users and devices require the communication resources relatively infrequently; but when they do, they require a relatively rapid response. If a fixed dedicated end-to-end circuit were to be set up connecting the end users, then one must assign enough transmission bandwidth to the circuit in order to meet the delay constraint with the consequence that the resulting channel utilization is low. If the circuit of high bandwidth were set up and released at each message transmission request, then the set-up time would be large compared to the transmission time of the message, resulting again in low channel utilization. Therefore, for bursty users (which can also be characterized by high peak-to-average data rate requirements), store-and-forward transmission techniques offer a more cost-effective solution, since a message occupies a particular communications link only for the duration of its transmission on that link; the rest of the time it is stored at some intermediate message switch and the link is available for other transmissions. Thus the main advantage of store-and-forward transmission over circuit switching is that the communication bandwidth is dynamically allocated, and the allocation is done on the fine basis of a particular link in the network and a particular message (for a particular source-destination pair).

Packet switching achieves the benefits discussed so far and offers added features. It provides the full advantage of the dynamic allocation of the bandwidth, even when messages are long. Indeed, with packet switching, many packets of the same message may be in transmission simultaneously over consecutive links of a path from source to destination, thus achieving a "pipelining" effect and reducing considerably the overall transmission delay of the message as compared to message switching. It tends to require smaller storage allocation at the intermediate switches. It also has better error characteristics and leads to more efficient error recovery procedures, as it deals with smaller entities. Needless to say, packet switching presents design problems of its own, such as the need to reorder packets of a given message that may arrive at the destination node out of sequence.

Fig. 2 illustrates the three switching modes for an

example of a communication subnet involving four nodes and three transmission links. The figure shows the advantage of packet switching over message switching and of message switching over circuit switching. Clearly, this comparison involves a number of tradeoffs, and it is not hard to imagine situations where the conclusion may be reversed. This depends on a number of factors, among others the number of hops from source to destination, the length of the message, the amount of overhead incurred in the header and checksum of each message and packet, the circuit set-up delay, etc. For example, fast circuit switching accomplished with solid-state implementation of the switches can achieve a set-up time on the order of a fraction of a second (a few milliseconds per switch), which renders this technique a viable solution. In most cases, however, the picture shown in Fig. 2 reflects the real situation.

The advantages of store-and-forward transmission are obtained at the expense of higher processing and storage capabilities at all switches. Overall, however, the present economics are in favor of store-and-forward. Roberts† has shown that since the early 60s, the

(B) Circuit switching.

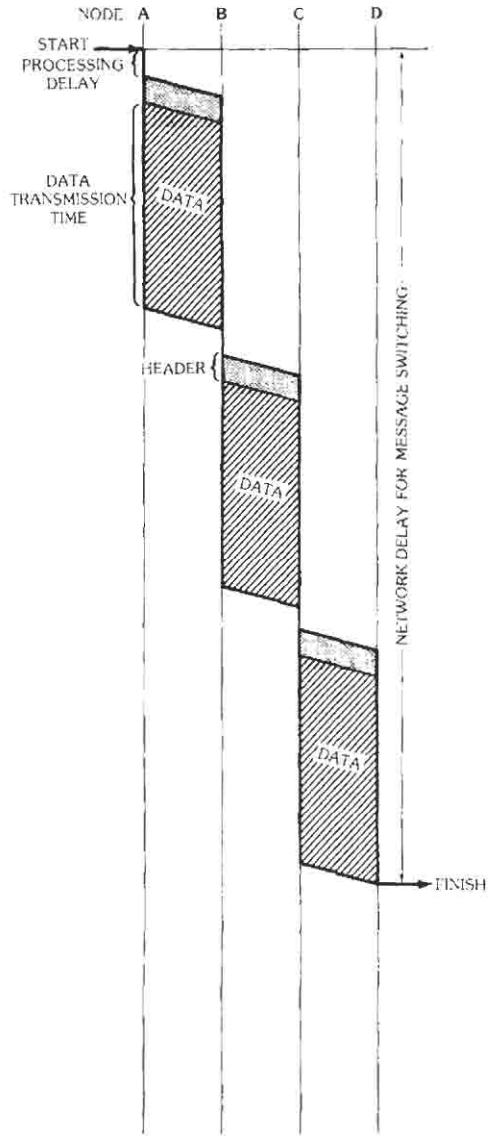
Fig. 2. Comparison of network delay for circuit, message, and packet switching. (*From Leonard Kleinrock*, Computer Applications,

incremental cost of computing needed to send one megabit of data through a nationwide network has been decreasing at a much faster rate than the incremental cost of the communication land lines in a national net, with a crossover point having occurred about 1969. Fig. 3 summarizes Roberts' findings concerning these cost trends (the reader is referred to the portion of the figure corresponding to the range up to 1974).

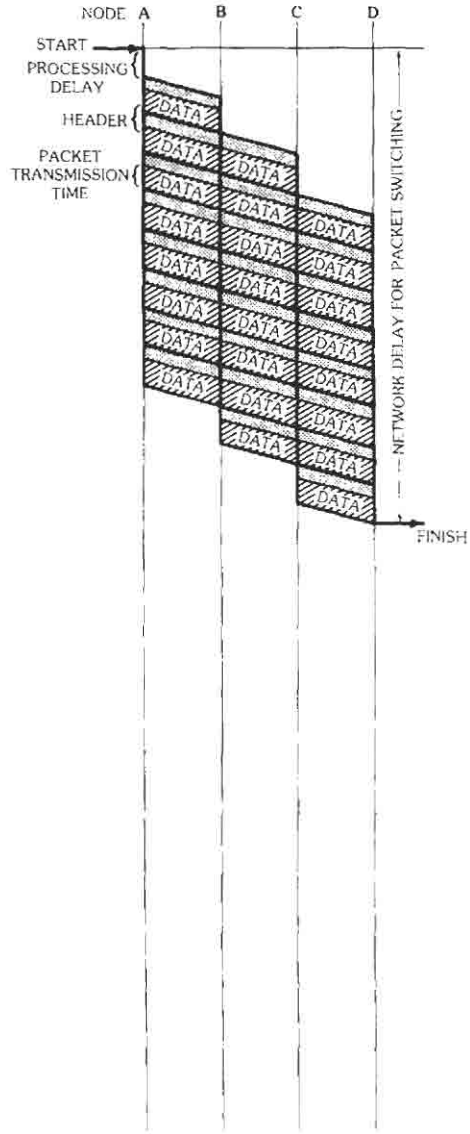
In the development that follows, the three terms message switching, packet switching, and store-and-forward are used interchangeably unless the distinction is made explicitly.

Types of Computer Communications Networks

A distinction is first made between *circuit-switched networks* and *packet communication networks*. Clearly, circuit-switched networks are those that use circuit switching. When used for local communication, these networks have a star topology with a single switch in the center, and they may often be privately owned (e.g., CBX). Long-haul or nationwide networks, on the other hand, have a hierarchical mesh topology: subscribers are connected to local central offices via two-wire



(C) Message switching



(D) Packet switching

Vol. II of Queueing Systems, © *1976 by John Wiley & Sons, Inc., New York.*)

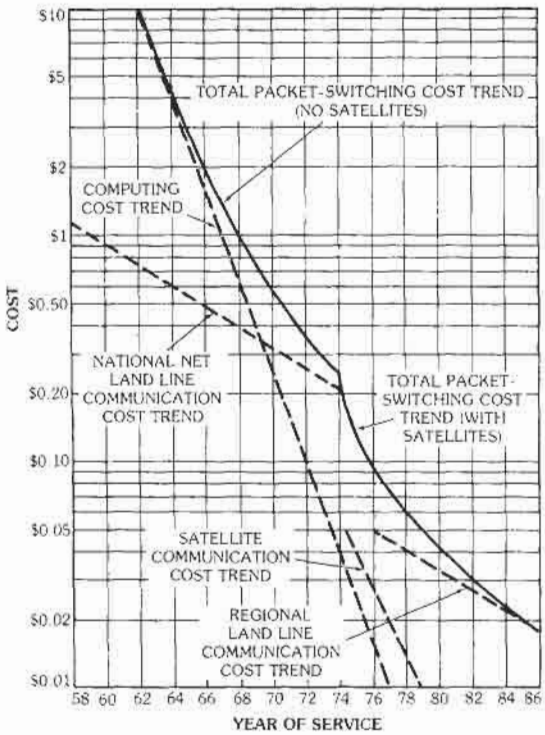


Fig. 3. Incremental cost for sending 1 kilopacket (1 megabit) through a nationwide network. (*From Leonard Kleinrock,* Computer Applications, *Vol. II of* Queueing Systems, © *1976 by John Wiley & Sons, Inc., New York.*)

connections to form a star local network; local offices are connected to toll offices via toll connecting trunks; toll offices are interconnected via very high bandwidth intertoll trunks and other intermediate switching offices to form a highly redundant mesh topology.

Packet communication networks are all based on packet switching and may be of three types. The first is referred to as the *point-to-point store-and-forward* type. In this type, packet switches are interconnected by point-to-point data channels to form a mesh topology. Each channel is used only by the two switches adjacent to it, one in each direction; thus there exists no contention. The channels are usually full duplex, allowing transmission to take place in both directions simultaneously. Examples of such networks are the ARPANET, the Cigale Network, TELENET, TYMNET, DATAPAC, TRANSPAC, EURONET, etc.† This type is usually for large geographical scope, although it is also used for terminal access and local area communication; in the latter case, the network typically has a star topology with a packet switch at its center.

The second type of packet communication network is the *multiaccess-broadcast* type. This type of network consists of a *single* transmission medium that is shared by all subscribers; they access the medium according to some multiaccess scheme, each access being for the duration of a single packet. Any user's transmission is heard by all other users, hence the broadcast attribute. The single-hop broadcast nature of these networks achieves full connectivity at a very small cost: each subscriber is connected to the common channel through an interface that listens to all transmissions and accepts packets addressed to it. Examples of this type of network can be found in both long-haul and local-area communication systems. One example is that of a *satellite channel* (Fig. 4): a satellite transponder in a geostationary orbit above the earth can receive signals from any earth station in its coverage pattern and can transpond these signals to all such earth stations (unless the satellite uses spot beams). Broadband satellite channels offer a cost-effective alternative to store-and-forward networks for long-haul communication, as can be easily seen from Roberts' projections in Fig. 3. Another example is that of *ground packet radio* systems where the radio medium is used for terminal access and local-area communication among a large population of terminals, possibly mobile (Fig. 5). The multiaccess and broadcast attributes are achieved when all users share a common radio frequency, employ omnidirectional antennas (thus facilitating communication among the mobile users), and are in line-of-sight and within range of each other. Yet another example is the so-called *broadcast bus* system in which all users are connected to a single cable via simple passive taps (Fig. 6). These systems prove to be ideal for short-distance

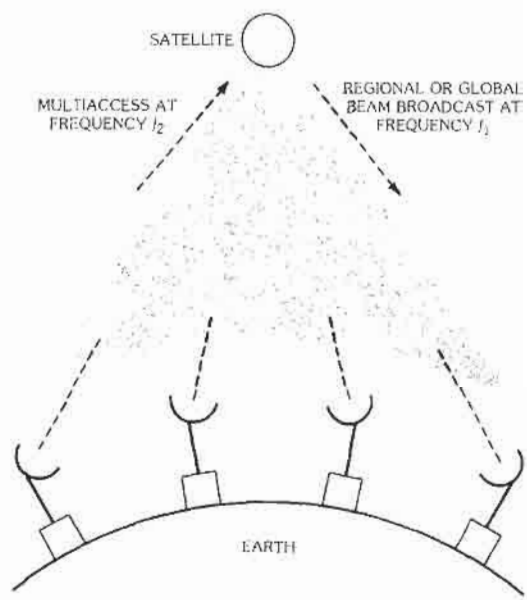

Fig. 4. A satellite channel. (*From Leonard Kleinrock,* Computer Applications, *Vol. II of* Queueing Systems, © *1976 by John Wiley & Sons, Inc., New York.*)

† References 2 and 3.

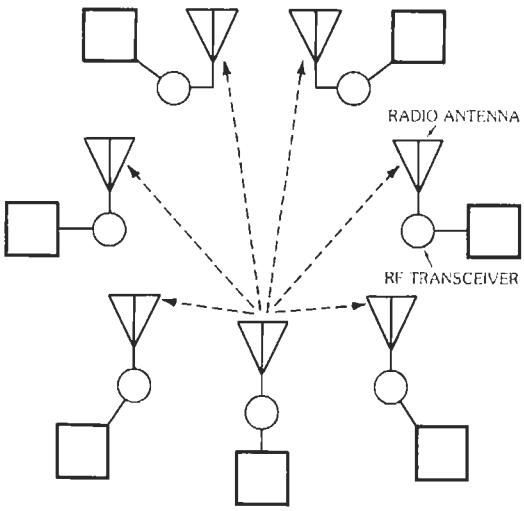

Fig. 5. A single-hop fully connected ground packet radio network.

local-area communication within a building (up to a few kilometers) involving a large and often variable number of inexpensive devices requiring interconnection. The simple topology and simple and inexpensive connection interfaces of broadcast bus systems provide great flexibility in accommodating the high degree of variability in such environments while achieving a desired level of reliability. A final example that falls into this category is the *ring* network (Fig. 7). Each node is connected only to two neighbors via point-to-point unidirectional links. Messages (or packets) are circulated around the ring (hence achieving the broadcast feature), incurring a delay of only one or more bit times within each of the intermediate nodes. The multiaccess schemes available to operate multiaccess-broadcast networks are discussed in more detail below in the section on multiaccess link control.

A third type of packet network can be identified. It is the (multihop) *store-and-forward multiaccess/broadcast* type, which combines the features exhibited in the two types mentioned above. The best (and perhaps only) example is DARPA's packet radio network (PRNET). (See Fig. 8.) Its goal is to provide direct communication by a ground radio network among mobile users over wide geographical areas. This requires store-and-forward switches called repeaters to become integral components of the system. Here too, for easy communication among mobile users and for rapid deployment in military applications, all users employ omnidirectional antennas and share a high-speed radio channel.

Today all these types of networks have progressed considerably, and each plays an important role of its own. Communication systems that are efficient and easy to use involve several types of networks coexisting and integrated to form a single system, the constituents of which are totally transparent to the user. The interconnection of several networks forms what is referred to as an internetworking environment.

NETWORK FUNCTIONS

The basic function of a computer network is to make it possible for geographically remote end users to communicate. "End users" means any entities that require to communicate; these are application processes that may reside in computers, terminals, or any interface between a piece of equipment (or a human) and the communication network itself. Communication should be accomplished efficiently, by making efficient use of the communications resources, and in a way that is responsive to the specific needs of the end users. It should also be made possible in spite of various types of errors that may occur in the transmission process, and in spite of the differences that exist between the end users with respect to the data formats used, the data rates supported, the patterns of intermittency, etc.

As this global function is a very complex one, it is best accomplished by dividing it into a sequence of more elementary functions that are organized in some fashion. The precise definition and structure of this aggregate set of functions is called a network *architecture*. Most typically, network architectures follow a

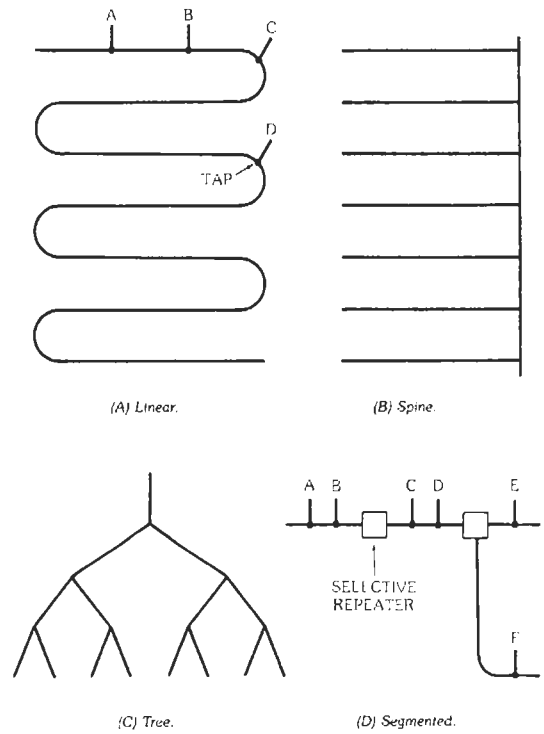

Fig. 6. Cable topologies. (*From Andrew S. Tanenbaum, Computer Networks, © 1981. Used by permission of Prentice-Hall, Inc., Englewood Cliffs, N.J.*)

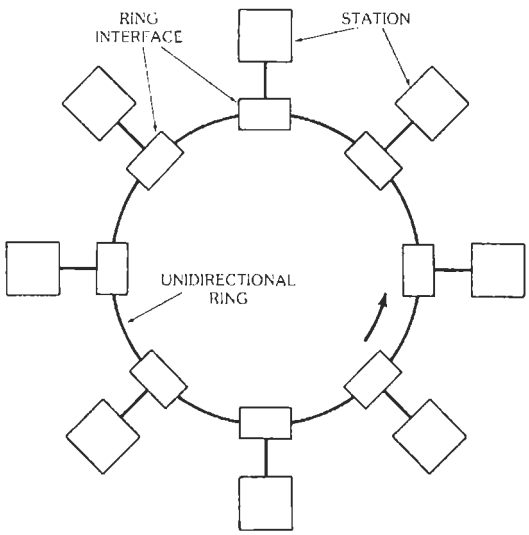

Fig. 7. A ring network. (*From Andrew S. Tanenbaum, Computer Networks, © 1981. Used by permission of Prentice-Hall, Inc., Englewood Cliffs, N.J.*)

linearly hierarchical model; i.e., the functions are organized into a linear succession of so-called *layers*. Such architectures are referred to as *layered* architectures. At the lowest level of the hierarchy, for example, are those functions that concern themselves with providing a physical connection between the end users and with the transmission of raw bits (i.e., regardless of their meaning) across the physical transmission resources. These functions constitute the physical layer. At the highest level, we find those portions of the application processes residing at the end users' machines that are the originators and destinations of the communication requests, and which directly serve the end user as far as the global communication function is concerned. The other intermediate layers comprise all other functions ranging from detecting and correcting errors to achieving efficient utilization of the resources; performing routing functions; preventing congestion; regulating the flow of data; preventing unfairness; supporting the patterns of intermittency and specific service requirements of the end users; and finally resolving the differences among the users pertaining to formats, character codes, device control procedures, and the like. In such a hierarchical structure, each layer is considered to be wrapping the lower layers and isolating them from the higher layers. Each layer offers a well specified service that it provides to the adjacent layer above it. In supplying that service, the layer obtains service from the adjacent layer just below it and performs its own functions. The rules for performing the functions at a given layer, once specified, are called *protocols*. The interactions between adjacent layers (at their boundaries) are called *interfaces*. The rules for achieving interactions and communication between adjacent layers, once specified, are called *interface protocols*. Also essential to a layered architecture is the concept of *peer protocols* or *peer interaction*. The processes implementing protocols within a layer at one machine (host or intermediate mode) communicate only with the processes implementing protocols within the same layer at another machine. Compatibility between protocols of the same level at (virtually) adjacent machines must be guaranteed. This layered approach to network functions for their description and design is now universal, and most (if not all) existing networks follow a layered architecture.

Layered architectures offer a number of advantages. The first is the prevention of ad hoc methods of network design, which, due to the intricacies involved, would certainly lead to a proliferation of designs difficult to understand, implement, or interact with. This is particularly beneficial when systems designed by different organizations or manufacturers are to be interconnected. The second advantage is that of modularity: If one specifies the interfaces between adjacent layers in a general way that is independent of the particular protocols designated at the interacting layers, then it becomes possible to modify the protocols at some layer without affecting the rest of the system. This is particularly beneficial in order to take advantage of newly emerging technologies, and in order to experiment with new protocols without the need for a major redesign of the entire system. For these reasons, the International

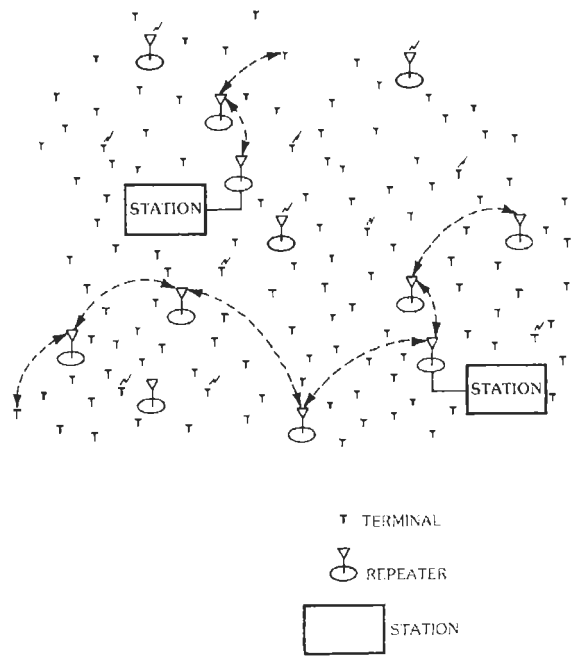

Fig. 8. A multihop packet radio network.

Organization for Standardization† (ISO) and other standards organizations were urged to come up with standards for "Open Systems Interconnections" (OSI). The objective is that by conforming to those international standards, a system will be capable of interacting with all other systems obeying the same standards throughout the world. The standard architecture adopted by ISO, also the best known one, is a layered architecture with seven layers. It is only an architecture, in the sense that it only defines the services to be performed by a layer for the next higher layer, independent of how these services are performed. Accordingly, it is often referred to as ISO's OSI reference model. It is the first stage toward a complete standardization of network functions, although very few protocols and interfaces have been standardized so far.

The number of layers decided upon is the result of long debates and of a number of principles followed in the process. Some of these principles are:

1. To collect "similar" functions into the same layer and separate "manifestly different" functions into separate layers.
2. To create a layer of those functions that are easily localized and that may be totally redesigned in the future when taking advantage of new technological advances, without the need to change the services or the interfaces with the adjacent layers.
3. To create boundaries at those service points where the interactions across the boundaries are minimized, those which past experience has demonstrated to be successful, and those where it may be useful at some point in time to standardize the corresponding interface.

Another principle calls for a limitation on the number of layers so as to keep the engineering task of describing them and integrating them a simple one, but it allows further subgrouping of functions within a layer so as to form sublayers that may be bypassed if the corresponding services are not needed.

The seven layers of the ISO OSI reference model (Fig. 9) are: (1) the physical layer, (2) the data link layer, (3) the network layer, (4) the transport layer, (5) the session layer, (6) the presentation layer, and (7) the application layer. Specific protocols and their description are considered in subsequent sections.

While the ISO reference model is used here as a guide to describe network functions and protocols, it is to be noted that there are a few existing network architectures, either designed for experimental networks, such as the ARPANET, or supplied by computer manufacturers, such as the Digital Equipment Corporation DECNET and the IBM Systems Network Architecture (SNA). These architectures are layered but do not correspond exactly to the ISO reference model. See Table 1. For more information on these architectures, the reader is referred to references 2 and 3.

THE PHYSICAL LAYER

The physical layer is concerned first of all with the transparent transmission of a bit stream (regardless of its meaning) across physical communication resources. In local networks, the physical medium may be a twisted pair, a coaxial cable, an optical fiber, or radio, and it may be privately owned. For long-haul links, the medium may be either copper wires or optical fibers as in terrestrial links, or radio as in satellite links; it is supplied by a common carrier. The methods used for the transmission of bits across the physical medium depend on the type of medium used. The description of these techniques is out of the scope of this chapter, but suffice it to mention here that bit transmission is done either in analog form by means of *modems* or in digital form by means of *line drivers*, and it involves determining such attributes as data encoding, timing, voltage levels, data rates, type of operation (half-duplex or full-duplex, synchronous or asynchronous), etc.

The second concern of the physical layer is to provide a physical interface between the end-user machine—which may be a terminal, a computer, or any other data-processing box, and which is referred to by the telecommunications administrations as the *Data Terminal Equipment* (DTE)—and the termination point of the communications circuit—that is the modem, line driver, etc., referred to as the *Data Circuit-Terminating Equipment* (DCE). (See Fig. 10.) The definition of such an interface requires the determination of four important characteristics: the mechanical, electrical, functional, and procedural characteristics.

The mechanical aspects pertain to the point of demarcation, which most typically consists of a pluggable connector. They include specifications of the connector, its latching and mounting arrangements, its location with respect to the DCE, etc. Fig. 11 illustrates the various connectors known, along with their ISO identification numbers. The number of pins per connector ranges from 9 to 37.

The electrical aspects pertain to the electrical characteristics of the generators and receivers. They specify such parameters as the range of the signal voltage level, rise-time characteristics of the generator, data signaling rates as a function of the interconnecting cable distances, generator and receiver impedances, etc. They also include specifications regarding the reference with respect to which signal levels are measured; two cases exist: the "unbalanced" case where a single common return lead is used (or perhaps one common return for each direction), and the "balanced" case where each

† The International Organization for Standardization (ISO) is a voluntary nontreaty group, the membership of which includes the principal standardization body of each represented nation. The US member body is the American National Standards Institute (ANSI). ANSI is a nonprofit, nongovernmental organization. It serves as the national clearing house and coordinating activity for voluntary standards in the US.

interchange circuit uses a pair of wires creating a differential signal. A balanced configuration is more desired because it permits longer distances and higher data rates.

The functional characteristics specify the number of interchange circuits used and their assigned functions. The functions are classified into four categories: data, control, timing, and grounds. Timing circuits are used for bit (and sometimes byte) synchronization, whereas control circuits are used for the exchange of status information, commands, and responses. Some interfaces employ only one function per interchange circuit

(e.g., CCITT V.24†), whereas others multiplex DCE control functions and data over a single "data" interchange circuit in each direction, resulting in a considerably more compact interface (e.g., CCITT X.24).

The procedural characteristics consist of the set of procedures for using the interchange circuits, in order to achieve the transmission of bit streams as well as to provide maintenance test loops.

Three examples of widely used physical interface protocols are considered here to illustrate the concepts and physical characteristics discussed above. These are EIA RS-232-C,§ EIA RS-449, and CCITT X.21. They are all serial data DTE/DCE interfaces. The dominant interface in use today between terminals and modems is RS-232-C. The connector is the 25-pin ISO 2110 (Fig. 11). Its electrical characteristics are compatible with CCITT recommendation V.28. This specifies a single-ended generator that produces a 5 to 15 volt signal with respect to signal ground, negative for binary 1 and positive for binary 0; a single common return lead is used for all interchange circuits (thus unbalanced); the generator rise time is fast (1 ms to cross ±3 V); the data signaling rates are limited to below 20 Kbits/s; the cable distances are limited to within 15 m. The functional characteristics of RS-232-C are compatible with CCITT recommendation V.24. Recommendation V.24 defines 43 interchange circuits, one function per circuit; RS-232-C uses 21 of the 43 interchange circuits; not all 21 circuits are needed in every application (for example, timing circuits are omitted for asynchronous applications). The procedural characteristics of RS-232-C are many and complex. They contain procedures equivalent to those in recommendation V.24 describing the interrelationships between interchange circuits, as well as those in recommendation X.20bis and X.21bis, which specify asynchronous and synchronous operation on a public data network for DTEs designed to interface with V-series asynchronous and synchronous modems, respectively. (As indicated earlier in a footnote, the V-series recommendations correspond to data communications over telephone facilities.) For a detailed description of the procedural characteristics of RS-232-C, see reference 3.

In 1973, EIA began work on a new interface with improved performance over RS-232-C (longer cable distance and higher maximum data rates) and with additional interface functions such as maintenance loopback testing. The result was RS-449, published in November 1977. The new interface was carefully designed so as to allow interoperability with existing RS-232-C equipments. The RS-449 interface uses connectors of the same family as that used for RS-232-C: it uses a 37-pin connector (ISO 4902) for the basic interface, and a separate 9-pin connector if a "secondary channel" operation is in use (Fig. 11). Furthermore, a careful pin assignment plan is chosen to minimize cross talk in multipair cables and to facilitate the design of an adapter to RS-232-C. As in RS-232-C, the functional characteristics of RS-449 are compatible with V.24, one function per interchange circuit. There are 10 new circuits with respect to RS-232-C, among which we note the following: send common (SC) and receive common (RC), which are the common return leads for all unbalanced interchange circuits employing one wire in the direction toward the DCE and the DTE, respectively; terminal in service (IS), which indicates to the DCE whether the DTE is operational or not; local loopback (LL), remote loopback (RL), and test mode (TM), which are used in checking and testing; select standby (SS) and standby indicator (SB), which are used when standby facilities are in use in order to facilitate the rapid restoration of service when a failure has occurred. The electrical characteristics are defined in RS-423-A (compatible with V.10/X.26) and RS-422-A (compatible with V.11/X.27). Standard RS-423-A, referred to as the "new unbalanced" electrical characteristics, specifies a single-ended generator that produces 4 to 6 volts with respect to the common return; a single common return is used for each direction; data signaling rates are up to 3 Kbits/s over cable distances of 1000 meters and can be as high as 300 Kbits/s for distances up to 10 meters. Standard RS-422-A, referred to as the "new balanced" characteristics, specifies a balanced generator producing a 2 to 6 volt differential signal; each interchange circuit employs

† The International Telegraph and Telephone Consultative Committee (CCITT) is a committee of the International Telecommunication Union (ITU), a specialized agency of the United Nations Organization. The CCITT work on data communications is focused in two study groups. CCITT Study Group XVII is responsible for data communications over telephone facilities. Its work is contained in V-series recommendations. CCITT Study Group VII is responsible for data communications over data networks. Its work is contained in X-series recommendations.

§ The Electronic Industries Association (EIA) is a trade association that represents manufacturers in the US electronics industry. EIA standards on data communications are published in the RS-series.

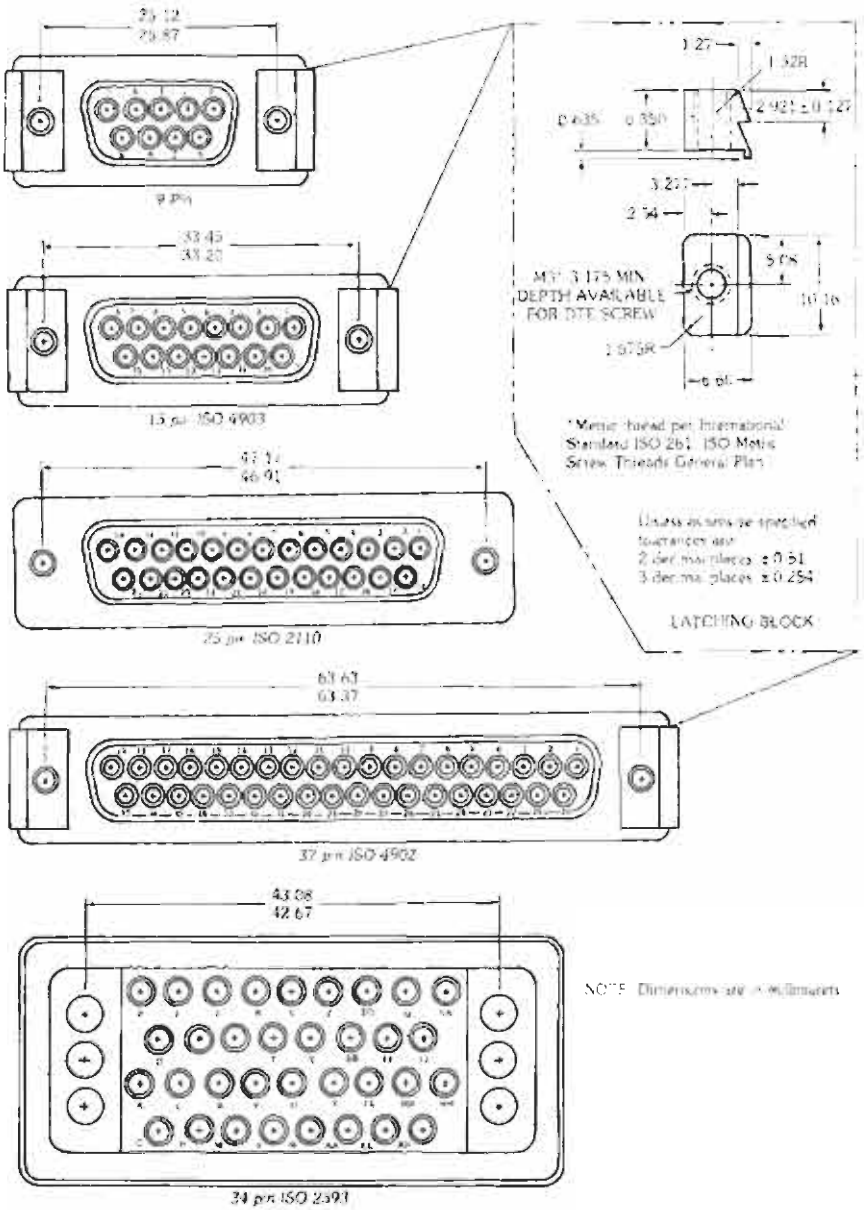

Fig. 11. DCE connectors. (*From Paul E. Green, Jr.*, Computer Network Architectures and Protocols, © *1982. Used by permission of Plenum Publishing Corp., New York.*)

two wires; data rates are up to 100 Kbits/s over cable distances of 1000 meters and can be as high as 10 Mbits/s over 10 meters. Standard RS-449 uses the new unbalanced characteristics, RS-423-A, for all interchange circuits when the data rate is below 20 Kbits/s. This permits direct interoperability with RS-232-C since RS-423-A (V.10/X.26) is interoperable with both V.28 (RS-232-C) and RS-422-A (V.11/X.27). At data rates above 20 Kbits/s and up to 2 Mbits/s, the new balanced EIA RS-422-A must be used on 10 specific interchange circuits (send data, receive data, send timing, . . .) employing two wires per circuit, while RS-423-A is used for all other circuits.

As for the procedural characteristics of RS-449, all those procedures defined in RS-232-C carry over to RS-449. The newly added test and standby functions are conceived on the basis of action-reaction and thus are simple. For example, after the DTE turns on the local loopback (LL), it waits until the DCE responds with test mode on. The DTE can then proceed with test

data transmission on the send data circuit, expecting to receive them back on the receive data circuit. Deactivation follows a similar procedure.

The physical characteristics for a general-purpose DTE/DCE interface for synchronous digital transmission on public data networks are defined in CCITT recommendation X.21. The DCEs are linked by means of real digital circuits, possibly through circuit-switching equipment. When circuit-switched services are provided, X.21 also specifies the call control procedures, i.e., the protocols by which to establish (and later to disconnect) a physical connection between two DTEs. Since the establishment of a circuit clearly requires knowledge of the address of the remote DTE (or its corresponding DCE) and the understanding of the various call progress signals, and since these requirements are supposed to be met only at the network layer (as discussed below), there is a general consensus that the call control procedure span the first three layers with the resulting service being offered by the network layer to the transport layer. Thus, these issues are dealt with in the network layer. The benefit of such a viewpoint is that of consistency in the network architecture, whereby the classification of functions is the same regardless of whether the data network is of the circuit-switched type or the packet-switched type. Indeed, in packet networks, the network layer takes care of opening a "connection," called the "*virtual circuit*," with the remote DTE before the flow of packets takes place.

Simplicity and enhanced performance were prime objectives in the design of X.21. It permits interface operation over distances considerably greater than that available with V.28, and for the synchronous data rates specified by X.1—that is, 600, 2400, 4800, 9600, and 48 000 bits/s. Accordingly, the new balanced electrical characteristics (Recommendation X.27, introduced above as EIA RS-422-A) are specified for the DCE side of the interface. To allow flexibility in DTE design at the data rates 600, 2400, 4800, and 9600 bits/s, the DTE is permitted to use either the new balanced or the new unbalanced (X.26 or RS-423-A) electrical characteristics. The mechanical interface for X.21 is the 15-pin ISO 4903 connector. There is a careful assignment of interchange circuits to connector pin numbers, a pair of pins for each interchange circuit. The number of interchange circuits is reduced to 5 (Fig. 12). A transmit (T) circuit and a receive (R) circuit are used to convey both user data and network control information, depending on the state of the control (C) circuit and the indication (I) circuit; bit timing is continuously provided by a signal element timing (S) circuit; a sixth interchange circuit that provides byte timing information is optional; a signal ground circuit is also provided.

Among all the procedures specified in X.21, those associated with the quiescent phase are agreed upon to be within the physical level. Two quiescent signals are defined for the DCE: *DCE not ready*, indicating that no service is available, and *DCE ready*, indicating that the DCE (network) is ready to enter the operational phase. Three quiescent signals are defined for the DTE: *DTE uncontrolled not ready*, indicating that the DTE is unable to enter operational phases because of abnormal conditions, *DTE controlled not ready*, indicating that the DTE is operational but is temporarily unable to enter operational phases, and *DTE ready*, indicating that the DTE is ready to enter operational phases. Fig. 13 shows the various combinations of quiescent states of the X.21 interface and the possible transitions between these states.

THE DATA LINK CONTROL LAYER

The data link control layer offers the capability for error-free conveyance of messages between machines that are physically connected by a communication channel. It consists of two sublayers. The upper sublayer deals with such issues as synchronization, error control, and link management and is present in all cases. The lower sublayer deals with the multiaccess link control and is present only when there is a shared channel that provides an any-to-any topological connectivity between stations. The focus in this section is on the upper sublayer. Multiaccess link control is described in the following section.

Asynchronous DLC Protocols

The DLC protocols used in early teleprinters are of the *asynchronous* type: the amount of data transmitted at a time is one character (5 to 8 bits—Fig. 14); when

no transmission is taking place, the channel is in the idle state, which is represented by a continuous 1. When a character is to be transmitted, the terminal transmits a 0 (the start bit) followed by the character (of fixed length), and then followed by a 1 (the idle state) for a minimum period of time called the stop interval. The receiver determines the initial sampling from the 1 to 0 transition, using a clock sixteen times the transmission rate. The sampling period is known from the bit transmission rate. Bit synchronism is maintained only during the transmission time of a character. Anytime following the stop interval, another character can be transmitted.

The start-stop protocols are simple but present several disadvantages, among others the overhead of a start bit and a stop interval associated with each character, and the lack of any inherent link control capability.

Synchronous DLC Protocols

To improve the efficiency of a data link and provide link control capability, *synchronous* protocols were introduced. A block of several characters referred to as a *frame* is transmitted as a whole, with bit synchronism

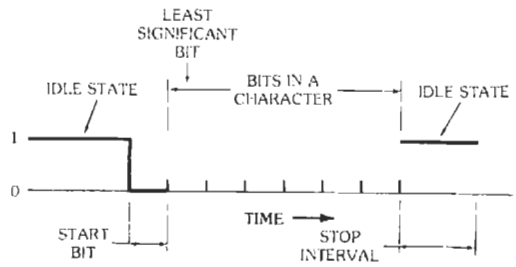

Fig. 14. Asynchronous DLC protocol.

maintained during the entire transmission time of the frame. These protocols provide the following functions: (1) frame synchronization (a mechanism needed to delimit the beginning and end of transmission blocks, and to acquire bit synchronization), (2) error control (mechanisms needed to detect errors, acknowledge correctly received blocks, request the retransmission of incorrectly received blocks, and control the sequence of blocks to identify lost and duplicate blocks), (3) link management (mechanisms needed to establish a data link over a communication facility that has been idle and, in the case of multipoint facilities, to identify sender and receiver), (4) flow control (mechanisms needed to regulate the flow of information), and (5) functions to permit the recovery from abnormal conditions such as illegal sequences, loss of response, etc. Two types of synchronous DLC protocols exist: character-oriented and bit-oriented.

Character-Oriented DLC Protocols—These protocols are suitable for two-way alternate operation on full-duplex or half-duplex multipoint, switched, or dedicated link configurations. These protocols started with IBM's binary synchronous communication (BSC) protocol in the late 1960s; following it, there has been a proliferation of different protocols by various manufacturers, which are optimized for specific implementations. Although of the same type (all are character-oriented), these are incompatible with each other. A standardization effort was undertaken by ANSI and ISO. Today, the most widely used protocols are IBM's BSC, ANSI X3.28 (1971, updated 1976), ISO's IS/745 (1975), and DEC's DDCMP. To illustrate this type of DLC protocol, ANSI 3.28 is used here.

In this protocol, the definitions of a message and a block are as follows: While a message is an ordered sequence of characters arranged to convey information from the originator user to the destination user (including a header portion), a block is a group of characters arranged for technical or logical reasons that is transmitted as a unit. A block may contain an entire message or a portion of a message.

Ten ASCII characters are designated as communication control characters. The first is SYN (synchronization character). It is used at the beginning of a data stream (following an idle time) to allow the receiver to establish byte synchronization. A minimum of two SYN characters are usually used to guarantee proper operation. This character is also used following the data stream (during the idle time) to allow the receiver to maintain synchronization, if this is desired. Two characters, ENQ (enquiry) and EOT (end of transmission), are used to manage the link. Using ENQ, a station solicits a response (such as status or identification) from another user. In particular, this character is used by a master station in a nonswitched multipoint configuration to poll a secondary station, and thus to establish a link between it and the secondary station. The EOT character is used to indicate the end of transmission of one or more messages and to relinquish the data link. Four characters are used to delimit blocks that are being transmitted: SOH (start of heading) and STX (start of text) are used to designate beginning of a block containing message header information and message text, respectively; ETB is used to designate end of transmission block; and ETX (end of text) is used at the end of the last block of a message. Two characters, ACK and NAK, are used as affirmative response and negative response (e.g., a block received in error) to a sender, respectively. Since all these characters have a specific control meaning, they should not normally appear in the user's data. To remove such a restriction and allow control characters to be in the user's data stream (that is, to achieve transparency), a tenth character, DLE (data link escape) is added; for any control character to be interpreted as such, it must be preceded by DLE. If DLE itself is to be transmitted as data, then it is transmitted as the sequence DLEDLE.

For error detection, three techniques are available: the *vertical redundancy check* (VRC), the *longitudinal redundancy check* (LRC), and the *cyclic redundancy check* (CRC). The vertical redundancy check consists of appending one parity bit to each character; thus it can only detect an odd number of bit errors in a character. The longitudinal redundancy check consists of computing parity on the entire sequence of successive characters in a block, and transmitting the result as an additional check character; thus it is vulnerable to double bit errors in the row of characters. With CRC, the bit stream constituting a block or a packet is treated as a polynomial, $M(x)$, with the least significant bit considered to be the coefficient of x^0. With k bits in the block, the polynomial is of degree $k - 1$. A generator polynomial, $G(x)$, of degree r is agreed upon by both sender and receiver. After appending r zero bits to the low-order end of the message to form the corresponding polynomial $x^r M(x)$, the latter is divided by $G(x)$ (polynomial division modulo 2), and the remainder is subtracted from $x^r M(x)$ (modulo 2). The result, $T(x)$, is the checksummed message. With the proper choice of $G(x)$, the CRC technique can safely detect single bit errors, double errors, any odd number of errors, and any burst error of length $\leq r$. For burst errors longer than $r + 1$, there is a nonzero probability of a bad message going undetected. Three international standards for a CRC generator exist. These are

$$\text{CRC-12} = x^{12} + x^{11} + x^3 + x^2 + x^1 + 1$$

$$\text{CRC-16} = x^{16} + x^{15} + x^2 + 1$$

$$\text{CRC-CCITT} = x^{16} + x^{12} + x^5 + 1a$$

Of the three techniques (VRC, LRC, and CRC), CRC offers the best protection against undetected errors.

Error-free transmission of messages is accomplished by the use of the ACK and NAK control characters in conjunction with an error-detection procedure and the retransmission of blocks with errors. Moreover, timers are provided at both the sender and the receiver in order to recover from abnormal conditions. The *response timer* (typically 2–3 seconds) at the sending station protects against invalid or missing response, and the receive timer (about 500 ms) protects against failure to receive or recognize ETB or ETX. With these definitions and features, ANSI 3.28 specifies a number of specific protocols, each suitable to a particular scenario (or situation). For example, "subcategory 2.4" is for two-way alternate transmission on a nonswitched multipoint configuration with centralized operation; "subcategory D1" is for message-independent blocking, with cyclic checking, alternating acknowledgements, and transparent heading and text.

Bit-Oriented DLC Protocols—A number of deficiencies exist in character-oriented DLC protocols. First of all, such protocols are best suited for the two-way alternate transmission mode (i.e., half-duplex transmission) and thus make inefficient use of full-duplex lines. Secondly, error checking is done only on text, leaving control sequences unprotected, and thus leading to complex recovery procedures. Thirdly, a single data link function is performed with each transmission (e.g., either data transmission, or acknowledgement, or polling command, etc.), which leads to a larger number of turnarounds and to an unsatisfactory ratio of data transfer exchange to control exchange. Finally, character-oriented DLC protocols are too rigid and do not allow for easy expansion.

The new bit-oriented DLC protocols have been designed to overcome all the above limitations. Examples are ANSI's Advanced Data Communication Control Protocols (ADCCP), ISO's High-Level Data Link Control (HDLC), and IBM's Synchronous Data Link Control (SDLC). The ADCCP and HDLC protocols are compatible. In this discussion, ADCCP is used to illustrate bit-oriented DLC protocols.

Bit-oriented DLC protocols have been designed to support all possible environments: point-to-point and multipoint configurations using two-way alternate or two-way simultaneous operation over switched and nonswitched transmission lines, with both terrestrial and satellite connections. Three data transfer modes have been defined: the normal response mode (NRM) and the asynchronous response mode (ARM) for use in point-to-point and multipoint configurations, and the asynchronous balanced mode (ABM) for use in point-to-point configurations. In NRM and ARM, a so-called *primary station* controls the operation of the data link, while one or more *secondary stations* act as subservient to the primary. The primary issues commands and receives responses; the secondary station receives commands and issues responses in accordance with the command received and the mode of operation. In NRM, a secondary station initiates transmission only as a result of receiving explicit permission to do so. This mode is suitable for polled multipoint operation between a central location and a number of outlying stations. In ARM, a secondary station can initiate transmission without waiting for an explicit permission. It is suitable for a single primary and a *single* activated secondary wishing to transmit freely to one another without the overhead of polling. The ABM mode provides a *balanced* type of data transfer between two stations referred to as *logically equal* or *combined* stations. Each station operates as a primary for its data transfer, and is thus capable of initializing the link, activating the other combined station, and logically disconnecting the link. Typically, each combined station may be a host computer, an intelligent network node (e.g., a packet-switching node), or a highly intelligent terminal that has the capability to control the data link.

In bit-oriented DLC protocol, the basic transmission unit is called a *frame*. In order to achieve enhanced capabilities over character-oriented DLC protocols, a well defined frame format as shown in Fig. 15 is used, including an address field, a control field, and a frame check sequence (FCS).

The flag sequence (F) is the unique eight-bit pattern 01111110 used to delimit the start and end of each frame, and to fill idle time between frames during the transmission of multiple frames. In order to prohibit the occurrence of the flag in the address, control, information, and FCS fields, and thus achieve transparency, a technique called bit-stuffing is used. The transmitter inserts a 0 bit following any five contiguous 1 bits encountered in the above mentioned fields; the receiver deletes the 0 bit following five contiguous 1 bits following a 0 bit anywhere before receiving the closing flag sequence.

The address field in a command frame identifies the station (secondary or combined) that is to receive the command; in a response frame, it identifies the station (secondary or combined) that is sending the frame. Thus in NRM and ARM, the address always identifies the secondary station; in ABM, it identifies the response-generating portion of a combined station. There are two mutually exclusive address-field options: either a single octet accommodating up to 256 stations, or multiple octets recursively extendable by having the first bit of each octet be a 1 bit if the octet is the last one in the address or a 0 bit otherwise. Broadcast addressing is also possible by using the all-zero address.

The control field identifies the function and purpose of the frame. Three different formats exist, defining the three types of frames: information transfer type (I

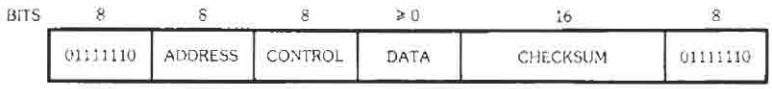

Fig. 15. Frame format for bit-oriented protocols. (*From Andrew S. Tanenbaum,* Computer Networks, © *1981. Used by permission of Prentice-Hall, Inc., Englewood Cliffs, N.J.*)

frame), supervisory type (S frame), and unnumbered type (U frame). See Fig. 16. The P/F bit in the control field provides for a check-pointing mechanism allowing a response frame to be logically associated with the appropriate initiating command frame. In NRM, the primary station sets the P/F bit to 1 to poll a secondary station. The secondary station sets P/F to 1 in the last frame sent in response to a poll. In ARM and ABM, receipt of a frame with the P/F bit set to 1 causes the responding station to set the P/F bit to 1 in the next appropriate frame.

The I frames are used to transfer user information across a data link. A so-called *window mechanism* is used to guarantee sequential error-free delivery of the information without degrading the performance of the link. Successive frames are numbered sequentially (modulo some number 2^n), where the numbers range from 0 to the maximum, $2^n - 1$. The frame sequence number is transmitted in the control field $N(S)$. The sender maintains a list of consecutive sequence numbers called the *sending window* corresponding to frames it is permitted to send. Likewise, the receiver maintains a list of consecutive sequence numbers called the *receiving window* for frames it is permitted to receive. Most acknowledgements in these DLC protocols are handled in a *piggyback* fashion. A receiver that has correctly received all frames numbered up to some number, k, will send in the $N(R)$ field of the next I frame the number $N(R) = k + 1$; i.e., the sequence number of the next frame the receiver is expecting. In case an I frame is not ready for transmission, the receiver will send an S frame with $N(R) = k + 1$. Upon receiving an acknowledgement, the sender advances the lower edge of its sending window to $N(R)$ and the upper edge to $N(R) + W_S$. The sequence numbers of frames already transmitted that are within the sender window represent frames sent but as yet not acknowledged. The window size, W_S, represents the maximum number of such frames. It is determined as a function of the frame transmission time and the end-to-end propagation delay so as to "fill the pipe" and achieve high throughput. This feature is particularly important when dealing with wideband satellite channels where the ratio of round-trip delay to frame transmission time is high. The receive window, W_R, is determined as a function of the buffer space available at the receiver. The sending window, W_S, and receive window, W_R, need not be the same. The window mechanism protects against the loss of a frame and the loss of acknowledgement, detects and filters out duplicates, and guarantees that the network level receives the frames in sequential order. It is important, however, that the condition $W_S + W_R \leq 2^n$ be satisfied. In the ADCCP and HDLC standards, two sequence ranges are available: the unextended case, which is modulo 8, and the extended case, which is modulo 128.

There are four supervisory frames. Receive ready (RR) is used to indicate that the receiver is ready to receive I frames; receive not ready (RNR) is used to indicate a temporary busy condition. Both RR and RNR S frames acknowledge I frames already received. Reject (REJ) is used to request retransmission of all I frames starting with N(R); selective reject (SREJ) is used to request the retransmission of a single designated I frame, N(R).

There are 32 U-frame commands and/or responses that can be defined, although fewer than 32 are in fact determined in the current standards. They do not contain a sequence number and thus are not accounted for in the normal flow of frames. They are mainly used in the control of the data link. Examples are: the set mode commands (SNRM, SARM, SABM, etc.), disconnect command (DISC), an unnumbered poll command, an unnumbered information (UI) command/response, an unnumbered acknowledgement (UA), and a frame reject (FRMR). (The frame reject is used to indicate that a received frame was in error and cannot be corrected by retransmission, such as, for example, an information field greater than the maximum established length, receipt of a control field that is either invalid or not implemented, etc.)

CONTROL FIELD FOR	CONTROL FIELD BITS							
	1	2	3	4	5	6	7	8
INFORMATION TRANSFER COMMAND/ RESPONSE (I FRAME)	0	N(S)			P/F	N(R)		
SUPERVISORY COMMANDS/ RESPONSES (S FRAME)	1	0	S	S	P/F	N(R)		
UNNUMBERED COMMANDS/ RESPONSES (U FRAME)	1	1	M	M	P/F	M	M	M

The FCS consists of the 16-bit checksum obtained from the CRC error detection technique using the CRC-CCITT generator. An optional 32-bit FCS is also available if a higher degree of error detection is needed. The corresponding generator polynomial is $x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$. Just as with character-oriented DLC protocols, classes of procedures are defined in order to provide organization and direction for the application of the bit-oriented data link control procedures. Certain commands belong to all the classes, while others are viewed as being optional. Examples are: UNC, 3, 4—unbalanced NRM with SREJ and UI capabilities; BAC, 2, 8—balanced ABM with REJ and the restriction on the use of I frames as commands only.

MULTIACCESS LINK CONTROL

Multiaccess protocols arise whenever a communication channel is shared by many independent contending users. Two major factors contribute to a multiaccess situation: the need to share an expensive communication channel in order to achieve its efficient utilization, and the need to provide a high degree of connectivity for communication among independent subscribers. The main issue of concern is how to control access to the common channel to allocate the available bandwidth efficiently. The solutions to this problem form the set of protocols known as *multiaccess protocols*. These protocols and their performance differ according to the environment and the specific requirements to be satisfied. In satellite channels, there is an inherent long propagation delay of approximately 0.25 s, a delay that is usually long compared to the transmission time of a packet given the bandwidth usually available. In ground radio environments, the opposite is true: the transmission radius is relatively small due to a limited power supply at the radio units and a heavy signal attenuation, and the data rate is relatively low, so that the propagation delay is relatively short compared to the transmission time of a packet. Finally, local area environments are characterized by a large and often variable number of inexpensive devices; they call for networks with simple topologies and inexpensive connection interfaces; the propagation delay is short but the bandwidth can be high; the propagation delay may or may not be larger than the packet transmission time.

Multiaccess schemes are evaluated according to various criteria: bandwidth utilization, message delay, the ability to support traffic of different types simultaneously (with different priorities, variable message lengths, and differing delay constraints), and robustness (defined here as the insensitivity to errors resulting in misinformation).

Multiaccess protocols differ by the static or dynamic nature of the bandwidth allocation algorithm, the centralized or distributed nature of the decision-making process, and the degree of adaptivity of the algorithm to changing needs. Accordingly, these protocols can be grouped into several classes described hereafter.

Fixed Assignment Techniques

Fixed assignment techniques consist of allocating the channel to the users, independently of their activity, by partitioning the time-bandwidth space into slots that are assigned in a static predetermined fashion. These techniques take two common forms: *orthogonal*, such as frequency division multiple access (FDMA) or synchronous time division multiple access (TDMA), and "*quasi-orthogonal*," such as code division multiple access (CDMA).

The FDMA technique consists of assigning to each user a fraction of the bandwidth and confining its access to the allocated subband. Orthogonality is achieved in the frequency domain. The TDMA technique consists of assigning fixed predetermined channel time slots to each user; the user has access to the entire channel bandwidth, but only during its allocated slots. Here, signaling waveforms are orthogonal in time. The TDMA approach is more complex to implement than FDMA, but an important advantage is the connectivity that results from the fact that all receivers listen to the same channel while senders transmit on the same common channel at different times. Accordingly, with TDMA, many network realizations, both in ground and satellite environments, are easier to accomplish.

The CDMA technique allows overlap in transmission both in the frequency and time coordinates. It achieves orthogonality by the use of different signaling codes in conjunction with matched filters (or equivalently, correlation detection) at the intended receivers. Each user is assigned a particular code sequence, which is modulated on the carrier with the digital data modulated on top of that. Two common forms exist: the frequency-hopped SSMA and the phase-coded SSMA. In the former, the frequency is periodically changing according to some known pattern; in the latter, the carrier is phase modulated by the digital data sequence and the code sequence. Multiple orthogonal codes are obtained at the expense of increased bandwidth requirements (in order to spread the waveforms). With CDMA, there is also a lack of flexibility in interconnecting all users (unless, of course, matched filters corresponding to all codes are provided at all receivers). However, CDMA has the advantage of allowing the coexistence of several systems in the same band, as long as different codes are used for different systems.

Random Access Techniques

Since data traffic in computer communication is characterized as bursty, a more advantageous approach than fixed assignment is to provide a single sharable high-speed channel to the large number of users. The strong law of large numbers then guarantees that, with a very high probability, the demand at any instant will be approximately equal to the sum of the average demands of that population. When dealing with shared channels in a packet-switched mode, one must be prepared to resolve conflicts that arise when more than one demand

is placed on the channel. For example, in packet-switched channels, whenever a portion of the transmission of one user overlaps with the transmission of another user, then the two collide and "destroy" each other (unless a code division multiple-access scheme is used). The existence of some positive acknowledgement scheme permits the transmitter to determine if a transmission is successful or not.

ALOHA—Pure ALOHA permits a user to transmit any time it desires. If a user transmits a packet, and within some appropriate time-out period following its transmission it receives an acknowledgement from the destination, then it knows that no conflict occurred. Otherwise, it assumes that a collision occurred and it must retransmit. To avoid continuously repeated conflicts, the retransmission delay is randomized across the transmitting devices, thus spreading the retry packets over time. A slotted version, referred to as *slotted ALOHA*, is obtained by dividing time into slots of duration equal to the transmission time of a single packet (assuming constant-length packets). Each user is required to synchronize the start of transmission of its packets to coincide with the slot boundary. When two packets conflict, they will overlap completely rather than partially, providing an increase in channel efficiency over pure ALOHA. Due to conflicts and idle channel time, the maximum channel efficiency available with ALOHA is less than 100 percent, 18 percent for pure ALOHA and 36 percent for slotted ALOHA. Note that, although the maximum achievable channel utilization is low, the ALOHA schemes are superior to fixed assignment schemes when there is a large population of bursty users and low packet delay is of the essence. (See reference 3.)

Carrier Sense Multiple Access (CSMA)—In the CSMA technique, an attempt is made to avoid collisions by listening to the carrier due to transmission from another user before transmitting, and inhibiting transmission if the channel is sensed busy. This is advantageous when the propagation delay between any source-destination pair is small compared to the packet transmission time. Many CSMA protocols exist; they differ according to the action that a terminal takes to transmit a packet after sensing the channel. In all cases, however, when a terminal learns that its transmission has incurred a collision, it reschedules the transmission of the packet according to a randomly distributed delay. At this new point in time, the transmitter senses the channel again and repeats the algorithm dictated by the protocol. In *nonpersistent* CSMA, a ready terminal senses the channel and operates as follows. If the channel is sensed idle, the terminal transmits the packet. If the channel is sensed busy, then the terminal schedules the retransmission of the packet to some later time according to the retransmission delay distribution. At this new point in time, it senses the channel and repeats the algorithm described.

In the *1-persistent* CSMA protocol, a ready terminal senses the channel and operates as follows. If the channel is sensed idle, it transmits the packet with probability one. If the channel is sensed busy, it waits until the channel goes idle and then immediately transmits the packet with probability one. In 1-persistent CSMA, whenever two or more terminals become ready during a packet transmission period, they wait for the channel to become idle (at the end of that transmission), and then they all transmit with probability one. A conflict will also occur with probability one. Randomizing the starting time of transmission of packets accumulating at the end of a transmission period reduces interference and improves performance. The *p-persistent* scheme involves including an additional parameter p, the probability that a ready packet persists ($1 - p$ being the probability of delaying transmission by τ seconds, where τ is the maximum propagation delay among all pairs). Parameter p is chosen to reduce the level of interference while keeping the idle periods between any two consecutive nonoverlapped transmissions as small as possible.

The CSMA technique has been applied to ground radio (e.g., PRNET), and to local area communications (e.g., ETHERNET). In ETHERNET, CSMA is used on a tapped coaxial cable to which all the communicating devices are connected. On the coaxial cable, in addition to sensing carrier, it is possible for the transceivers to detect collisions. This is achieved by having each transmitting device compare the bit stream it is transmitting to the bit stream it sees on the channel. When transmitting users detect interference among several transmissions (including their own), they abort the transmission of colliding packets. This variation of CSMA is referred to as *carrier sense multiple access with collision detection* (CSMA-CD).

The performance of CSMA is heavily dependent on the ratio, a, of propagation delay to packet transmission time. The maximum throughput of a CSMA protocol degrades significantly as a gets larger. For a ratio $a = 0.01$, nonpersistent CSMA achieves a channel utilization equal to 0.815, a significant improvement over the ALOHA schemes.

While until recently most of the concepts described in this section had been realized in experimental systems (namely, the ALOHA System, PRNET, and Xerox's experimental ETHERNET), it is important to note that today many contention systems of the ETHERNET type are available on the market. Examples are the Hyperchannel and the Hyperbus of Network Systems Corporation, Z-Net of Zilog, Omninet of Corvus, and ETHERNET itself. The latter has been announced as a product made available jointly by Xerox Corporation, Digital Equipment Corporation, and INTEL. Complete specifications of the data link and physical link protocols have been issued and constituted the basis of a standard for the IEEE Computer Society Project 802 on the standardization of local networks. A key feature that distinguishes this product from other already available systems is the LSI implementation of many of the data link and physical link protocols. The LSI implementation of network protocols clearly marks

a trend in the evolution of computer networking, a trend that is indicative of the existence of a wide market and the need to provide reasonably priced components.

Busy-Tone Multiple Access (BTMA)—In ground radio environments, it is possible for two terminals to be within range of the intended receiver, but out of range of each other or separated by some physical obstacle opaque to radio signals. The existence of hidden terminals in such an environment significantly degrades the performance of CSMA. The hidden-terminal problem can be eliminated by frequency dividing the available bandwidth into two separate channels, a busy-tone channel and a message channel, thus giving rise to *busy-tone multiple access* (BTMA). As long as a node senses carrier on the message channel, it transmits a (sine wave) busy-tone signal on the busy-tone channel. It is by sensing carrier on the busy-tone channel that nodes determine the state of the message channel. The action that a node takes pertaining to the transmission of the packet is again prescribed by the particular protocol being used, similar to those described for CSMA.

Capture—Capture in narrow-band channels can be defined as the ability of a receiver to receive a packet successfully (with nonzero probability) although the packet is partially or totally overlapped by another packet transmission. Capture is mainly due to a discrepancy in receive power between two signals that allows the receiver to receive the stronger correctly; both distance and transmit power contribute to this discrepancy. Clearly, capture improves the overall network performance, and, by means of adaptive transmit power control, it allows one to achieve either fairness to all users or intentional discrimination.

Spread-Spectrum Multiple Access (SSMA)—The SSMA technique is considered here to be a CDMA scheme. In one form of SSMA for packet radio, all transmitters employ the same code. Security, coexistence with other systems, and the ability to counteract the effects of multipath and capture are key benefits of SSMA. Contrary to the case of nonspread systems, the effect of interference in SSMA is minimized by the "capture effect," defined as the ability of the receiver to "lock on" one packet while all other overlapping packets appear as noise. The receiver locks on a packet by correctly receiving the preamble appended to the front of the transmitted packet. As long as the preambles of different packets do not overlap in time, and the signal strength of the late packets is not too high, capture of the earliest packet occurs with a high probability. In essence, SSMA allows a packet to be captured at the receiver, while CSMA allows a user to capture the channel. It is possible to use CSMA in conjunction with SSMA, but the channel sensing is more difficult. This mode will have the benefit of keeping away all users within hearing distance of the transmitter and thus help keep the capture effect and antijamming capability of the system at the desired level.

Centrally Controlled Demand Assignment

Demand assignment techniques require that explicit information regarding the need for the communication resource be exchanged. These techniques may be either centralized, whereby a central scheduler performs the assignment, or distributed, whereby all stations take active part in the assignment. Centrally controlled techniques are addressed in the present subsection.

Circuit Oriented Systems—In circuit oriented systems, the bandwidth is divided into FDMA or TDMA subchannels that are assigned on demand. The satellite SPADE system, for example, has a pool of FDMA subchannels that are allocated on request. It uses one subchannel operated in a TDMA fashion with one slot per frame permanently assigned to each user to handle the requests and releases of FDMA circuits. Intelsat's MAT-1 system uses the TDMA approach. The TDMA subchannels are periodically reallocated to meet the varying needs of earth stations.

The Advanced Mobile Phone Service (AMPS), introduced by Bell Laboratories, is another example of a centrally controlled FDMA system. The uniqueness of this system, however, lies in an efficient management of the spectrum based on space division multiple access (SDMA). That is, each subchannel in the pool of FDMA channels is allocated to different users in separate geographical areas, thus considerably increasing the spectrum utilization. To accomplish space division, the AMPS system has a cellular structure and uses a centralized handoff procedure (executed by a central office) that reroutes the telephone connections to other available subchannels as the mobile users move from one cell to another.

Polling Systems—In packet oriented systems, polling consists of having a central controller send polling messages to the terminals, one by one, asking the polled terminal to transmit. If the polled terminal has something to transmit, it goes ahead; if not, a negative reply (or absence of reply) is received by the controller, which then polls the next terminal in sequence. Polling requires this constant exchange of control messages between the controller and the terminals and is efficient only if (1) the round-trip propagation delay is small, (2) the overhead due to polling messages is low, and (3) the user population is not a large bursty one.

Adaptive Polling or Probing—The primary limitation of polling in lightly loaded systems is the high overhead incurred in determining which of the terminals have messages. A modified polling technique called *probing*, based on a tree searching algorithm, helps decrease this overhead. This technique assumes that the central controller can broadcast signals to all terminals. First the controller interrogates all terminals, asking if any of them has a message to transmit, and repeats this question until some terminals respond by putting a signal on the line. When a response is

received, the central station divides the population into subsets (according to some tree structure) and repeats the question to each of the subsets. The process is continued until the terminals having messages are identified. When a single terminal is interrogated, it transmits its message. This probing technique can be made adaptive by having the controller start a cycle by probing groups of smaller size as the probability of terminals having messages to transmit increases.

Split-Channel Reservation Multiple Access (SRMA)—An attractive alternative to polling is the use of explicit reservation techniques. In dynamic reservation systems, it is the terminal that makes a request for service on some channel whenever it has a message to transmit. The central scheduler manages a queue of requests and informs the terminal of its allocated time. In SRMA, the available bandwidth is divided into two channels, one used to transmit control information and the second used for the data messages themselves. The request channel is operated in a random access mode (ALOHA or CSMA). Upon correct reception of the request packet, the scheduling station computes the time at which the backlog on the message channel will empty and transmits back to the terminal an answer packet containing the address of the terminal and the time at which it can start transmission.

Demand Assignment With Distributed Control

There are two reasons why distributed control is desirable. The first is reliability: with distributed control the system is not dependent on the proper operation of a central scheduler. The second is improved *performance*, especially when dealing with systems with long propagation delays, such as those using satellite channels. The basic element underlying all distributed algorithms is the need to exchange control information among the users, either explicitly or implicitly. Using this information, all users then execute independently the same algorithm, with the result that there is some coordination in their actions.

Reservation-ALOHA—Reservation-ALOHA for a satellite channel is based on a slotted time axis where the slots are organized into frames of equal size. The duration of a frame must be greater than the satellite propagation delay. A user that has successfully accessed a slot in a frame is guaranteed access to the same slot in the succeeding frame, and this continues until the user stops using it. "Unused" slots, however, are free to be accessed by all users in a slotted ALOHA contention mode. A slot in a frame is an unused slot if in the *preceding* frame it either was idle or contained a collision. Users need simply to maintain a history of the usage of each slot for just one frame duration. Since no request is explicitly issued by the user, this scheme has been referred to as an *implicit reservation* scheme. Clearly, Reservation-ALOHA is effective only if the users generate stream type traffic or long multipacket messages. Its performance will degrade significantly with single packet messages, since every time a packet is successful the corresponding slot in the following frame is likely to remain empty.

A First-in First-out (FIFO) Reservation Scheme—In this scheme, reservations are made explicitly. Time division is used to provide a reservation subchannel. The channel time is slotted as before, but every so often a slot is divided into V small slots that are used for the transmission of reservation packets (as well as possibly acknowledgements and small data packets); these packets contend on the V small slots in a slotted ALOHA mode. All other slots are data slots and are used on a reservation basis, free of conflict. To execute the reservation mechanism properly, each station must maintain information on the number of outstanding reservations (the "queue in the sky") and the slots at which its own reservations begin. These are determined by the FIFO discipline based on the successful reservations received. To maintain synchronization of control information at the proper time and to acquire the correct count of packets in the queue if out-of-sync conditions do occur, each station sends information regarding the status of its queue in its data packet. This information is also used by new stations that need to join the queue. The robustness of this system is achieved by a proper encoding of the reservation packets to increase the probability of their correct reception at *all* stations.

A Round-Robin (RR) Reservation Scheme—The basis of this scheme is fixed TDMA assignment, but with the major difference that "unused" slots are assigned to the active stations on a round-robin basis. This is accomplished by organizing packet slots into equal-size frames of duration greater than the propagation delay and such that the number of slots in a frame is larger than the number of stations. One slot in each frame is permanently assigned to each station. To allow other stations to know the current state (used or unused) of its own slot, each station is required to transmit information regarding its own queue of packets piggybacked in the data packet header (transmitted in the previous frame). A zero count indicates that the slot in question is free. All stations maintain a table of the queue lengths of all stations, allowing them to allocate among themselves unassigned slots in the current frame. Round-robin or other scheduling disciplines can be used. A station recovers its slot by deliberately causing a conflict in that slot, which other users detect.

Distributed Tree Retransmission Algorithms—Tree algorithms are based on the observation that a contention among several active sources is completely resolved if and only if all the sources are somehow subdivided into groups such that each group contains at most one active source. (See probing in the section on centrally controlled demand assignment.) Each source corresponds to a leaf on a *binary* tree. The channel time

axis is slotted, and the slots are grouped into pairs. Each slot in a pair corresponds to one of the two subtrees of the node being visited. Starting with the root node of the tree, we let all terminals in each of the two subtrees of the root transmit in their corresponding slots. If any of the two slots contains a collision, then the algorithm proceeds to the root of the subtree corresponding to the collision and repeats itself. This continues until all the leaves are separated into sets such that each of them contains at most one packet. This is known to all users, as the outcome of the channel is either a successful transmission or an idle slot. Collisions caused by the left subtree (first slot of a pair) are resolved prior to resolving collisions in the right subtree. This scheme provides a maximum throughput of 0.347 packets/slot. Clearly, a binary tree is not always optimum. If, each time a return to the root node is made, the tree is reconfigured according to the current traffic conditions, it can be shown that the optimum tree is binary everywhere except for the root node, whose optimum degree depends on traffic conditions.

The preceding four schemes have been proposed for satellite channels. All assumed fixed-size slots, and thus can be implemented in systems that have been built for synchronous TDMA. If used in systems with small propagation delay, such as ground radio, then they will perform significantly better. Due to the inherent small propagation delay in ground radio and local environments, other access modes with distributed control are also possible if all devices are in line-of-sight and within range of each other. A description of these follows.

Minislotted Alternating Priorities (MSAP)—The MSAP technique is a "carrier-sense" version of polling with distributed control. The time axis is slotted with the slot size again equal to the maximum propagation delay (and referred to hereafter as a minislot). All users are synchronized and may start transmission only at the beginning of a minislot. Users are considered to be ordered from 1 to M. When a packet transmission ends, the alternating priorities (AP) rule assigns the channel to the same user that transmitted the last packet (say user i) if it is still busy; otherwise the channel is assigned to the next user in sequence (i.e., user $[i(\text{mod } M) + 1]$). The latter (and all other users) detects the end of transmission of user i by sensing the absence of carrier over one minislot. At this new point in time, either user $[i(\text{mod } M) + 1]$ starts transmission of a packet (which will be detected by all other users) or it is idle, in which case a minislot is lost and control of the channel is handed to the next user in sequence. The overhead at each poll in this scheme is one minislot. Scheduling rules other than AP are also possible, such as round-robin and random order.

The Assigned-Slot Listen-Before-Transmission Protocol—Time is minislotted and divided into frames, each containing an equal number of minislots (say L). To each minislot of a frame is assigned a given subset of M/L users. A user with a packet ready for transmission in a frame can sense the channel only in its assigned minislot. If the channel is sensed idle, transmission takes place; if not, the packet is rescheduled for transmission in a future frame. Parameter M/L is adjusted according to the load placed on the channel. For high throughput, $M/L = 1$ is found to be optimum, and the scheme becomes a conflict-free one that approaches MSAP. For very low throughput, $M/L = M$ (i.e., $L = 1$) is found to be optimum; this corresponds to pure CSMA. In between the two extreme cases, intermediate values of M/L are optimum.

The URN Scheme—The time axis is divided into packet slots, and all users are synchronized. Assuming that all users know the exact number, n, of busy users, the scheme consists of giving full access right (i.e., the right to transmit with probability 1) to some number, k, of users. A successful transmission will result if there is exactly one busy user among these k. The probability of such an event is maximized when $k = [M/n]$, where $[M/n]$ denotes the integer part of M/n. Assume the system is lightly loaded (for instance $n = 1$). A large number of users are given access right (in the example $n = 1$, the number is $k = M$), but only a few and hopefully only one will make use of it (in the example $n = 1$, a successful transmission takes place). As the load increases, k decreases and the access right is gradually restricted. For the extreme case of $n = M$, $k = 1$ and the scheme converges to TDMA. One possible scheme for estimating n with good accuracy is to include a single reservation minislot at the beginning of each data slot. An idle user that turns busy sends a standard reservation message of few bits. All users are able to detect the following three events: no new busy users, one new busy user, and more than one new busy user (termed an erasure). As it is impossible with this minimal overhead to estimate the exact number of new busy users when the latter is greater than one, errors in estimation result; however analysis and simulation have shown that this error is negligible and, furthermore, that the scheme is insensitive to small perturbations in n. This last statement is even more important with respect to the robustness of the scheme, since it means that all users need not have exactly the same estimate for n. As for coordinating the selection of the k users, an effective mechanism is the use of synchronized pseudorandom generators at all users, which allow them to draw the same k pseudorandom numbers. Another mechanism, referred to as a round-robin slot sharing window mechanism, consists of having a window of size k move over the population space. When a collision occurs, the window stops and decreases in size. When there is no collision, the tail of the window is advanced to the head of the previous window, and the size is again set to k as determined by n.

Distributed Control Algorithms in Local Area Networks—In addition to the random-access schemes described previously, all above algorithms are also applicable to local-area (broadcast) *bus* networks, as

these exhibit the required characteristics of small propagation delay and full connectivity. But in local-area communication, a slightly different topology, namely the *ring* (or loop), has also been widely considered. As described previously in connection with Fig. 7, in the ring topology messages are not broadcast but rather passed from node to node along unidirectional links, until they return to the originating node. A simple scheme suitable for a ring consists of passing the access right sequentially from node to node around the ring. (Note that in a ring, the physical locations of the nodes define a natural ordering among them.) One implementation of this scheme is exemplified by the Distributed Computing System's network where an 8-bit *control token* is passed sequentially around the ring. Any node with a ready message may, upon receiving the control token, remove the token from the ring, send the message, and then pass on the control token. Another implementation consists of providing a number of *message slots* that are continuously transmitted around the ring. A message slot may be empty or full; a node with a ready message waits to see an empty slot pass by, marks it as full, and uses it to send its message. A still different strategy is known as the *register insertion* technique. Here, a message to be transmitted is first loaded into a shift register. If the ring is idle, the shift register is just transmitted. If not, the register is inserted into the network loop at the next point separating two adjacent messages; the message to be sent is shifted out onto the ring while an incoming message is shifted into the register. The shift register can be removed from the network loop when the transmitted message has returned to it.

Priority-Oriented Demand Assignment (PODA)—In the context of a satellite channel, PODA has been proposed as the ultimate scheme that attempts to incorporate all the properties and advantages seen in many of the previous schemes. It has provision for both implicit and explicit reservations, thus accommodating both stream and packet-type traffic. It may also integrate the use of both centralized and distributed control techniques, thus achieving a high level of robustness. Channel time is divided into two basic subframes, an information subframe and a control subframe. The information subframe contains scheduled packets and packet streams that also contain, piggybacked, control information such as reservations and acknowledgements. The control subframe is used exclusively to send reservations that cannot be sent in the information subframe in a timely manner. In order to achieve integration of centralized and distributed assignments, the information subframe is further divided into two sections, one for each type. Access to the control subframe (which is divided into slots accommodating fixed-size control packets) can take any form that is suitable to the environment. It can be by *fixed assignment* (TDMA) if the number of stations is small (giving rise to the so-called FPODA), or by *contention* as in ALOHA if the stations have a low duty cycle (giving rise to CPODA), or a combination of both. The boundary between the control subframe and the information subframe is not fixed, but varies with the demand placed on the channel. As in the FIFO and RR reservation schemes, distributed control is achieved by having all stations involved in this type of control keep track of their queue length information. Priority scheduling can thus be achieved. For stream traffic, a reservation is made only once and is retained by each station in a stream queue. Centralized assignment may be used when delay is not the crucial element. This scheme has been proposed in the context of a satellite channel but may be applied to other environments as well.

THE NETWORK LAYER

The network layer consists of those functions that control the transportation of data from source-host to destination-host. It serves directly transport entities residing at the network hosts, relieving them from any concern about network issues such as switching, routing, and congestion control. The network-layer functions are implemented at all switching nodes of a network. This layer is the highest one that resides at the switching nodes. It makes use of the data-link layer to accomplish the error-free transmission of data over individual links.

The Network Services

The nature of the services provided by the network layer varies considerably depending on the switching technique used in the communication subnet and the transport-layer requirements pertaining to the delivery of data from one end to the other.

A network-layer protocol for a circuit-switched network is found in CCITT Recommendation X.21 (1972). As stated earlier, X.21 is a general-purpose interface between DTE and DCE for synchronous operation on public data networks. When circuit-switched services are provided, X.21 includes a data-link-layer function and a network-layer function needed for call establishment. The data-link layer is character oriented and includes only the minimum elements necessary for basic operation, namely character synchronization (using two or more SYN characters) and error detection (using odd parity). The network layer clearly defines the procedures used in processing the various phases of call requests, incoming calls, facility requests, call progress, and call clearing. The reason these procedures belong to the network layer as opposed to the physical layer (although the end result is a direct physical connection between the two end hosts) is that the network layer receives the remote DTE (or DCE) address from the transport layer and makes use of the data-link layer in processing the calls.

With packet switched networks, two types of network services exist: the *datagram service* and the *virtual*

circuit (VC) *service*. In the VC model, the network layer provides the transport layer with a "perfect" connection: no errors, no duplicates, and all packets are delivered in order. In the datagram model, the network layer accepts messages from the transport layer and simply makes the best effort to deliver them independently (and not necessarily in order). The implementation of the datagram mode is simple; it merely consists of a routing algorithm that attempts delivery of the messages to their destination. For VC, in addition to routing the messages, error control and sequencing must be implemented at the end nodes. In theory, packets may travel on different routes and arrive in any order. Resequencing at the destination node would then be required. In practice, the implementation of a VC in the subnet is by establishing a route between the source and destination end nodes at connection time, and by continuously using the same route for all packets belonging to the same virtual circuit. The implementation requires the packet to carry a virtual circuit number, and each node to contain a table with an entry for each VC traversing it, relating incoming packets from an adjacent neighbor with a VC number to an outgoing link and a VC number on that link. Forwarding packets to the destination node is then straightforward. All nodes use the first-come-first-served service discipline, thus preserving the order of packets for each VC. End-to-end reliability and sequencing are achieved by means of a window mechanism, which also provides flow control. It is to be noted, however, that the network layer does not achieve complete end-host to end-host reliability, since it is subject to node and link failures; depending on the environment and on the application, higher level functions (at the transport layer) must exist to guarantee that reliability.

Routing

In multihop store-and-forward networks, the network layer includes a routing algorithm that is responsible for deciding on which output link a packet should be transmitted. Although one primary objective is that each packet reaches its destination, there are several other objectives that are also very important, such as to minimize packet transit times, to avoid congestion and deadlocks, to maximize the network throughput, etc. It is also desirable that the algorithm be simple, robust, stable, and fair to all users. There is a broad spectrum of routing algorithms. They vary according to various attributes pertaining to the nature of decision-making (centralized or distributed), the degree of adaptivity, the frequency of updates, etc. Several routing techniques are described below.

Directory Routing—In directory routing, each node maintains a table with one row for each destination. The row gives one or several outgoing links together with relative weights assigned to them. Upon receipt of a packet with a given destination address, the node simply performs a table look-up and chooses one of the alternatives, using the relative weights as probabilities. The selection of routes and their weights may be based on the number of hops. If the source-destination traffic requirement of the network is stationary, then it is possible to use routes that minimize the average message delay in the network. For a given destination, the routes from an intermediate node to that destination are entirely determined by the tables and independent of the source. This is not restrictive, since if node j is on the optimal path from source i to destination k, then the optimal path from j to k should follow the same route. This is known as the optimality principle. As a result, the set of routes from all sources to a given destination form a tree with the destination as a root; such a tree is called the *sink tree* for that destination.

Hierarchical Routing—If the size of the network is large, then hierarchical routing is used. The network is partitioned into regions; node addresses are hierarchical and contain a region number and a node number within the region. In the table at each node, there is an entry for each destination in the region in which the node is located, and an entry for each of the other regions. Hierarchical routing decreases the overhead incurred in terms of storage and processing requirement. If the network is very large, a hierarchy with more than two levels may be needed.

Static Versus Dynamic Routing—Static routing refers to the case in which the table content is fixed. Static routing is adequate if the topology and traffic conditions do not change much. Dynamic routing refers to the case in which table contents change as the network condition changes. This is also referred to as *adaptive routing*. For example, if routing tables are based on minimizing message delay, then the routes are modified as the traffic pattern changes. There is a wide range of adaptivity depending on the frequency of changes, the type and amount of information used, and the means for implementing the changes. For example, static routing may be used, but changed only when there is a failure. To construct the best routing tables in the nodes at all times, information is needed about the instantaneous state of the network and its traffic. Unfortunately, it is not possible for the nodes to have complete and up-to-date information about the entire network. To provide it would also constitute too great an overhead. Several practical alternatives are presented below.

Centralized Routing—In centralized routing, a node is designated as the *routing control center* (RCC). Each node periodically sends status information to the RCC. The RCC thus acquires global information, based upon which it computes optimal routes. New routing tables are periodically distributed to the nodes in the network. While centralized routing may achieve global optimal and relieve the node from the task of routing computation, it has some drawbacks: the information collected at the RCC may be old due to the delay in the

network; the communication overhead incurred in collecting status information and distributing routing information may be substantial; the reliability of the entire network rests on the proper operation of the control center.

Isolated Routing—Isolated routing is the most extreme case of decentralized routing. In isolated routing, each node makes its own routing decision based on information it has at hand. The *hot potato* technique consists of passing the packet on as quickly as possible, by sending (or queueing) it on the outgoing link with the shortest queue. Variations of this shortest-queue routing are obtained by applying various biases. For example, the link selected may be determined by a combination of the weights assigned to the static alternate routes and the queue size at each. Another isolated technique is the *backward learning* technique. It consists of having a node attempt to estimate the number of hops (or delay) of a route going from it to some destination (starting with an outgoing link) by measuring the number of hops (or delay) incurred by packets arriving from that destination on that route (i.e., on that outgoing link). To implement this technique, using the delay measure for example, each packet is time-stamped when it sets off on its journey, and from this time-stamp each node compiles a table of information about delays. One main problem with that implementation is that the delays measured are incurred by packets traveling in the direction opposite to that of concern.

Delta Routing (or Hybrid Routing)—The delta routing algorithm consists of using both central and local decisions. Using information periodically sent to it by the nodes, the RCC computes the k best paths for each pair of nodes, where only paths that differ in the initial line are considered. The RCC then sends to each node all equivalent paths (i.e., those with cost or delay differing by less than some number δ) for each of its possible destinations. In routing a packet, the node may choose any of the equivalent paths either at random, or by choosing the line with the smallest current cost (or delay). By adjustment of k and δ, the scheme can be made more or less centralized. Transpac, the French public packet switching network, uses delta routing.

Distributed Algorithms—In this class of algorithms, the nodes exchange information about delays by sending control messages to one another. To keep the overhead low, this information is exchanged only among adjacent nodes. Each node communicates to its neighbors its estimate of the minimum delay to every other node of the network. When receiving such estimates from its neighbors, a node adds to them its own delay to reach each of the neighbors, and selects the best outgoing link for each destination. Information exchange may take place either periodically at regular intervals or asynchronously, such as when the estimates change by more than some amount. The old ARPANET routing algorithm was of this type.

Session Routing and Logical Circuit Routing—In the routing algorithms discussed above, the routing decision is made for different packets independently. In session routing, the route is chosen when a session is established. All packets in the session go on the same path. In logical circuit routing, the route is chosen by means of a route set-up packet when the virtual circuit is established. The route setup packet finds its way to the destination using any of the schemes described above. All packets belonging to a virtual circuit are then transmitted on the same route. Packets must only carry the virtual circuit number. Routing in the subnet is implemented as described in the subsection headed "The Network Services." Different logical circuits between the same pair of hosts may take different routes.

Broadcast Routing—Broadcast routing refers to those techniques by which to deliver a packet originating at some source to all possible destinations in the network. Of course, this can be accomplished by sending multiple copies of the same packet, one for each destination. However, more efficient techniques exist. In the *multidestination routing* scheme, a packet is issued with a list of destinations. At an intermediate node, a copy of the packet is sent out on an outgoing line if the latter is the best route for some destination (i.e., on the sink tree for that destination); the copy will then contain the list of destinations that are to use that line. After some number of hops, each copy will contain a single address and is treated as a normal packet. A more efficient technique makes use of the sink tree associated with the source of broadcast. Assuming knowledge of the spanning sink tree in both directions, each node will broadcast the packet on all links belonging to the spanning tree except the one on which it arrived. Normally, the spanning sink tree is known only in the direction toward the sink. In that case, an approximation of the above algorithm is as follows. Copies arriving at some node on a link belonging to the spanning sink tree are repeated on all links except the one on which they came. Copies arriving on all other links are discarded. This algorithm is called *reverse path forwarding*.

Congestion Control

Congestion in an uncontrolled network is inevitable due to the fact that all resources (line capacities, buffer space, and processing capability) are limited. It is also often due to the protocols in use, such as, for example, the need to retransmit packets that are in error, the need for sequencing, etc. Some types of congestion may be relieved by the routing element that, if made dynamic, would attempt to route traffic on underutilized paths. But unfortunately, routing is not sufficient to prevent congestion altogether; it merely helps reduce it or delay it. Other flow control procedures are needed to prevent congestion. Many of these functions are present in the network layer and thus are presented here. There are,

however, other flow control procedures that reside at other layers of the hierarchy of protocols. Fig. 17 illustrates the various levels at which flow control is exercised. As will be clear from the following discussion, flow control helps prevent loss of efficiency, deadlocks, and unfair allocation of the resources.

Hop-Level Flow Control—Channel-Queue-Limit Flow Control: The *direct store-and-forward deadlock* occurs in nonlossy networks when all buffers in some node A are destined to an adjacent node B and vice versa. Channel-queue-limit flow-control techniques are used to prevent such deadlocks. They consist of partitioning the buffers available at a node among the various outgoing channels. Complete partitioning is such a scheme that does not allow any sharing of buffer among the channels. Sharing with maximum queues, with minimum queues, or with maximum and minimum queues are variants. In addition to preventing deadlocks, these techniques achieve more efficient and fairer operation of the network by avoiding hogging.

Structured Buffer Pool Flow Control: Given that a channel-queue-limit flow control is implemented, thus preventing the direct store-and-forward deadlock, another type of deadlock, called the *indirect store-and-forward deadlock*, might still occur. Consider a closed chain of consecutively adjacent nodes N_0, $N_1, \ldots N_{n-1}, N_0$. Assume all buffers on the outgoing queue from N_i to N_{i-1} are occupied by packets destined to N_{i+2}, for $i = 0, 1, \ldots, n-1$ (addition on indices is modulo n). This situation clearly leads to a deadlock. A solution to this problem is given by the structured buffer pool technique. Packets arriving at an outgoing link queue are classified according to the number of hops they have already traveled. With N nodes in the network, the maximum number of hops is $N - 1$. The buffers available for that queue are allocated to the various classes (either in a fixed fashion or adjustable as needed). A packet of class k can use all buffers available to classes 1 through k. It has been shown that such a technique avoids completely cycles such as those described above that lead to the indirect S/F deadlock.

Hop-Level Flow Control With Virtual Circuits: The above techniques are used with both datagram and virtual circuit modes. In virtual circuit modes, it is also possible to exercise selective flow control on individual virtual circuit streams. An example consists of setting a maximum limit, M, on the number of packets for each VC in transit at each intermediate node. Limit M may be fixed or dynamically adjusted. This scheme is effective in slowing down VCs that directly feed into congested areas; by backpressure the control is exercised at the source, which in response reduces its input. In the absence of this control, congestion is bound to spread to other areas of the network and affects other sources originally not responsible for the congestion.

Entry-to-Exit Flow Control—This level of flow control is primarily aimed at preventing buffer congestion at the exit node that may be due to conditions of overload of local lines connecting the exit node to the host. If the exit node must reassemble the messages before handing them to the host, then the problem is further complicated by reassembly and resequence deadlocks. An example illustrating a reassembly buffer deadlock is shown in Fig. 18. In this figure, A_i, $i = 1, 2, 3, 4$ are packets belonging to the same message. Similarly, B_j, $j = 1, 2, 3, 4$ and C_k, $k = 1, 2, 3$ represent packets of two other messages. Node 3 is the exit node. It is currently assembling message $A_1A_2A_3A_4$. Packet A_2 is missing. The deadlock occurs because packet A_2 cannot make it through node 2, where the buffers are full. An example illustrating resequence deadlocks is given in Fig. 19. Here A, $B, \ldots, K$ are consecutive packets. The exit node (node 3) must deliver packets to host 1 in sequence. The deadlock takes place because node 3 cannot deliver any of its packets, and packet A cannot reach node 3 via node 2.

The most common solution to reassembly deadlocks is to reserve a reassembly buffer for each message entering the network. The solution to the sequence deadlock is simply to discard out-of-sequence messages at the destination. The ARPANET applies this technique. A logical pipe is assumed to exist for all messages from some host A to some host B. Each pipe is individually flow controlled by a window mechanism of size $W = 8$. Messages arriving out-of-range are discarded. A request for next message (RFNM) is issued by the destination node to the source node to permit the source node to issue the next message. Buffer allocation for message reassembly at the destination is

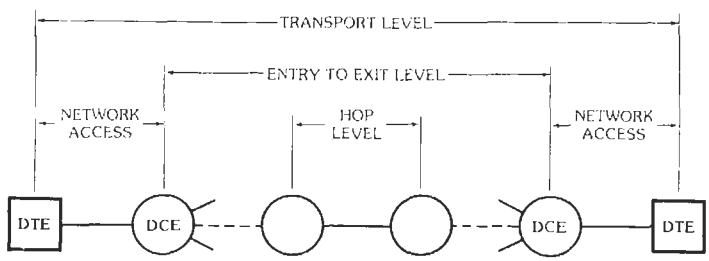

Fig. 17. Flow control levels. (*From Paul E. Green, Jr.*, Computer Network Architectures and Protocols, © *1982. Used by permission of Plenum Publishing Corp., New York.*)

guaranteed prior to message transmission by the source node. In GMDNET, a network based on virtual circuits, entry-to-exit flow control is exercised individually on each VC. A window mechanism is used for each VC with the window size large enough to attain efficient utilization. However, the window size is variable: it is reduced if the destination is slow in accepting packets; it is increased otherwise.

Network Access Flow Control—Network access flow control is aimed at throttling the external input to the network with a view toward preventing overall internal network congestion. This control is based on measurements of internal network congestion, where the measures collected may be local (e.g., buffer occupancy at the entry node), global (e.g., total number of empty buffers available in the network), or selective (e.g., some measure of congestion on the path leading to the destination). Three techniques are described hereafter.

The Isarithmic Scheme: This scheme consists of setting an upper limit on the number of packets that can circulate in the network at any one time. It is based on the concept of *permits*. A number of permits are present in the network. Each packet offered to the network must secure a permit at the entry node before being admitted. Once a permit is so secured, it remains in use until the corresponding packet is delivered to its destination and hence exits from the network. The permit becoming free is added to the pool of permits at the node where it is freed. This scheme as described functions adequately if the traffic pattern is uniform and balanced. Otherwise, one must avoid having a large number of permits accumulate in certain parts of the network at the expense of other parts. This is accomplished by setting limits on the number of permits at each node. The question of how to distribute the permits in the network then arises. The performance of the network under this scheme is sensitive to the permit distribution algorithm in use. A few such algorithms have been investigated analytically and by simulation.

The Input Buffer Limit Scheme: At each node, a distinction is made between (external) input traffic and transit traffic. The input is throttled based on buffer occupancy data at the entry node. This scheme rests on the observation that congestion at the entry node is a good indication of global congestion due to the back-pressure effect propagating internal network congestion back to the source nodes. Different versions exist. The structured buffer pool technique discussed previously falls into this category. Input traffic (which is in the 0-hop class) is discarded when all class-zero buffers are occupied. The number of class-zero buffers has been shown to have a great effect on the network performance under heavy load. Another version defines a limit, N_l, smaller than the total number of buffers, N, and new packets are limited to N_l while transit packets have no limitation imposed upon them. The performance here is sensitive to the ratio N_l/N. Another version yet consists of discarding an input packet if the total number of packets in the entry node exceeds a given threshold.

Choke Packet Scheme: In this scheme, a link is said to be congested if its utilization over some history window is beyond some threshold. A path is said to be congested if any of its links is congested. Along with routing information, congestion information is propagated in the network. When a packet is received by a node for some destination whose path is congested, then (1) if the packet is new external input, it is dropped; (2) otherwise, it is forwarded and a choke packet is sent back to the source, slowing the source. The path to the destination is unblocked gradually as no choke packets are received during a specified period of time.

CCITT Recommendation X.25

Recommendation X.25 is a widely accepted standard entitled "Interface Between a DTE and a DCE for Terminals Operating in the Packet Mode on Public Data Networks." It is a set of three peer protocols: a physical level, which is the same as in Recommendation X.21 (discussed in the section "The Physical Layer"); a link control level, which is essentially HDLC; and a network layer, which is discussed in the present subsection.

Recommendation X.25 is based on the concept of virtual circuits. These virtual circuits can be either temporary or permanent. A temporary virtual circuit referred to as a virtual call requires three phases: setting up the call, the data-transfer phase, and disconnecting the call. In setting up a virtual call, a logical channel number is assigned to the call. With a permanent virtual call, the numbers are assigned when the customer leases the facility from the common carrier. In such a case, the two phases of setting up and disconnecting the circuit do not exist.

It is important to note that Recommendation X.25 describes only the DTE/DCE interface. It is not concerned about how the network operates and how virtual circuits within the network are implemented. Recommendation X.25 defines the services rendered to the transport layer of the ISO model that resides in the user's equipment. Thus X.25 is known as a network access protocol standard. In many cases, the DTE is a terminal that handles characters rather than packets and that uses the start-stop asynchronous DLC protocol. In such cases, common carriers operating X.25 networks provide interface machines to which these terminals are connected. These interface machines, called PAD (Packet Assembly/Disassembly), are extensions to X.25 but not part of it.

The network layer of X.25 defines explicitly the formats of packets and the operational phases of a virtual circuit connection. Two types of packets exist: data packets and control packets. A data packet has a variable-length information field to carry user data. A control packet can be of different types, many of which are discussed below.

When a DTE sets up a virtual call, it selects a free logical channel number from the set allocated to it. Such a number consists of two parts: a logical channel group number and a logical channel number. A DTE has available to it up to 15 logical channel groups (addressed with 4 bits) and up to 255 logical channels within each group (addressed with 8 bits). Using a CALL REQUEST packet, the DTE sends the selected logical number along with its own address, the address of the destination, and other facility codes to the DCE to which it is attached. (For efficiency purposes, the CALL REQUEST packet may also carry user data up to 16 bytes.) The request to establish a connection arrives at the remote DTE from its attached DCE as an INCOMING CALL packet. The called DTE decides whether to accept or refuse the call. If it accepts it, then a CALL ACCEPTED packet is sent back to the DCE. The indication of acceptance of the call is achieved via a CALL CONNECTED packet, which is sent by the local DCE to its calling DTE. The disconnection of a call follows similar procedures. It uses the control packets CLEAR REQUEST, CLEAR CONFIRMATION, and CLEAR INDICATION. Once a connection is established, the flow of data packets can take place. Data packets are sequenced, and the flow is regulated according to a window mechanism as described in the section "The Data Link Control Layer." As with ADCCP and HDLC, the two sequence ranges of 8 and 128 are available. The control packets RECEIVE READY and RECEIVE NOT READY, similar to those described for ADCCP and HDLC, are used in a supervisory mode to acknowledge data packets. Other packets such as INTERRUPT, RESET, RESTART, and their confirmations are used for further control and to recover from certain minor and major problems. The INTERRUPT packet contains only one byte of user data and has no sequence number. It is transmitted as quickly as possible, preempting the queues of normal data packets. It is delivered (out of sequence) even when data packets are not being accepted. It is normally used to convey the fact that a terminal user has hit the break key to stop a flow of data from a distant computer. An INTERRUPT packet is acknowledged by the local DCE with an INTERRUPT CONFIRMATION packet. The RESET commands are used to reinitialize the window parameters corresponding to a particular virtual circuit to zero. Both DTEs and DCEs can initiate a reset. Reset packets contain up to two bytes of data explaining the reasons for the reset. These may be: the remote DTE is out of order, the network is congested or one of its nodes had failed, etc. Following a reset, the DTE has no knowledge about the status of outstanding (unacknowledged) packets. Recovery must be accomplished by higher levels. The *restart* condition provides a mechanism to recover from major failures. It has the effect of clearing all the virtual calls that a DTE has connected and resetting the permanent virtual calls, bringing the user/network interface to the state it was in when the service was initiated.

Since X.25 is an interface between a DTE and the local DCE to which it is attached, the receipt of an acknowledgement by a DTE from the DCE means that the latter has received the packet, but does not imply that the remote DTE has received it. To provide some level of end-to-end acknowledgement, a bit called the delivery confirmation bit, or *D*-bit, has been provided in the packet format. The DTE sets *D* to 1 to request confirmation of delivery to the remote DTE. An acknowledgement for this packet by the DCE would then have to be a guarantee of its delivery to the remote DTE.

In addition to the standard features of X.25, there are also some optional features that may be requested by a user when a call is set up. Examples are: reverse charging, closed user group (where members of a closed group can communicate only with one another), packet retransmission (where a DTE can ask its DCE to retransmit one or several data packets, and this is

accomplished by the use of the REJECT command as in ADCCP), etc.

HIGHER-LEVEL PROTOCOLS

This section is concerned with layers four through seven of the ISO model. The brevity of this section is due to three factors: (1) many of the concepts and techniques needed at these higher levels, such as sequencing, acknowledging, and flow control, are similar to those used in lower layers and have already been described and discussed in previous sections; (2) many of the functions residing at these layers have not yet been well defined, and there are no internationally accepted standards yet; and (3) some of the functions (especially concerning the presentation and application layers) are not strictly speaking communication functions, and thus are considered out of the scope of this chapter.

The Transport and Session Layers

Internally to a host computer, application programs are represented by processes. Communication between such processes across a network is accomplished by means of "reliable connections" called *sessions* between specific pairs of processes, and it is the role of the session layer to establish and maintain such connections. It is possible to imagine that each such connection is achieved as a virtual circuit that the network layer provides. In that case, the session layer is trivial, the transport layer is nonexistent, and most of the work is done by the network layer. However, there are many problems with that design. The first problem arises when the network layer provides only a datagram service; the session layer will then have to be constructed appropriately so as to overcome the deficiencies of the network. In such a design, the session layer will also have to interface to the networks differently, depending on their type. It will have to be concerned with managing the buffers at the host where the processes reside, guaranteeing end-to-end reliability between the end hosts (which the network does not guarantee even when it is providing the virtual circuit service, since crashes, resets, and restarts can occur), and controlling the flow. As the protocols for many of these functions again differ depending on the network, it is best to render the session layer independent from network issues by the introduction of the transport layer. Thus, while the transport layer provides truly reliable host-to-host communication, the session layer connects two processes together in a session without worrying about any of the implementation details of the actual network. It merely requests from the transport layer its services. The functions of a session layer are thus considerably reduced. At session setup time, it establishes the conventions necessary for the connection, conventions relating to the data-transfer mode (half-duplex versus full-duplex), the character codes, the flow control window sizes, how to recover from failures at the transport layer, etc. It also allows processes to refer to destinations using symbolic names by doing itself the mapping onto transport addresses.

The transport layer within a host defines a set of *transport addresses* or *sockets* through which connections are established. A transport address consists of a *network* number, a *host* number, and a *port* number assigned by the host. A CCITT numbering plan exists which uses 14-digit numbers. The first three identify the country; the fourth identifies the network within the country; the last ten digits are assigned by each network operator, some to indicate hosts, the remaining ones to indicate ports. There is a distinct difference between a transport address and a network layer address (which defines a virtual circuit), and the mapping need not be one-to-one. The transport layer uses network addresses to create transport connections. If the mapping is not one-to-one, then *multiplexing* is said to be in effect. In *upward multiplexing*, several transport connections are multiplexed onto the same network virtual circuit connection. In *downward multiplexing*, a single transport connection uses several virtual circuits. The choice of one type of multiplexing or the other is a function of the charging procedure used in the public network, the traffic volume exercised by a transport connection, and the window size of virtual circuits within the network.

The transport layer functions to establish and close connections as well as to control the flow across each connection. The techniques are similar to those described for lower levels. However, due to the ultimate end-to-end reliability that is to be guaranteed, several problems need to be solved. First of all, it is important to guarantee that old packets that for some reason have been delayed in the subnet but whose sequence numbers fall within the current receive window of the destination are not delivered to the destination. This is done by limiting the amount of time that a packet can exist in the network and by using a sequence space so large (e.g., 32 bits) that no packet can live for a complete cycle. For this method to be successful, however, it is important to have each connection initialize its sequence numbers to a value higher than the previous end sequence number by some margin so as to guarantee it is higher than any existing packet number. The second problem to deal with is to guarantee synchronization between the source host and destination host with regard to their respective initial sequence numbers. The solution to this problem is the *three-way handshake* mechanism. It consists of the following. The sender sends a CALL REQUEST packet with initial sequence number S. The destination responds with a CALL ACCEPTED with a sequence number A along with the source sequence number, S. Upon receipt of this packet, the source sends a packet with S and A. Thus, only when source and destination have confirmation of the combined sequence numbers would they consider the connection to have been established. The control of flow over a connection between source and destination is achieved by using a window mechanism similar to that of lower levels. The

window sizes must be chosen appropriately. To be effective, it is important in some cases to distinguish acknowledgements from the destination confirming correct reception of packets from so-called *credits*, which are sent by the destination to inform the sender that receive buffers are available. Acknowledgement of a packet allows the sender to free its own buffer, while receipt of a credit allows the sender to advance its send window.

The Presentation Layer

The presentation layer performs transformation on the data generated by or destined to application programs before they are sent to or after they arrive from the session layer, respectively. The objectives and nature of such transformations are diverse. In order to save on communication bandwidth, the presentation layer compresses text and reduces the amount to be transmitted across the network. In order to guarantee the security of data, the presentation layer encrypts it at the source and decrypts at the destination. Many compression and encryption techniques are available. They are out of the scope of this chapter, and thus are not described here.

Another objective of the presentation layer is to resolve the differences that exist among the various equipments connected to the network. Advances of this nature have been made in two areas: (1) resolving the differences that exist among the various types of terminals in the networks leading to the so-called *virtual-terminal protocols*, and (2) resolving the differences that exist among the various hosts so that files stored in one host can be transferred to another host. This has led to the so-called *file transfer protocols*.

Terminals are basically of three types: *scroll-mode* terminals, which have no intelligence and generally use the start-stop protocol; *page-mode* terminals, which handle about 25 lines of 80 characters each at a time and have some local editing capabilities; and *form-mode* terminals, which are micro-based, have more intelligence, and handle specific forms that the operator fills out using local editing facilities. Besides the differences that exist among the different types of terminals, many differences exist within each class with regard to such attributes as the character set, line length, carriage-return and tab rules, cursor addressing, blinking, local editing capabilities, etc. Virtual-terminal protocols attempt to hide the differences by mapping real terminals onto a hypothetical network virtual terminal. For *scroll-mode* terminals, such a conversion is straightforward. Each time a new version of such a terminal type is to be supported, the corresponding conversion rules are added to the presentation layer at the host computer. For the more sophisticated types, a *data structure model* has proven useful and effective. Each end of the session has a data structure representing the state of the virtual terminal. Every time the application program changes the data structure on its machine, the presentation layer sends a message to the remote machine telling it how to change its data structure, and vice versa.

While the terminal conversion problem has been adequately solved, file transfer has proven to be much more difficult, and no general solutions exist. In particular, the concept of a network standard file format is not attractive due to the great difficulties involved in converting a file from one machine format to another. There are, however, several ad hoc file-transfer protocols particular to specific networks, e.g., ARPANET's FTP (reference 2).

HIGH SPEED LOCAL AREA NETWORKS

The advances in technology and the pull of new, more demanding user applications are stimulating the development of *Local Area Networks (LANs)* at speeds much higher than those available just a few years ago. High speed LANs in the 100 Mbps range are now commercially available, and prototypes operating at speeds of 1 Gbps are being tested. In this section, we trace the evolution of the LAN technology from low to high speed, identify the technology push and the market pull, survey the novel high speed LAN products that are now coming to market, and examine some of the most recent LAN proposals and prototypes designed to operate at speeds beyond the Gbps range.

The first LAN products were introduced in the late '70s in offices, campuses, and production plants in order to interconnect with each other and to a growing number of terminals, workstations, and peripherals. Typical applications were word processing, interactive computing, data-base queries, and file transfers—a predominantly data-oriented environment with peak data transfer speeds on any user session well below 1 Mbps. Thus, LAN speeds from 1 to 10 Mbps were adequate for these applications.

In the mid '80s, the original LAN environment underwent an important series of transformations which forced LAN designers to look ahead for new network technologies. First, the proliferation of LANs on campuses and industrial plants led to the need to interconnect them—via other LANs capable of carrying aggregate traffic several orders of magnitude higher than the traffic found in an individual LAN. Thus, speeds of up to 100 Mbps and geographical coverage of several miles are now required. In addition to the data applications, new applications and services start now to emerge: voice, video, imaging. For example, in an office we desire to combine the telephone and the data terminal in the same multimedia workstation, and to carry both voice and data on the same cable. In a campus environment, we wish to distribute video lectures and to support video conferencing. In a hospital, we wish to permit the radiologist to retrieve X rays from an image data base.

New high-speed LAN requirements emerge also in supercomputer labs. An important application here is "scientific visualization," i.e., the ability to visualize,

through a high-definition graphics screen, a physical phenomenon (e.g. the fluid dynamic turbulence of a jet engine) which is simulated in the supercomputer. Currently, most of the visualization set-ups are supported by high-speed dedicated point-to-point connections between the supercomputer and the graphics workstation. Data rates of up to 100 Mbps are observed on such connections. Specialized, high-speed "supercomputer" LANs are now proposed to reduce the cost and increase the flexibility of such interconnections, by sharing a common network. Many other applications besides visualization will benefit from the supercomputer LAN; examples are memory-to-memory transfers, distributed processing and load sharing among supercomputers, etc.

Advances in light-wave technology have greatly influenced the development of high-speed LANs. Performance and cost are the principal advantages of light-wave technology, as compared to copper-based or radio-frequency technologies. The improvement in light-wave technology has been rapid and steady in the areas of optical fibers, light sources, light detectors, couplers, amplifiers, connectors, switches, and signal processors. Advanced research in other areas of light-wave technology—such as coherent processing, WDM, and photonic switching—is also yielding new results that can be exploited in constructing even higher-performance and more-cost-effective networks.

Whereas today's high-speed LANs are based on simple light-wave technology, the LANs of the future will rely on more advanced light-wave principles to achieve higher performance and increased functionality. High-speed LANs such as FDDI and DQDB employ direct-detection, LED-based transmission over multimode optical fibers, which can easily accommodate data rates in the range of about 100 Mbps. Using LDs to transmit over single-mode optical fibers, higher-speed networks can reach speeds in the range of about 1 Gbps. Research proposals for future LANs and MANs are often postulated on the emergence of WDM, which would allow the easy implementation of multichannel networks. Such proposals therefore depend on the successful development of the coherent techniques that multichannel transmission requires, especially in the areas of modulation, heterodyne and homodyne detection, and the tunability of lasers and detectors. More advanced research proposals might even assume that all-optical transmission is to be used, in which optical signals are switched by purely photonic means, thereby eliminating undesirable electro-optical conversions within the network. Such advanced proposals thus rely on technological progress in areas such as photonic switching and passive optical amplification.

Furthermore, current LANs based on light-wave technology use simple topologies to distribute optical signals essentially in a point-to-point manner. These LANs regenerate the optical signal by means of electro-optical conversions at every network interface, which eases considerably the difficulty of meeting the link budget. Link distances are usually constrained to only a few kilometers, and network interfaces are typically connected to or isolated from the optical fiber through an optical bypass switch. However, such simple point-to-point topologies limit the designer's flexibility and make the implementation of multichannel networks problematic. By making effective use of optical couplers and broadband optical amplifiers, one can design LANs and MANs with nonpoint-to-point topologies, e.g. trees and stars. Tree-Net, for instance, can be used as a physical tree topology for distributing optical signals to a large number of users over a wide geographical area, using only passive optical couplers and optical amplification at the root of the tree. The commercialization of a broadband optical amplifier would be necessary before tree-like multichannel networks become a reality. All-optical networks could be constructed as arbitrary mesh-connected topologies using linear combiners/dividers or wavelength-selective switches. These devices are not currently available, but active research into their design is under way.

Technological progress in light-wave transmission must be accompanied by progress in digital electronics. High-speed data transmission relies on fast electronics that can provide serial data to a transmitter at network rates. The speed of digital electronic circuits must therefore grow as rapidly as the speed of light-wave transmission systems. Given that the bandwidth of a single-mode optical fiber is in the Tbps range, it is clear that WDM must be used to allow a serial electronic interface to tap into this enormous bandwidth. In order to transmit at Gbps speeds, electronic transceivers must be clocked at GHz rates, which suggests the use of high-performance integrated circuitry such as GaAs or ECL. Since the processing of data-link-layer protocols is normally hardware-assisted in high-speed LANs, it is essential to implement state machines as integrated circuits that can keep up with the transmission system. Some LANs, such as HPPI, employ complex, large switching fabrics to operate at very high speeds, which also implies the need for technological advances in integrated-circuit technology.

A Taxonomy of Local Area Networks

In the past LANs have been classified according to several different criteria (topology, access protocol, transmission medium, etc). For the purposes of this section, which is focused on high-speed LANs, the most appropriate criterion for classification is data rate. Thus, we define the following four classes:

(1) Low- and Medium-Speed LANs: Data rate up to 10 to 20 Mbps. This class includes the great majority of conventional LANs (Ethernet, Token ring, etc.), as well as the recently introduced wireless LANs.
(2) High-Speed LANs: Data rates ranging from 50 to 150 Mbps. Typical entries are FDDI and DQDB. The most common medium is the fiber.

(3) Supercomputer LANs: Data rate in the order of 800 Mbps. Typical entries are UltraNet and Nectar. Due to the limited geographical range, the most common transmission medium is the cable (32 or 64 parallel connections).
(4) Ultragigabit LANs: Data rates well above the Gbps range. Although no commercial offerings exist in this area, several experimental prototypes are being developed (e.g., ATT Multihop Network). The medium is the single-mode fiber. The technology of choice is Wavelength Division Multiplexing (WDM).

Low- and Medium-Speed LANs

The appearance of Ethernet in the late 70s marks the birth of first generation LANs. Within the next few years, the Token ring and Token bus LAN architectures also become well established, and are all eventually standardized by the IEEE 802 committee.† These first generation LANs have comparable characteristics in terms of speed (around 5–10 Mbps), geographical range (around 1000 feet), and station connectivity (a few dozen). They offer, however, markedly differently features so as to gain a competitive advantage in different applications. For example, Ethernet prevails in office and campus environments because of its low cost, good fault tolerance, and easy maintenance. Token ring and Token bus offer guaranteed delay and therefore better real-time traffic support. In particular, the Token bus was chosen as the MAC layer for MAP (Manufacturing Automation Protocol) because of its suitability for carrying the real-time control messages common in manufacturing plants.

A detailed survey of first generation protocols is clearly beyond the scope of this section; the interested reader can consult the excellent survey by Tobagi in reference 5. Rather, we would like to comment on the ability to scale up the speed of these LANs by one or two orders of magnitude, from 10 Mbps to the 100–1000 Mbps range. At the same time, we explore the possibility of stretching the geographical coverage from the 1-km range to the 10-km range. These speed and range upgrades are of interest because of the broadening of LAN applications in the early 80s.

If we denote by τ the end-to-end propagation delay on the bus and by P the frame transmission time, we find that Ethernet performance degrades dramatically when the ratio $a = \tau/P$ becomes 1. For channel speed = 100 Mbps, bus length = 10 miles, and frame length = 1000 bits, channel utilization becomes 0.03. The reason for this dramatic drop is that it takes more time (on the order of τ) to ensure that the transmission will not suffer a collision than to transmit the frame itself (P seconds).

The Token bus does not fare much better. The time to pass the token from one station to the next in the polling sequence can be as large as τ plus the token processing time. Assuming that a station transmits a single frame per token visit, the channel utilization is given by the following expression:

$$\text{Token bus utilization} \leq P/(P + \tau) = 1/(1 + \tau/P)$$

Thus, again, utilization decreases as the product of bandwidth times length ($B \times L$) increases.

In contrast with Ethernet and Token bus, the Token ring does not have any intrinsic limitations imposed by the hardware. In principle, the ring can be maintained fully utilized even at very high $B \times L$ products if stations attach their frames to the token one after the other forming a "train." The higher $B \times L$, the larger is the number of frames simultaneously outstanding on the ring. However, the IEEE 802.5 standard implementation requires that only one station be allowed to maintain one (or more) frames outstanding on the ring at any one time.† This requirement is dictated by the particular implementation of priorities in IEEE 802.5. Namely, stations announce their priority in the header of a passing frame. Thus, the station currently holding the token must wait for the header of its frame(s) to come back before it can reissue the token at the highest announced priority. Assuming that each station transmits one single frame per token acquisition, and letting τ' be the ring latency (propagation + shift register delay), the maximum ring utilization is $\leq 1/(1 + \tau'/P)$. Again, we find that performance degrades as $B \times L$ increases.

The interested reader can verify that in general first generation LA architectures do not scale well with speed and distance.§ This is not to say that such LANs are obsolete; they are simply designed to satisfy requirements of the 10-Mbps, 1000-feet type.

High-Speed LANs

In the early '80s, two separate developments contributed to the start of a new generation of LANs (and MANs): the rapid advancement of fiber-optic technology, and the emergence of very-high-speed local and metropolitan applications. In the former area were the fabrication of low-cost, low-attenuation fibers and of high quality optical transmitters, detectors, and passive components. In the latter area came the proliferation of private LANs and the need to interconnect them across metropolitan regions through a high-speed backbone. We must thus introduce a new version of "stretched" LAN, called the Metropolitan Area Network (MAN), which shares many common characteristics with the LAN, and therefore will be covered along with the LANs in this survey.

We also note growing interest in videoconferencing

† Reference 2.

† Reference 2.
§ Reference 5.

and in the integration of voice, data, and video communications in a single network. The integration is motivated both by the desire to reduce network cost (by sharing facilities) and by the need to support new applications (e.g., multimedia communications).

To satisfy these requirements, a new family of LANs is required, with data rates in the order of 100 Mbps and above, with geographical coverage on the order of 10 km, and with the ability to support a large number of stations (in the hundreds). Also, good fault recovery properties are required, since metropolitan networks span areas outside of the customer and network operator control, and are therefore more vulnerable to link failures.

The most natural way to meet the new challenge is to start from first generation LAN architectures, replacing the cable with fiber and modifying the protocols so as to remove the $B \times L$ limitations observed in previous schemes. This is exactly what happens in the case of the ring.

Rings—FDDI (Fiber Distributed Data Interface) is a 100 Mbps, multimode fiber ring which implements a "multitoken" protocol (i.e. several stations can simultaneously maintain outstanding frames on the ring). See Fig. 20. The multitoken variant removes the inefficiencies of the 802.5 token ring protocol and makes it possible to operate the ring at high speed over large distances (up to 200 km). Priorities can, of course, no longer be handled with header reservations. Thus, new priority mechanisms based on maximum token rotation time are implemented. Fault tolerance to link failures is achieved by using a double-counter rotating ring topology. Isochronous traffic support is provided by a variant of FDDI (called FDDI-II). In FDDI-II the ring is slotted. Each slot corresponds to a channel that can be reserved by isochronous traffic. The asynchronous traffic is still managed by the token protocol through the use of unreserved slots.

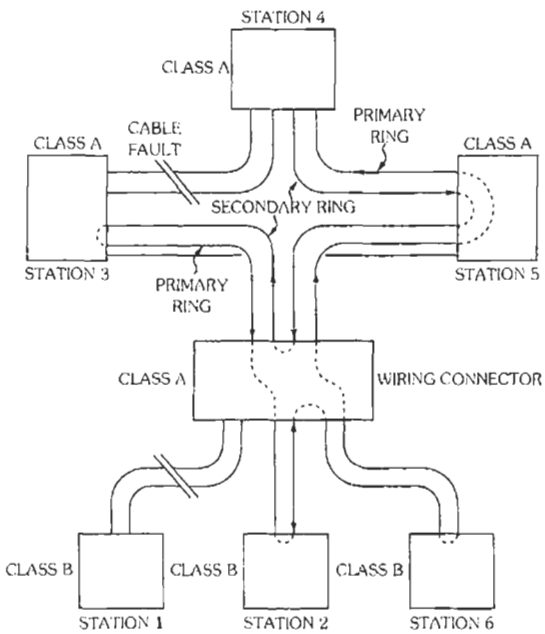

Fig. 20. FDDI topology.

In FDDI and FDDI-II, each frame is removed by the origin, after a full rotation around the ring. Efficiency can be improved (by as much as 4 times on average) if the destination removes the frame, thus allowing spatial reuse of portions of the ring. A recently proposed buffer insertion ring, the Meta Ring, does in fact offer destination removal and spatial reuse, upgrading the FDDI speed to 800 Mbps (using a 2-counter rotating ring).

Linear Buses—The linear bus topology was also investigated for possible fiber-optic upgrade. It was found that the fiber bus cannot be used effectively in a bidirectional mode (such as in Ethernet), because of the optical coupler implementation. Thus, two candidate configurations emerged: twin parallel unidirectional buses, and a single, unidirectional folded bus.‡ Since CSMA-CD and token bus protocols do not scale up to high speeds, a new access protocol, called "implicit" token (or "ordered access") was introduced. Basically, the implicit token is a burst of carrier issued by a designated end station. Backlogged stations append their frames in sequence after the token, forming a train. Upon completion of a cycle, the end station starts the next cycle. Good efficiency at high $B \times L$ speeds is achieved by virtue of the fact that no time is wasted in passing the token from one station to the next (in contrast to what was happening in IEEE 802.4). In fact, stations are automatically "polled" in sequence, based on their position on the bus. Furthermore, no token processing is required. One drawback of linear fiber buses, however, is fiber and coupler attenuation. This problem is corrected by regenerating and amplifying the signal at each interface. Fault tolerance to link failures is achieved by coiling the topology in a pseudo loop. Real-time (isochronous) traffic is carried in reserved slots, or in alternating cycles. A large number of implicit token fiber-bus architectures were proposed and implemented in the '80s. Among them were Express-Net, U-Net, and FasNet.‡

An alternative approach to multiple access in linear buses is reservation. This scheme differs drastically from the implicit token approach in that stations are given the opportunity to place reservations in a separate logical channel (implemented by using special fields in the data packet headers, or dedicated portions of a cycle). Thus, the order of packet transmissions is first come first served, as opposed to the round robin order in token schemes.

The best known implementation of a reservation strategy is DQDB (Distributed Queue Dual Bus), a 150-Mbps twin bus in which each station records and

‡ Reference 6.

maintains the reservations in a local queue. In ideal situations, all local queues are perfectly consistent with each other, thus yielding an exact FCFS schedule. The strong points of DQDB are simplicity and extreme efficiency of the distributed reservation mechanism. Reservations are piggybacked on data packets, thus avoiding cycle latency and providing channel efficiency close to unity for a single sending station. As in previous protocol proposals, the bus is slotted to provide isochronous traffic support. The bus is installed as a pseudoloop topology to permit recovery from single link failures (Fig. 21). DQDB has encountered rapid and broad acceptance, and has been chosen as the MAN standard by the IEEE 802.6 committee.

Trees—During the '80s, new LAN and MAN topologies such as the tree and the mesh also emerged. Trees are particularly desirable for the efficient coverage of metropolitan areas. A well known fiber-optics tree architecture is Hubnet. Hubnet implements a random-access protocol with capture (i.e., if there is a collision, one of the contendents prevails and captures the channel). Contention resolution is implemented at the nodes (which, therefore, include an active processing element).

Another tree architecture with random access and capture is CAMB (Collision Avoidance Multiple Broadcast). In CAMB, tree nodes have the ability to route frames on-the-fly within subtrees (instead of sending all frames to the root of the tree as in Hubnet). Subtree routing yields spatial reuse, and therefore better overall throughput, at the cost of additional processing in the nodes.

A general limitation of the above tree architectures is the inability to guarantee delays and, therefore, to support real-time traffic. It will be shown later that this limitation can be overcome by using tree topologies with passive nodes and token or reservation access schemes.

Grids—Spatial reuse is also the driving force behind mesh architectures. The best known mesh architecture is MSN (Manhattan Street Network), organized as a square grid. To avoid store and forward buffering and therefore improve efficiency at high speeds, a very simple routing scheme, deflection routing, is implemented at the nodes (i.e., grid crosspoints). Recall that in a grid each node has exactly two inputs and two outputs, and consider the case of both inputs competing for the same output. One packet is sent to the correct output. The other, instead of being buffered, is sent to the "wrong" output, and is thus forced to take a "round-the-block" detour. This feature, albeit somewhat wasteful in terms of delivered throughput, makes it possible to avoid nodal buffering, thus speeding up the operation. The positive aspects of MSN are the good metropolitan coverage, the simplicity of protocols and nodal implementations, and the potentially unlimited throughput offered by a topology with multiple concurrently available paths. In this sense, MSN is a major step forward with respect to more traditional LAN and MAN architectures, where a single broadcast channel (bus, tree, or ring) inevitably becomes the bottleneck. The drawback of the mesh topology, however, is the inability to provide efficient broadcast and isochronous traffic support, properties in which the bus, tree, and ring topologies excel. It will be seen later how the path concurrency of MSN and the broadcast and isochronous support features of more conventional MANs can be combined in a single architecture, the WON (Wavelength division Optical Network).

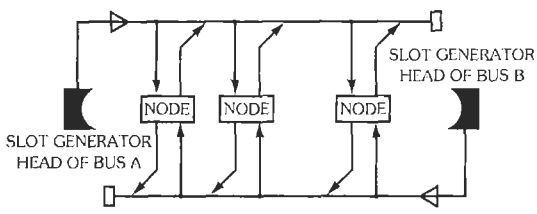

Fig. 21. DQDB topology.

Supercomputer Networks

Another important development in the area of high-speed local and campus-wide networking is the emergence of the networks especially designed to connect supercomputers, massive storage devices, frame buffers, and high-end graphics workstations. Typical applications are scientific visualization, load sharing among supercomputers, and, more generally, distribution of tasks among supercomputers and workstations. Very high data rates (in the order of Gbps) are required to support real-time applications and an interactive mode. A high-speed interface for such "supercomputer" networks has been proposed, namely HPPI (previously known as High Speed Channel), and is evaluated by an ANSI committee. We will mention two network architectures which have been developed to interface with HPPI and to satisfy the above needs. One is Ultranet, basically a datagram network, consisting of high performance ultrabus switches interconnected by intelligent, high throughput bridges. In contrast, the CP* network, developed by the Los Alamos National Laboratory, is a fast circuit switched network. It features crossbar switches and basically sets up a circuit for each message exchanged across the network. Both Ultranet and CP* operate at near Gbps speed. They have been designed for a specific application and therefore cannot be easily extended to satisfy the general requirements of a metropolitan network. On the other hand, a challenging question for network designers is whether the future LAN and MAN architectures will be sufficiently powerful and flexible to satisfy HPPI users.

Ultragigabit Networks

Many of the above architectures have been successfully demonstrated at speeds ranging between 100 and 200 Mbps, and some have been pushed up to Gbps speeds. These speeds are quite adequate for introductory LAN and MAN solutions. Traffic projections for the mid '90s, however, show that a single MAN will be required to carry simultaneously a large number of very high speed connections (e.g., scientific visualization, high-quality videoconferencing, multimedia communication, etc.) along with the support of a large population of more conventional users. The statistical aggregation of these traffic components in a large metropolitan area will probably require an overall network capacity in the order of hundreds of Gbps. Clearly, current LANs and MANs cannot deliver such performance. First, the presence of active processing elements along the network path poses a limitation on speed. In fact, intermediate station interfaces along the DQDB bus or the FDDI ring must process in real time, at line speed (as part of the access protocol) some of the incoming information (as opposed to buffering it and processing it later). For example, in DBDQ the Busy and Reservation bits must be read and set "on the fly" in the packet headers. Likewise in FDDI, the header of a packet must be inspected at channel speed while it transits through the shift register at each interface.

Another limitation common to most of the above architectures stems from the fact that loops and rings cannot be easily (and effectively) configured to cover a distributed metropolitan area. The common solution is to resort to a multilayer architecture with a backbone loop at the top of the hierarchy and several layers of distribution loops. The weak point of the multilayer configuration, however, is the bridge that connects the layers. The bridge is basically a store-and-forward processor which buffers packets, inspects the headers, and performs some simple flow control and traffic filtering functions. But, simple as these functions may be, they still pose a practical limit on the throughput that can be handled by a bridge, probably in the order of 100K packets/second (state of the art bridges today can forward at most 20K packets/second). Furthermore, it will be difficult to satisfy the tight delay constraints of voice and video connections across several bridges.

Manhattan Street Networks can potentially yield the desired throughput (by exploiting parallelism, spacial reuse, and locality) and can provide efficient metropolitan coverage. However, they cannot efficiently support broadcast and real time services. Also, they require fairly sophisticated controls in order to avoid unfairness and congestion.

Finally, none of the above architectures are well suited to exploiting WDM (Wavelength Division Multiplexing). WDM makes it possible to maintain multiple channels in a fiber and can, in principle, expand the effective data rate of a single fiber from the Gbps to the Tbps range. In order to implement WDM, an FDDI or DQDB network requires a splitter, a filter, and a combiner at each interface, plus a wideband amplifier to make up for the power loss—a very expensive proposition!

The above considerations suggest that in order to achieve ultragigabit speeds, the network must be totally "transparent" to WDM, and thus must avoid any processing components (e.g., shift registers, busy-bit manipulators, bridges, etc.) along the communications path between source and destination. This has led to the development of a new generation of LANs and MANs, based on passive optical components and WDM techniques.

The key components of a wavelength division optical network are:

- Passive optical network, including couplers, splitters, combiners, and optical amplifiers. Electrically controllable couplers and switches are also required for some proposed architectures.
- Wavelength division gear, namely: tunable lasers, detectors (conventional and coherent), and filters. For some architectures, wavelength switches are also required.
- Network management, to control wavelength allocation and dynamically reconfigure the virtual topologies according to traffic patterns and user demands.

Several wavelength division proposals and prototypes have been reported in the literature. The most common architecture consists of a passive optic broadcast medium (star, tree, bus)—the so-called "mass of glass"—on which several wavelengths (a few dozen with conventional, coarse WDM; thousands with coherent, dense WDM) can be multiplexed. The multiplexing and switching are done at the perifery of the "mass of glass." Indeed, the main challenge is how to use this abundance of bandwidth efficiently (i.e., channel access control).

Two main approaches have been proposed. The first approach is the time/frequency division approach. A global, time-slotted reference frame is defined (as on a satellite multiple access channel). A source/destination pair must reserve in advance a slot in the frame for the transmission of each packet and must agree on the frequency (i.e., wavelength) to be used. This system can achieve high efficiency, but it involves high overhead for source/destination coordination and high cost (and technology risk) due to the quickly retunable transmitters and receivers.

The second approach assigns a limited number of fixed wavelengths to each user station (say two for transmission and two for reception). By means of these wavelengths, users can interconnect with each other with a "virtual" topology (as opposed to the "physical" topology—e.g., a star or a tree—corresponding to the fiber layout). Fig. 22 shows a virtual topology, in this case a "perfect shuffle" topology, mapped on a

physical tree. Transmissions between arbitrary source/destination pairs are accomplished via "multihop" (i.e., store and forward) through the user stations. The main advantages of the multihop solution are lower transmitter and receiver costs at each station and lower control overhead. On the negative side, however, broadcast, multicast, and real-time traffic support is not very efficient. In view of these limitations, hybrid solutions combining the benefits of the two approaches are now under investigation.

In contrast to the broadcast, fully transparent, mass-of-glass topology, other approaches propose the use of mesh type topologies and wavelength sensitive optical switches. Light paths can then be established in the same manner as connections in a conventional circuit switched network. An attractive feature of these networks is the spacial wavelength reuse.

HIGH SPEED WIDE AREA NETWORKS

Progress in fiber optics and high-speed switching technology and increasing user demands have recently stimulated the research and development of *Broadband Integrated Services Digital Networks (B-ISDNs)*. B-ISDNs will carry several services (data, voice, video graphics, etc.) on very high speed fiber optics link with user interfaces and interswitch trunks operating a 150 Mbps speeds.

For the implementation of B-ISDN, CCITT ha targeted Asynchronous Transfer Mode (ATM) as th switching and multiplexing technology of choice. ATM networks use fixed-size data units called *cell* which are routed independently according to thei destination address in a connection oriented environment. The advantage of using ATM resides in it flexibility in accommodating the variety of new an existing services requirements, and in the statistica gain obtained by multiplexing bursty sources.

ATM networks pose many research challenges rang ing from the design of fast packet switching fabrics t the development of capacity planning tools. This i because, with the decreasing cost of fiber trunks, an the higher data rates required by the users, the networ bottleneck has shifted from the communications chan nels to the switches. Consequently, while conventiona packet networks were designed to minimize link costs ATM networks are designed with the notion that th switch is the most expensive resource.

---

* Reference 7.

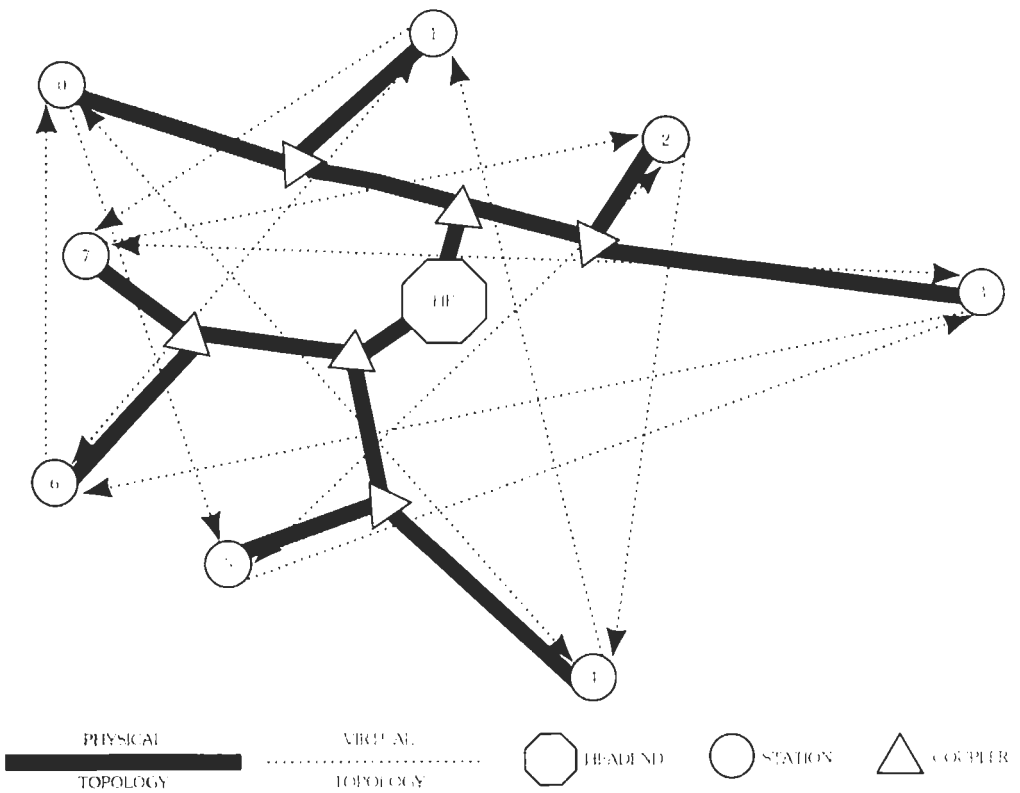

Fig. 22. Optical network (WDM) topology.

In order to enable the fast packet switch to process millions of packets per second, the internal network protocols have been drastically streamlined. In particular, almost all flow control features have been dropped from the link and packet level. The lack of internal flow control mechanisms combined with the inadequacy of buffers to handle sustained overloads at such high speeds and the strict response time requirements of voice and video traffic make the problem of flow control, congestion protection, and traffic management of B-ISDNs a formidable one.

In this section, we focus on two aspects of the ATM network which make its design and operation unique, namely bandwidth allocation and congestion control.

Bandwidth and Traffic Allocation in ATM Networks

One of the most critical issues in the design and operation of an ATM network is bandwidth and traffic management. This is because of two main reasons: (1) the bulk of ATM traffic will be of a real-time nature (voice, video, etc.), which is intolerant of cell loss and retransmission and which requires bandwidth and delay guarantees; and (2) the network level protocols have been streamlined (for processing efficiency) to the point that little or no flow control can be applied to a source after the user connection has been accepted. Thus, congestion must be *prevented* through careful allocation of bandwidth ahead to time.

In an ATM network, bandwidth can be allocated at the *physical level* and at the *transport* (i.e., ATM) level. At the physical level, the ATM topology can be dynamically reconfigured by adding/removing trunks between ATM switches. This allocation of bandwidth is made possible by the presence of Synchronous Transfer Mode (STM) Digital Cross Connects (DCS). We will refer to this allocation as STM allocation. At the ATM level, we can allocate bandwidth to individual Virtual Circuits (ATM-VC allocation) as well as to Virtual Paths (ATM-VP allocation).

ATM-VC allocation is the conventional type of allocation and the most commonly studied by researchers. The other two allocation schemes, however, are also very important and play a key role in the efficient use of bandwidth resources and the prevention of congestion.

STM Allocation—In order to explain how STM allocation works, we recall that ATM switches will be connected by bundles of 150 Mbps fiber optics trunks. These trunks are obtained from an underlying "pool" of fiber facilities interconnected by circuit switches (DCS) operating in the STM mode. Thus, a trunk in the ATM network may consist of a chain of segments connected by DCS switches. In other words, the ATM network is "embedded" into the STM network.

The topology design of the "embedded" packet switched network differs from that of a traditional packet switching (P/S) network. In traditional designs, we minimize total trunk cost subject to delay constraints. Here, the available facilities are given, and therefore the cost is fixed (at least for the short term). The problem thus becomes one of optimally configuring the P/S network topology and capacities, within the constraints set by the underlying C/S network. Furthermore, this reconfiguration can be carried out dynamically and can be "tuned" to traffic fluctuations (i.e., STM allocation).

To illustrate the point, consider the network shown in Fig. 23. From the original (physical) topology, several logical packet topologies can be derived. The embedded topology of Fig. 24 is identical to the physical topology, whereas the topology in Fig. 25 has introduced a number of "express pipes" between remote nodes. Express pipes reduce the number of intermediate hops along the path and thus reduce store-and-forward delay and nodal processing overhead. They also simplify the congestion control problem since, when a pipe becomes congested, the sources can be immediately stopped.

Express pipes also reduce the number of packet switch terminations. Note that the topology of Fig. 24 requires 192 packet switch terminations, whereas the topology of Fig. 25 (which has more express pipes) requires 152 terminations. Using a fully piped network with a direct pipe (of capacity 4, say) also between nodes B and D will further reduce the number of terminations to 144. This is a very important point, since current trends in transmission and processing costs indicate that terminations costs will soon dominate the cost of fiber trunks. Thus, adding more express pipes will lead to overall cost reductions.

There are, however, drawbacks in the implementation of fully piped (i.e., fully connected) logical topologies. For example, in networks with a large number of nodes the bandwidth may become too fragmented, and the advantage of statistically multiplexing several sessions on the same trunk may be lost. Thus, a good balance must be struck between express pipes and large trunks.

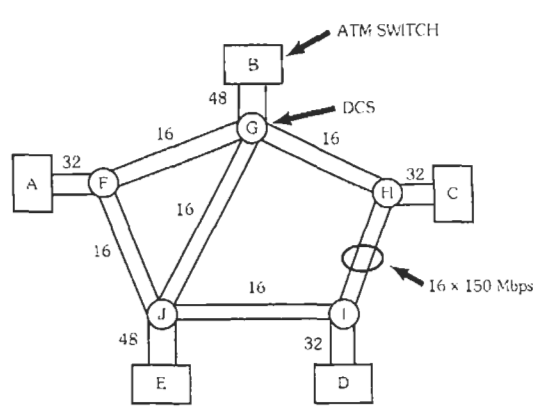

Fig. 23. Backbone topology.

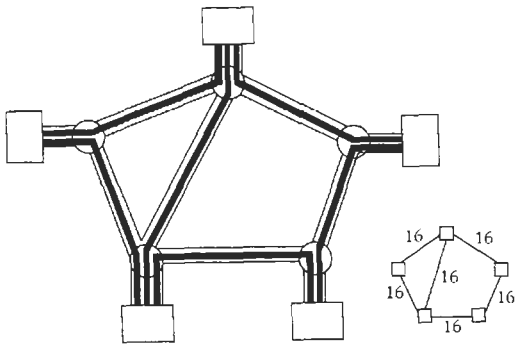

Fig. 24. Embedded topology A.

ATM-VP Allocation—We now move on to describe the *ATM-VP allocation* technique. We recall that a virtual path in ATM is basically a "virtual pipe" established between an origin/destination pair of ATM switches, for the purpose of multiplexing several VCs. The VP may traverse several transit nodes (also called ATM cross connects). The VC's are carried through the transit nodes transparently; i.e., the VC header need not be inspected at such nodes. A VP may be set up at network initialization and is typically assigned a "peak" bandwidth. This is basically a "contract" between the VP users and the network: the users will not exceed the declared peak bandwidth (otherwise, cells will be dropped). Likewise, the network commits the peak bandwidth along the path (instead of implementing statistical allocation among paths). Thus, from the bandwidth-sharing point of view, there is little difference between ATM-VP and STM allocation: both schemes allocate the peak, with no statistical sharing among "pipes." From the implementation standpoint, however, we recall that the VP is a "virtual" pipe, while the STM connection is a "physical" pipe. This implies that in VP the bandwidth can be allocated/deallocated much more dynamically than in STM.

The aggregation of several VCs into a VP pipe yields many advantages, including: (1) lower VC call set overhead; (2) lower VC bandwidth allocation and policing overhead (only the entry node gets involved); (3) connectionless traffic support; (4) better network congestion protection; and (5) better fault tolerance if redundant VPs are in use. On the negative side, the VP peak bandwidth allocation precludes some of the statistical sharing advantages available when bandwidth is allocated (statistically) to individual VCs.

Congestion Control in ATM

Recall that congestion control in conventional P/S nets is based on the principle of *detection* (of congestion) and *recovery*. When congestion builds up in the network, causing buffers to overflow, some mechanisms (e.g., selective back pressure in VC nets, or "choke" packets in datagram nets) are triggered to relay this information to the traffic sources so that further inputs are slowed down or stopped.

Unfortunately, detection and recovery schemes are not well suited to ATM nets for the following reasons: (1) the protocols have been streamlined, thus precluding the implementation of sophisticated flow control mechanisms (e.g., rotating windows in X.25, "choke" packets, etc.); (2) voice and video traffic (the predominant component in ATM nets) cannot tolerate slowdowns or interruptions; and (3) at hundreds-of-Mbps trunk speeds and coast-to-coast round-trip delays, no buffer is large enough to absorb the temporary overload while the flow control mechanisms are trying to stop the traffic sources.

A better approach is to use *prevention* (instead of detection and recovery). For prevention, the key assumption is that traffic rates on user sessions can be predicted. This is generally true for voice and video connections. With this assumption in place, the network can perform bandwidth allocation and can verify during call setup that all the trunks along the path can accept the declared load. Alternatively, a background "bandwidth control" procedure can be used to keep track of the amount of bandwidth available (on the average) on various paths from a source to all destinations. Each node maintains a table with values of available bandwidth to each destination. When a connection request, with associated average bandwidth requirement, is submitted to the network, it is accepted only if a path with adequate bandwidth to satisfy such a request is found in the table. Otherwise, the request is rejected. Note that the bandwidth control implementation in the switch does not impact packet processing performance, since the bandwidth control algorithm is run in the background.

With the above preventive methods in place, congestion is, in principle, avoided since the network never

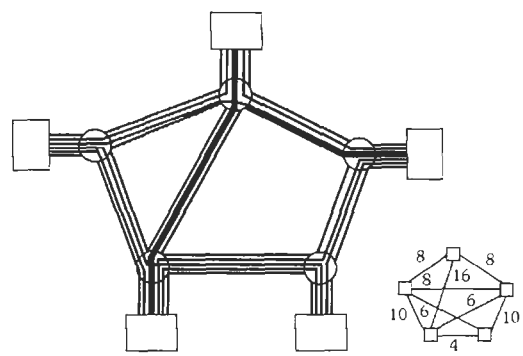

Fig. 25. Embedded topology B.

accepts more than it can carry. In practice, however, users may sometimes violate the initial bandwidth contract, either intentionally or, most commonly, because they estimated (and declared) their requirements incorrectly. In this case, congestion may still occur in the network, and it must be eliminated by using appropriate congestion control schemes.

There are several approaches to ATM congestion control. The first one is the *brute force* approach. With this approach, the network will indiscriminately drop packets when buffers are full. This alternative, however, is unacceptable for real-time traffic, and it may cause even more congestion (because of end-to-end retransmissions) in data traffic. Another possibility is *selective dropping* of least significant packets. With this approach, voice and video are encoded in such a way that less significant bits are carried in separate packets. When congestion builds up, the less significant packets are dropped, causing degradation (but no disruption) of service. This alternative, however, works only on voice/video and allows (at best) only up to 50% regulation of traffic volume. Furthermore, either scheme is unfair because it affects users indiscriminately, instead of selecting and penalizing those users who are abusing the network (i.e., who are transmitting at a higher than initially declared rate).

Another approach is to apply *input rate control*. Each user is monitored (or *policed*) for compliance with the initial bandwidth declaration. If the user exceeds the declared bandwidth, the excess traffic will be dropped directly at the source. A popular, extensively studied enforcement mechanism is the "leaky bucket," which is basically a queue with prenegotiated (at call setup time) service rate and buffer storage. If the user burst exceeds the buffer capacity, subsequent cells are dropped. The leaky bucket is definitely more fair than indiscriminate dropping. It suffers, however, from several inefficiencies. For one thing, the parameters cannot be easily set in such a way as to get an accurate enforcement. Furthermore, it is quite possible that the extra traffic (although in violation of the contract) could actually be tolerated by the network at that particular time (and therefore should be admitted because there is enough extra bandwidth available on the path).

An approach related to input rate control is Distributed Source Control (DSC). Each source is assigned a "smoothing interval" "T" and an allowance "W" of packets which can be transmitted in such interval. "T" and "W" are properly chosen so that the network has sufficient internal buffering to accommodate the corresponding input rate without risk of overflow. If a burst is generated by the source, it must be distributed over several smoothing intervals. If the burst overruns the source buffers, it is dropped at the source before entering the network (similar to what was happening in a leaky bucket). This packet loss at the source may occur even if the network happens to have enough bandwidth to tolerate the burst. In fact, DSC resource allocation tends to be quite conservative.

These considerations lead to yet another approach which is based on *marking*, rather than discarding, abusive packets. More specifically, the policer sets the CLP (Cell Loss Priority) bit to one in the abusive packet header. The marked packet is forwarded thus in the network. If congestion occurs, marked packets are discarded first. A further refinement on the marking scheme is possible in conjunction with the previously mentioned bandwidth control scheme. If the policer knows how much residual bandwidth is available on the path, then it can accept (and mark) abusive traffic at a rate up to the value of the available bandwidth. Traffic beyond that value is discarded. This way, even the marked traffic has a very good chance of making it through.

27 Satellite and Space Communications

Geoffrey Hyde and Pier L. Bargellini

Advances in rocketry and microwave engineering inspired early proposals for communications satellites. Experiments of the late 1950s and early 1960s culminated in the successful launch of *Early Bird* in 1965, by Comsat (the Communications Satellite Corporation), established by act of the US Congress for this purpose, from which time satellite communications can be dated.

In space systems, earth stations operate in conjunction with orbiting spacecraft that probe the space environment—the earth as observable from space, the moon, a planet, or any other celestial body. In satellite communications systems, two or more stations located on or near the earth communicate via satellites that serve as relay stations in space. In both instances, control and monitoring of the spacecraft require that telemetry and command links be added to the main function of the mission. Space systems include terrestrial missions (e.g., earth and/or sea surface observations of different kinds), weather satellites, and navigation satellites. Beyond the earth, space systems can be classified in terms of the mission range (i.e., cislunar, lunar, translunar, or planetary) as well as in terms of the specific nature of the observations to be carried out.

Communications satellite systems are classified in terms of their territorial coverages, e.g., global, regional, or national (domestic); in terms of the type of services offered, e.g., fixed, mobile, maritime, aeronautical, etc., or point-to-point, broadcasting, commercial, military, amateur, experimental, etc.; or in terms of their orbit, e.g., geostationary (GEO), medium earth orbit (MEO), or low earth orbit (LEO).

Regulatory bodies (FCC, ITU) often categorize capabilities by service. In satellite communications, there are three broad service categories: fixed, mobile, and broadcast. Fixed satellite services (FSS) cover links between satellites and fixed (nonmoving) earth stations. Mobile service covers satellite links to stations that may be in motion (mobile), including ships (maritime mobile [MMSS]), aircraft (aeronautical mobile [AMSS]), and land vehicles (land mobile [LMSS]). Broadcast services include TV (DBS-TV) and audio (DBSA). It should be noted that services are evolving, and while the FCC and ITU designations will change very slowly, the reality is changing rather more quickly, as will be discussed briefly in the section on Other Services below. Examples of this are DTH (direct to home), which covers a broader swath than just TV as interactive services emerge, and DARS (digital audio radio service), which covers nationwide satellite digital radio to automobiles (and possibly homes).

The ITU internationally and the FCC in the United States allocate frequency bands for the use of these services, and where the bands overlap, they designate which service has priority.

The environment of space affects the design of communications systems in several ways that make it different from the design of terrestrial systems. Major differences are:

A. Space and satellite communications systems can and often do cover distances far exceeding those encountered on earth.
B. As spacecraft power and allocated bandwidth are limited resources, trade-offs of space and earth segment design characteristics affect the overall system cost.
C. As the conditions along the signal paths are much more time invariant in space than on earth, it is possible to design space-to-space communications systems with great precision. Space–earth and earth–space signal paths traverse the troposphere and ionosphere and are subject to the vagaries thereof, but these tend not to be so severe as those encountered on long terrestrial paths (see section on Propagation).

Three categories characterized by different environmental constraints can be identified, as follows.

Spacecraft-to-Spacecraft: In principle, the designer has maximum freedom in the choice of the operating frequency. The major difficulty resides in maintaining tracking between spacecraft.

Earth-to-Spacecraft (Up-Link): The choice of the operating frequency is primarily determined by the availability of spectral windows in the signal path. The window boundaries are dictated by absorption and dispersion phenomena in the ionosphere and troposphere, the attenuation and depolarization effects of hydrometeors (rain, snow, ice, etc.,) and also by the spectral and spatial distributions of natural noise sources. On earth, the ubiquitous availability of electrical power and the relatively benign environment make it possible to use large amounts of transmitter power enhanced by high-gain, large antennas that must be precisely aimed at the spacecraft.

Spacecraft-to-Earth (Down-Link): Launch-vehicle limitations restrict the size of the spacecraft transmit and receive antennas, and the spacecraft receiver is affected by the background noise of the earth. The spacecraft transmitter is limited by the power available, which in turn is limited by the size of the solar cell arrays, again launch-vehicle limited. These limitations are increasingly less severe. Spacecraft originally (1963–1965) had dipole antennas and only a few hundred watts of dc electrical power from solar arrays. In the year 2000, spacecraft on orbit had 15-meter antennas and dc power up to 15 kW.

In earlier days, limited spacecraft transmitter power and antenna sizes (gain) were compensated for by electrically large earth-station receive antennas and low-noise receivers. Today, spacecraft eirps (equivalent isotropically radiated power) have reached the

point where handsets with antennas not unlike those used in terrestrial cell phones are coming into service. The trend toward multibeam narrow-beam spacecraft antennas has increased the requirements for precise spacecraft positioning, station-keeping, and antenna pointing with a consequent increase in the amount of onboard fuel required for the above-mentioned functions. The very stringent reliability requirements necessary to guarantee spacecraft design lifetime are achieved by painstaking selection of the equipment for all subsystems and provision for redundancy of critical components.

EVOLUTION OF COMMUNICATION SATELLITE SYSTEMS AND THEIR ROLE IN WORLDWIDE COMMUNICATIONS

From 1965 until around 1980, communication satellites were used chiefly to provide long-distance high-capacity communications links across the oceans, archipelagos, and large landmasses. The capacity and reliability of satellite circuits exceeded those of other communications systems such as HF, VHF, and UHF radio (ionospheric, troposcatter, and line-of-sight circuits), as well as coaxial cables. The majority of traffic was telephony, with data transmission growing at an accelerated rate. The relaying of TV programs across the oceans was made possible for the first time through the use of satellites. TV distribution and TV Satellite News Gathering (SNG) are major and growing niches. Geostationary satellites proved perfectly capable of interfacing with existing land-based communications systems as echo problems were circumvented through the use of echo cancellers. Analog transmission techniques initially adopted are still in use, albeit no longer dominant, while digital transmission now is the dominant form and continues its rapid expansion. In point-to-point links, satellites carrying "transparent" transponders have served at times as "cables in the sky." However, it became clear from the very beginning of satellite communications that the most valuable characteristic of satellites was their capacity of providing multipoint and multimedia communications links in star-configured networks (multiple access). Therefore, the efforts of systems planners and spacecraft designers were directed toward a more efficient use of the multiple-access characteristic.

Enhancement of the multiple-access capability implied the addition to the basic function of signal amplification and frequency-band changing found in "transparent transponders" the functions of switching (beam and/or transponder) and of signal processing of various kinds such as demodulation, remodulation, storage, buffering, etc. With the rise of digital-signal onboard processing through the past two decades, some satellites can be increasingly thought of as signal processing and routing nodes in the sky.

The evolution of spacecraft design was characterized by increases of size, mass, and power, made possible by the availability of more powerful launchers, in combination with substantial improvements in the design of the various onboard subsystems in both the communications and noncommunications areas. Within less than 25 years, communications capacity was increased by more than three orders of magnitude with only about a fifty-fold increase in spacecraft mass and power. This process continues, although at a lesser rate. As the power and mass available for the communications payload has increased, those payloads have grown in capability, and the overall system trade-offs have shifted toward placing more burdens on the spacecraft payload. Onboard processing, especially for the communications signals but also for the satellite bus housekeeping, continues to increase. The total radiated rf power has increased by orders of magnitude, and antenna diameters have reached 15 meters (46 feet), resulting in great increase in eirp. One of the most significant consequences of the above-mentioned evolution is the reduction in the size of earth-station aperture and transmitters. Such reductions and the opening of communications at the higher frequency bands allocated to satellite systems made it possible to install earth terminals directly at the customers' premises. The introduction of low-powered, very small antenna terminals (VSATS) allowed the development of numerous independent communications networks linking industries, banks, and other institutions. All of this resulted not only in great cost reductions but also in enabling users a degree of operational freedom hitherto unavailable through conventional communications facilities. Although the majority of the current VSAT systems operate with the peripheral terminals communicating with and/or through a central station (hub) on earth, it is envisaged that in the future the functions of the hub will be available on board more sophisticated satellites. In this manner, the double-hop situation encountered in present VSAT systems will be eliminated with consequent various advantages. The process of continued reduction in the size of the terminals has, in the late 1990s, led to the introduction of ultrasmall antenna terminals (USATs) in the FSS, and in the year 2000, handsets not unlike and compatible with those used in terrestrial mobile communications, for example, the GSM.

The use of satellites has facilitated worldwide TV distribution for special events in real time and, in most cases, with delays as required by the different time zones, regularly scheduled programs with participants in two or more locales connected by satellite, as well as the SNG services noted above. In the United States, the nationwide distribution of TV programs to cable networks has become an industry of its own with little or no competition from other means of transmission, including fiber-optic cables. For rural areas not reached by conventional TV broadcast stations and not served by cable TV systems, higher levels of power radiated by satellites made possible direct reception of

TV from satellites by receive-only earth terminals (TVRO) equipped with parabolic antennas with diameters between 2 and 5 m. These developments have paved the way for direct TV broadcast from satellites operating in the K_u-band with powers between 100 and 250 watts and received with antennas down to 0.5 m in diameter. Direct TV broadcasting from satellites, earlier initiated in Europe and Japan, has finally become widespread in the United States. Other direct to home (DTH) satellite services are starting to appear, including interactive ones such as Internet service via satellite.

At this point in time, almost all voice and data transmission is digital. Analog TV, i.e., "old TV," is a decreasing sector as TV goes digital. For example, DBS is digital. The Internet is digital. Digital radio services such as DARS are emerging. Analog is dying out. This is in spite of the fact that voice, video, and radio are analog at the end users (throat, eye, and ear, respectively). One major reason is that digital methods provide source encoding and processing such that compression techniques can, have, and are being developed so that more and more voice circuits and TV channels are being transmitted through less and less bandwidth. Because bandwidth is a limited resource in satellite communications, this is highly desirable. The earliest digital voice service over satellite used 56 kbps to achieve "toll quality." Today (year 2000) one can achieve very near toll quality with 4 kbps using advanced coding techniques. Comparable advances are available for TV. The other reason is that the much greater eirps permit the use of digital modulation schemes that can provide more bits per Hertz as part of the systems trade-offs.

An area in which satellites are bound to maintain a significant role is mobile communications. After the establishment of the MARISAT system in 1976, the follow-on INMARSAT global system underwent a considerable expansion marked by the sequence of three generations of ever-increasing capacity providing ship-to-shore as well as air-to-ground communications services on a global scale. Satellite systems capable of serving earth vehicles such as trucks, trains, and automobiles have been implemented; they provide not only communications services but also additional important functions such as determination of vehicle location, monitoring of the status of critical shipment loads, etc. The 1990s saw the emergence of several satellite mobile systems and numerous satellite mobile communications providers. There has been a blurring of the lines among the satellite services for marine, aeronautical, and ground mobile users.

As noted above, satellite mobile service in the year 2000 has been extended to hand-held sets not much different in size than those used in terrestrial wireless service. The consequent issues of compatibility and complementarity with terrestrial-based mobile communications systems are being addressed. Indeed, at this time, handsets that can access a satellite system and the European GSM have been introduced. The emergence of "software radio" systems makes it likely that the issues of compatibility will be overcome by chip sets in the handsets in the next few years. The so-called third generation of mobile services in Europe is being planned so that satellite-based services complement the terrestrial networks. More of such efforts are in the offing.

The emergence of terrestrial and submarine fiber-optic cables in the early and mid-1980s induced a shift in the use of satellite systems toward those applications for which they are either indispensable or better suited. Clearly, the two above-mentioned cases of mobile communications and direct broadcasting are best performed via satellites in many regions of the world. However, even for overland and transoceanic routes, satellites will remain competitive vis-à-vis optical cables not only in terms of economic factors but also especially in consideration of the complementary characteristics of cable and satellite systems. The need to have satellite circuits at readiness to restore interrupted cable circuits has been repeatedly demonstrated. Quick restoration of communications services via satellite during often long-term submarine cable outages has been frequent and effective with considerable, albeit unadvertised, benefits to the users. From a topology viewpoint, a cable that constitutes a link and a satellite that functions as a node are bound to provide, respectively, fixed trunk capabilities and nodal connectivity to serve many users, especially in the case of thin traffic routes. In addition, because of the portability of smaller satellite earth terminals, where temporary and/or emergency services are needed, communications services can be provided or restored in a much shorter time frame than can terrestrial services.

The integration of satellite and cable circuits, which already has proven beneficial, has become indispensable in the case of the Integrated Digital Services Network (ISDN) currently under development. The definitions of the characteristics of the ISDN by consultative bodies such as the ITU-T and the ITU-R lead to the conclusion that satellites need to be taken into consideration not just as another transmission medium, but also because of their unique capabilities of higher connectivity, flexibility, assignment of capacity to meet rapidly changing traffic needs, and readiness to confront emergencies. Compatibility and complementarity of fiber-optic cables and satellite systems, already well assured with advantages to users at the current ISDN transmission rates, must be pursued and extended throughout the development phases of the future higher-transmission-rates ISDN (B-ISDN) hierarchy. Communications satellites will maintain a very important role within the overall ISDN development scenario, possibly widening it in terms of network growth anticipation, planning, design, and operation.

Satellite-based services are beginning to emerge for the Internet. There is every evidence that this trend will continue. Although one can expect the bulk of Internet traffic to be carried over terrestrial facilities, for the same reasons that satellite mobile services will always be needed, so will satellite-based Internet services.

At the dawn of the 21st century, improving and changing technology are the enablers for expanding services and lower costs. The single greatest area of change is digital technology, both with regard to hardware and software. Microwave antenna technology and solar cell power generation efficiency improvements are also critical areas. As these technologies evolve, one can expect satellite communications to continue to thrive through the foreseeable future.

SATELLITE ORBITS

Satellites move around the earth as planets do around the sun. Kepler's laws apply:

First Law: Planetary orbits are elliptical with the sun at a focus.
Second Law: The radius vector from the sun to a planet sweeps equal areas in equal times.
Third Law: The ratio of the square of the period of revolution and the cube of the ellipse semimajor axis is the same for all planets.

These laws can be mathematically derived in terms of Newtonian mechanics and universal gravitation.

When the satellite mass is negligible with respect to the mass of the earth, the balance between gravitational and centrifugal force leads to the vector differential equation

$$d^2\vec{r}/dt^2 + \mu\vec{r}^3 = 0 \qquad \text{(Eq. 1)}$$

in which $\vec{r}$ is the radius vector from the center of the earth to the satellite and

$$\mu = GM = gR^2 = 3.99 \times 10^{14}\ \text{m}^3/\text{s}^2$$

where

$G = 6.67 \times 10^{-11}\ \text{N m}^2/\text{kg}^2$
$M = 5.98 \times 10^{24}\ \text{kg}$
$g = 9.81\ \text{m/s}^2$
$R = 6.38 \times 10^6\ \text{m}$, the radius of the earth

As the centrifugal and gravitational forces are aligned and opposed, the satellite moves on a plane (orbit plane). Lengthy manipulations of Eq. 1 lead to Kepler' s laws. The first law is verified by showing that the satellite moves along a conic on the orbit plane, the equation for which is

$$r = p/(1 + e\cos v) \qquad \text{(Eq. 2)}$$

where

p is a parameter,
e is the eccentricity,
v is the central angle (true anomaly).

The value of the eccentricity determines the type of the conic.

$$e \begin{cases} = 0 \text{ circle} \\ < 1 \text{ ellipse} \\ = 1 \text{ parabola} \\ > 1 \text{ hyperbola} \end{cases}$$

With reference to Fig. 1, the following relationships, which hold for elliptical orbits, are frequently used:

$$x = r\cos v = a(\cos E - e)$$

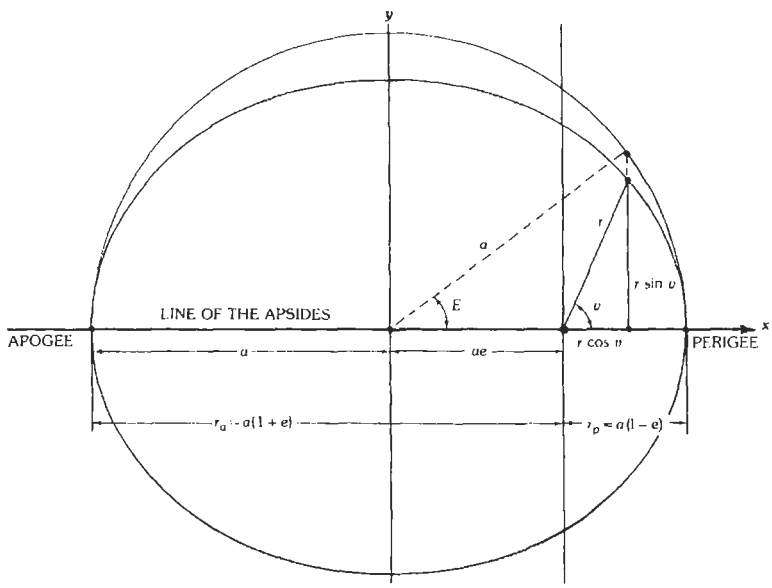

Fig. 1. Elliptical-orbit geometry.

$$y = r \sin v = a \sin E\,(1 - e^2)^{1/2}$$

Eccentricity:

$$e = c/a = (r_a - r_p)/(r_a + r_p)$$

Semimajor axis:

$$a = (r_a + r_p)/2$$

Apogee distance:

$$r_a = a + c = a(1 + e)$$

Perigee distance:

$$r_p = a - c = a(1 - e)$$

Locus parameter:

$$p = a(1 - e^2) = 2r_a r_p /(r_a + r_p)$$

Semiminor axis:

$$b = a(1 - e^2)^{1/2} = (r_a r_p)^{1/2}$$

Kepler's second and third laws can be derived from Eq. 1 through manipulations based on conservation of energy and angular momentum considerations whereby

$$v^2/2 - \mu/2 = \text{constant} \qquad \text{(Eq. 3)}$$

and

$$\vec{r} \times \vec{v} = \vec{h} \qquad \text{(Eq. 4)}$$

The orbit period, P, is then

$$P = 2\pi a^{3/2}/\mu^{1/2} \qquad \text{(Eq. 5)}$$

Angle E (eccentric anomaly) is the central angle measured from the x axis to the vertical projection of the satellite point over the circle of radius a. The true anomaly, v, and the eccentric anomaly, E, are related by any of the expressions:

$$\cos E = (e + \cos v)/(1 + e \cos v)$$

$$\cos v = (e - \cos E)/(e \cos E - 1)$$

$$\tan (v/2) = [(1 + e)/(1 - e)]^{1/2} \tan (E/2)$$

For the hypothetical case of uniform motion on the circle circumscribing the ellipse, where t = time, the fictitious angle M (mean anomaly) can be defined as

$$M = 2\pi t/P \qquad \text{(Eq. 6)}$$

Angles M and E are related by the equation

$$M = E - e \sin E \qquad \text{(Eq. 7)}$$

It can also be shown that

$$v^2 = 2\mu/r - \mu/a \qquad \text{(Eq. 8)}$$

and that the orbit velocity vector has two constant components respectively normal to the radius vector and the major axis of the ellipse.

To define the satellite position in inertial space, three additional angles are required. These are: the inclination, i, of the orbit plane with respect to the equatorial plane of the earth; the right ascension (longitude), Ω, of the ascending node [i.e., the angle between the direction, γ, of the vernal equinox (point of Aries) and the intersection of the orbit and equatorial planes]; and finally the argument of perigee, ω, i.e., the angle measured in the orbit plane between the direction of the ascending node and that of the perigee.

The nonsphericity of the earth, the nonuniform distribution of its mass, as well as the effects of lunar and solar gravitation make the actual motion of satellites depart from that described so far, which is based on the simple two-body problem.

The gravitational potential of the earth, which is no longer simply proportional to the inverse of the distance, can be expressed as a series of spherical functions. Two motions known as *secular variations* result from the above-mentioned causes; these are nodal regression and rotation of the line of the apsides.

Nodal regression is a rotation of the orbit plane in the direction opposite to the satellite motion around the axis of rotation of the earth. The rate of this motion (in degrees per day) is

$$\dot{\Omega} = -[10/(1 - e^2)^2\,](R/a)^{7/2} \cos i \qquad \text{(Eq. 9)}$$

Rotation of the line of the apsides is rotation of the ellipse major axis around the center of the earth on a fixed orbit plane. Apogee and perigee move then with respect to the earth, and the rate of motion of the argument of perigee is also a function of the orbit inclination angle, i, or:

$$\dot{\omega} = [5/(1 - e^2)^2\,](R/a)^{7/2}\,(5 \cos^2 i - 1)°/\text{day} \qquad \text{(Eq. 10)}$$

The critical value $i = \cos (1/\sqrt{5}) = 63°24'$ stops this motion. Smaller values of i make the ellipse rotate in the same sense as the satellite motion along it; higher values of i make the ellipse rotate in the opposite sense. The effect becomes smaller for higher orbits.

Gravitational forces due to the moon and the sun also influence satellite motion. For low-altitude orbits, the gravitational field of the earth is preponderant and solar and lunar effects can be neglected. For high-altitude orbits, gravitational disturbances of the moon and the sun cannot be neglected. In the case of a geostationary orbit, the sun and moon perturbation forces, respectively, amount to about 1/37 and 1/6000 of the gravitational force of the earth. The combined effect would change the orbital inclination of a satellite originally placed in a perfectly equatorial orbit by about 1 degree per year.

INFORMATION TRANSMISSION IN SPACE

In a link between two points in space, A and B, separated by the distance r, a transmitter located at A of

power P_t, radiated by an antenna having a gain G_t, produces at point B a power flux density

$$\phi = P_t G_t/(4\pi r^2) \qquad \text{(Eq. 11)}$$

A receiving antenna of effective aperture A_r at B intercepts a signal power

$$P_r = P_t G_t A_r/(4\pi r^2) \qquad \text{(Eq. 12)}$$

which equals the product of the rate of information transmission, R, and the energy, E, required to transmit one bit of information, whence

$$R = BP_t G_t A_r/(4\pi\beta N r^2) \qquad \text{(Eq. 13)}$$

where β is the ratio of the energy required to transmit one bit of information and the noise power density (i.e., $\beta = E/N_0$ and $N_0 = N/B$ where N is the noise power in bandwidth B). This parameter, which is a function of the ratio of the channel bandwidth, B, and the information rate, R, characterizes the efficiency of modulation–demodulation schemes.

Equation 13 was derived by assuming an antenna of given gain at one end of the link and an antenna of given aperture at the other. In this case, frequency, or wavelength, does not appear explicitly in the equation, although the noise power density, N_0, is in general frequency dependent.

By assuming antennas of given gain at both ends, and using the well-known relationship

$$A_e = (\lambda^2/4\pi)G$$

where A_e = effective aperture, the following result is obtained:

$$R = (\lambda^2/16\pi^2)\,[(BP_t G_t G_r/(\beta N r^2)] \qquad \text{(Eq. 14)}$$

In contrast, assuming antennas of given aperture at both ends of the link yields

$$R = BP_t A_t A_r/(\lambda^2 \beta N r^2) \qquad \text{(Eq. 15)}$$

The above equations allow the information transmission rate, R, of a single space communications link to be computed. Since the noise encountered in space may be regarded as Gaussian, white, and additive, the Shannon model yields an upper bound on transmission rate. Equation 13 can be rewritten as

$$R = BP_t G_t A_r/(4\pi r^2 \beta N) = (B/\beta) \cdot (P_r/N) \qquad \text{(Eq. 16)}$$

The two factors on the right-hand side relate to the two cases of bandwidth- and power-limited transmission.

The lower bound of parameter $\beta = E/N_0$ has the value $\log_e 2 = 0.693$ in the limiting case of infinite bandwidth and ideal (Shannon) modulation–demodulation processes. Then the signal-to-noise ratio goes to zero, and the information rate takes the value

$$\lim_{B\to\infty} R = 1.44\, P_r/N_0 \qquad \text{(Eq. 17)}$$

In physical systems, limited bandwidth and departure from ideal modulation–demodulation processes require higher values of E/N_0 and P_r/N. The ratio of the actual information transmission rate and channel capacity (in the Shannon sense) becomes smaller than unity, and compromises amongst signal-to-noise ratio, bandwidth-to-information transmission rate ratio, and message error probabilities (or signal quality in analog systems) must be made.

THE CHOICE OF THE ORBIT

The orbit height influences the communications range, the transmission delay, and the duration of the connection, which is determined by the time interval between satellite rise and set for points on the surface of the earth separated by a given angle measured from the center of the earth. The actual coverage is also a function of the minimum elevation angle of earth-station antennas. With reference to Fig. 2, the following relationship can be used to compute the coverage angle:

$$R/(R + h) = \cos(\beta + \theta)/\cos\theta \qquad \text{(Eq. 18)}$$

where

R = earth radius
h = orbit height
β = coverage angle
θ = elevation angle

The transmission delay can reach a maximum

$$t_d = [2(R + h)/c](\sin\beta/\cos\theta) \qquad \text{(Eq. 19)}$$

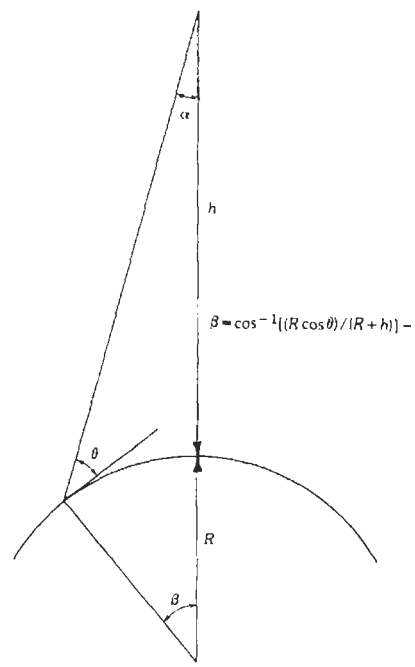

Fig. 2. Coverage and elevation angles.

Curves for the period, P, the earth coverage, and the maximum transmission delay, t_d, are shown in Fig. 3 for circular orbits.

Satellite systems can be classified in terms of the inclination angle, i, between the orbit plane and the equatorial plane:

$i = 90°$, i.e., polar orbits

$0 < i < 90°$, i.e., inclined orbits

$i = 0$, i.e., equatorial orbits

If the orbit is circular and the orbital height is 35.863×10^6 meters, the period equals a sidereal day (23 hr 56 min 4 s), and if the orbital plane coincides with that of the equator of the earth, the satellite becomes geostationary. In the absence of perturbations, such satellites hover over fixed points of the equator and subtend the earth with an angle of 17°27′. Communications can thus be established between any two points "visible" from the satellite over an area that amounts to about 40% of the entire surface of the earth. In this case, the handover problem, i.e., the passing of traffic from one satellite to another, which would be necessary with nonstationary satellites, is avoided. Other significant advantages are simplification of tracking by earth stations and near-zero Doppler effects.

The transmission delay, which ranges from 0.238 to 0.275 second for single-hop circuits, has been found acceptable for telephone communications provided that the echo at times generated in terrestrial telephone plants at the transition points between four- and two-wire circuits is kept under control. This has been done by using echo cancellers.

SOLAR ECLIPSES

A satellite is illuminated by the sun continuously except for the periods during which it is shadowed by the earth. As a spacecraft enters the shadow of the earth, the supply of electrical energy derived from solar-cell panels is cut off, and a substantial drop in the temperature of the spacecraft body occurs; reversal of these phenomena takes place when the satellite comes out of the shadowed region. In the case of communications satellites, where continuity of service is needed during eclipses, it is clear that some alternate source of electrical energy must be provided. Storage batteries, usually of the Ni–Cd or Ni–H_2 type currently, provide this energy, being charged by a fraction of the energy obtained by sunlit solar-cell panels and discharged during eclipse periods. With regard to thermal effects, great care must be exercised in the construction of all spacecraft subsystems so that all functions are properly maintained, notwithstanding the large temperature excursions encountered.

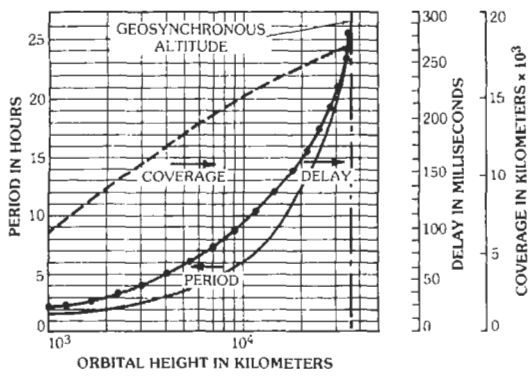

Fig. 3. Orbit period, earth coverage, and transmission delay versus orbit height.

Eclipses have known onset times and duration; i.e., they are highly predictable events calculated from ephemeris data. Although such calculations tend to be complex for satellites orbiting the earth at different altitudes and inclinations, they become fairly simple for satellites whose orbits lie in the equatorial plane of the earth, such as geostationary satellites. For this case, solar eclipses occur around the spring and autumn equinoxes. Fig. 4A illustrates what happens around the spring (vernal) equinox: Shadowing of the satellite begins at point A when it becomes positioned tangentially to the shadowed area. This occurs at the end of February. Subsequently, the duration of the eclipse increases until the spacecraft finds itself at point B on the equinox day (March 21), which yields an eclipse of maximum duration. After this, the eclipse phenomenon continues with decreased duration until point C (April 11), when the satellite position is again tangential to the shadow of the earth. The situation repeats itself from September 12 to October 14 around the autumnal equinox (September 23), at which date the eclipse duration hits a maximum again.

For a satellite having zero inclination (i.e., on the equatorial plane), the computation of the maximum duration of the eclipse is easily done, with reference to Fig. 4B under the reasonable approximation of the earth shadow as a cylinder of radius r_e equal to the radius of the earth. For a satellite orbiting at a distance R from the center of the earth, the angle α that subtends the shadowed arc of the orbit is

$$\alpha = 2 \sin^{-1} (r_e/R) \qquad \text{(Eq. 20)}$$

Maximum eclipse duration T_e can then be obtained from the equation

$$T_e = P\alpha/2\pi \qquad \text{(Eq. 21)}$$

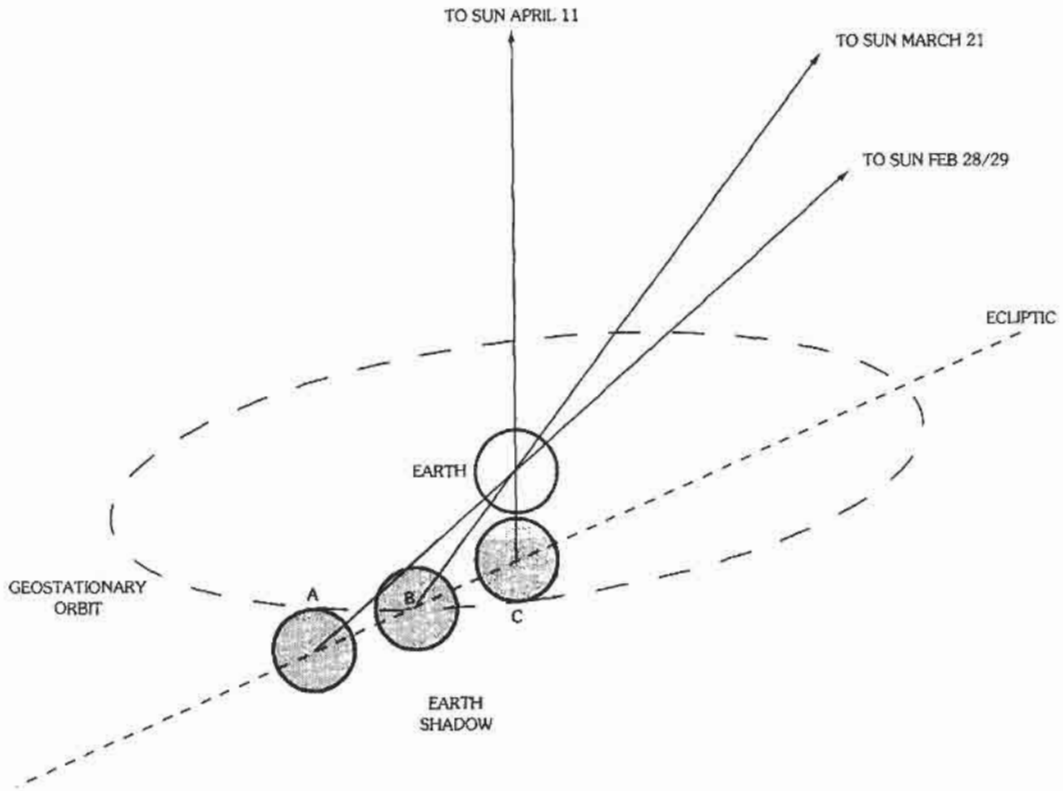
where P is the orbital period. Substitution of the appropriate values for the geostationary case yields

$$\alpha = 2 \sin^{-1} (6378/42\ 164) = 0.304 \text{ rad}$$

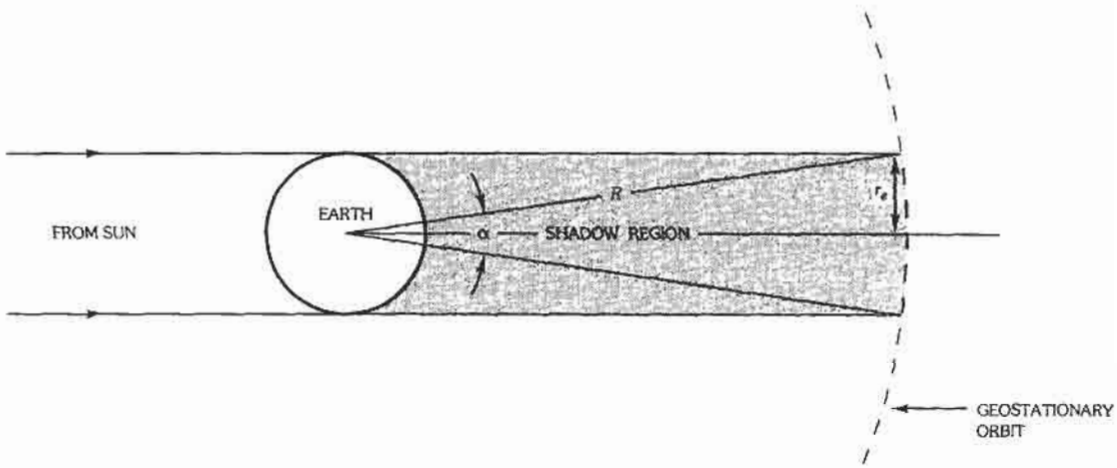
and

$$T_e = (86\ 164.091/6.2831)0.304 = 4168 \text{ s}$$

$$= 69.48 \text{ min}$$



(A) Eclipse around Spring Equinox.



(B) Geometry at equinoxes.

Fig. 4. Solar eclipse.

For a more precise computation, additional geometrical data such as the radius of the sun and the earth–sun distance are needed. The existence of umbra and penumbra zones also must be recognized. The above simplified derivation is adequate for assessing storage-battery requirements. By keeping in mind that the

maximum eclipse duration at each of the equinoxes is about 80 minutes and adding the lesser contributions during the entire eclipse periods, it is found that the total time of darkness amounts to about 3 hours/year.

NONGEOSTATIONARY ORBITS

Since the necessary rockets and know-how related to the complex in-orbit injection maneuvers were developed, the majority of commercial communications satellites were of the geostationary type until the 1990s. However, because the elevation angle at an earth station drops at higher latitudes, geostationary satellites cannot serve the near-polar regions. For this purpose, other orbits have been used. Polar orbits are also used for non-communications-type missions such as earth observations, weather, surveillance, etc.

From Eq. 19, the maximum latitude that can be served is

$$\beta = \cos^{-1}[(R\cos\theta)/(R+h)] - \theta \qquad \text{(Eq. 22)}$$

Hence, for a minimum elevation angle θ of 5°, β = 76°21′. Thus, inclined orbits are required to serve those regions further north. On the basis of energy considerations, it can be shown that for a given rocket, the lower the perigee the higher the apogee. The slower satellite motion around apogee results in the dual benefit of making communications possible over greater distances on earth and for longer periods of mutual visibility; the tracking problems are also eased.

As previously mentioned, an orbit inclination of 63.5° is advantageous because of the zero rotation of the line of the apsides for this critical angle. The inclined orbit discussed above, 63.5° inclination, 12-hour period, turns out to be highly advantageous. A satellite in such an orbit spends about 8 hours near geosynchronous altitude. Thus three such satellites can provide continuous service at altitude. Further, properly adjusted, the satellites return to the same station every 24 hours. Finally, because of the inclination, at altitude the satellites can be seen in polar regions. The former USSR (and the current Russia) had extensive polar regions and used the *MOLNIYA* series of satellites in the above-mentioned inclined orbit to provide point-to-point telephony (fixed satellite services), data relay, mobile communications, TV distribution, and DBS services very successfully. Variants of this orbit will be used in the United States (for DARS) and in Japan (for multimedia).

Advances in technology permitting high levels of sophistication on board smaller satellites have led to a variety of proposals for constellations of satellites in low earth orbit (LEO) and in medium earth orbit (MEO) to provide mobile or data relay, remote sensing, radio location services, or combinations thereof. Some, such as data relay satellites (*TDRSS*), radiolocation (*LOCSTAR*), mobile communications (*Iridium*, *Globalstar*, and others) and messaging/paging (*ORBCOMM*) are in service (in all or in part) and others, such as *ICO*, are actively under construction at the date of publication of this book. The basic reason that these systems have emerged in the 1990s is that the cost of the technology required and the reliability of the components (largely digital), combined with their reduced weight and power requirements (of VLSICS), have made such systems practical to build, launch, and maintain in orbit.

Because of the van Allen belts with their much higher radiation levels, which significantly and deleteriously affect the satellite electronics, the choice of orbits is limited. LEOs lie below the inner van Allen belt; MEOs lie between them and GEOs above them.

The LEO systems have certain advantages. They have much shorter earth–satellite paths, which leads to lower eirp requirements and much shorter delays. Further, especially of advantage in mobile/urban communications, elevation angles to the useful part of the LEO are high, thus making for less "multipath." However, their lower orbits require sizable constellations of satellites for continuous service (e.g., 66 for *Iridium*).

MEO systems are, as might be expected, intermediate in their delay and their eirp requirements, and their constellations are smaller. The trade-offs made in system design determine the altitude and inclination of the orbits and the rf frequency/elevation angle/availability considerations combine to define the constellations. (GEO systems are well known and amply described herein.)

ELEVATION AND AZIMUTH ANGLES

For the case of a geostationary satellite and an earth station having latitude ϕ and longitude λ relative to the subsatellite point on the equator, the elevation angle (i.e., the angle above the horizon) and the azimuth angle (i.e., the angle measured clockwise from the direction of true North) can be computed by using standard spherical and plane trigonometry relationships. With reference to Fig. 5 and the spherical triangle $S'EB$ at B, we have

$$\cos\beta = \cos\phi\cos\lambda \qquad \text{(Eq. 23)}$$

Then considering plane triangle OES, we obtain the elevation angle, θ.

$$\theta = \cos^{-1}\{[(R+h)\sin\beta]/d\} \qquad \text{(Eq. 24)}$$

where

$$d = \sqrt{R^2 + (R+h)^2 - 2R(R+h)\cos\beta}$$

The azimuth angle is obtained from the spherical triangle by first using the relationship

$$\gamma = \cos^{-1}(\tan\phi\cot\beta) \qquad \text{(Eq. 25)}$$

which provides the angle at e; the true azimuth is then obtained from Table 1. The earth-station quadrant is

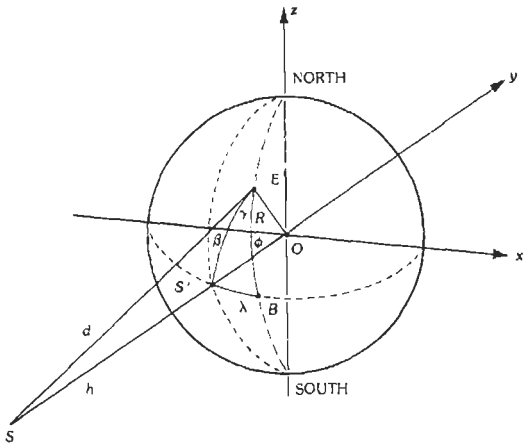


Fig. 5. Geometry of elevation and azimuth angles.

THE CHOICE OF FREQUENCY

From a purely technical point of view, the choice of the operating frequency is primarily dictated by the external and internal noise sources that contribute to the noise system temperature and by the existence of spectral windows for which signal attenuation is small. External noise originating outside the solar system is designated as "cosmic," whereas sources within the solar system (terrestrial sources included) contribute to the "solar noise." At optical frequencies, the sun acts as a blackbody with temperature of about 6000 K, but below 30 GHz deviations from Planck's law result in much higher equivalent blackbody temperatures. These deviations depend on the solar activity during the 11-year sunspot cycles, with increases up to six orders of magnitude. A strong frequency dependency is observed.

The ionosphere, the troposphere, and in particular the atmosphere, contribute as "terrestrial" sources. Ionospheric effects include Faraday rotation (of linear polarized signals) and gigahertz ionospheric scintillation. These effects fall off sharply with frequency and may be neglected above 10 GHz. They are also diurnally, seasonally, and solar-cycle dependent. Tropospheric effects include tropospheric scintillation, a phenomenon that increases rapidly for decreasing elevation angle below 10° and increases with increasing frequency. It may be neglected for frequencies below 3 GHz except at the lowest elevation angles (< 3°). Hydrometeors contribute to depolarization, attenuation, and increased noise temperature. Rain- and ice-induced depolarization arises because of the nonspherical nature of the hydrometeors, resulting in differential phase shift and attenuation for vertically and horizontally polarized components of the signal. This phenomenon is important down to at least 3 GHz. Increase in attenuation through the atmosphere and in effective sky noise temperature arises from absorption and scattering by the hydrometeors, especially rain. The attenuation reduces signal strength. The increased noise temperature adds to the system noise and is particularly troublesome when a very low noise receiver is used. Increase in attenuation and noise temperature is particularly marked above 10 GHz.

As shown in Fig. 7, the "clear sky" noise temperature observable at the surface of the earth has a broad minimum from 0.8 to 8 GHz and increases rapidly at the lower frequencies on account of terrestrial contributions and at frequencies higher than 10 GHz on account of atmospheric phenomena. Fig. 7 applies to clear-sky conditions; rain and other hydrometeors introduce additional noise as well as signal attenuation. There is a water-vapor absorption-induced peak at about 23 GHz, followed by a decrease in noise temperature to about 33 GHz. There follows a sharp rise resulting from the broad oxygen absorption-induced peak at 59–60 GHz.

The effects of varying the antenna beam inclination angle are also shown. For low values of the elevation

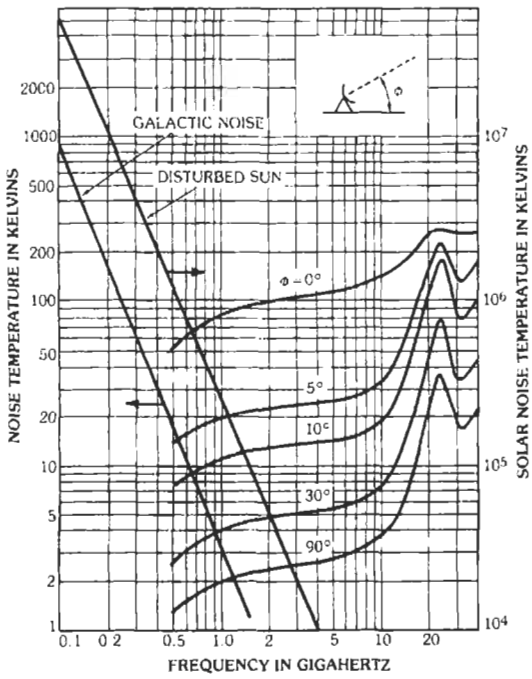

Fig. 7. Noise temperature versus frequency (clear sky).

angle, larger amounts of noise power are collected by the main beam of the antenna in the atmosphere, and, in addition, the antenna side lobes pick up noise radiated by the surface of the earth and that part of the atmospheric noise reflected by it.

A more detailed discussion of the various propagation effects is presented in the section of this chapter entitled "Propagation."

In conclusion, an optimum region for communications systems involving earth-to-space paths exists between 0.8 and 8 GHz. As it is relatively easy to build low-noise, high-gain electronic amplifiers for these frequencies, space communications systems have been preferentially designed to operate in this portion of the spectrum. In the end, it is the allocation of frequency bands to satellite communications at World Administrative Radio Conferences (WARCs) under the aegis of the ITU that determines what frequencies are available. Beyond this, to prevent interference between systems, individual system use must be coordinated by the appropriate entities—the ITU internationally and the local government agencies, such as the FCC in the United States, as well.

The expansion of satellite communications systems has resulted in overcrowding of these frequencies and has forced the opening of higher frequency bands. Allocations in the 10–15 GHz bands have been opened up for the fixed satellite service (FSS) since the late 1970s and are now used extensively. Use of allocations for the broadcasting satellite service (BSS) in these frequency bands was begun in the 1980s. Efforts in the late 1980s in Japan and Europe and in the 1990s in the United States have opened up the very broad frequency band allocations at 20 and 30 GHz. Despite the severe rain-impairment environment, one can anticipate ever-increasing use of the 20 and 30 GHz bands for FSS and ISS. Bands above this are being used outside the United States. There is always, in this era, a shortage of bandwidth, especially for the mobile services. Allocations to the fixed satellite service, intersatellite service (ISS), broadcasting satellite service, and mobile satellite services (MSS) can be found in Chapter 1.

LINK BUDGETS

Fig. 8 shows a model of an earth-space-earth communications system that comprises an up-link from an earth station to a spacecraft and a down-link from the spacecraft to earth. In the case of space systems, the information rates in the up- and down-links are different because the up-link carries only command and control information, while the down-link carries the information gathered by the spacecraft instruments. However, in satellite communications systems, because the spacecraft functions as a relay station in space, the information flow can be the same in the up-link and the down-link. Messages (voice, video, data, etc.) generated by individual users and converted into electrical signals in the terrestrial network are routed to satellite earth stations, where, after suitable signal processing, modulated RF carriers are beamed to the satellite by a high-gain antenna. Conversely, the signals received from the satellite are processed, fed into the terrestrial network, and eventually distributed to the users.

Although direct computation of the information transmission rate can be done in terms of Eq. 16 for the up- or down-link, or for their combination, it is convenient to derive relationships for the signal-to-noise power ratio in the two links taken separately. In this manner, specific contributions to the link budgets

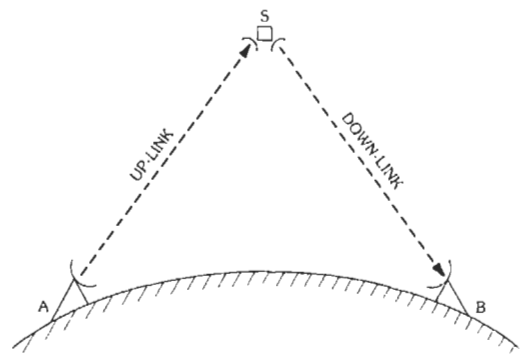

Fig. 8. Earth-space-earth links.

can be identified. In a successive step, the overall signal-to-noise power ratio is obtained by taking into account any additional noise contributions, such as interference or intermodulation. Finally, the number of channels (telephone, TV, or other) is computed for specific combinations of multiplexing, modulation, and multiple access techniques.

For the up-link, the power flux density at the satellite is given by

$$\phi = P_t G_t / 4\pi r_u^2 \qquad \text{(Eq. 26)}$$

Then the received signal power is

$$P_u = \phi A_{su} = \phi G_{su} \lambda_u^2 / 4\pi = P_t G_t G_{su} \left(\frac{\lambda_u}{4\pi r_u} \right)^2 \qquad \text{(Eq. 27)}$$

where

A_{su} = effective area of the satellite receive antenna
G_{su} = gain of the satellite receive antenna
λ_u = up-link wavelength

The signal is received in the presence of thermal noise contributed by the receiver (internal noise) and the background (external noise). Both contributions can be assumed Gaussian and white; hence the total noise power density is $N_0 = kT_s$, where $k = 1.38 \times 10^{-23}$, J/K is Boltzmann's constant, and T_s is the system temperature. Thus the noise power in the RF transmission bandwidth, B, is $N = N_0 B$. Substitution in Eq. 27 yields the up-link signal-to-noise power ratio:

$$P_u / N_u = \left(\frac{P_t G_t G_{su}}{kT_s B} \right) \left(\frac{\lambda_u}{4\pi r_u} \right)^2 \qquad \text{(Eq. 28)}$$

and, in decibels,

$$\underset{(\text{dB})}{P_u / N_u} = \underset{(\text{dBW})}{10 \log P_t G_t} - \underset{(\text{dB})}{20 \log (\lambda_u / 4\pi r_u)}$$

$$- \underset{(\text{dB·Hz})}{10 \log B} + \underset{(\text{dB/K})}{10 \log (G/T)\big|_s} - \underset{(\text{dB/Hz·K})}{10 \log k} \qquad \text{(Eq. 29)}$$

The first term represents the earth station eirp; the second, the "free space loss"; the third, the RF channel bandwidth; the fourth, the satellite GIT ratio (G_{su}/T_s); and the fifth, Boltzmann's constant.

A similar procedure yields the down-link budget:

$$P_d / N_d = \left(\frac{P_s G_{sd} G}{kT_e B} \right) \left(\frac{\lambda_d}{4\pi r_d} \right)^2 \qquad \text{(Eq. 30)}$$

and, in decibels, noting that $\frac{G_r}{T_e}$ is $(G/T)\big|_e$,

$$\underset{(\text{dB})}{P_d / N_d} = \underset{(\text{dBW})}{10 \log (P_s G_{sd})} - \underset{(\text{dB})}{20 \log (\lambda_d / 4\pi r_d)}$$

$$- \underset{(\text{dB·Hz})}{10 \log B} + \underset{(\text{dB/K})}{10 \log (G/T)\big|_e} - \underset{(\text{dBW/Hz·K})}{10 \log k} \qquad \text{(Eq. 31)}$$

The numerical value of the Boltzmann's-constant term in Eqs. 29 and 31 is

$$10 \log (1.38 \times 10^{-23}) = -228.6 \text{ dBW/Hz} \cdot \text{K}$$

and the "free-space loss" expressed in decibels is

$$\underset{(\text{dB})}{L_{fs}} = 92.44 + \underset{(\text{km})}{20 \log r} + \underset{(\text{GHz})}{20 \log f} \qquad \text{(Eq. 32)}$$

A plot of free-space loss versus frequency for the geostationary orbit appears in Fig. 9. If signal-power–to–system-noise-temperature ratios (dBW/K) are used in lieu of signal-to-noise power ratios (dB), the Boltzmann's-constant term disappears in Eqs. 28 through 31. The RF channel bandwidth also disappears when signal-power–to–noise-power-density ratios (dB · Hz) are used. The choice of the notation is immaterial, but consistency is required in the use of units. Whenever angle modulation is employed, the symbol C (for carrier power) can be used in lieu of P (for signal power), as these two quantities have equal values.

SPACECRAFT ARCHITECTURE

The communications function is supported by the following subsystems:

A. Main structure
B. Primary propulsion subsystem, i.e., apogee/perigee motor(s)
C. Auxiliary propulsion subsystem for station-keeping and orientation
D. Thermal control subsystem
E. Power subsystem
F. Telemetry, command, and control subsystem

The communications subsystem consists of antennas, receivers, and transmitters. Its mass plus that of the power subsystem defines the useful payload mass, M_u. The ratio of this mass and the total mass, M, of the spacecraft in orbit determines the spacecraft utilization factor:

$$u = M_u / M \qquad \text{(Eq. 33)}$$

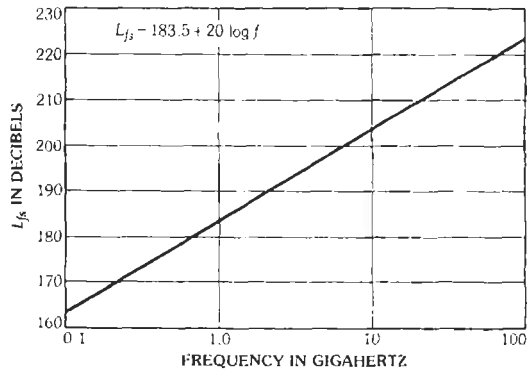

Fig. 9. Free-space loss versus frequency (GEO).

Typical values of u range from 0.35 to 0.60. The difference,

$$M_b = M - M_u = M(1 - u) \qquad \text{(Eq. 34)}$$

represents the mass of the bus (items A, C, D, and F of the above-mentioned support subsystems). Finally, the spacecraft mass at launch, M_l, is

$$M_l = M + M_b \qquad \text{(Eq. 35)}$$

where M_b represents the mass of the primary propulsion subsystem.

The three satellite parameters—transmit power, antenna gain, and bandwidth—that contribute to communications capacity are proportional to the total spacecraft mass. Designers' efforts aim at obtaining values as high as possible of the utilization factor (defined by Eq. 33), and for a given communications capacity, the total spacecraft mass should be kept as small as possible to keep launch costs down. Ever-increasing communications capacity can be achieved not just by constructing bigger and more powerful satellites but also by the introduction of advanced technologies in all spacecraft subsystems as well as in the transmission system design.

TRANSPONDERS

Transponders are microwave repeaters carried by communications satellites. Three possible configurations are shown in Fig. 10. The first case (Fig. 10A), in which no signal processing takes place other than heterodyning from the up- to the down-link frequencies and amplification, represents a class of transponders designated as "transparent." It can handle any signal whose format can fit in the transponder bandwidth. The second case (Fig. 10B) involves switching at rf, and the third case (Fig. 10C) involves switching at base band with demultiplexing, demodulation and remodulation, and possibly other signal processing such as routing, buffering, or storage.

The receive and transmit antenna configurations (including frequency reuse by orthogonal polarization and/or separate beams) depend on the earth-station topology and traffic flow. The transponder front end, which includes filters, low-noise amplifiers, local oscillators, mixers, and preamplifiers, is designed for linear operation over the entire bandwidth of the up-link to minimize volume, mass, and power consumption of the down-converter portion of the transponder. Field-effect transistors are commonly used as active circuit elements. Distortionless transmission is ensured by flat amplitude and group-delay (linear phase) responses over the passband. Equalizers (mostly for compensation of group delay distortion) are also used. However, limiters are used when anti-jam protection is needed.

Various contributions enter into the system noise temperature. If the receive antenna input port is taken as the reference point for the configuration shown in Fig. 11, the system noise temperature is

$$T_s = T_{\text{ANT}} + [(L - 1) + L(F_{pr} - 1) + L(F_r - 1)/G_{pr}]T_{\text{ref}} \qquad \text{(Eq. 36)}$$

where

T_{ANT} = antenna noise temperature
L = transmission line (waveguide) loss
F_{pr} = preamplifier noise factor
G_{pr} = preamplifier power gain
F_r = receiver (down-converter) noise figure
T_{ref} = 290 K

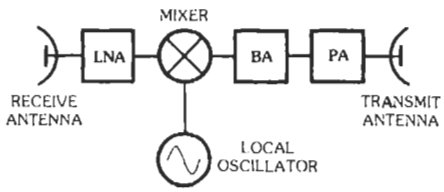
For a satellite antenna looking at the earth, the contribution of the term T_{ANT} is near 290 K. Low-loss waveguides and high-gain, low-noise preamplifiers are clearly desirable. After the signal is converted to the down-link frequency and preamplified, its level needs to be raised to the required rf power output. Redundant receivers are used to ensure survivability over the planned spacecraft lifetime.

The linearity requirements, which are fairly easy to achieve in the receiver, are difficult to meet in the power amplifiers. Transmitters having output power from 5 to 20 watts are typically used in communications satellites and in deep-space probes; hundreds of watts will be used in satellites for direct broadcasting. The high efficiency in the energy-conversion process from dc to rf that is desirable for maximum utilization of spacecraft mass and prime power conflicts with the linearity requirements.

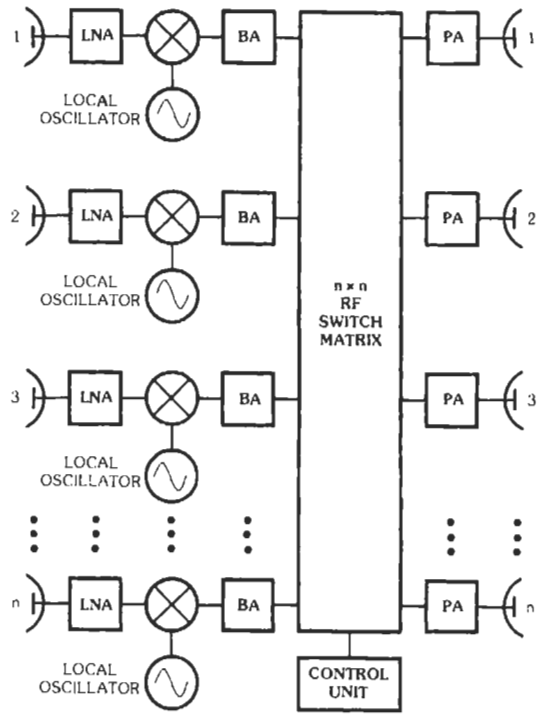
Traveling-wave tube amplifiers (TWTAs) dominated as satellite high-power amplifiers (HPAs) into the 1980s because of their wide-band, high-gain, and high-efficiency characteristics accompanied by their light weight, long life, and high reliability. They remain the satellite HPA of choice when higher power is needed, and at higher frequencies (above 15 GHz). The typical TWTA characteristics shown in Fig. 12 indicate maximum conversion efficiency at saturation with departure from linearity. Reduction of the input signal level yields linear, or quasilinear, operation at lower conversion efficiency and power output.

Traveling-wave tubes also produce AM-to-PM modulation conversion effects because the phase of the output signal is affected by the input signal amplitude. Intermodulation noise caused by amplitude nonlinearity is maximum when the TWT is driven at saturation. Reducing the input signal amplitude yields an almost linear operation, but the interaction of the electron beam and the wave advancing along the helix structure of the tube is such that AM-to-PM conversion effects are worst in the quasilinear region of the tube characteristics.

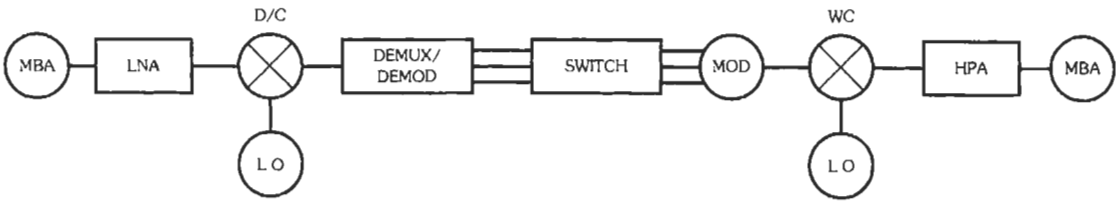
When several modulated carriers are present at the input, the resultant signal envelope fluctuates and produces phase variations in the output signal, resulting in intermodulation products. Third-order intermodulation products of the form $(f_1 + f_2 - f_3)$ and $(2f_1 - f_2)$ are



(A) Single conversion.



(B) With switching at RF.



(C) Baseband processing.

Fig. 10. Transponders.

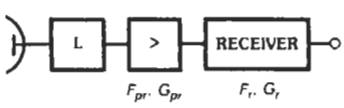


Fig. 11. Receiver front end.

objectionable because they fall inside the transponder passband; the amplitude of the $(f_1 + f_2 - f_3)$ product is about 6 dB higher than that of the $(2f_1 - f_2)$ product. For a small number of carriers, the third-order intermodulation products are mainly dictated by the coefficient of the third-power term of the power series expansion representing the nonlinear element. A 1-dB

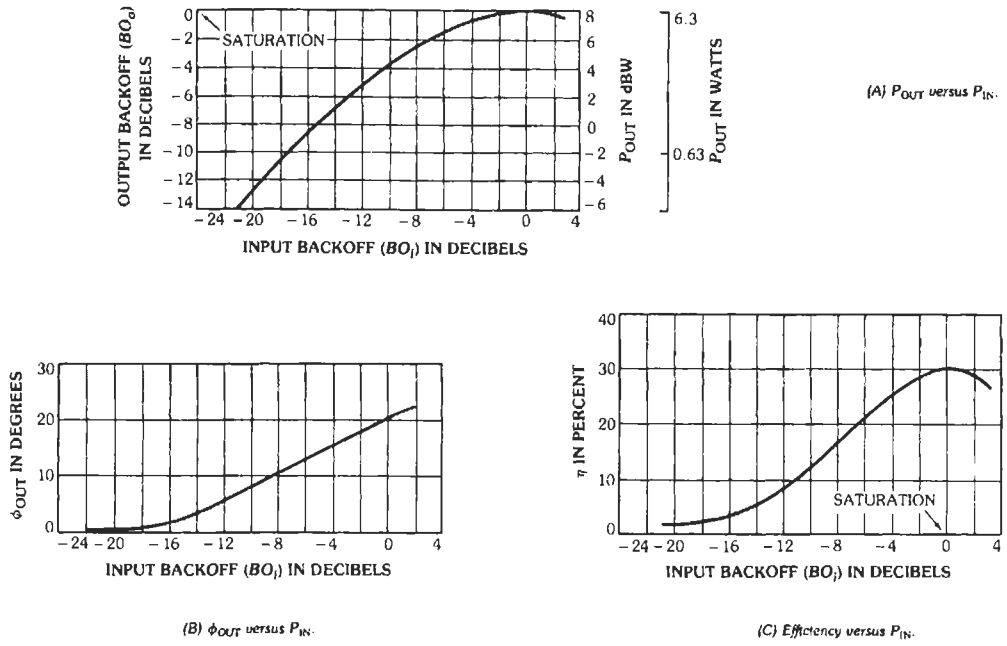

Fig. 12. TWTA characteristics.

change in the input produces a 3-dB change in the third-order intermodulation product, and hence a 2-dB change in the output carrier-to-noise ratio. When the number of carriers is increased, the intermodulation products are compressed toward the limit case of $n = \infty$, and for large n, the fifth-order product $(3f_1 - 2f_2)$ becomes negligible compared with third-order products. In practice, an input level is chosen that leads to a compromise between the amplitude-to-amplitude and amplitude-to-phase distortions.

Advances in solid-state devices have made it possible to replace TWTAs with solid-state power amplifiers (SSPAs), usually using FETs at frequencies up to 15 GHz, for all but the higher-power applications. However, the limits of frequencies and power for SSPAs are continually moving upward as new structures emerge from research work in solid-state devices and production techniques. New devices include high-electron-mobility transistors (HEMTs), and new techniques include molecular beam epitaxial (MBE) deposition and electron-beam writing of circuit/transistor structures. Although the characteristics of SSPAs differ from those of TWTs, the two above-mentioned sources of signal distortion and intermodulation noise (AM to AM and AM to PM) can still be identified, and, in general, intermodulation noise is lower in solid-state amplifiers. Complementary nonlinear elements cascade-connected with nonlinear power amplifiers can provide considerable overall linearity improvement.

The down-link bandwidth is divided into sub-bands, each one of them accepting a limited number of modulated carriers to keep intermodulation products under control. Input demultiplexers separate the down-converted signals and distribute them among several transmitters, each one using a fraction of the entire down-link bandwidth. Output multiplexers are used at the interface between the transmit power amplifiers and the transmit antenna-feed waveguides.

Transponders are usually counted by the number of separate transmit channels in the down-link and the corresponding portions of the up-link wide-band receivers.

For given amounts of power and mass available for the communications subsystem, the number of transponders and their bandwidth depends on trade-offs of power, bandwidth, and intermodulation noise. With a fraction of the bandwidth lost to guard bands, the total usable bandwidth decreases when the number of transponders increases. A similar situation arises in regard to the available power per transponder, on account of the direct arithmetical proportion and also because of the increased complexity of the distribution network.

Transponders of equal bandwidth are advantageous for fixed allocations of traffic but do not provide flexibility when a network is reconfigured within a given coverage area or when a satellite is moved to serve an area characterized by different network topology and traffic requirements.

Until the mid 1970s, the prevalent use of FDM/FM/FDMA transmission led to a standardization of transponder bandwidth around 36 MHz and to the number of transponders per spacecraft of around 12 for

single-polarization satellites and 20–24 for dual-polarization satellites. The introduction of the 11/14-GHz frequency bands and of high-speed digital transmission has accelerated the use of wider-band transponders (80 and 200 MHz) in addition to those having 36–40 MHz nominal bandwidth.

The increasing number of transponders (reaching 46 in *INTELSAT VI*) needed to provide ever greater amounts of communications capacity has required advances in the design of flight-qualified microwave filters and multiplexers. Light weight has been achieved by using thin-wall Invar or graphite-fiber-reinforced plastic cavities. The requirement for flat amplitude and group time delay necessary to maintain low signal distortion and minimal crosstalk contrasts with the high skirt selectivity needed for efficient spectrum utilization. The design has evolved from conventional single-mode cascade rectangular-cavities Chebychev filters (Fig. 13) to longitudinal cross-coupled dual-mode circular-cavities filters as shown in Fig. 14, improved skirt selectivity being obtained at the expense of a finite but sufficiently large out-of-band attenuation. True elliptical response can be achieved in the canonical dual-mode filter shown in Fig. 15, in which the same physical cavity provides the input and output ports. This arrangement is also mechanically advantageous because of mass and volume reduction. Further reduction in mass and volume

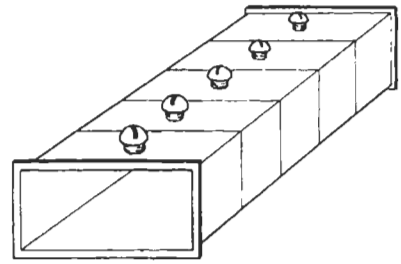

Fig. 13. Single-mode cascaded-cavities filter.

can be achieved by use of dielectric pucks, which drastically reduce cavity size. Another approach uses still higher-order-mode filters, such as those of fourth order. Finally, recent advances in high-T_c superconductors have permitted development of microwave filters employing such materials. These offer still greater promise, but practical realization for flight use is probably a decade off.

Technology is evolving at such a rapid pace that it is useful to look ahead a few years. One is never certain about the technological future. But, based on what is currently emerging from the R&D facilities, it is possible to indicate what looks likely to be available for commercial use in space in the next 5–10 years.

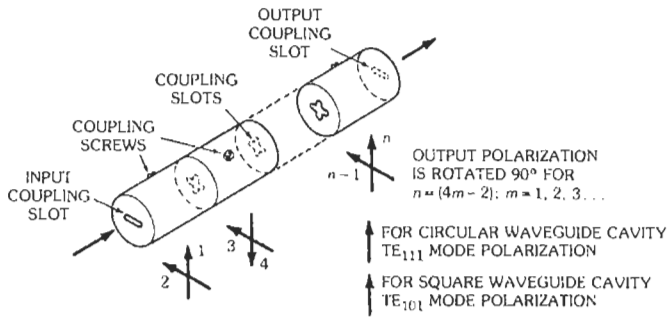

Fig. 14. Coupled dual-mode circular-cavities filter.

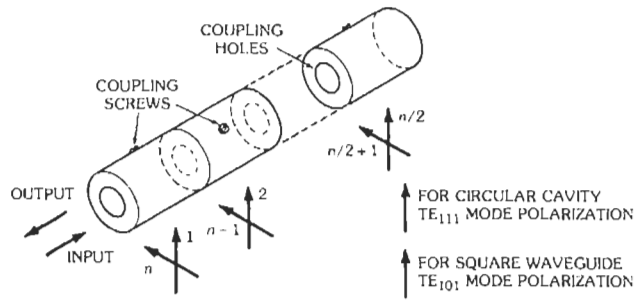

Fig. 15. Canonical dual-mode filter.

In recent years, the evolution of the transponder from a simple microwave repeater to a node, which provides a variety of communications processing functions, has been progressing rapidly. The initial phases of development of onboard processing (OBP) included de- and remodulation and satellite-switched TDMA (detailed in its own section below), followed by deployment and service. Other forms of OBP rerouting have been developed, including OBP ATM (Asynchronous Transfer Mode) switches and packet switches. OBP error correction and de- and recoding are also in the OBP mix. An OBP ATM switch is scheduled for flight and on-orbit testing. Deployment can be anticipated. What can be anticipated for the first 10 years of the 21st century is the use of a wide variety of transponder types ranging from microwave repeaters used for single links, to multicast in their simpler forms, all the way to full OBP processor-equipped payloads. These latter will be able to receive the signals from a multibeam multifrequency antenna farm, take them down to baseband, perform error correction, reroute them as needed, encode and modulate the newly formed bit streams, and transmit them through the multibeam multifrequency antenna farms to their destinations. Every element needed for these latter payloads either has been developed or is under development. Obviously system and service needs will define the transponder types deployed in any system. But the capability will be there.

One further type of transponder needs mention at this time. Laser and optical technology has reached the point where commercial deployment of laser communications links in space and satellite applications awaits only the final demonstration. Equipment has been deployed in space for such a demonstration, for example, on the Japanese *ETS-VI*, which unfortunately failed to reach the planned orbit. Currently, the *SPOT-4* satellite carries an optical package in space, awaiting the launch of the *ARTEMIS* satellite by ESA, which will carry the already developed SILEX optical system with which it will communicate. Further, the Japanese *OICETS*, already ready, will be launched to also work with the SILEX system. One can foresee that the success of these efforts will presage the commercial use of optical transponders and links in space. The more difficult links, optically, are earth–space, because of atmospheric impairments to the signal. However, if current ongoing efforts in Japan, Europe, and the United States to develop high-altitude platform systems (HAPS) that hover above the stratosphere at altitudes above 18 km are successful, links between satellites and such platforms will be eminently feasible.

OVERALL TRANSMISSION SYSTEM CONSIDERATIONS

With transparent transponders and analog transmission, the total signal- (carrier-) to-noise power ratio can be computed from the expression

$$(C/N_{\text{total}})^{-1} = (C/N_{\text{up}})^{-1} + (C/N_{\text{down}})^{-1} + (C/N_{\text{im}})^{-1} + (C/N_{\text{in}})^{-1} \quad \text{(Eq. 37)}$$

where, in addition to the up- and down-link noise, the third term represents intermodulation noise, and the fourth term represents interfering signals. In the presence of intermodulation noise, C/N_{total} can be maximized by reducing the transponder input drive. Backing off the TWTA reduces C/N_{up} and also C/N_{down} (via the power input/output relationship of the transponder), but as C/N_{im} increases rapidly when the input drive is reduced, an optimum value of C/N_{total} is obtained at a specific backoff level, as shown in Fig. 16. Interference noise is kept down by proper antenna design, transponder selectivity, and planned coordination of satellite systems sharing given frequency allocations.

Satellite communications systems involve the three interacting processes of multiplexing, modulation, and multiple access. Signals appearing at the interface of the terrestrial and the satellite transmission system include single voice channels, groups and supergroups of voice channels, analog TV channels, and digital bit streams. Multiplexing combines these diverse signals into a composite baseband signal with individual inputs distinguishable in the frequency or time domain. Modulation can be either analog (i.e., continuous) or discrete (digital), and in the latter case, sampling and quantization occur prior to the modulation

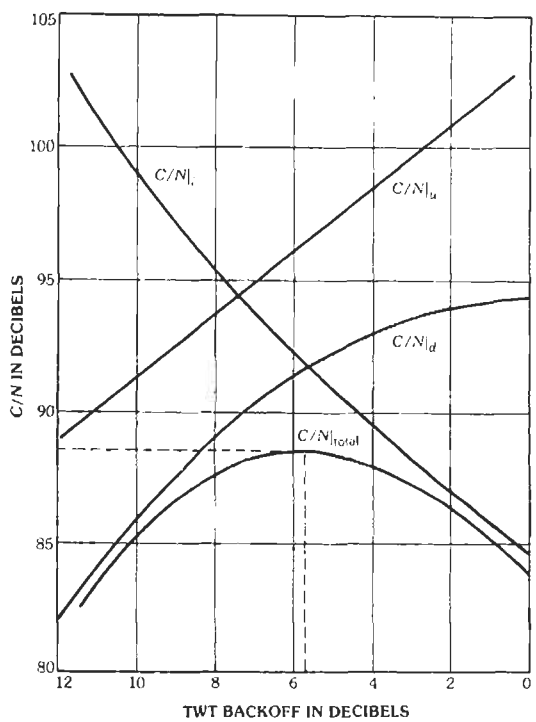

Fig. 16. *C/N* ratios.

process itself. Amplitude modulation has been little used; analog phase or frequency modulation or digital BPSK and QPSK modulations have been widely used.

Multiple access is a unique feature of satellite communications: When m earth stations are "visible" from a satellite, transponders can be shared by several earth-station pairs. The number of possible connections is then

$$n = m(m-1)/2 \qquad \text{(Eq. 38)}$$

This "n-port" network feature is very attractive in comparison with the inflexibility of the "2-port" configuration encountered in most earth-based communications systems.

Individual accesses are kept separate in a physical domain such as frequency, time, or space (i.e., by separate antenna beams) or by encoding. The accesses can be preassigned in a static mode or dynamically assigned on demand. Fig. 17 illustrates three principal modes of multiple access, and Table 2 outlines their major features.

Because modulation and multiple access are interactive processes, the choice of a specific method of multiple access depends on the best utilization of the available power and bandwidth. The number of accesses should be made as large as possible while signal impairments caused by imperfections of the transmission channel are kept within specified margins. The overall system design is also influenced by the characteristics of the terrestrial interface. Analog voice and video transmission systems predominant in the mid-1960s in terrestrial systems led to the adoption of

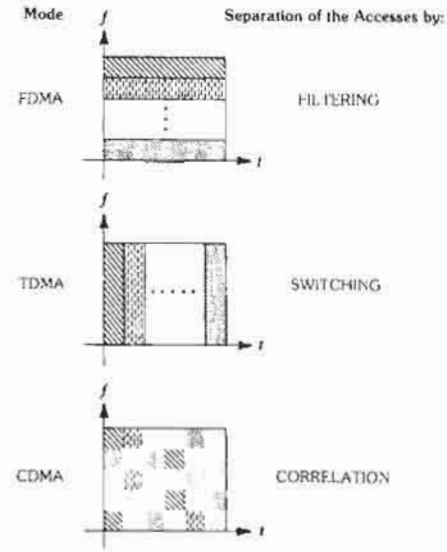

Fig. 17. Multiple-access schemes.

TABLE 2. FEATURES OF MULTIPLE-ACCESS SCHEMES

Type	Characteristics	Advantages	Disadvantages
FDMA	Constant envelope signals Angle modulation (analog or digital) Separation by filtering	Easy interfacing with terrestrial analog facilities No need for synchronization Simple earth-station equipment	Intermodulation noise in nonlinear amplifiers reduces communications capacity Backoff required Up-link power coordination is required Transmission plan is difficult to reconfigure
TDMA	Bursts from and to different stations do not overlap Only one burst present at a given time Separation by time gating	Fairly easy interfacing with terrestrial digital facilities Power amplifiers operate near saturation at higher efficiency Highest communications capacity No need for power control and coordination Transmission plan is flexible	Need for coordinated synchronization More complex earth-station equipment A/D and D/A conversion required
CDMA	Constant envelope signals Each access takes the whole transponder bandwidth Separation by correlation	Spread spectrum provides protection against jamming	Synchronization is required Communications capacity is somewhat limited Signal quality worsens when number of accesses increases Power coordination is needed

FDM/FM/FDMA techniques in most commercial satellite systems, notwithstanding the loss of communications capacity resulting from the nonlinear channel characteristics when several carriers occupy a transponder. The expansion of digital systems, accelerated by the advances in solid-state devices that have made possible rugged, reliable, and cost-effective signal-processing equipment, has lead to a wider use of time-division multiple access (TDMA). As noted above, digital technology has advanced to the point where digital transmission is now dominant. Other multiple-access techniques such as code-division multiple access (CDMA) have proved to be competitive with TDMA.

Digital transmission offers the following major advantages:

A. Guarantee of error control
B. Reduced sensitivity to channel nonlinearity
C. Efficient trade-off of power and bandwidth
D. Flexibility with regard to multiplexing diverse signals
E. Easy combination of the functions of transmission switching and routing
F. Capability of signal regeneration
G. Implementation with rugged hardware

In satellite systems, points A, B, C, F, and G are especially meaningful. The up- and down-link can be separately designed to provide specified amounts of bit error rate (BER). For a given type of modulation, BER is primarily a function of the carrier-to-noise power ratio, C/N (or the energy-per-bit-to-noise-power-density ratio, E/N_0), in the channel. Assuming independent noise performance of the links, the BER of their combination is the sum of the individual BERs. This condition is satisfied with repeaters capable of providing signal regeneration in the case of "transparent repeaters." Otherwise, the up-link BER must be much smaller than the down-link BER.

Digital methods are especially attractive in demand assigned multiple access (DAMA) and TDMA systems.

ANALOG TRANSMISSION SYSTEMS

In satellite systems, multiplexing, modulation, multiple-access methods, and the channel characteristics interact in the determination of communications capacity. With analog transmission, the quality of the signal delivered to the user is a function of the post-detection signal-to-noise ratio, S/N, through a general functional relationship of the form

$$S/N = f(C/N_0, \text{CH, SIG, MUX, MOD, MA}) \qquad \text{(Eq. 39)}$$

where

C/N_0 = carrier-to-noise power density ratio in the RF channel
CH = RF channel characteristics (amplitude and phase, nonlinearity)
SIG = original signal descriptors
MUX = type of multiplexing
MOD = type of modulation
MA = type of multiple access

System performance can be assessed with reference to the Shannon bound (rate distortion theory and communications capacity) and, in practice, by the number of telex, telephone, or video channels that can be handled.

FDM/FM (Single-Carrier Case)

When a transponder handles a single carrier modulated by a baseband signal resulting from frequency-division multiplexing of numerous voice channels and with no interference, Eq. 37 simplifies to

$$(C/N|_{\text{tot}})^{-1} = (C/N|_{\text{up}})^{-1} + (C/N|_{\text{down}})^{-1} \qquad \text{(Eq. 40)}$$

The signal-to-noise power ratio in the worst (top) voice channel at the output of the FM demodulator can be computed by using the appropriate FM equations.

First, the weighted signal-to-noise ratio for a 1-mW test tone is computed by taking into account ITU-R (formerly CCIR) recommendation on satellite systems channel noise performance, which requires the average noise power not to exceed 10 000 pW psophometrically weighted (pWp). Allowing 1000 pWp for the earth-station equipment noise, 1000 pWp for interference noise, and 500 pWp for the earth-station out-of-band noise, the balance of 7500 pWp is the noise allowed for the combination of the up- and down-links. Hence,

$$S/N = 10^{-3}/(7500 \times 10^{-12}) = 1.33 \times 10^5 \qquad \text{(Eq. 41)}$$

or

$$S/N_{\text{dB}} = 51.25 \text{ dB} \qquad \text{(Eq. 42)}$$

The relationship between the signal-to-noise ratios at the output and the input of the FM detector operating beyond threshold is*

$$S/N = (C/N)B/b(f_r/f_m)^2 pW \qquad \text{(Eq. 43)}$$

where

S/N = weighted signal-to-noise power ratio at 1-mW test-tone level
C/N = carrier-to-noise power ratio over the RF channel bandwidth
B = RF channel bandwidth
b = audio channel bandwidth (3.1 kHz)
f_r = rms test-tone frequency deviation

* For a limiter–discriminator FM detector, the threshold is often taken as (C/N) = 10 to 13 dB. FMFB and PLL detectors can provide up to 3 to 5 dB of threshold extension.

f_m = maximum baseband frequency $\simeq 4.2 \times n$ kHz, with n the number of voice channels
p = psophometric factor (1.78 or 2.5 dB)
W = preemphasis factor (2.5 or 4.0 dB)

Carson's rule defines the RF channel bandwidth as

$$B = 2(f_p + f_m) \qquad \text{(Eq. 44)}$$

where

f_p is the peak frequency deviation,
f_m is the maximum frequency component of the baseband modulating signal,

Because this signal is Gaussianly distributed, the peak frequency deviation is undefined; however, a peak factor p, which is the ratio of the peak to the rms frequency deviations, can be assumed, with values from 3.16 (10 dB) to 8.5 (18.6 dB), the lower value corresponding to large n.

If we consider the load factor

$$L = \begin{cases} -15 + 10 \log n, & n \geq 240 \\ -1 + 4 \log n, & 12 < n < 240 \end{cases} \qquad \text{(Eq. 45)}$$

which yields the average power of the baseband signal in dBm0, the quantity

$$g = \text{antilog}\,(L/20) \qquad \text{(Eq. 46)}$$

is the ratio of the rms multichannel frequency deviation to the test-tone deviation. By introducing both factors in Eq. 44, the value of the rms test-tone deviation is determined:

$$f_r = (B/2 - f_m)/\rho g \qquad \text{(Eq. 47)}$$

As the value of B is fixed for a given transponder design, the number of voice channels per transponder can be computed by an iterative procedure. Starting with an estimate for n, computed values of f_m and f_r are introduced into Eq. 43 together with the RF channel C/N power ratio. If the resulting S/N turns out to be greater (or smaller) than the prescribed 51.25 dB, the estimate for n was too low (or too high) and needs to be changed until the correct value of S/N is found.

In practice, each voice channel requires from 40 to 50 kHz of RF bandwidth; hence the channel density falls in the range from 20 to 25 voice channels per megahertz. The use of companded FDM/FM permits greater capacity; typically a doubling of the capacity can be achieved for a given transponder bandwidth.

FDM/FM/FDMA (Multicarrier Case)

As transponder bandwidth and power are shared among the modulated carriers, the 7500 pWp must include the intermodulation noise arising from the transponder nonlinearity. Although the intermodulation noise is reduced by backing off the traveling-wave-tube power amplifier, the ultimate result is a reduction of the number of voice channels that can be handled by a transponder in proportion to the number of accesses. The smaller value of the loading factor contributes also to reducing communications capacity. Fig. 18 illustrates the performance of a typical commercial satellite using FDM/FM/FDMA in a global beam.

Within the constraints of the available bandwidth and power, and by taking into consideration interference and frequency-coordination problems, the actual value of the maximum transponder capacity depends on tradeoffs among the following causes of signal impairment:

A. Spacecraft TWTA impairments, which include in-band intermodulation products arising from both amplitude and phase nonlinearity and intelligible crosstalk due to AM–PM conversion.
B. Frequency-modulation transmission impairments not attributable to the TWTA characteristics. These impairments include adjacent-channel interference due to spectral overlap, which produces convolution and impulse noise at baseband; dual paths between transponders on a given spacecraft; interference produced by intermodulation in adjacent transponders; co-channel interference in frequency reuse systems; and earth station RF out-of-band emission.

At the earth stations, the baseband signals frequency modulate preassigned multidestination carriers, which are transmitted via satellite to various receiving stations. After demodulation of the RF signals and demultiplexing of the baseband, the individual voice channels are recovered. This transmission method is rather inflexible with respect to changing traffic requirements, but it has been widely used for high-density trunks.

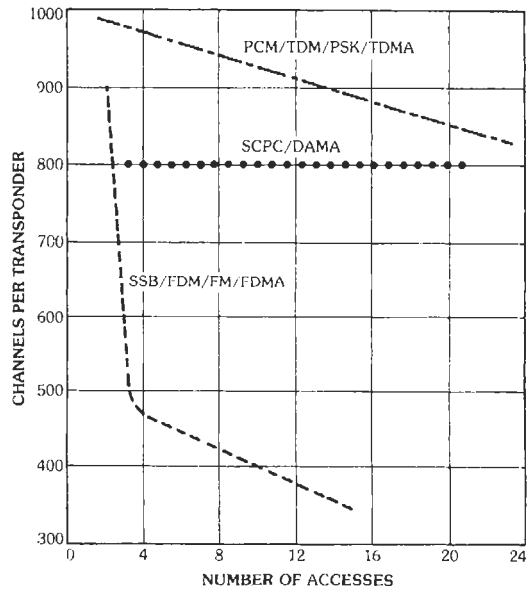

Fig. 18. Multiple-access systems performance.

DIGITAL TRANSMISSION SYSTEMS

Since

$$C/N = (E/N_0)(R/B) \qquad \text{(Eq. 48)}$$

where

C = carrier power
N = noise power
E = energy per bit
N_0 = noise power density
R = transmission rate
B = channel bandwidth

the transmission rate in digital systems is limited either by power or by bandwidth constraints. In the power-limited case, and for a given modulation type, the bit error probability, p_e, is a function of E/N, and, hence, of C/N_0R; thus, the allowable rate is

$$R_p = f(C/N_0, p_e) \qquad \text{(Eq. 49)}$$

where the subscript p indicates a power-limited situation.

In the band-limited case

$$R_b = F(B, \text{MOD}) \qquad \text{(Eq. 50)}$$

where the subscript b indicates a band-limited situation and MOD indicates the modulation type.

Thus, in general

$$R_{\max} = \min(R_p, R_b)$$
$$= f(\text{MOD}, C/N_0, B, p_e) \qquad \text{(Eq. 51)}$$

Expressing bit error probability as a function of E/N_0 determines modulation performance. In general,

$$p_e = f(E/N_0)$$
$$= (1/2)\,\text{erfc}\,[(E/2N_0)(1-\rho)]^{1/2} \qquad \text{(Eq. 52)}$$

where

$$\text{erfc}\,(x) = (2/\sqrt{\pi})\int_x^\infty e^{-t^2}\,dt$$

and

$$-1 \le \rho = \left(\frac{1}{E}\right)\int_{-\infty}^{+\infty} s_1(t)s_2(t)\,dt \le 1$$

where the normalized correlation coefficient of the waveforms $s_1(t)$ and $s_2(t)$ are used to represent zeros and ones.

The most frequently used digital modulation systems are binary phase shift keying (BPSK) and quaternary phase shift keying (QPSK), for both of which

$$p_e = (1/2)\,\text{erfc}\,[E/N_0]^{1/2} \qquad \text{(Eq. 53)}$$

since in QPSK the symbol energy is twice the bit energy. Various forms of modulation characterized by constant envelope have been proposed to achieve more efficient spectrum utilization and to avoid the amplitude changes occurring in BPSK and QPSK, which are objectionable in band-limited nonlinear systems. Plots of the bit error probability, p_e, as a function of E/N_0 and various types of modulation appear in Fig. 19. The R/B ratio, which is a function of E/N_0, provides a measure of bandwidth utilization efficiency and, since R cannot exceed Shannon's channel capacity

$$C = B\log_2[1 + C/(N_0B)]$$

a lower bound for E/N_0 is

$$\frac{E}{N_0} \ge [\exp(0.69R/B) - 1]/(R/B)$$

In practice, since $R/C \ll 1$, E/N_0 must be well above 0 dB. In power-limited situations, when the desired transmission rate cannot be achieved with a prescribed value of bit error probability, channel coding (forward error correction (FEC)) can be helpful. Error control in the channel requires the addition of redundant bits to the information bits and, hence, an increase of the overall rate and of the required bandwidth. Under certain conditions, the receiver can exploit the redundancy and significantly reduce the error probability of the recovered message.

Various kinds of codes have been proposed and used in satellite systems; the two major distinct approaches are block and convolutional codes. Although the

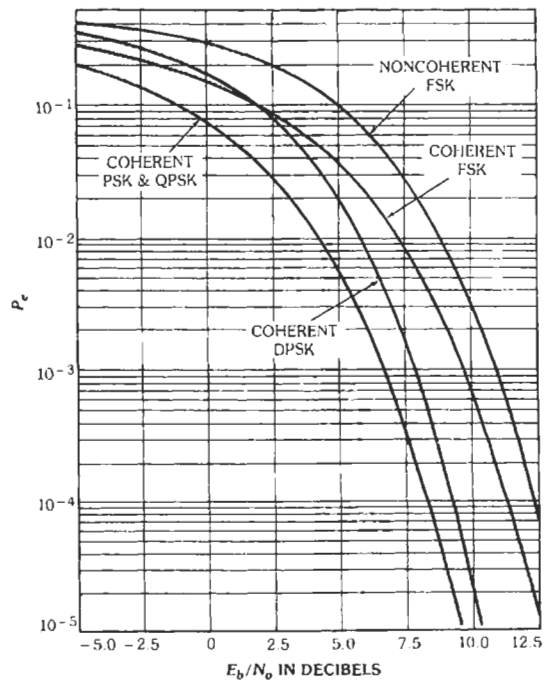

Fig. 19. Curves of BER versus EIN. (From H. L. Van Trees, Ed., *Satellite Communications*. New York: IEEE Press, 1979, Fig. 12, p. 76.)

former may be attractive in certain cases, the latter have been found preferable because of ease of implementation and availability of efficient schemes such as Viterbi and sequential decoding.

In the power-limited case, the link budget is calculated from Eq. 48:

$$R_p = (C/N_0) \cdot (N_0/E) \qquad \text{(Eq. 54)}$$

which is often written in logarithmic form as

$$\begin{aligned} R_p|_{\text{dB}} &= C/N_0|_{\text{dB·Hz}} - E/N_0|_{\text{dB}} \\ &= \text{eirp} + G/T - \text{free space loss} \\ &\quad + 228.6 - E/N_0|_{\text{dB}} \end{aligned} \qquad \text{(Eq. 55)}$$

For the bandwidth-limited case:

$$R_b = B \cdot \log_2 m \, R_s/B \qquad \text{(Eq. 56)}$$

where

m = number of bits/symbol
R_s = channel symbol rate (symbols/s or bauds)

Using logarithmic units

$$R_b|_{\text{dB}} = B|_{\text{dB}} + 10 \log_{10}(\log_2 m) - B/R_s|_{\text{dB}} \qquad \text{(Eq. 57)}$$

The lower bound of Eqs. 56 and 57 is the actual communications capacity.

The two operations of modulation and coding can be combined in a process known as "coded trellis signaling." By mating FEC coding to the modulation signal space, the minimum Euclidean distance between "words" can be maximized with the result of enhanced bit error rate performance versus E/N_0. In this unified approach, redundancy for FEC coding is achieved without sacrificing bandwidth by first doubling the dimension of the modulation signal space to an M-ary alphabet ($M = 2^n$). Then a convolutional code of rate $(n-1)/n$ is used to obtain the coding gain that provides better utilization of the available power.

At present, QPSK is the most commonly used modulation method. The advent of reliable low-power LSICs and VLSICs and, more recently, programmable-gate arrays has made practical implementation of soft decision decoding (Viterbi decoding) with a significant ($\approx$ 3 dB) improvement in coding gain possible. At high rates, recent developments include coded octal PSK (COPSK) and other higher-order modulation methods. Coding rates vary from rate 1/2 to rate 15/16; use of inner and outer codes at different rates permits quite efficient and high-coding-gain systems with very low error rates ($\approx 10^{-10}$ or better).

DEMAND-ASSIGNED MULTIPLE ACCESS (DAMA)

In DAMA systems, satellite circuits are assigned to earth-station pairs upon request. Each voice channel is transmitted on a separate carrier, which is activated by the speech input. Thus, transponder power and bandwidth are more efficiently used than in preassigned systems. Modulation can be analog or digital, the latter being preferred, with either PCM or AM voice encoding combined with BPSK or QPSK. Carriers are taken from a pool of frequencies that can be shared by the entire network of earth stations (fully variable DAMA) or limitedly assigned to certain destinations or origins (semivariable DAMA). The choice of the approach impacts on the complexity of the earth-station equipment. These techniques are particularly applicable to thin-route traffic situations.

An early example of the use of DAMA techniques was the SPADE system of *INTELSAT*. The terminal shown in Fig. 20 comprises a terrestrial interface unit, several transmit/receive units, a signaling and switching unit, and an IF subsystem. Through the terrestrial interface unit, calls originated in the local transmit center activate the signaling and switching unit, which selects a pair of frequencies and alerts the destination. Modulation/demodulation and A/D and D/A functions were performed by QPSK modems and PCM codecs. Single-channel per carrier transmission (SCPC) was used.* The common signaling system operated in a TDMA broadcast mode at 128 kbits with BPSK modulation at an error rate of 10^{-7}, which is three orders of magnitude better than that of the 64-kbits QPSK communications channel. A variety of signaling and switching systems as used by different countries can be accommodated. Fig. 21 shows the signaling flow, and Fig. 22 shows the communications flow.

As shown in Fig. 18, the SPADE system provides 800 voice channels with an *INTELSAT IV* type transponder connected to a global beam antenna independently of the number of accesses. A voice activation factor of 0.4 implies that when all 800 channels are in use to provide up to 400 two-way conversations, only 320 channels are simultaneously active 90 percent of the time; thus, a power savings of 800/320 = 2.5, or 4 dB, is achieved.

Although DAMA systems such as SPADE (providing FSS) have limited utility in the current environment, DAMA is a basic strategy. As such, DAMA is used as a set-up protocol, in mobile services, for example.

TIME-DIVISION MULTIPLE ACCESS (TDMA)

In time-division multiple access (TDMA), transponder power and bandwidth are shared by several earth stations. Each station transmits RF bursts at the same carrier frequency at different times; the carriers are modulated by signals coming from different sources. Because all stations are synchronized, only one burst occupies the transponder at any given time, and bursts from different stations never overlap. Power amplifiers can be operated at saturation, i.e., at maximum effi-

* SCPC/FM/FDMA transmission is also used in the *INTELSAT* preassigned network for small earth terminals.

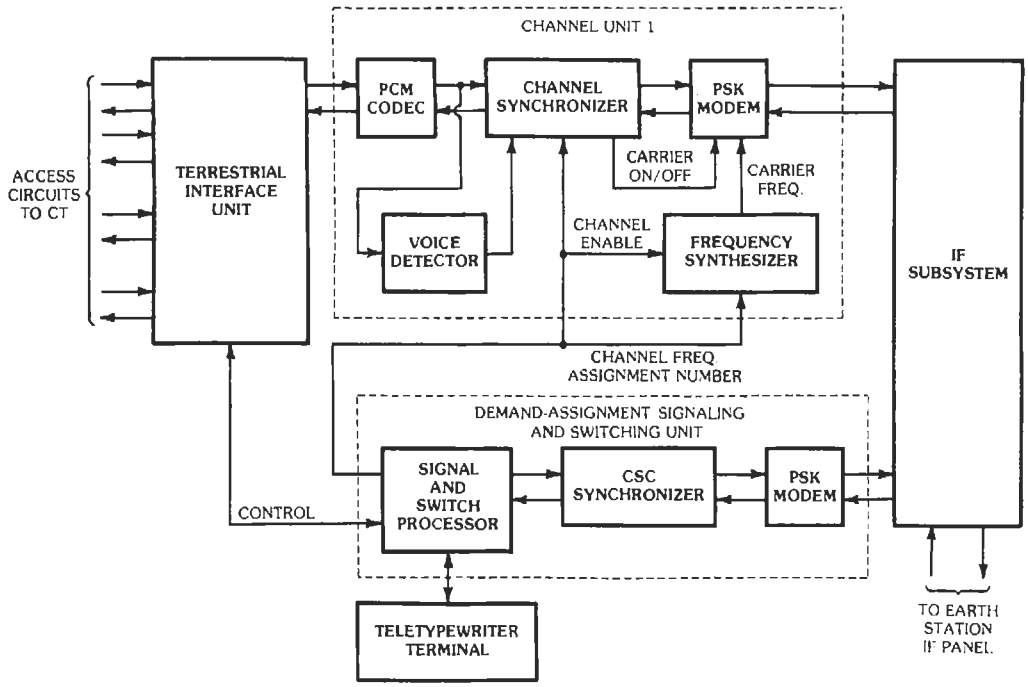

Fig. 20. SPADE terminal block diagram. (From *COMSAT Technical Review*, Vol. 2, No. 1, p. 226, Spring 1972.)

ciency. Consequently, since intermodulation noise is absent, communications capacity is higher than that achievable with analog FDM/FM/FDMA. The bursts are amplified by the satellite transponder and beamed down to earth to various earth stations. The down-link bursts are received and detected, and the demultiplexed signals are delivered to their destinations. Other advantages of TDMA include compatibility with terrestrial digital systems and flexibility in accommodating transmission systems growth. The requirements of up-link power control, which are very stringent in FDM/FM/FDMA systems, are greatly reduced in TDMA systems. However, when bandwidth is only slightly greater than the signal symbol rate, the combined effect of transmit-side filtering and nonlinearities produces intersymbol interference and signal distortion that cannot be eliminated by linear filtering at the receive side. In such a case, backoff of the power amplifier is still required to keep signal degradation within limits.

Earth stations have parallel steady inputs, some already in digital form and others in analog form that need to be converted to digital format. Since each station transmits periodically in bursts at a rate much higher than the bit rate of any of the input signals, memory circuits are needed for data buffering. The burst periodicity determines the TDMA frame duration; thus, for voice inputs (f_{max} = 4 kHz), the minimum value of the TDMA frame duration corresponds to a Nyquist interval of 125 μs. Multiples of this minimum duration can be used, leading to increased communications capacity through trade-offs of TDMA frame duration and amounts of memory capacity. An upper bound to frame duration is determined by the transmission delay from earth station to earth station (about 270 ms for geostationary satellites at 10° elevation).

Table 3 illustrates trends of operational and planned TDMA systems. Fig. 23 shows the TDMA frame structure adopted in field trials conducted by *INTELSAT* during 1978–1979. The transmission rate of 60 Mbits/s (935 voice channels) achieved with PCM/QPSK via a 40-MHz transponder yields a channel density of 23 channels/MHz.

A reference burst consisting of 30 symbols for carrier and clock recovery, 10 symbols for unique word, and 3 symbols for station identification, transmitted by a primary reference station (two standbys were provided) permits all other stations to transmit their bursts in proper sequence, i.e., without mutual overlap. Transmission rate and channel density can be doubled with the use of digital speech interpolation (DSI).

The number of voice channels in a TDMA system is

$$n = (1/r)(R - NP/T) \qquad \text{(Eq. 58)}$$

where

r = voice channel bit rate
R = satellite channel bit rate (power or band limited)

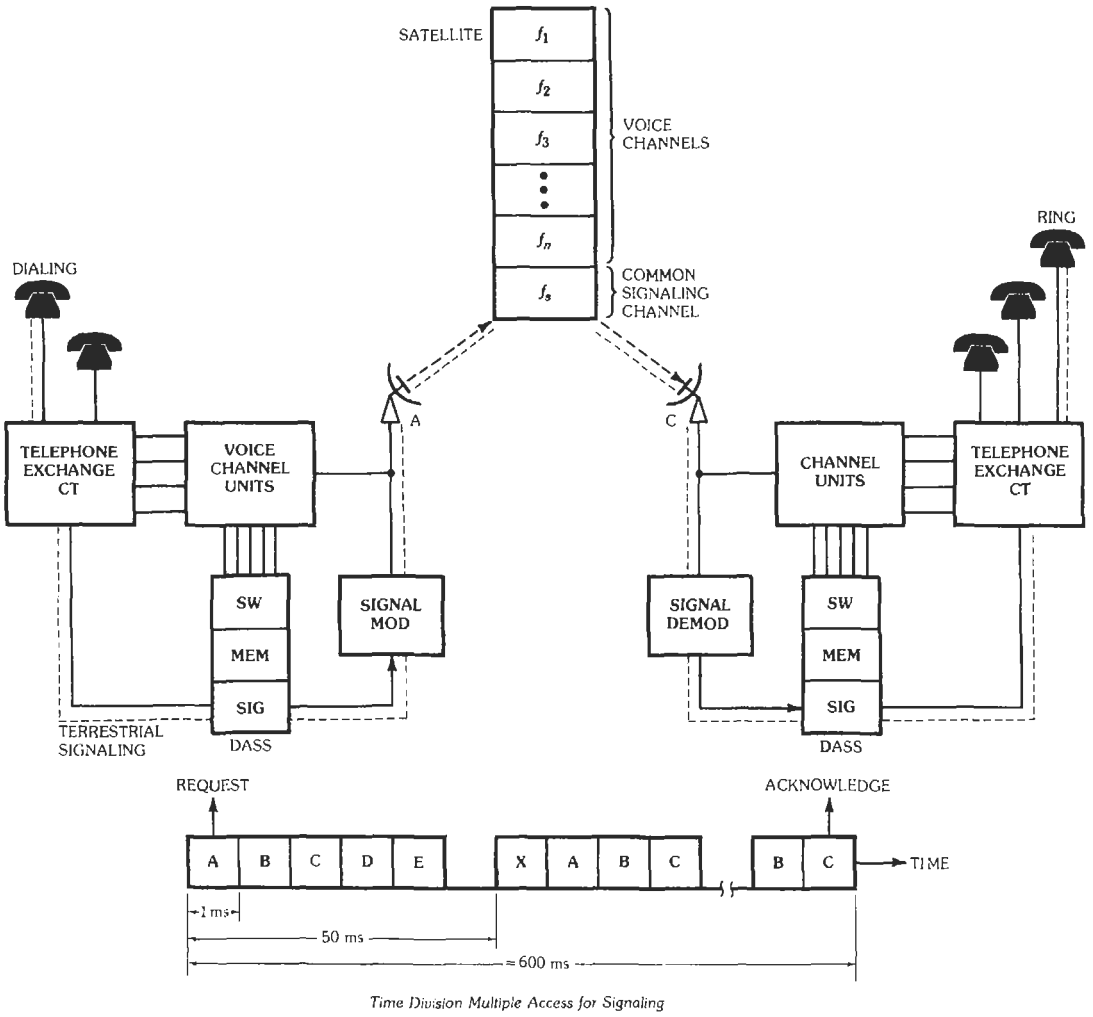

Fig. 21. SPADE signaling flow. (From *COMSAT Technical Review*, Vol. 2, No. 1, p. 229, Spring 1972.)

N = number of bursts in a frame
P = number of digits in the preamble
T = frame period

Synchronization and acquisition in TDMA systems can be implemented via closed- or open-loop techniques. In the closed-loop case, each earth station can monitor its own signals returned by the satellite via global or wide-coverage-area beam antennas. However, when narrow-beam antennas (which provide greater eirp and communications capacity) are used, open-loop techniques must be employed.

Notwithstanding the loss of communications capacity encountered with FDM/FM/FDMA when several accesses share a transponder, its simplicity and its "natural" interfacing with analog terrestrial networks made it almost universally the primary transmission method of the first decade of commercial satellite systems. With the growth of available spacecraft power and a view of bandwidth limitations, more complex transmissions techniques such as TDMA have been used.

Fig. 18 illustrates the multiple-access performance of the three transmission systems—FDM/FM/FDMA, SCPC/DAMA, and TDM/PCM/PSK/TDMA—when used with a global-coverage transponder. Clearly, bandwidth is more efficiently used by the latter two methods, which require, however, more complex equipment at the earth stations. TDMA, whose potential was identified many years ago, is now more than competitive with FDMA and has already supplanted it operationally in many systems.

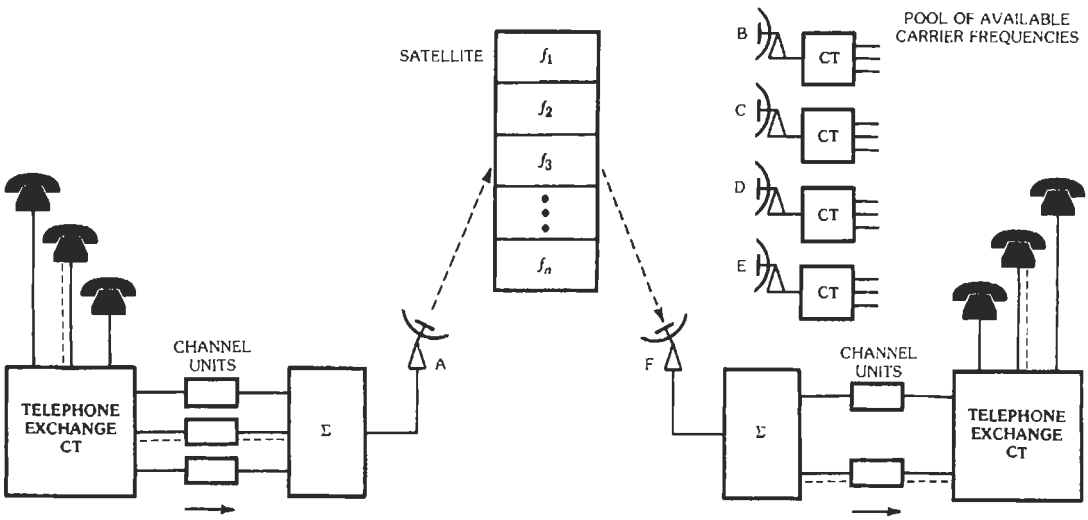

Fig. 22. SPADE communications flow. (From *COMSAT Technical Review*, Vol. 2, No. 1, p. 229, Spring 1972.)

TABLE 3. TDMA SYSTEMS CHARACTERISTICS

	TELESAT Canada	INTELSAT V	Advanced WESTAR	TELECOM I	INTELSAT VI
Operational Date	1975	1983	1983	1984	1989
Frequency	6/4 GHz	6/4 GHz and 14/11 GHz	14/12 GHz	14/12 GHz	6/4 GHz
Transmission Mode	TDMA	TDMA	SS-TDMA	TDMA	SS-TDMA
Transponder Hopping	No	Yes	No	Down-link switching	Yes
Modulation	QPSK	QPSK	QPSK	BPSK	QPSK
Bit Rate (Mbits/s)	61	121	250	25	120
Frame Period	250 μs	2 ms	125–750 μs	20 ms	2 ms
Channel Assignment	Fixed	Fixed	Fixed	Demand assignment	Fixed
Acquisition	Open-loop	Open-loop	?	Open-loop	Open-loop
Synchronization	Closed-loop	Feedback	?	Feedback	Feedback

The trend toward digital communications in terrestrial networks has been a major factor favoring the use of TDMA in satellite systems.

SATELLITE-SWITCHED TIME-DIVISION MULTIPLE ACCESS (SS-TDMA)

Narrowing satellite antenna beamwidth increases communications capacity but decreases connectivity among coverage areas. By introducing onboard switching, connectivity can be restored. Fig. 24 illustrates the basic concept of satellite-switched time-division multiple access. Spacecraft so equipped operate not only as repeaters but also as switchboards. With time- division multiplexing and digital modulation, the separation of the accesses is more effectively implemented in the time domain. It is also possible to use SS-FDMA techniques, but their more complex implementation would require heavier spacecraft.

Switching can be done at RF or at baseband. In the first case, up- and down-links are interconnected via a microwave switching matrix (MSM) whose output signals

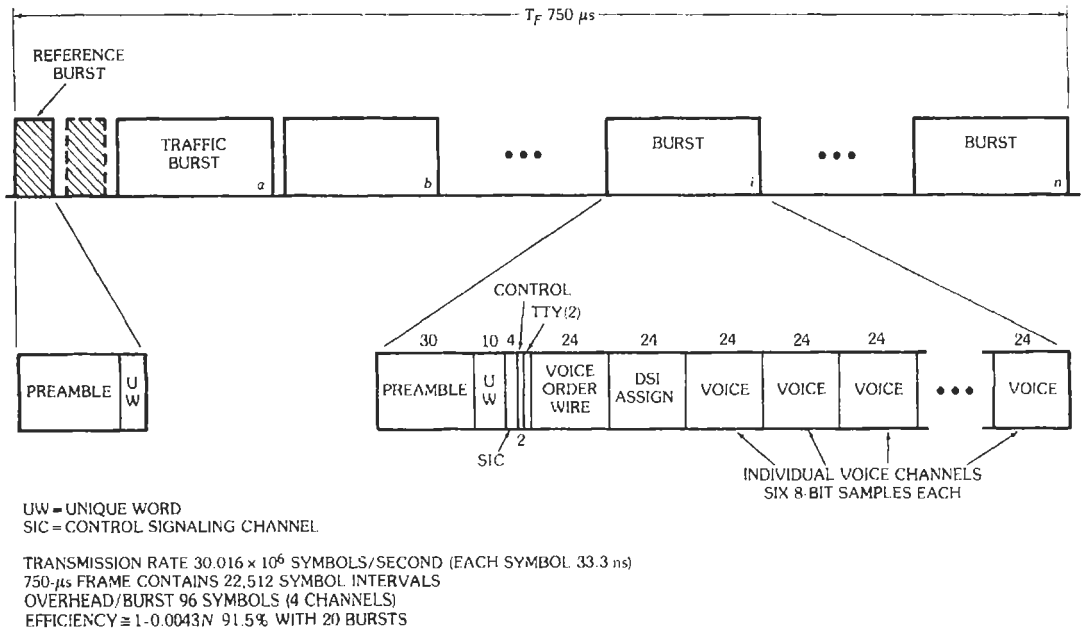

Fig. 23. TDMA frame structure.

are amplified and eventually fed to the antennas. The MSM is steered by a distribution control unit (DCU), and an acquisition and synchronization unit provides the time references necessary for TDMA operation. Configurations have been designed to provide bandwidth up to 500 MHz at 4 GHz.

Fig. 25 shows a block diagram of an SS-TDMA satellite carrying a 6 × 6 MSM. Data controlling the programmable cyclic switching states are transmitted via the telemetry, tracking, and command (TTC) channel for storage in the DCU memory circuits. To achieve the required reliability on board the *INTELSAT VI*, a 10 × 6 MSM is used in the SS-TDMA onboard package. SS-TDMA is in operational use in the *INTELSAT VI* system. The onboard package was configured to permit "transparent" use by the *INTELSAT V/VA* system TDMA and thus allow an easy transition. This highlights a major concern when introducing new access methods or any other significant change. The introduction should not interrupt service and should be transparent to the end user.

The capabilities of digital satellite transmission can be further enhanced by providing onboard signal processing. Switching is then performed at baseband after demodulation and demultiplexing of the up-link signals. The onboard switch is followed by remodulation of the down-link signals. Enhancement of overall link performance is obtained as other forms of signal processing can be introduced, such as onboard demand assignment, handling of bit streams at different rates, destination-directed packet transmission, etc.

OTHER SERVICES

Two further *INTELSAT* digital services warrant discussion. One is the International Business Service (IBS), which is the basis for private networks using the *INTELSAT* system. It carries digital traffic at bit rates from about 64 kbits/s to about 8.448 Mbits/s using QPSK and coding rates from rate 1/2 and higher. The other is the Intermediate Data Rate (IDR) service, intended originally to bridge the gap between SPADE and SCPC at 64 kbits/s (effectively 56 kbits/s) and *INTELSAT* TDMA at 120 Mbits/s, working into the public switched telephone networks (PSTN). IDR carries digital information at hierarchical rates from 64 kbits/s to 44.736 Mbits/s, using QPSK and a coding rate 3/4 (this implies transmission rates of 85.33 kbits/s to 59.776 Mbits/s). Recent advances in voice processing and digital interpolation allow up to a factor of 6 in digital circuit multiplication (DCM). Thus a 45-Mbits/s IDR channel could carry up to about 2800 voice circuits, under optimum conditions of DCM. Even higher DCM factors can be anticipated in the future.

Mobile services operate under quite different parameters than those for FSS. Such systems and their trade-offs will not be fully described here. Suffice it to say that allocated bandwidths are limited to a few tens of megahertz, at L-band (1.5 and 1.6 MHz) and S-band between satellite and mobile terminals and C-band and K_u-band (feeder link allocations in FSS band) from satellite to coastal or base earth stations. Consequently, bandwidth is a most precious resource. Only 5 kHz is

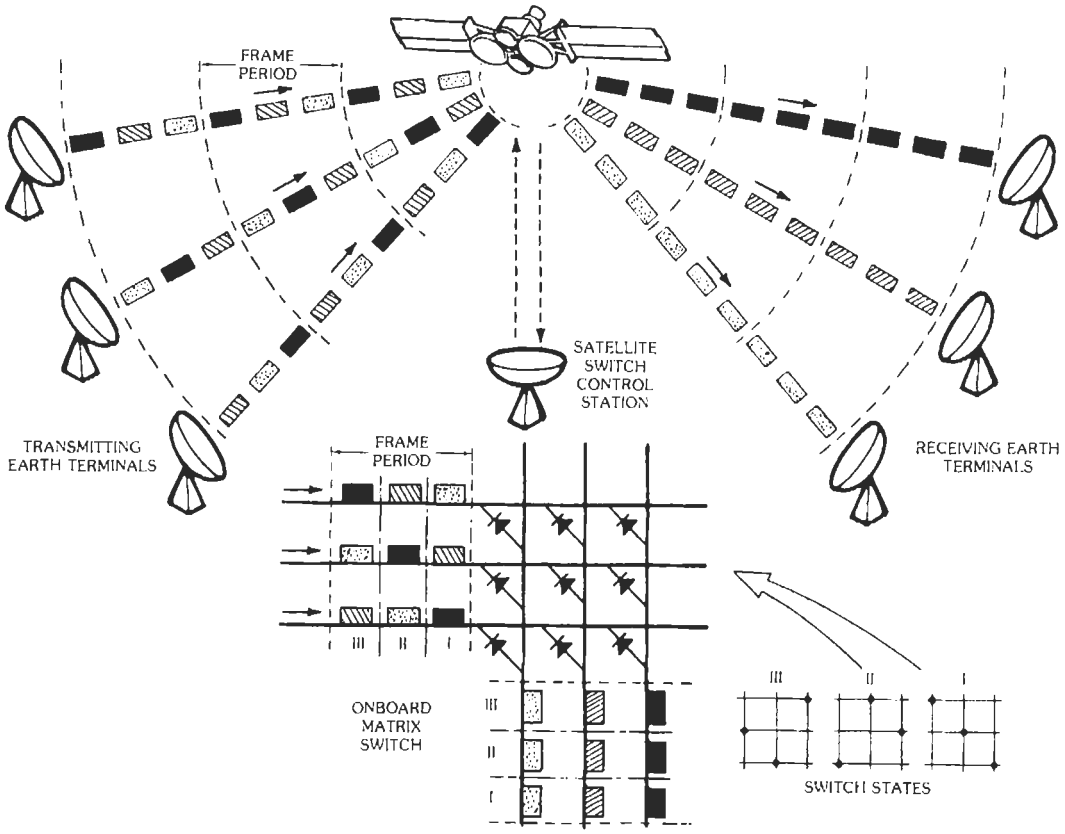

Fig. 24. Basic concept of SS-TDMA. (Courtesy S. J. Campanella.)

used per voice channel, in general, although wider channels are available for special purposes (such as higher-rate data transmission). Because mobile terminals cannot be high gain or high eirp, in general, there is a heavier burden on the satellite for the L-band links. Finally, the economics of the system are entirely different than for FSS, as even with frequency reuse and lower quality narrow-band voice channels, capacity could be at most of the order of a few thousand channels. In this regard, it should be noted that although *INTELSAT V* had a capacity above 10 000 circuits, *MARISAT* capacity was less than 50, and they were contemporaneous.

As satellite eirp grew with the introduction of zone/country coverage beams, it became evident that by using transmission in and out of a central high-gain high-eirp hub, it would be possible to send modest data rates (up to 64 kbits/s) or a single 64-kbits/s voice channel to or through that hub from earth stations with quite small antennas (down to 1 meter diameter), thus allowing very-small-aperture terminals, or VSATs. The basic configuration (shown in Fig. 26) is a star wherein the satellite (hub) is the node of the star and one or more VSAT networks are the star points. The hub-star-point links are usually higher-speed links using some form of destination-addressed packet transmission. The hub-star-point links transmission and access methods depend on the activity anticipated. For low activity, random-access systems (with retransmission for failed access) such as ALOHA work reasonably well. For higher levels of activity, more complicated access techniques and protocols have to be used, usually entailing demand-assigned channels after a failed access is reported. Up to a few hundred VSAT terminals can be serviced in a single network, and a hub can support several such networks. VSAT antennas of 1 to 3 meters using K_u- and C-bands, transmitters at the VSAT of 1 to 5 watts (SSPAs), and PSK modulation (sometimes using FEC, sometimes not) are sufficient to support 56- to 128-kbits/s service into the hub. The hub is usually a substantial earth station with an antenna of the order of 10 to 20 meters in diameter and a TWTA with an output of the order of hundreds of watts. It usually supports outbound data rates of 512 kbits/s or less per network. The hub usually has direct access (which may even be on the premises of the HQ facility of the entity establishing the VSAT network). Much of the

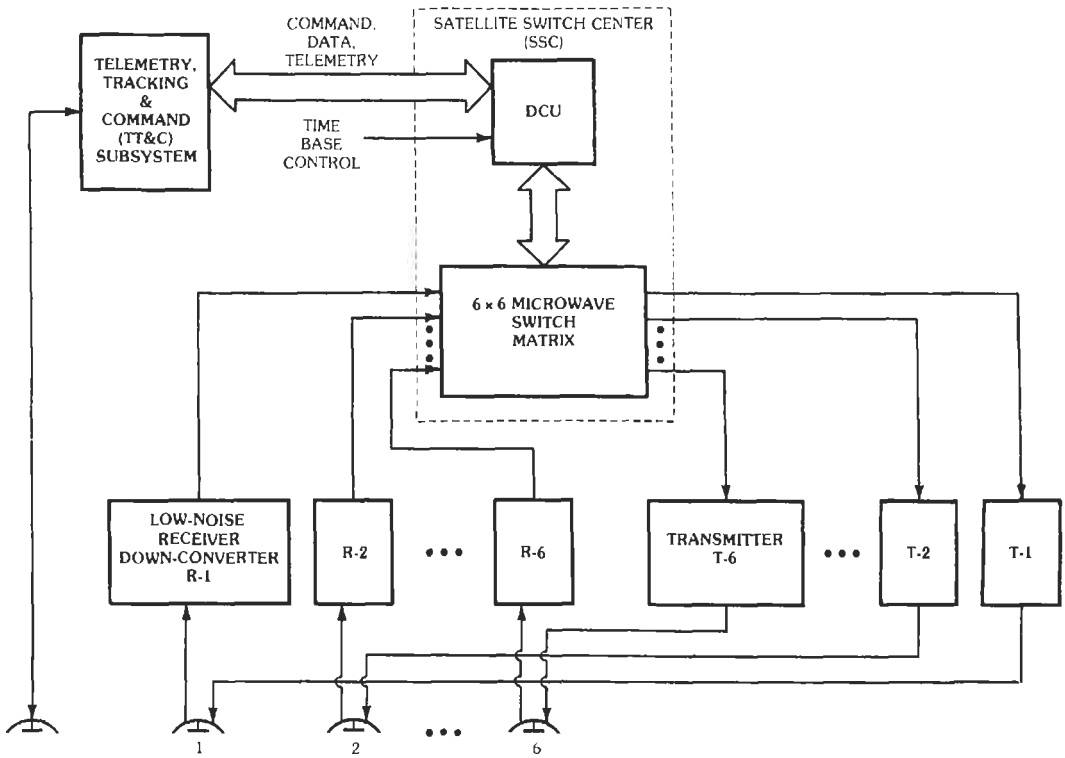

Fig. 25. Simplified block diagram of an SS-TDMA satellite.

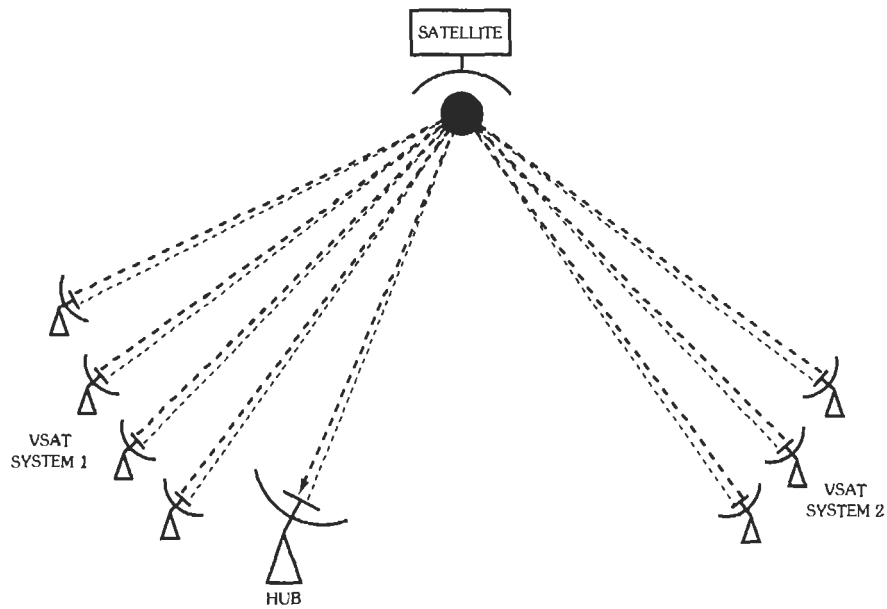

Fig. 26. VSAT network configuration.

transmitted data is broadcast to the star points or comes into the hub only. However, using double-hop, the input to the hub can be retransmitted to another star point.

As noted above, recent advances in satellite eirp have permitted the introduction of even smaller user's premises antennas and terminals, termed USATs in FSS. In the Mobile Satellite Service (MSS), hand-held terminals have begun to appear. It is expected that Internet services will access users through these and perhaps DBS-like terminals.

In a sense, DBS-TV or DBSA can be considered an extreme form of VSAT, where the VSATs on the user's premises are truly small (down to 0.3-meter antennas) and receive-only, and the hub station transmits the program material to the satellite at feeder link frequency allocations in the FSS to be transmitted at K_u-band at very high eirps (using onboard TWTAs of the order of 200 watts). Of course, there are (potentially) millions of star points; there are FM as well as digital signals; and the information rates from hub to star point are quite high (in the tens of megabits per second equivalent). DBS-TV systems have long been established in Japan, Europe, and the former USSR. Others have been implemented in Canada, the United States, South and Central America, and elsewhere.

NETWORKS

One must view the vast communications capacity of satellites not as a collection of links but as networks or parts of networks, interfacing with terrestrial networks. Thus, much attention must be placed on the interfaces, the signaling systems (such as signaling system 7), the many protocols (such as X.25 and the seven-layer ISO structure shown in Fig. 27), and services such as ISDN and B-ISDN.

SPACECRAFT ANTENNAS

Differences in the design of antennas used in space and on earth were quite marked in early communications satellite systems. Large apertures and very low noise system temperatures were then necessary at the earth stations because satellites were very much power-limited. Satellite antennas were small and had little directivity; this was especially the case with satellites in low- or medium-altitude orbits. Dipoles aligned with the spacecraft spin axis produced toroidal radiation patterns, and consequently the energy radiated outside the 18° angle subtending the earth from geosynchronous altitude was wasted. Around 1968, mechanically de-spun antennas consisting of a conical

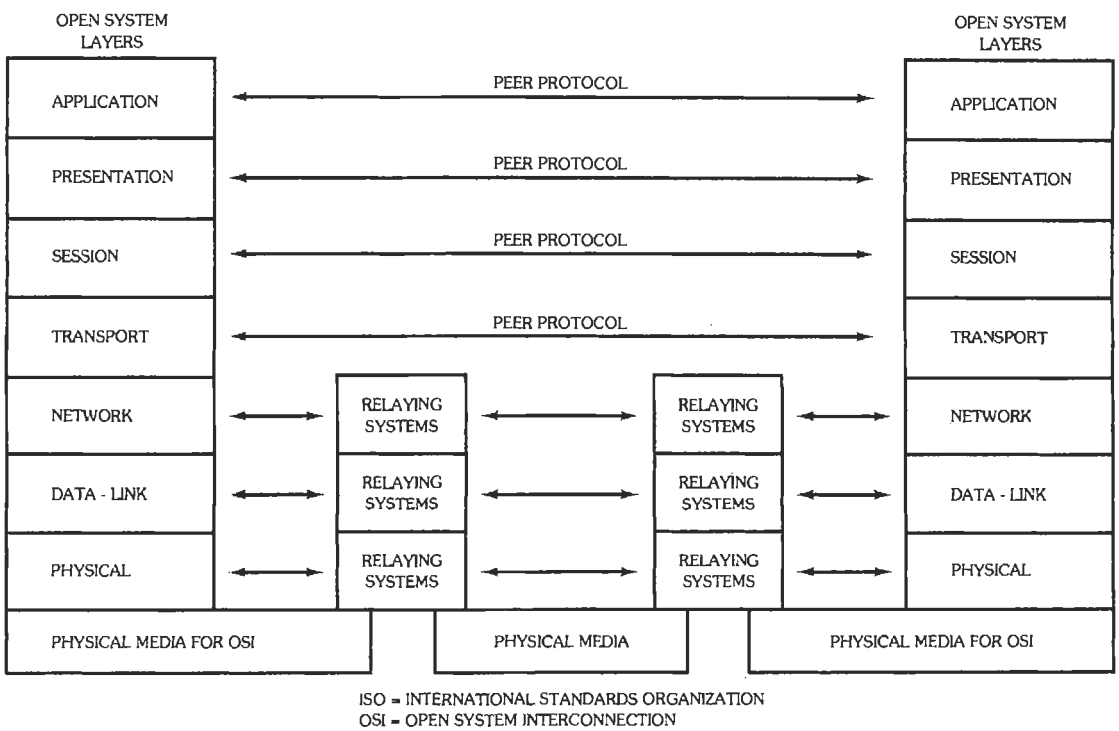

Fig. 27. ISO Reference Model.

horn and a reflector provided about 19 dB of gain (subtending an angle slightly greater than 18°) at 4 and 6 GHz (*INTELSAT III*). Progress has continued since then along two lines. First, large parabolic antennas have provided spot beam coverage down to a few degrees. Second, through frequency reuse the allocated frequency bands are utilized many times over by means of orthogonal polarizations (vertical/horizontal linear or clockwise/counterclockwise circular) and/or by means of spatially separated beams. Finally, zone beams have been synthesized to follow the contours of specific geographical areas such as national or regional boundaries, continents, etc. By assembling numerous suitably arranged feed horns, each excited with proper amplitude and phase, the radiated energy impinges upon a reflector and illuminates the desired areas on earth. It should be noted that earth-coverage horns are still used for a few C-band transponders.

In the design of contour-shaped beams and frequency-reuse systems, it is difficult to maintain isolation between dually polarized and/or spatially separate beams, especially when the number of beams is large. Until recently, parabolic reflectors with offset feed assemblies in the focal region have been adequate. The major role played by the antenna subsystem is exemplified by the design shown in Fig. 28 (*INTELSAT V*) with the coverage areas in the Atlantic Ocean Region shown in Fig. 29. In addition to beacon and TTC&M (TTC and Monitoring) antennas, circularly polarized conical horns provide global coverage at 6 GHz (receive) and 4 GHz (transmit). The 18° transmit horn is steerable up to ±2°; the receive horn, which has a wider beamwidth (22°), is fixed. Two parabolic reflectors of 2.44- and 1.54-m diameter provide hemispherical and zone area coverage for reception and transmission at 6 and 4 GHz. The offset hemi/zone antenna feeds are clusters of square horns with excitation in amplitude and phase producing the required shaped beams. Hemispherical and zone coverages are simultaneously obtained with opposite-sense circular polarizations. Feed characteristics, reflector size, and focal length are selected to yield high gain, sharp beam edges, low side lobes, and the high polarization purity required to achieve isolation between beams up to 27 dB.

Nominal 1-m diameter mechanically steerable parabolic receive and transmit antennas with linear orthogonal polarizations are used at 11/14 GHz to provide circular 1.6° beams in the west spot area and elliptical 1.8° by 3.2° beams in the east spot area. Spatial discrimination at 6/4 and 14/11 GHz and polarization discrimination at 6/4 GHz provide a fourfold frequency reuse of portions of the allocated spectrum and a total maximum usable bandwidth of 2137 MHz. Thus, it is clear that communications capacity can be effectively increased by adding sophistication to the antenna subsystem.

The *INTELSAT VI* antenna farm is a logical extension of that of *INTELSAT V/VA*. Earth coverage is still achieved with horns. Two hemispheric and four zone beams each for transmit and receive are generated using somewhat larger reflectors (3.2-m and 2.0-m diameter transmit and receive, respectively). The feed array provides six-fold frequency reuse at C-band. The K_u-band spot beams are essentially the same as in *INTELSAT V/VA*. There is, as in *INTELSAT V/VA*, a triple layer of beam-forming networks (BFNs) behind the feed arrays, switchable to select each ocean region.

As more beams (i.e., greater amounts of frequency reuse) and better isolation among beams are required, two approaches appear possible. Since feed blockage limits the use of single-offset reflectors, dual-offset reflectors with Gregorian or Cassegrain feeds could be used to allow better control of the illumination and permit the use of larger reflectors without incurring excessive focal lengths. Reflectors fed by phased arrays or phased arrays by themselves can also be used. Ultimately, size and mass limitations are encountered. The launch vehicle payload volume geometry limits the maximum diameter of fixed antennas. This limitation can be circumvented by using deployable apertures. Deployable reflectors have been used since the 1970s (e.g., *ATS-6*). Currently, deployable reflectors for the MSS at L-band are in use with diameters the order of 15 meters. Great care in structural, thermal, and mechanical design is required to maintain the specified surface tolerances after deployment, throughout eclipses and other thermal exposure, over the life in orbit. Such antennas provide many high-gain, high-eirp beams. Such beams are the basis for the use of handsets that offer cellular service via satellite.

PROPAGATION

Electromagnetic waves traveling along an earth–space path encounter four distinct regions: the troposphere, inner free space, the ionosphere, and outer free space.

Free space is lossless and has unity refractive index, and the troposphere and the ionosphere have refractive indices respectively greater and smaller than unity; hence, refraction and absorption phenomena arise. In addition, the ionosphere, a magnetoionic medium, induces Faraday rotation. All these phenomena affect space and satellite communications systems. Propagation delays resulting from ray bending influence the performance of satellite navigation systems.

Faraday Rotation

A linearly polarized wave can be regarded as the sum of two counterrotating circularly polarized waves. Because the phase velocities of the two waves differ in a magnetoionic medium, the polarization plane rotates. Faraday rotation effects are negligible above 10 GHz; below 10 GHz they can be circumvented by using circular polarization. Faraday rotation can, however, degrade cross-polarization discrimination in frequency-reuse systems. As with most ionospheric

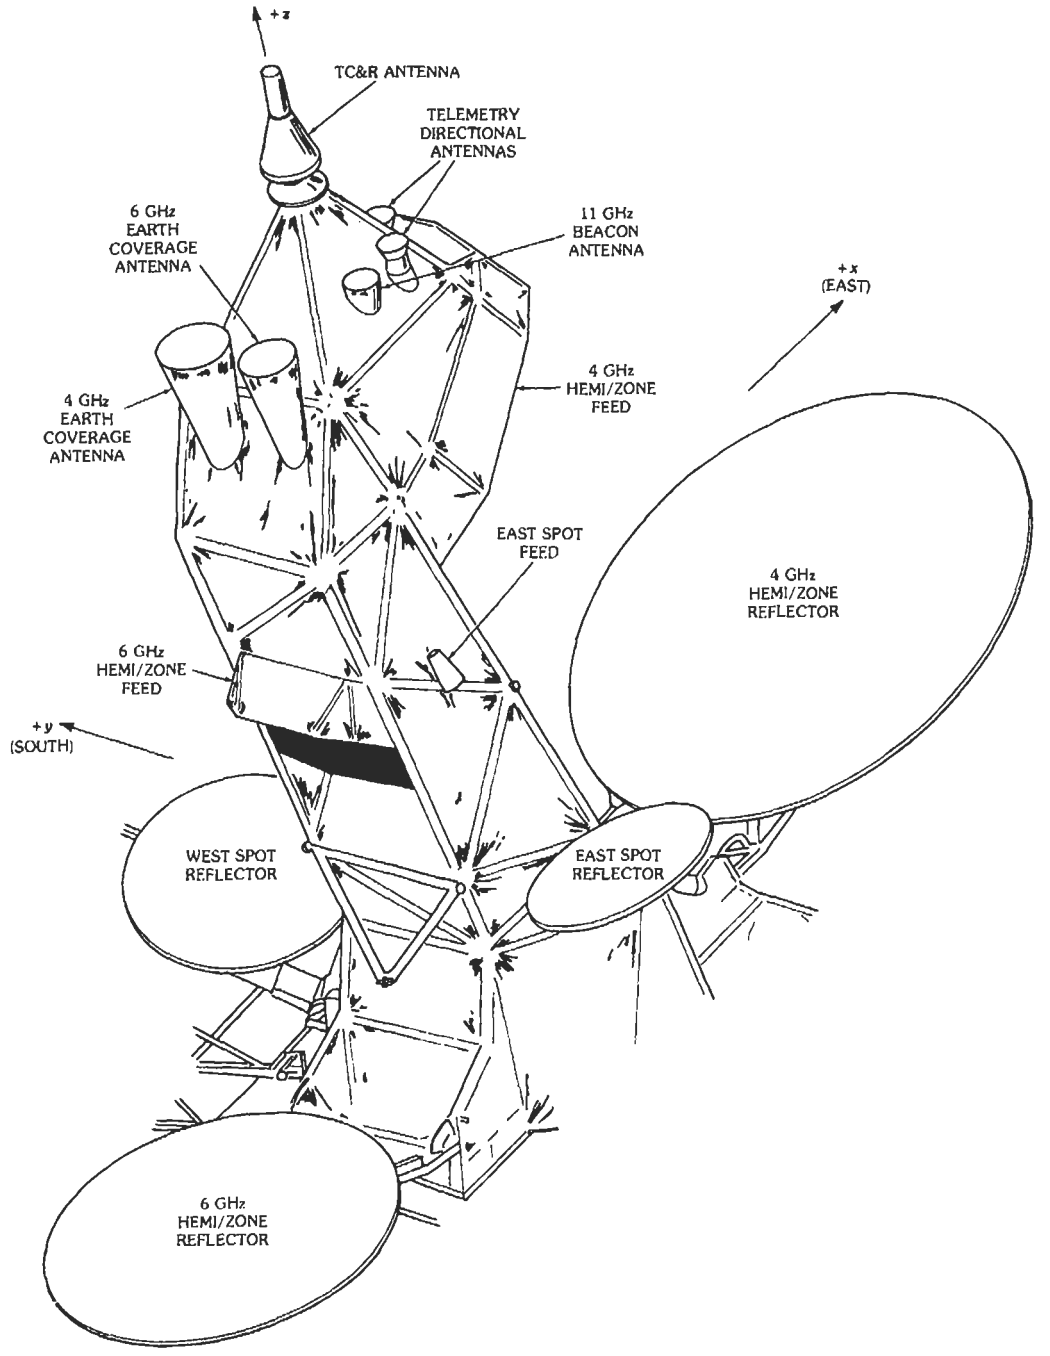

Fig. 28. *INTELSAT V* antenna subsystem. (Courtesy Ford Aerospace and Communications Corp.)

effects, there is a strong diurnal and seasonal dependence as well as increase with increasing solar activity; i.e., Faraday rotation follows the solar cycle, peaking approximately every 11 years.

Ionospheric Scintillations

Strong short-term (1- to 15-s) variations of the amplitude, phase, polarization angle, and angle of

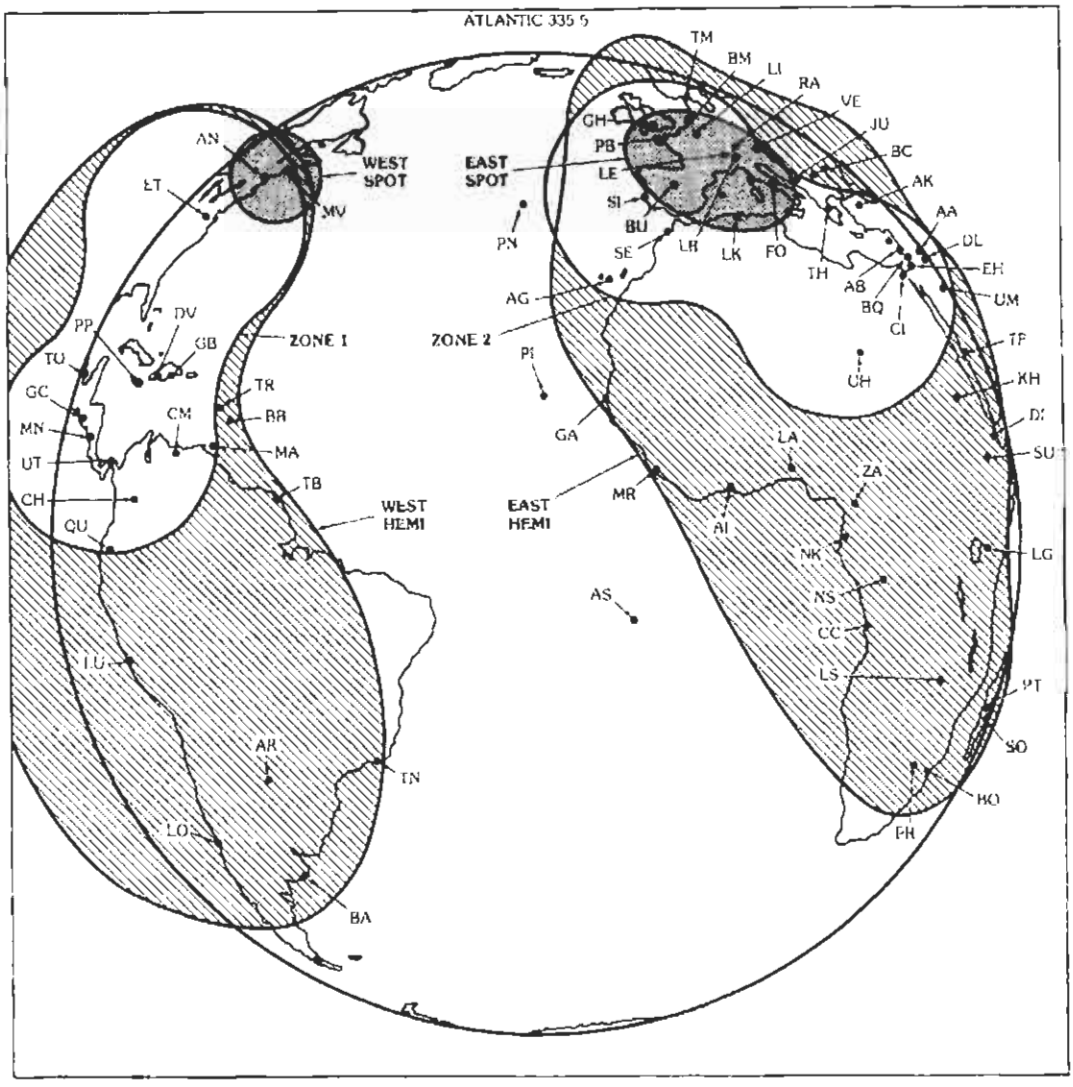

Fig. 29. *INTELSAT V* coverage of the Atlantic Ocean Region. (From *COMSAT Technical Review*, Vol. 7, No. 1, p. 314, Spring 1977.)

arrival of electromagnetic waves reaching the earth from space observed up to microwave frequencies are known under the general name of ionospheric scintillations. These are attributable to fluctuations of the electron density in the sporadic E layer and to the spreading of the F layer. Earth-station location, season of the year, local time, and amount of solar activity influence the magnitude and occurrence of ionospheric scintillations; geomagnetic latitude, solar activity, and local time are the most influential factors.

Within ±20° from the geomagnetic equator, heavy scintillation can occur for a few hours just after sunset in the ionosphere on the earth–satellite path, with magnitude proportional to the number of sunspots (i.e., following the solar cycle) and maxima occurring around the equinoxes.

The scintillation index, S_4, defined as

$$S_4 = (1/\bar{R}^2)\{\overline{(R^2 - \bar{R}^2)^2}\}^{1/2} \qquad \text{(Eq. 59)}$$

has an $f^{-\alpha}$ frequency dependence with

$$\alpha = \begin{cases} 1/2 \text{ to } -1 & \text{at vhf} \\ -1 & \text{from 1.5 to 4.0 GHz} \\ -2 & \text{above 4 GHz} \end{cases}$$

Scintillations become less intense at intermediate latitudes but increase at higher latitudes beyond the boundary of the auroral region.

Additional ionospheric effects are angle-of-arrival variations and absorption. Both phenomena follow an

f^2 law; hence, their impact on communications systems operating at gigahertz frequencies is negligible.

Tropospheric Effects

Ray bending, scintillation, attenuation, and increased sky noise temperature are major effects. Tropospheric bending is opposite to ionospheric bending; it is frequency independent, whereas ionospheric bending follows an f^2 law. Because the refractive index, n, is slightly greater than one, the quantity N (refractivity) is used

$$N = (n - 1) \times 10^6$$

It is empirically given as

$$N = (77.6/T)\,[p + 4810\epsilon/T] \qquad \text{(Eq. 60)}$$

where

T = air temperature in kelvins
p = atmospheric pressure in millibars
ϵ = partial water vapor pressure in millibars

Since N decreases with height, the apparent elevation of a space object is greater than the geometrical elevation angle, and the radio range is greater than the geometric distance. Eq. 60 does not hold in extremely humid climates; ducting will occur if the vertical gradient of N is high. All the above phenomena are not significant in the design of satellite communications systems except for operation at very low angles of elevation. In tropical climates, mean values of ray bending around 0.5°–0.6° have been observed at elevation angles between 1° and 2°. Ducting can produce interference to earth-based microwave radio relays by high-power earth stations of communications satellite systems radiating at low angles.

Scintillations are induced by atmospheric turbulence with time dependence about ten times greater than that of ionospheric scintillations. The phenomenon is strongly dependent on elevation angle, increasing with decreasing elevation angle, and may be neglected above 15°. Between 5° and 10°, peak-to-peak scintillations in excess of 6 dB have been encountered at 6 GHz.

Under clear-sky conditions, water vapor and oxygen give origin to molecular resonance absorption bands whose width is affected by the atmospheric pressure (i.e., change with altitude). Clear-sky atmospheric loss (attenuation) is of the form

$$L_a = \int_0^l \left\{\gamma_{O_2}(r,f) + \gamma_{H_2O}(r,f)\right\} dr \qquad \text{(Eq. 61)}$$

where

l = total propagation distance
γ_{O_2}, γ_{H_2O} = absorption coefficients for oxygen and water vapor in dB/km

Plots of the attenuation per unit length as a function of frequency are given in Fig. 30.

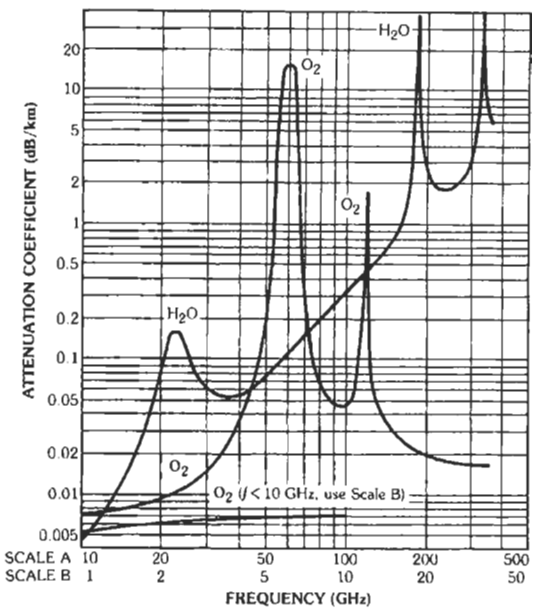

Fig. 30. Clear-sky attenuation per unit length versus frequency. (From K. Miya, Ed., *Satellite Communications Technology*. Tokyo: KDD Engineering and Consulting, Inc., 1982.)

The simplified expression

$$L_a = \gamma'_{O_2} L_{O_2} + \gamma'_{H_2O} L_{H_2O} \text{ in dB} \qquad \text{(Eq. 62)}$$

may be used for horizontal paths, assuming that the absorption coefficients, γ', at the surface and the effective path length, L, for oxygen and water vapor are known. It is generally assumed that

$$L_{O_2} \cong 4 \text{ km}$$

$$L_{H_2O} \cong 2 \text{ km}$$

For a vertical path, total clear-sky loss versus frequency is shown in Fig. 31. For slant paths, a factor about equal to the cosecant of the elevation angle (valid down to about 5°) must be introduced.

Clear-Sky Noise Temperature

In the absence of hydrometeors, the absorption by O_2 and H_2O molecules contributes to clear-sky noise temperature T_{cs}:

$$T_{cs} = T_{gal}/L_{cs} + [(L_{cs} - 1)/L_{cs}]\,T_m \qquad \text{(Eq. 63)}$$

where

$T_{gal} \cong 26/f_{GHz}$ kelvins
$L_{cs} = 10^{L_a/10}$, clear sky loss factor
$T_m \cong 1.12\,T_{surface} - 50$, mean raindrop temperature along the path

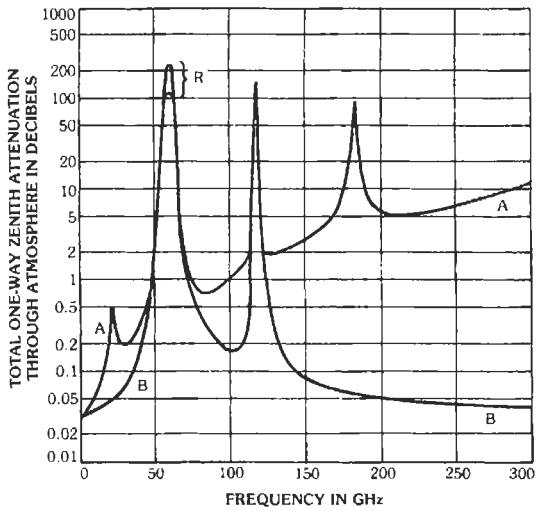

Fig. 31. Total clear-sky loss versus frequency. (From K. Miya, Ed., *Satellite Communications Technology*. Tokyo: KDD Engineering and Consulting, Inc., 1982.)

The dependence of clear-sky noise temperature on frequency and elevation angle is shown in Fig. 7.

Above 10 GHz, the term T_{gal}/L_{cs}, which represents the galactic noise contribution after passage through the clear sky, can be neglected. Then

$$T_{cs} \cong [(L_{cs}-1)/L_{cs}]T_m = T_m(1-10^{-L_{cs}/10}) \quad \text{(Eq. 64)}$$

Hydrometeors

On account of the basic interaction of electromagnetic waves with water in liquid form, raindrops cause absorption, scattering, and depolarization phenomena. The first two result in signal attenuation (not to be confused with either water-vapor attenuation or attenuation by rain clouds) and an increase in sky noise temperature. These effects are quite noticeable above 10 GHz. Depolarization is of little or no harm to communications systems using only one polarization, but it worsens the performance of dual-polarization systems and may also result in interference between systems. Rain may also limit signaling bandwidth.

Rain Attenuation

The amount of attenuation depends on the type of rain (stratiform, convective, cyclonic) and intensity (rain rate). As raindrop size distribution is a function of rain type and intensity, various models have been proposed to best fit specific situations. Rainfall data are available for most parts of the world; different climate types have been identified, with their regions on the earth's surface identified and their associated rain-rate exceedance statistics defined. Cumulative rain statistics provide information about probability of exceedance, i.e., the total time that a specific rain rate will be exceeded over a sufficiently long observation period. Cumulative statistics do not provide information about the frequency of occurrence and the duration of the periods of exceedance.

The attenuation per unit length (specific attenuation), α_r(dB/km), is tied to the rain rate, R (mm/hr), by the empirically derived relationship

$$\alpha_r = a(f)R^{b(f)} \quad \text{(Eq. 65)}$$

where $a(f)$ and $b(f)$ are frequency-dependent coefficients. The approximate analytic expressions given in Table 4 are adequate for engineering use. Up to 50 GHz, $b(f)$ is near unity; hence specific attenuation is essentially proportional to rain rate. However, since $a(f)$ is heavily frequency dependent, attenuation per unit length increases rapidly with frequency. Fig. 32 shows the frequency dependence of α_r for various rain rates. If the concept of equivalent path length, $L_{eq}(R)$, is introduced, the total rain attenuation loss in decibels is simply

$$A_r = \alpha_r \times L_{eq}(R) \quad \text{(Eq. 66)}$$

Equivalent path length is primarily determined by the height of the melting layer, which depends on latitude and season, and by the cosecant of the elevation angle (for latitudes within ±30°, the melting layer is at 4.8 km). A correction coefficient is required to take into account the distribution of rain over a long path; however, except for very light or very heavy rain, the value of the correction is near unity. Equivalent path length can be expressed in terms of rain rate and elevation angle θ as follows:

$$L_{eq}(R,\theta) = [7.413 \times 10^{-3}R^{0.766} + (0.232 - 1.803 \times 10^{-4}R)\sin\theta]^{-1} \quad \text{(Eq. 67)}$$

Curves of equivalent path lengths versus elevation angle and for different rain rates are shown in Fig. 33.

Rain rate can be modeled by the Rice–Holmberg distribution

$$P(R) = ae^{-0.03R} + be^{-0.258R} + ce^{-1.63R} \quad \text{(Eq. 68)}$$

with

$a = M\beta/2922$
$b = M(1-\beta)/438.3$
$c = 1.86\beta$

TABLE 4. PROPAGATION COEFFICIENTS

Frequency f(GHz)	$a(f)$	$b(f)$
8.5–25	$4.21 \times 10^{-5}(f)^{2.42}$	$1.41(f)^{-0.0779}$
25–54	$4.21 \times 10^{-5}(f)^{2.42}$	$2.63(f)^{-0.272}$
54–100	$4.09 \times 10^{-2}(f)^{0.699}$	$2.63(f)^{-0.272}$

Fig. 32. Attenuation per unit length versus frequency and rain rate. (From K. Miya, Ed., *Satellite Communications Technology*. Tokyo: KDD Engineering and Consulting, Inc., 1982.)

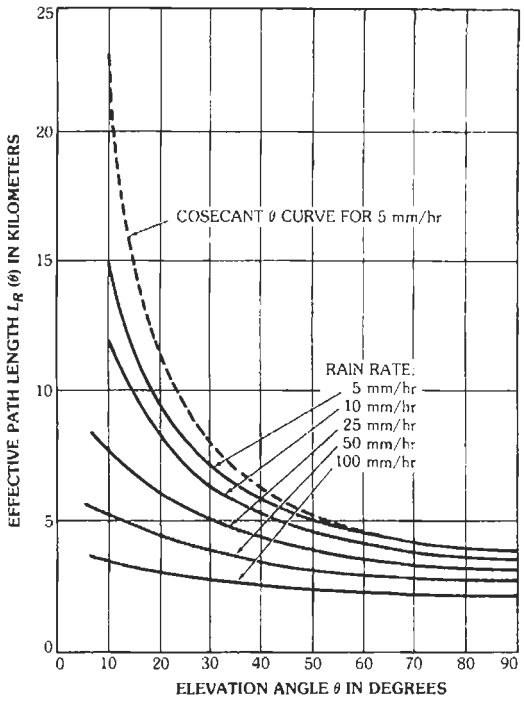

Fig. 33. Equivalent path length versus rain rate and elevation angle. (From K. Miya, Ed., *Satellite Communications Technology*. Tokyo: KDD Engineering and Consulting, Inc., 1982.)

where

M = total mean yearly rainfall in millimeters
β = ratio of thunderstorm rain accumulation to total accumulation

In Eq. 68, each term represents the predominant component for specific ranges of R. Comparative data of measured surface rain rate and theoretical model distributions are shown in Fig. 34. Cumulative attenuation statistics are shown in Figs. 35, 36, and 37. Formulae and constants used in them are continuously being refined. Although those given herein are adequate for many purposes, see the latest ITU-R reports for more current information.

The comparison of rain attenuation at different frequencies leads to a scaling relationship of the form

$$A_r(f_2) = A_r(f_1)\,(f_2\,f_1)^{\alpha} \qquad \text{(Eq. 69)}$$

with $1.7 < \alpha < 2.0$.

Water-cloud attenuation is about the same as that produced by rainfall at rates less than 5 mm/hr. Ice-cloud attenuation is at least two orders of magnitude lower and hence negligible.

Sky Noise Temperature with Rain

Neglecting the galactic contribution, the sky noise temperature in the presence of rain, T_s, is

$$T_s = T_{cs}/L_r + [(L_r - 1)/L_r]T_m \qquad \text{(Eq. 70)}$$

If the first term, which represents the contribution of the clear sky through the lossy rainy medium, is negligible compared to the second term, one can write

$$T_s \cong [(L_r - 1)/L_r]T_m = T_m(1 - 10^{-A_r/10}) \text{ (Eq. 71)}$$

with all symbols as previously defined. Then the decibel difference (excess loss) between the attenuation caused by rain and clear sky attenuation is

$$(A_r - A_a)\,|_{\text{dB}} = 10 \log\,[(T_m - T_{cs})/(T_m - T_s)] \quad \text{(Eq. 72)}$$

Conversely, the excess noise temperature is

$$(T_s - T_{cs})\,|_{\text{kelvin}} = T_m(L_r - L_a)/L_r L_a \qquad \text{(Eq. 73)}$$

Corrections should be introduced when antenna sidelobe noise pickup and/or receiver front-end noise

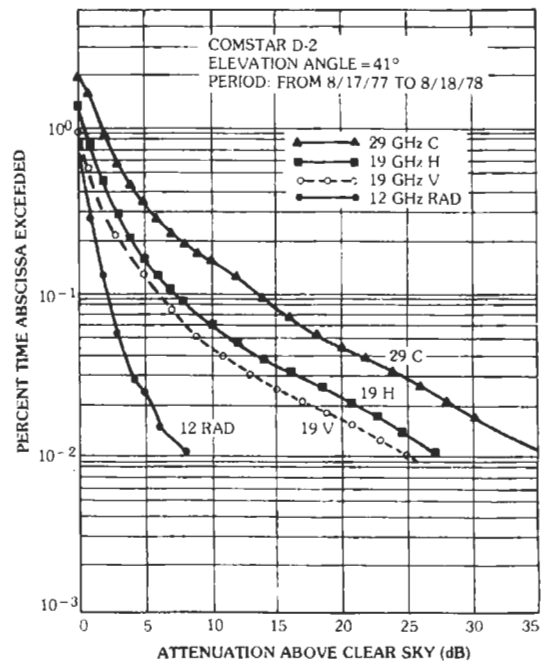

Fig. 36. Cumulative attenuation statistics (*COMSTAR D-2*). (From *COMSAT Technical Review*, Vol. 12, No. 1, p. 12, Spring 1982.)

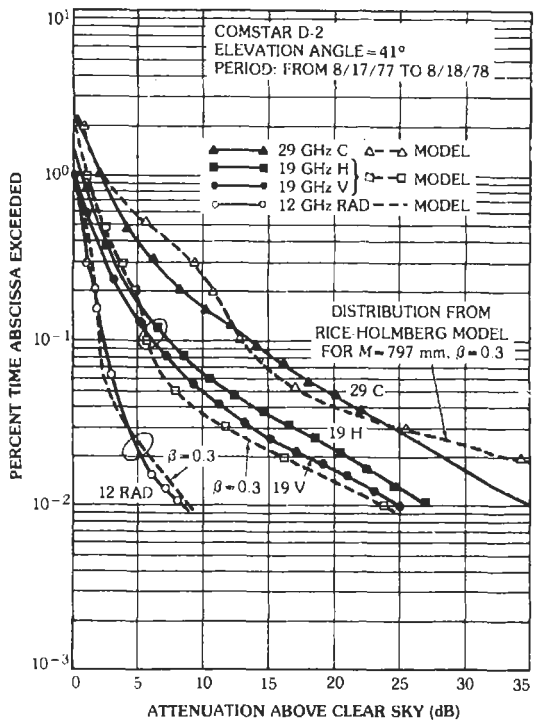

Fig. 37. Comparison of measured attenuation with theoretical distributions. (From *COMSAT Technical Review*, Vol. 12, No. 1, p. 13, Spring 1982.)

become nonnegligible. The following points should be emphasized:

A. The cumulative distributions of rain rate and attenuation depend greatly on the type of climate.
B. Rates below 10 mm/hr are usually associated with stratiform rain, which occurs over wide areas; attenuation is proportional to the cosecant of the elevation angle.
C. Rates above 20 mm/hr are usually associated with convective rain, which occurs over smaller areas. Attenuation is proportional to less than the cosecant of the elevation angle, but the vertical extent of the rain can be quite large (up to 10 km).
D. Very intense rates are encountered in cyclones, hurricanes, or typhoons, which may affect wide areas at times. Their probability of occurrence, although low over the year, is often seasonally high.
E. Rain attenuation that is not a serious obstacle below 10 GHz becomes important at the higher frequencies. Up to 11–15 GHz, continuity of service can be maintained at quite high levels of availability by allowing adequate power margins (3–12 dB) in the link design. Higher power margins are uneconomical in most cases. Significant additional margin can be obtained by using coding and forward error correction.

Especially at the higher frequencies (20/30 GHz) at which rain-induced attenuation can be quite severe, unless a lower value of service continuity is acceptable, means other than power margins and coding and forward error correction may be needed.

Diversity

One proposed alternate solution is site diversity based on having two earth stations jointly operating with a given satellite. By placing the two stations at a distance for which the rain statistics along the two paths become sufficiently uncorrelated, and selecting at any time the best path, diversity gain over single-site operation can be obtained.

With reference to Fig. 38, once the attenuation statistics for a single and a double path have been acquired, diversity gain G_{div} can be defined as

$$G_{\text{div}} = A_{r1} - A_{r1,2}\big|_p \qquad \text{(Eq. 74)}$$

where the single and double subscripts refer to the same value of single and joint event probabilities. Otherwise, for a given value of the abscissa A_r, the ratio

$$I_{\text{div}} = p_1/p_{1,2}\big|_{A_r} \qquad \text{(Eq. 75)}$$

defines diversity advantage, i.e., the factor by which exceedance time is improved.

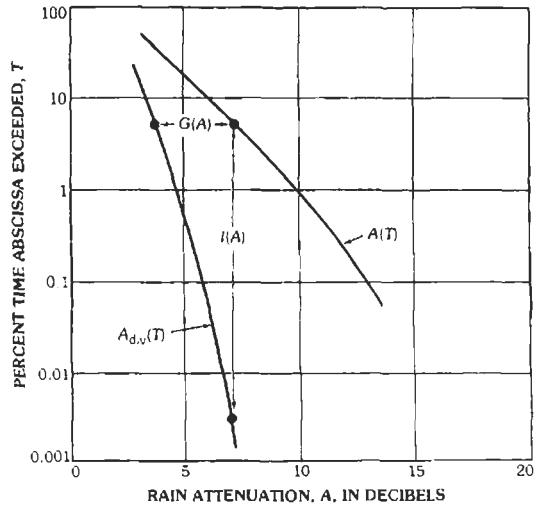

Fig. 38. Diversity and advantage gain definitions. (From L. J. Ippolito, R. D. Kout, and R. G. Wallace, *Propagation Effects Handbook for Satellite Systems Design*. NASA Reference Publication 1082, Dec. 1981.)

Experiments have shown that both diversity gain and advantage increase with increasing spacing of the two sites, but at a decreasing rate, leveling off at the distance for which the path statistics become independent.

Depolarization

Although very small raindrops such as those encountered in light drizzle are spherical, the larger drops associated with heavier rain depart substantially from spherical shape under the combined effects of gravity, hydrostatic forces, and aerodynamic forces. Nonspherical drops and their canting angle cause differential attenuation and phase shift for different wave components and hence depolarization.

For linear- or circular-polarized waves, the power ratio of the copolarized and cross-polarized components

$$XPD = 10 \log_{10} (P_{\text{copol}}/P_{\text{xpol}}) \qquad \text{(Eq. 76)}$$

gives a measure of polarization purity or cross-polarization discrimination. Once differential attenuation A and differential phase shift B are determined, cross-polarization discrimination can be computed. For circular polarization, it is

$$XPD = 20 \log_{10} |(1 + e^{A+jB})/(1 - e^{A-jB})| \qquad \text{(Eq. 77)}$$

and for linear polarization

$$XPD = 20 \log_{10} |(1 + \tan^2 \chi\, e^{A+jB})/(1 - e^{A+jB} \tan \chi)| \qquad \text{(Eq. 78)}$$

where χ is the angle between the incident wave polarization plane and the major axis plane of the raindrops. With linear polarization, when $\chi = 0°$ or 90°, XPD becomes infinite; for $\chi = \pm 45°$ XPD takes a minimum value. With circular polarization, XPD is always at a minimum. At 4 and 6 GHz, rain depolarization arises from differential phase effects and can be a significant impairment in dual-polarized systems.

Proper operation of frequency reuse systems with dual polarization requires XPD of 27 dB or more. As a residual coupling usually originating in the antennas and feeds always exists, the presence of rain worsens the situation and further reduces the value of XPD. Depolarization compensation networks can be used at the earth stations to restore orthogonality.

Ice depolarization is also encountered, due to the nonspherical shape of ice particles, generally encountered just above the melting layer. This can be significant at frequencies above 15 GHz and can be identified by the absence of appreciable concurrent attenuation.

EARTH STATIONS

At the earth stations that form the ground segment of space and satellite communications systems, a variety of equipment is needed depending on: (A) function of the station, (B) type of service, (C) frequency bands used, (D) transmitter, (E) receiver, and (F) antenna characteristics.

Three categories can be distinguished: (1) transmit-and-receive, (2) receive-only, and (3) transmit-only stations. The first is encountered in two-way communications systems. Receive-only stations are presently used in CATV systems in the United States and in great numbers in DBS systems around the world. Transmit-only earth stations are found in data collection systems and DBS feeder links. Types of service include fixed, mobile, broadcasting, and others. Spectrum use is regulated by international allocations with actual bandwidth occupancy as needed for different services, type of traffic, and modulation.

In satellite communications systems, earth-station transmitter power ranges from a few watts generated by SSPAs to about ten kilowatts generated by klystrons or TWTs. Transmitters up to 400 kW are used in the deep-space network. Receivers cover a wide range of sensitivity and bandwidth with noise temperature from a few tens of kelvins achieved with cryogenically cooled amplifiers to hundreds of kelvins in uncooled amplifiers. A highly simplified block diagram of a typical transmit-and-receive earth-station layout is shown in Fig. 39. The station has six major subsystems:

A. The power subsystem
B. The terrestrial interface
C. The transmit chain
D. The receive chain
E. The antenna subsystem
F. The control subsystem

Signal paths and functions are as indicated. The value of the intermediate frequency (IF) in the receive and transmit chains is usually the same, with 70 MHz being commonly used. The up-link signals may be transmitted by means of waveguides to high-power amplifiers located just behind the feed, or in IF form via coaxial cables to the up-converters and high-power amplifiers located there. It is also possible to locate all the equipment at the base of the antenna and to extend the input and output feeds via beam waveguides. High-power-amplifier (HPA) outputs can be combined through bandpass filters and circulators or by means of hybrids. In the receive chain, the weak signals from the satellite are accepted by the same feed that carries the transmitter output. These two signals, which differ in power by several orders of magnitude, are kept separate by means of orthogonal polarizations and diplexers used to enhance the separation in the frequency domain. Orthomode transducers and polarizers are employed, respectively, to couple orthogonally polarized signals into a single waveguide and to convert linear into circular polarization and vice versa. After preamplification in a low-noise amplifier (LNA), the received signals are down-converted to IF and demodulated to baseband.

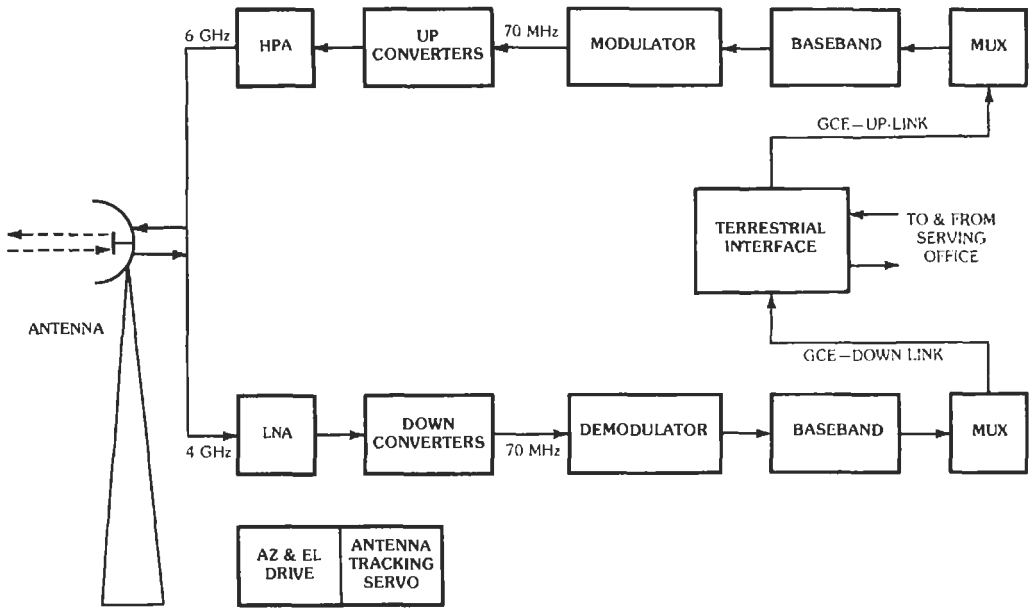

Fig. 39. Earth-station block diagram.

The antenna is a very important part of an earth station, since it affects eirp, receive figure of merit (G/T), and interference. Antenna size varies considerably, from a diameter of 0.5 meter or less used for DBS-TV receive only in private homes to much larger transmit and receive antennas (up to 32-meter diameter parabolas) used in high-capacity systems, and even larger antennas (up to 64-meter diameter) used in the deep-space network. In addition to parabolic reflectors, which are widely used, other forms of antennas such as horns, torus-shaped reflectors, Yagis, helices, and phased arrays have been used.

In terms of the general relationship,

$$G = (4\pi/\lambda^2)A_{\text{eff}} = (4\pi/\lambda^2) \cdot \eta \cdot A_{\text{geom}} \quad \text{(Eq. 79)}$$

where

$$\eta = A_{\text{eff}}/A_{\text{geom}} \quad \text{(Eq. 80)}$$

is the antenna efficiency. In the case of parabolic reflectors,

$$G = \pi^2(D/\lambda)^2 \cdot \eta \quad \text{(Eq. 81)}$$

In practice, values of D/λ ranging from about 20 to 700 are common in communications satellite systems, and values up to 2000 are encountered in deep space systems. With efficiency in the range from 0.5 to 0.8, gains between 30 and 75 dBi (dB above isotropic) have been achieved with corresponding half-power beamwidths from a few degrees to a few hundredths of a degree. Very high gain values imply electrically as well as mechanically large antennas and consequently large and costly structures because cost is approximately proportional to aperture area.

Various forms of mounts have been used with limited or full steerability as required by the specific system characteristics. Antenna-mount types can be 2-axes (x, y or azimuth, elevation), 3-axes (x, y, y' or azimuth, elevation, and cross-elevation), or 4-axes for maritime applications.

Reflector antennas can be classified according to the number of reflecting surfaces and/or the type of feed positioning. The overall antenna efficiency factor, η, in Eq. 80 can be broken into four parts:

$$\eta = \eta_1 \times \eta_2 \times \eta_3 \times \eta_4 \quad \text{(Eq. 82)}$$

where

η_1 = illumination factor
η_2 = spillover factor
η_3 = blockage factor
η_4 = surface tolerances factor

A decrease in main-lobe gain often implies an increase in an increase of side-lobe energy and consequently leads to a higher noise temperature and a decrease in interference-rejection capability. The term η_4 is due to departure of the reflector surface from the ideal. Assuming randomly distributed profile errors over the surface, efficiency is reduced by a factor

$$\eta' = e^{-(4\pi\epsilon/\lambda)^2} \quad \text{(Eq. 83)}$$

where ϵ is the rms surface tolerance. As the gain loss in decibels is

$$\eta'|_{dB} = 685.8\,(\epsilon/\lambda)^2 \qquad \text{(Eq. 84)}$$

if the maximum permissible gain loss is set at 1 dB, the rms surface tolerance, ϵ, must be held to $\lambda/25$ or less. The ratio D/ϵ represents a measure of the quality of a parabolic antenna. For the above-mentioned values of the D/ϵ ratio, the corresponding range of the D/ϵ ratio is between 500 and 25 000. In electrically larger antennas intended for radio astronomy, the higher D/ϵ values have been achieved with protective means against the environment. In satellite communications systems, aside from early designs of large horn-type antennas with radome protection against the weather, open-air antennas are generally used.* The only weather protection device is electric heaters for melting snow and ice buildups.

The other three losses—blockage, spillover, and illumination—apply most significantly to folded optics systems such as the widely used Cassegrain configuration, which is characterized by a hyperbolic subreflector and parabolic main reflector. Since aperture illumination and far-field radiation are related by Fourier transforms, uniform illumination leads to a $\sin x/x$ type of radiation pattern, unity illumination factor, but relatively high-level side lobes. With tapering of the illumination, the illumination factor falls below unity, but better side-lobe control can be achieved.

Although folded optics systems such as the Cassegrain and Gregorian configurations provide perfect focusing, they do not provide it with optimum aperture illumination efficiency. Aperture efficiency can be enhanced by appropriately shaping subreflector and reflector to remove energy from the central area, blocked by the subreflector and feed, and redistributing it to achieve more uniform illumination across the remaining aperture. Such shaping can raise the gain of a reflector antenna by more than 1 dB. It is most effective for antennas with $D/\lambda > 100$.

The crowding of the geostationary orbit resulting from the expansion of satellite systems requires very strict control of antenna side lobes in order to satisfy the opposite requirements of minimum mutual interference and decreased in-orbit spacing (from 5° to 4° to 3° and even to 2°).

The side-lobe envelope of most electrically large Cassegrain antennas can be approximated by an expression of the form

$$G_{dBi} = A - B \log \theta \qquad \text{(Eq. 85)}$$

where A and B are constants and θ is the off-boresight angle. In 1965, the CCIR (now ITU-R) adopted the rule

$$G_{dBi} = \begin{cases} 32 - 25 \log \theta & 1° \le \theta \le 48° \\ 10 & \theta > 48° \end{cases} \qquad \text{(Eq. 86)}$$

The antennas of the *INTELSAT* system have been standardized to follow the CCIR rule. Until 1977, side lobes beyond 1° from boresight were not to exceed the −29 dB level, but after 1977 a new rule was introduced requiring that no more than 10 percent of the side-lobe peaks exceed the envelope as defined above. A more recent recommendation would change the value of the constant A from 32 to 29 in the above expression.

Increasingly, to meet the more stringent side-lobe requirements, earth-station antennas are being built in offset configurations. By placing the feed structure below the reflector optical line of sight, the reflector aperture remains unblocked, and much lower side lobes can be realized.

The parameter that characterizes system performance is the G/T ratio, usually expressed in dB/K. All contributions to the system noise temperature must be properly taken into account once the measurement port is chosen. Antenna-feed design is of great importance with regard to both gain and side-lobe considerations (as well as polarization).

The amounts of spillover and illumination taper for both the subreflector and main reflector depend on the design of the feed system. Much progress has occurred in the transition from pyramidal to conical horns of various types such as single mode (TE_{11}), multimode ($TE_{11} + TM_{11}$), and hybrid mode (EH_{11}). In the last mentioned case, corrugated horns with $\lambda/4$ grooves have made it possible to increase bandwidth, improve symmetry of the radiation pattern, reduce the side lobes, and achieve better off-axis polarization characteristics, a feature of special importance in dual-polarization systems. In this case, the isolation between the two orthogonally polarized co-frequency channels should be as high as possible. Experience in systems using linear or circular orthogonal polarizations has confirmed that 30-dB isolation is a representative design goal.

Sophisticated orthomode junctions and an arrangement of cascaded polarizers are required to satisfy the above-mentioned requirements.

The actual isolation depends on the polarization purity of the signal source and of the antenna system. Since rain along the signal path depolarizes the signal, automatic means of depolarization correction have been successfully introduced at 6/4 GHz.

When needed, monopulse tracking systems are employed to correct continuously the pointing of the antenna in the direction of the satellite. To maintain continuity of service, an auxiliary power source is provided as well as redundant communications equipment.

* Shipboard antennas of maritime satellite communications systems are an exception.

Much of the foregoing description of earth stations applies to those used as gateways for the PSTN. In the 1980s, a marked change occurred in the application of satellite communications. Many classes of earth stations are unmanned, located on the user's premises, mobile and with low G/T, receive-only, electrically small, or combinations of these qualities. As previously mentioned, VSATs are usually at the user's premises, unmanned, and relatively small. USATs are similarly deployed. The numbers of user's premises earth stations is rising rapidly, as is the amount of traffic they carry. DBS-TV home stations are on the user's premises, receive-only, and electrically fairly small. Mobile terminals for aircraft, land mobile, and smaller ships are on the user's premises (vehicle), mobile and with low G/T (< -10 dB/K) (and thus often suffer from multipath), and quite small electrically. The emerging handset terminals are even smaller physically and electrically. Terminals used for IBS or its domestic equivalents are usually on the user's premises and often unmanned.

What has made much of this possible is the availability of highly reliable low-cost LSICs, VLSICs, and DSPs, along with advances in modulation, coding, and protocols for baseband modules, and solid-state MICs and more recently MMICs of moderate cost and high reliability at microwave frequencies. Combined with the higher eirps available in satellites in service in the 1980s and 1990s, services using earth terminals such as those described above have greatly expanded and the expansion will increase at least at the same rate in the first decade of the 21st century.

28 Discrete-Time Signal Processing

W. Kenneth Jenkins,
Douglas L. Jones, and Bill J. Hunsinger

INTRODUCTION

During the last twenty-five years, there has been rapid advancement in the theory and application of digital signal processing (DSP) in various engineering disciplines. Interest has grown in digital signal processing because, not only has the general-purpose computer become more readily available, but digital integrated circuits have become more highly integrated and cheaper, a trend that will continue into the foreseeable future. Very large scale integration (VLSI) techniques have produced high-density read-only memories (ROM) and microprocessors that provide enormous flexibilities in the design of digital hardware systems.

Digital filters offer distinct advantages over analog (continuous-time) filters in many applications, although they are not good substitutes for all analog filters. The major advantages are good numerical accuracy, programmability, stability in the presence of changing environmental conditions, suitability for multiplexing, and convenience for processing data that is directly available in binary form. Some of the disadvantages of these filters are the relatively high per-unit costs for high-frequency applications, frequency limitations imposed by the speed of the digital hardware, and the necessity for a significant amount of clocking and control circuitry to sequence the binary operations properly.

The *design* of a digital filter involves determining either a set of time-domain difference equations or a z-domain digital transfer function that satisfies given specifications. A digital filter can be obtained by first designing an analog prototype and then transforming it into a discrete-time system by a sampled-data transformation. Another approach is to use a computer optimization to place the z-domain poles and zeros so the discrete-time system will meet specifications directly. The first approach takes advantage of well known analog design techniques, while the second provides greater flexibility because it does not depend on an analog design step. Digital filter *implementation* involves choosing a network topology and hardware modules for the final network. At this stage, the designer must analyze the effects of quantization error, because error performance and network topology are closely related. Digital *hardware design* consists of designing the individual circuit elements (adders, multipliers, shift registers, etc.). If the system is to be integrated, it also includes the IC layouts.

In many applications, implementation is ultimately accomplished in software on a general-purpose computer. In these cases, the emphasis is on the design and implementation stages, since hardware design and system architecture are dictated by the general computer system. However, with the rapid advances that are now being made in the automated design and manufacture of VLSI monolithic circuits, engineers enjoy the freedom to specify custom designed digital functions and have them quickly fabricated in low-cost silicon devices. This new capability will result in digital signal processing becoming less dependent on the general computer. New techniques for improving data rates, reducing circuit complexity, and improving reliability will become increasingly important as more custom-designed VLSI digital systems come into common usage.

Several sampled-data analog technologies exist which implement discrete-time filters. While lacking the flexibility of all-digital implementations, these technologies, which include switched-capacitor filters, surface-acoustic-wave filters, and acoustic-charge-transport devices, often represent the most cost-effective method of filtering in certain performance regimes.

FUNDAMENTALS FOR DISCRETE-TIME SYSTEMS

Basic Definitions

A *continuous-time* (CT) signal is a function, $s(t)$, that is defined for all time t contained in some interval on the real line. For historical reasons, CT signals are often called *analog signals*. If the domain of definition for $s(t)$ is restricted to a set of discrete points $t_n = nT$, where n is an integer and T is the sampling period, the signal $s(t_n)$ is called a *discrete-time* (DT) signal. Often, if the sampling interval is well understood within the context of the discussion, the sampling period is normalized by $T = 1$, and a DT signal is represented simply as a sequence $s(n)$. If the values of the sequence $s(n)$ are to be represented with a finite number of bits (as required in a finite state machine), then $s(n)$ can take on only a discrete set of values. In this case, $s(n)$ is called a *digital signal*. Much of the theory that is used in DSP is actually the theory of DT signals and DT systems, in that no amplitude quantization is assumed in the mathematics. However, all signals processed in binary machines are truly digital signals. One important question that arises in virtually every application is the question of how many bits are required in the representation of the digital signals to guarantee that the performance of the digital system is acceptably close to the performance of the ideal DT system.

Linear CT systems are characterized by the familiar mathematics of differential equations, continuous convolution operators, Laplace transforms, and Fourier transforms. Similarly, linear DT systems are described by the mathematics of difference equations, discrete convolution operators, Z-transforms, and discrete Fourier transforms. It appears that for every major concept in CT systems, there is a similar concept for DT systems (e.g., differential equations and difference equations, continuous convolution and discrete convolution, etc.). However, in spite of this duality of concepts, it is impossible to apply directly the mathematics of CT systems to DT systems, or vice versa.

Many modern systems consist of both analog and digital subsystems, with appropriate analog-to-digital (A/D) and digital-to-analog (D/A) devices at the inter-

faces. For example, it is common to use a digital computer in the control loop of an analog plant. Analytical difficulties often occur at the boundaries between the analog and digital portions of the system because the mathematics used on the two sides of the interface must be different. It is often useful to assume that a sequence $s(n)$ is derived from an analog signal $s_a(t)$ by ideal sampling, i.e.

$$s(n) = s_a(t)\Big|_{t=nT} \qquad \text{(Eq. 1)}$$

An alternative model for the sampled signal is denoted by $s^*(t)$ and defined by

$$s^*(t) = \sum_{n=-\infty}^{+\infty} s_a(t)\,\delta_a(t-nT) \qquad \text{(Eq. 2)}$$

where $\delta_a(t)$ is an analog impulse function. Both $s(n)$ and $s^*(t)$ are used throughout the literature to represent an ideal sampled signal. Note that even though $s(n)$ and $s^*(t)$ represent the same essential information, $s(n)$ is a DT signal and $s^*(t)$ is a CT signal. Hence, they are not mathematically identical. In fact, $s(n)$ is a "DT-world" model of a sampled signal, whereas $s^*(t)$ is a "CT-world" model of the same phenomenon.

Finite Convolution and Difference Equations

Let $y(n) = F\{x(n)\}$ define the input-output relation for a discrete-time system with input $x(n)$ and output $y(n)$. The following definitions are commonly used to define the properties of linearity, shift invariance, causality, and stability:

Linearity-F is linear if and only if $F\{ax_1(n) + bx_2(n)\} = a\,F\{x_1(n)\} + b\,F\{x_2(n)\}$, where a and b are scalar constants and $x_1(n)$ and $x_2(n)$ are two arbitrary input sequences.

Shift-Invariance- F is shift-invariant if and only if $y(n-n_0) = F\{x(n-n_0)\}$ for all integer values of n_0.

Causality - F is causal if and only if $y(n)$ depends on samples of $x(k)$ at times $k \le n$.

Stability (BIBO)- F is stable in the bounded-input bounded-output (BIBO) sense if and only if $y(n)$ remains bounded for all $x(n)$ that are bounded.

Whenever F is linear and shift-invariant, it is possible to express the zero state response, $y(n)$, due to an arbitrary input, $x(n)$, in terms of a discrete convolution of $h(n)$ and $x(n)$, where $h(n) = F\{\delta(n)\}$, and $\delta(n) = 0$ for $n \neq 0$ and $\delta(n) = 1$ when $n = 1$. The function $\delta(n)$ is called a unit pulse, $h(n)$ is the unit-pulse response* of F, and the finite convolution is expressed by

$$y(n) = \sum_{k=-\infty}^{+\infty} h(k)\,x(n-k) \qquad \text{(Eq. 3)}$$

If F is causal, $h(k) = 0$ for $k < 0$, and the lower limit on the summation in Eq. 3 becomes zero.

In certain types of DT systems, the unit-pulse response is zero outside of a finite interval containing N samples; i.e., $h(n) \equiv 0$ for $n < 0$ and $n \ge N$. This type of system is a finite impulse response (FIR) DT system. If $h(n)$ is supported over an infinite length interval, then F is called an infinite impulse response (IIR) DT system. These two classes constitute the two important types of digital filters, with each class having distinct advantages and disadvantages with regard to stability, quantization error performance, and computational efficiency.

An IIR system has an infinite memory because, in general, the output depends on the input all the way into the infinite past. Such a system can also be characterized by an Nth order linear difference equation, as given by

$$y(n) + a_1 y(n-1) + \cdots + a_{N-1} y(n-N+1) = b_0 x(n) + \cdots + b_{M-1} x(n-M+1) \qquad \text{(Eq. 4)}$$

A linear difference equation is a recursive relation that can be realized quite easily with digital multipliers, adders, and unit delay registers. Hence, in some of the older literature, IIRs are referred to as recursive filters. Similarly, FIRs were often referred to as nonrecursive (or transversal) filters. However, the terms recursive and nonrecursive refer more specifically to the implementation of the filter, rather than the mathematical structure. This fact is illustrated by the frequency sampling structure,† which is a recursive realization of a FIR system. The terms IIR and FIR are used in the modern literature to eliminate any ambiguity that was caused by the older terminology.

In general, IIR systems are cheaper to implement than FIR systems because the iteration of a difference equation requires fewer arithmetic operations per output sample, as compared to calculating a finite convolution. However, IIR systems have "poles," whereas FIR systems do not. This implies that IIR systems must be carefully designed to ensure stability. Also, IIR systems suffer from limit cycle oscillations and quantization error accumulation because quantization efforts are recycled through the inherent feedback in the recursion.

The *Z*-Transform

The Z-transform occupies the same position of importance in DT system theory as the Laplace transform does in CT system theory. They are very similar transforms that share many common properties. However, it is important to emphasize that they cannot be used interchangeably because they apply to different types of systems.

* The term "impulse response" is often used interchangeably with the term "unit pulse response."

† Reference 25.

The 2-sided Z-transform of a DT signal, $s(n)$, is defined by

$$S(z) = \mathcal{Z}\{s(n)\} = \sum_{n=-\infty}^{+\infty} s(n) z^{-n} \qquad \text{(Eq. 5)}$$

where $S(z)$ is said to exist for all $z \epsilon R$ such that the infinite summation converges. Symbol R represents the region of convergence (R.O.C.) of $S(z)$. If the summation is taken from $n = 0$, rather than $n = -\infty$ the result is called the 1-sided Z-transform. It is clear that for all $s(n)$ such that $s(n) \equiv 0$ for $n < 0$, the 1-sided and 2-sided Z-transforms are equivalent.

The inverse Z-transform is defined by

$$s(n) = (1/2\pi j)\oint_C S(z) z^{n-1} dz \qquad \text{(Eq. 6)}$$

where C is a closed contour that encircles the origin and lies entirely within the region of convergence for $S(z)$. Eq. 6 is valid for both positive and negative values of n. In many applications, the inverse Z-transform can be found from a table of Z-transform pairs, and therefore it is seldom necessary to find the inverse Z-transform from its definition. However, for cases where it is desired to apply the definition of Eq. 6, the contour integral can be evaluated by means of the well-known residue theorem.

$$(1/2\pi j)\oint_C S(z)\, z^{n-1}\, dz = \sum \left(\text{residues of } S(z) z^{n-1} \text{ at the poles inside } C\right) \qquad \text{(Eq. 7)}$$

The normal technique for finding the residues of $S(z)\, z^{n-1}$ is by the same method used in expanding $S(z)\, z^{n-1}$ in a partial fraction expansion. It is important to note that the residue theorem is applicable only when $S(z)\, z^{n-1}$ has singularities (poles) that occur at isolated points in the z-plane. Fortunately, virtually all one-dimensional DT systems and DT signals of practical interest produce Z-transforms that are ratios of polynomials in powers of z. The singular behavior of such systems is characterized by poles and zeros, and hence the residue theorem can be applied in virtually all cases of practical interest. Table 1 summarizes a number of Z-transform pairs that are frequently encountered in practical problems. More complete tables of Z-transforms can be found in References 16 and 30. Note that most of the sequences in Table 1 are right-

TABLE 1. Z-TRANSFORMS

	$x(n)$	$X(z)$
1.	$\delta(n)$ (unit pulse)	1, for all z
2.	$u(n)$ (unit step)	$1/(1-z^{-1})$, $1 < \lvert z \rvert$
3.	$n\,u(n)$	$1/(1-z^{-1})^2$, $1 < \lvert z \rvert$
4.	$n^r a^n u(n)$ (r = integer)	$-z(d^r/dz^r)\{1/(1-az^{-1})\}$, $\lvert a \rvert < \lvert z \rvert$
5.	$a^n\, u(n)$	$1/(1-az^{-1})$, $\lvert a \rvert < \lvert z \rvert$
6.	$n^r a^n u(-n)$ (r = integer)	$-z(d^r/dz^r)\{1/(1-az^{-1})$, $\lvert z \rvert < \lvert a \rvert$
7.	$a\lvert^n \rvert$	$(a-a^2)/(1-az)(1-az^{-1})$, $\lvert a \rvert < \lvert z \rvert < \lvert 1/a \rvert$
8.	$n^{-1}\, u(n)$	$-1n\,(1-t^{-1})$, $1 < \lvert z \rvert$
9.	$\cos(an)\, u(n)$	$\dfrac{(1-z^{-1}\cos a)}{(1-2z^{-1}\cos a + z^{-2})}$, $1 < \lvert z \rvert$
10.	$\sin(an)\, u(n)$	$\dfrac{z^{-1}\sin a}{(1-2z^{-1}\cos a + z^{-2})}$, $1 < \lvert z \rvert$
11.	$(K_1 \cos an + K_2 \sin an) u(n)$	$\dfrac{K_1 + z^{-1}(K_2 \sin a - K_1 \cos a)}{(1-2z^{-1}\cos a + z^{-2})}$, $1 < \lvert z \rvert$
12.	$(K_1 \cos an + G \sin an)\, u(n)$ where, $G = (K_2 + K_2 \cos a)/\sin a$	$\dfrac{K_1 + K_2 z^{-1}}{(1-2z^{-1}\cos a + z^{-2})}$, $1 < \lvert z \rvert$
13.	$(n+1)a^n\, u(n)$	$1/(1-az^{-1})^2$, $\lvert a \rvert < \lvert z \rvert$
14.	$(1/2)(n+1)(n+2)a^n\, u(n)$	$1/(1-az^{-1})^3$, $\lvert a \rvert < \lvert z \rvert$
15.	$[1/(r-1)!](n+1)$ $(n+2) \ldots (n+r-1)a^n\, u(n)$	$1/(1-az^{-1})^r$, $\lvert a \rvert < \lvert z \rvert$

sided; i.e., $x(n) = 0$ for $n < 0$. The exceptions are entry 6, which is left-sided, and entry 7, which is two-sided. For a given $X(z)$, the corresponding $x(n)$ may be right-sided, left-sided, or two-sided, depending on the nature of the region of convergence, R. Fig. 1 shows the three general types of regions of convergence for these three cases.

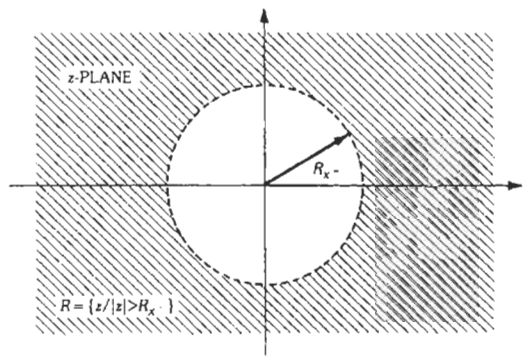
Table 2 summarizes some important properties of the Z-transform. Although the table is specifically given for the two-sided Z-transform, most of the properties hold for the 1-sided Z-transform also. A notable exception is property 4, the shift theorem. Since the shift theorem for 1-sided sequences is often needed for solving difference equations, it is stated here:

If $X(z)$ is the 1-sided Z-transform of $x(n)$ with a region of convergence R, then for $n_0 > 0$,

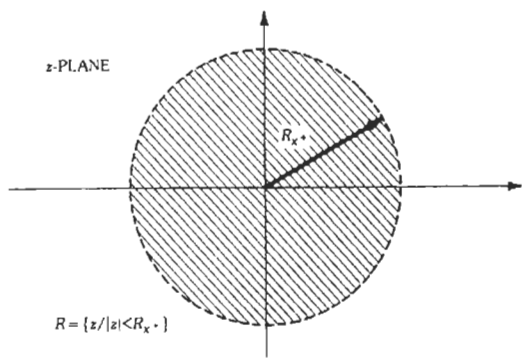
$$\text{(i)}\quad \mathcal{Z}\{x(n+n_0)\} = z^{n_0}\left\{X(z) - \sum_{k=0}^{n_0-1} x(k)z^{-k}\right\}$$

$$\text{(ii)}\quad \mathcal{Z}\{x(n-n_0)\} = z^{-n_0}\left\{X(z) + \sum_{k=-n_0}^{-1} x(k)\,z^{-k}\right\}$$

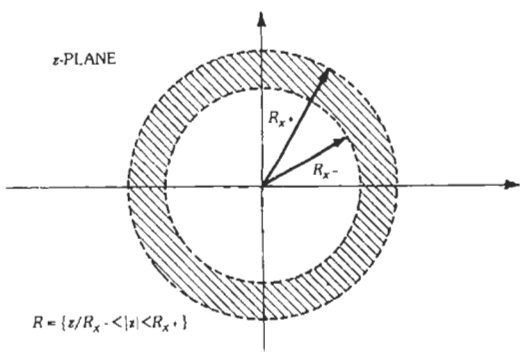
with region of convergence R.*



(A) Right-sided sequence.



(B) Left-sided sequence.



(C) Two-sided sequence.

Fig. 1. Typical regions of convergence for Z-transforms.

The Discrete-Time Fourier Transform

It is important to distinguish between the concepts of the discrete-time Fourier transform (DTFT) and the discrete Fourier transform (DFT). The DTFT is a transform-pair relationship between a DT signal and its continuous-frequency transform that is used extensively in the analysis and design of DT systems. In contrast, the DFT is a transform-pair relationship between a DT signal, and its discrete-frequency transform that is used in practical digital processing.

The DTFT of a sequence $x(n)$ is defined by

$$X(e^{j\omega}) = \sum_{n=-\infty}^{+\infty} x(n)e^{-jn\omega} \qquad \text{(Eq. 8)}$$

for all sequences $x(n)$ for which the sum converges. The spectrum $X(e^{j\omega})$ is a continuous-frequency function which is periodic, with period 2π. Eq. 8 is equivalent to evaluating the 2-sided Z-transform $X(z) = Z\{x(n)\}$ on the unit circle $z = e^{j\omega}$, provided that the unit circle lies within R, the region of convergence of $X(z)$. A sequence $x(n)$ can be recovered from its spectrum by

$$x(n) = (1/2\pi)\int_{-\pi}^{+\pi} X(e^{j\omega})e^{jn\omega}\,d\omega \qquad \text{(Eq. 9)}$$

which can be interpreted on the inverse-DTFT (IDTFT). An alternate interpretation is that Eq. 8 is a Fourier series expansion of the periodic function $X(e^{j\omega})$, the $x(n)$s are the Fourier coefficients, and Eq. 9 is an expression for finding the Fourier coefficients.

The DTFT obeys the same properties as those given for the Z-transform in Table 2, as long as the unit circle is contained within the various regions of convergence. In particular, the DTFT obeys the convolutional property (entry 11), which makes it useful for frequency analyses of DT systems. If $h(n)$ is the unit pulse response of a linear shift-invariant DT system, then

* Reference 25 describes pathological cases where R for the shifted sequence may no longer include the points $z = 0$ or $z = \infty$.

TABLE 2. SOME IMPORTANT PROPERTIES OF THE 2-SIDED Z-TRANSFORM*

	Sequence	Z-Transform	
1.	$x(n)$	$X(z)$	$R_{x-} < \|z\| < R_{x+}$
2.	$y(n)$	$Y(z)$	$R_{y-} < \|z\| < R_{y+}$
3.	$ax(n) + by(n)$	$aX(z) + bY(z)$	$\max [R_{x-}, R_{y-}] < \|z\| < \min [R_{x+}, R_{y+}]$
4.	$x(n + n_0)$	$z^{n0}X(z)$	$R_{x-} < \|z\| < R_{x+}$

$H(e^{j\omega})$ = DTFT $\{h(n)\}$ is interpreted as the frequency response of the DT system. Therefore, if a discrete sinusoidal waveform $x(n) = A \cos(n\omega_0)$ is applied as an input to a linear shift-invariant DT system, the sinusoidal steady-state output is given by $y_{ss}(n) = A|H(e^{j\omega 0})|\cos[n\omega_0 + \measuredangle H(e^{ej\omega 0})]$.

Sampling and Reconstruction

The traditional CT Fourier transform can be applied to the ideal sampled signal, $s^*(t)$, as follows:

$$\begin{aligned}\mathfrak{F}\{s^*(t)\} &= \sum_{n=-\infty}^{+\infty} s(nT)\mathfrak{F}\{\delta_a(t-nt)\} \\ &= \sum_{n=-\infty}^{+\infty} s_a(nT)e^{-jnT\omega} \\ &= \text{DTFT}\{s_a(nT)\} \qquad \text{(Eq. 10)}\end{aligned}$$

This verifies that the traditional Fourier transform of $s^*(t)$ is identical to the DTFT of $s(n)$, where $s(n) \equiv s_a(t)|_{t=nT}$; i.e., the sequence $s(n)$ is derived from $s_a(t)$ by ideal sampling. This proves that $s^*(t)$ and $s(n)$ are really different models of the same phenomenon, since their spectra (as computed with appropriate transforms) are identical. Suppose that $S_a(j\Omega)$ is the spectrum of $s_a(t)$ and $S(e^{j\omega})$ is the spectrum of $s(n)$. It can be shown that

$$S(e^{j\omega}) = (1/T)\sum_{r=-\infty}^{+\infty} S_a(j[\Omega - 2\pi r/T]) \qquad \text{(Eq. 11)}$$

where $\omega = \Omega T$ is often referred to as the "normalized digital frequency." Eq. 11 shows that the DT spectrum is formed from a superposition of an infinite number of replicas of the analog signal, as illustrated in Fig. 2. As long as the sampling frequency, $\Omega_s = 2\pi/T$, is chosen so that $\Omega_s > 2\Omega_B$, where Ω_B is the highest frequency component contained in $s_a(t)$, then each period of $S(e^{j\omega})$ contains a perfect copy of $S_a(j\Omega)$, and $s_a(t)$ can be recovered exactly from $s(n)$ by ideal low-pass filtering. Sampling under these conditions is said to satisfy the Nyquist sampling criterion, since the sampling frequency exceeds the Nyquist rate, $2\Omega_B$. If the sampling rate does not satisfy the Nyquist criterion, the adjacent periods of the analog spectrum will overlap, causing a distorted spectrum (see Fig. 2). This effect, called *aliasing distortion*, is rather serious because it cannot be easily corrected once it has occurred. In general, an analog signal should be prefiltered with an analog low-pass filter prior to sampling so that aliasing distortion does not occur.

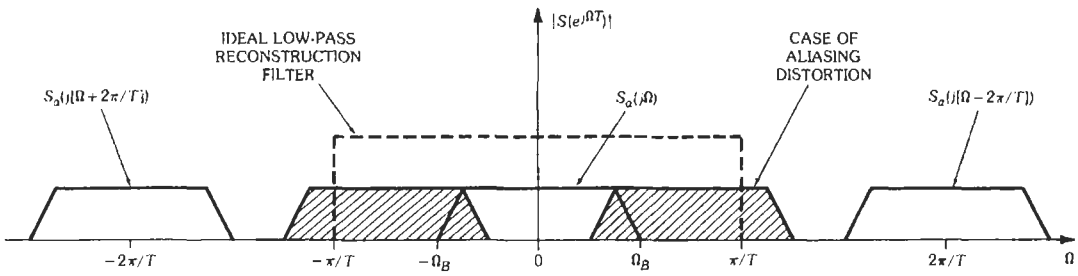

Fig. 2. Relationship between the spectrum of an analog signal and the spectrum of the ideally sampled signal.

If the Nyquist criterion has been satisfied, it is always possible to reconstruct an analog signal from its samples according to

$$s_a(t) = \sum_{k=-\infty}^{+\infty} s_a(kT)\,\mathrm{sinc}\big((\pi/T)(t-kT)\big) \quad \text{(Eq. 12)}$$

This reconstruction formula results by filtering $s^*(t)$ with an ideal low-pass analog filter with a bandwidth of $\Omega_B = \pi/T$ (see Fig. 2). In general, exact reconstruction requires an infinite number of samples, although a good approximation can be obtained by using a large but finite number of terms in Eq. 12.

Most practical systems use a digital-to-analog converter for reconstruction, which results in an analog staircase approximation to the true analog signal; i.e.

$$\hat{S}_a(t) = \sum_{k=-\infty}^{+\infty} s_a(kT)[u(t-kT) - u(t-(k+1)T)] \quad \text{(Eq. 13)}$$

It can be shown that $\hat{S}_a(t)$ is obtained by filtering $s_a^*(t)$ with an analog filter whose frequency response is

$$H_a(j\Omega) = 2Te^{\,j\Omega T/2}\,\mathrm{sinc}(\Omega T/2) \quad \text{(Eq. 14)}$$

The approximation $\hat{S}_a(t)$ is said to contain "sin x/x distortion," which occurs because $H_a(j\Omega)$ is not an ideal low-pass filter. The $H_a(j\Omega)$ response distorts the signal by causing a droop near the band edge, as well as passing high-frequency distortion terms that "leak" through the side lobes of $H_a(j\Omega)$. Therefore, a practical D/A converter is normally followed by a postfilter

$$H_p(j\Omega) = \begin{cases} H_a^{-1}(j\Omega), 0 \le |\Omega| \le \pi/T \\ 0, \Omega \text{ otherwise} \end{cases} \quad \text{(Eq. 15)}$$

which compensates for the distortion and produces the correct $s_a(t)$ analog output. Notice, however, that $H_p(j\Omega)$ can only be approximated in practice, so that the best reconstruction is necessarily an approximation. Fig. 3 shows a digital processor complete with sampling and reconstruction devices at the input and output.

DISCRETE FOURIER TRANSFORM

Definitions and Properties

Let $x(n)$ be a finite-length sequence of length N. The discrete Fourier transform (DFT) pair is defined by

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-j(2\pi/N)nk} \quad \text{(Eq. 16a)}$$

$$k = 0, \ldots, N-1$$

and

$$x(n) = (1/N)\sum_{k=0}^{N-1} X(k)e^{j(2\pi/N)nk} \quad \text{(Eq. 16b)}$$

$$n = 0, \ldots, N-1$$

The DFT treats $x(n)$ as though it were one period of a periodic sequence. This is an important feature that must be handled properly in signal processing to prevent the introduction of artifacts. Important properties of the DFT are summarized in Table 3. The notation $((k))_N$ denotes the least positive residue of k modulo N, and $R_N(n)$ is a rectangular window function such that $R_N(n) = 1$ for $n = 0, \ldots, N-1$, and $R_N(n) = 0$ for $n < 0$ and $n \ge N$.

* From A. V. Oppenheim and R. W. Schafer. *Digital Signal Processing*. Englewood Cliffs, N. J.: Prentice-Hall, Inc., 1975.

Most of the properties given in Table 3 for the DFT are the same as those of the z-transform, although there are some important differences. Property 4, the shift property, holds for *circular* shifts of the finite-length sequence $x(n)$. Also, the multiplication of two DFTs results in the *circular convolution* of the corresponding time-domain sequences (property 6).

Suppose it is desired to implement an FIR filter

$$y(n) = \sum_{k=0}^{N-1} h(k)x(n-k)$$

by transforming $h(n)$ and $x(n)$ into $H(k)$ and $X(k)$ using a DFT, multiplying pointwise to obtain $Y(k) = H(k)X(k)$, and then using the inverse-FFT to obtain $y(n) = \text{IFFT}\{Y(k)\}$. If $x(n)$ is a finite-length sequence of length M, then the results of the circular convolution implemented by the FFT will correspond to the desired linear convolution if and only if $N_{\text{FFT}} \geq N + M - 1$, where N_{FFT} is the block length of the FFT and $h(n)$ and $x(n)$ are each padded with zeros to create blocks of length N_{FFT}. In some applications, either the value of M is too large for the memory available, or $x(n)$ may not be finite in length, but rather it may be a continual stream of data that arrives at the filter for real-time processing. Two algorithms are available that partition $x(n)$ into smaller blocks and process the individual blocks with a smaller-length FFT: (1) overlap-save partitioning and (2) overlap-add partitioning. These are summarized below.

Overlap-Save—In this algorithm, N_{FFT} is chosen to be some convenient value with $N_{\text{FFT}} > N$. The signal, $x(n)$, is partitioned into blocks which are of length N_{FFT} and which overlap by $N - 1$ data points. Hence, the kth block is $x_k(n) = x(n + k(N_{\text{FFT}} - N + 1))$, $n = 0, \ldots,$

$N_{FFT} - 1$. The filter is augmented with $N_{FFT} - N$ zeros to produce

$$\hat{h}(n) = \begin{Bmatrix} h(n) & n = 0, \ldots, N-1 \\ 0 & N \le n < N_{FFT} \end{Bmatrix}$$

The FFT is then used to obtain $\hat{Y}(k) = \text{FFT}\{\hat{h}(n)\} \cdot \text{FFT}\{x_k(n)\}$, and $\hat{y}_k(n) = \text{IFFT}\{\hat{Y}(k)\}$. From the $\hat{y}(n)$ array, the values that correctly correspond to the linear convolution are saved; values that are "contaminated by wrap-around error" are discarded; i.e.,

$$y_k(n) = \begin{Bmatrix} \hat{y}_k(n), & N-1 \le n \le N_{FFT}-1 \\ 0, & 0 \le n < N-1 \end{Bmatrix}$$

The blocks of output data $y_k(n)$are then assembled to produce the correct output by

$$y(n) = \sum_{k=0}^{\infty} y_k\left(n - k\left(N_{FFT} - N + 1\right)\right)$$

For the overlap-save algorithm, each time a block is processed there are $N_{FFT} - N + 1$ points saved and $N - 1$ points discarded. Each block moves forward by $N_{FFT} - N + 1$ data points and overlaps the previous block by $N - 1$ points.

Overlap-Add—This algorithm is similar to the previous one except that the kth input block is defined to be

$$x_k(n) = \begin{Bmatrix} x(n + kL), & n = 0, \ldots, L-1 \\ 0 \quad , & n = L, \ldots, N_{FFT} - 1 \end{Bmatrix}$$

where $L = N_{FFT} - N + 1$. The filter function $\hat{h}(n)$ is augmented with zeros, as before, to create $\hat{h}(n)$, and the DFT processing is executed exactly as before. In each block $\hat{y}_k(n)$, that is obtained at the output, the first $N - 1$ points are "bad," the last $N - 1$ points are "bad," and the middle $N_{FFT} - 2(N - 1)$ points are "good." However, if the last $N - 1$ points from block k are overlapped with the first $N - 1$ points of block $k + 1$ and added pointwise, correct results corresponding to linear convolution are obtained in these positions. Hence, after this addition the number of correct points produced per block is $N_{FFT} - (N - 1)$, which is the same as that for the overlap-save algorithm. The overlap-add algorithm requires essentially the same amount of computation as the overlap-save algorithm, although the addition of the overlapping blocks is extra. This feature, together with the extra delay of waiting for the next block to be finished before the previous one is complete, has resulted in more popularity for the overlap-save algorithm in practical applications.

These block-filtering algorithms make it possible to filter continual data streams in real time because the efficiency of the FFT minimizes the total computation time and can achieve reasonably high overall data rates. However, block filtering generates data in bursts; i.e., there is a delay during which no filtered data appears, and then suddenly an entire block is generated. In real-time systems, buffering must be used. The block algorithms are particularly effective for filtering very long sequences of data that are prerecorded on tape or magnetic disk.

FFT Algorithms

"Fast Fourier transform" (FFT) is a generic name for a class of algorithms that efficiently compute the DFT (see Eqs. 16). The FFT is easily understood by examining a radix–2 FFT for the case $N = 2^3$. First, each of the indices k and n can be expressed in binary form, $k = k_2 4 + k_1 2 + k_0$ and $n = n_2 4 + n_1 2 + n_0$, where k_i and n_i are bits that take the values of either 0 or 1. If these expressions are substituted into Eq. 16a, all terms in the exponent that contain the factor $N = 8$ can be simply deleted, because $e^{j2\pi l} = 1$ for any integer l. Upon deleting such terms and regrouping, the product nk can be expressed in one of two ways:

$$nk = (4k_0)n_2 + (4k_0 + 2k_0)n_0 + (4k_2 + 2k_1 + k_0)\, n_0$$

(Eq. 17a)

$$nk = (4n_0)k_2 + (4n_1 + 2n_0)k_1 + (4n_2 + 2n_1 + n_0)k_0$$

(Eq. 17b)

Substituting Eq. 17a into Eq. 16a leads to the decimation-in-time (D-I-T) FFT, whereas substituting Eq. 17b into Eq. 16a leads to the decimation-in-frequency (D-I-F) FFT. Only the D-I-T FFT is discussed further here. The D-I-F FFT and various related forms are treated in detail in Reference 4.

The D-I-T FFT decomposes into $\log_2 N$ stages of computation, plus a stage of bit reversal. (Let $W_N = e^{j2\pi/N}$)

$$x_1(k_0, n_1, n_0) = \sum_{n_2=0}^{1} x(n_2, n_1, n_0) W_8^{4k_0 n_2}$$

(stage 1)

$$x_2(k_0, k_1, n_0) = \sum_{n_1=0}^{1} x_1(k_0, n_1, n_0) W_8^{(4k_1 + 2k_0)n_1}$$

(stage 2)

$$x_3(k_0, k_1, k_2) = \sum_{n_0=0}^{1} x_2(k_0, k_1, n_0) W_8^{(4k_2 + 2k_1 + k_0)n_0}$$

(stage 3)

$$X(k_2, k_1, k_0) = x_3(k_0, k_1, k_2)$$

(bit reversal)

In each summation above, one of the n_i's is summed out of the expression, while at the same time a new k_i is introduced. The notation is chosen to reflect this. For example, in stage 3, n_0 is summed out, k_2 is introduced as a new variable, and n_0 is replaced by k_2 in the result. The last operation, called bit reversal, is necessary to correctly locate the frequency samples $X(k)$ in the memory. It is easy to show that if the samples are

paired correctly, an in-place computation can be done by a sequence of butterfly computations. For example, in stage 3 the $k = 6$ and $k = 7$ samples should be paired, yielding a butterfly computation that requires one complex multiply, one complex add, and one complex subtract.

$$x_3(1,1,0) = x_2(1,1,0) + W_8^3 x_2(1,1,1)$$

$$x_3(1,1,1) = x_2(1,1,0) - W_8^3 x_2(1,1,1)$$

Therefore, samples $x_2(6)$ and x_2 (7) are read from memory, the butterfly is executed, and $x_3(6)$ and x_3 (7) are written back to memory, thereby destroying the original values of x_2 (6) and x_2 (7). In general, there are $N/2$ butterflies per stage and $\log_2 N$ stages, so the total number of butterflies is $(N/2) \log_2 N$. Since there is at most one complex multiply per butterfly, the total number of multiples is bounded by $(N/2) \log_2 N$ (some of the multiplies involve factors of 1, and should not be counted). A direct computation of the DFT requires on the order of N^2 complex multiplies. It is obvious that for large N, the order of complexity of the FFT, $0\{(N/2) \log_2 N\}$, is much less than the order of complexity $0\{N^2\}$ of the DFT. The saving is so dramatic for large N that the FFT has made possible the solution of many DSP problems that are compute-bound and impossible to solve with the direct DFT.

Fig. 4 shows the signal-flow graph for the D-I-T FFT with $N = 8$, which is referred to as an in-place FFT with normally ordered input and bit reversed output. Minor variations that include bit reversed input and normally ordered output, and non-in-place algorithms with normally ordered inputs and outputs are possible. Also, when N is not a power of 2, a mixed-radix algorithm can be used to reduce computation.* The mixed-radix FFT is most efficient when N is highly L composite, i.e.,

$$N = \prod_{i=1}^{L} P_i^{r_i}$$

where the p_i's are small primes and the r_i's are positive integers. It can be shown that the order of complexity of the mixed-radix FFT is

$$0\left\{N \sum_{i=1}^{L} r_i (p_i - 1)\right\}$$

Because of the lack of uniformity of structure among stages, this algorithm has not received much attention for hardware implementation. However, the mixed-radix FFT is often used in software applications, especially for processing data recorded in laboratory experiments where it is not convenient to restrict the block lengths to be powers of 2. The most widely used mixed-radix FFT program was published by Singleton.† Singleton's program is also contained in a collection of DSP programs published by the IEEE Signal Processing Society.

Other advanced algorithms, such as higher-radix algorithms and the prime-factor algorithm, are described in the literature. Algorithms specialized for

* Reference 29.

real-valued data lead to a reduction at the computational cost by a factor of two.

A radix-2 decimation-in-time FFT program, written in C, is listed in Chart 1 for reference.

The FFT in Spectral Analysis

An FFT program is often used to perform spectral analysis on signals that are sampled and recorded as part of laboratory experiments, or in certain types of data acquisition systems. There are several issues that should be addressed when spectral analysis is performed on (sampled) analog waveforms that are observed over a finite interval of time.

Windowing—The FFT treats the block of data as though it is one period of a periodic sequence. If the underlying waveform is not periodic, then harmonic distortion may occur because the periodic waveform created by the FFT may have sharp discontinuities. This effect is minimized by removing the mean of the data (it can always be reinserted) and by windowing the data so the ends of the block are smoothly tapered to zero and discontinuities do not occur when the FFT treats the windowed block as one period of a periodic sequence. A good rule of thumb is to taper 10 percent of the data on each end of the block using either a cosine taper or one of the other common windows from Table 4. An alternate interpretation of this phenomenon is that the finite length observation has already windowed the true waveform with a rectangular window that has large spectral side lobes. Hence, applying an additional window results in a more desirable window that minimizes frequency-domain distortion.

Zero-Padding—It would appear that more accuracy is produced in the spectral domain if the block length of the FFT is increased. This can be done by (1) taking more samples within the observation interval; (2) increasing the length of the observation interval, without increasing the sampling rate; or (3) augmenting the original data set with zeros. First, it must be recognized that the finite observation interval causes a fundamental limit on the spectral resolution, even before the signals are sampled. The CT rectangular window has a sin x/x spectrum, which is convolved with the true spectrum of the analog signal that is being observed. Therefore, frequency resolution is limited by the width of the main lobe in the sin x/x spectrum, which is inversely proportional to the length of the observation interval. Sampling causes a certain degree of aliasing; although this effect can be minimized by sampling at a high enough rate. Therefore, lengthening the observation interval increases the fundamental resolution limit, while taking more samples within the same observation interval minimizes aliasing distortion and provides a better definition (more sample points) on the underlying spectrum.

Padding the data with zeros and computing a longer FFT does give more frequency domain points, but it does not improve the fundamental resolution limit, nor does it alter the effects of aliasing. The resolution limits are established by the observation interval and the sampling rate. No amount of zero padding can improve these basic limits. However, zero padding is a useful tool for providing more spectral definition; i.e., it enables one to get a better look at the (distorted) spectrum that exists after the observation and sampling effects have occurred.

Leakage and the Picket-Fence Effect—An FFT with block length N can accurately resolve only frequencies $\omega_k = (2\pi/N)k$, $k = 0, \ldots, N-1$ that are harmonics of the fundamental, $\omega_1 = 2\pi/N$. An analog waveform that is

sampled and subjected to spectral analysis may have frequency components between the harmonics. A component at frequency $\omega_{k+1/2} = (2\pi / N)(k + \frac{1}{2})$ will appear to be scattered throughout the spectrum. The effect is illustrated in Fig. 5 for a sinusoid that is observed through a rectangular window and then sampled at N points. The "picket-fence effect" means that not all frequencies can be seen by the FFT. Harmonic components are seen accurately. Other components "slip through the picket fence" while their energy is "leaked" in the harmonics.* These effects produce artifacts in the spectral domain that must be carefully monitored to assure that an accurate spectrum is obtained from FFT processing.

DIGITAL-FILTER DESIGN

A common approach to designing IIR digital† filters is first to design an analog prototype, which is then transformed into a digital filter by one of several analog-to-digital mappings. This approach allows the designer to take advantage of many well-known techniques for analog-filter design. Computer-based design techniques are also used for IIRS, as evidenced by the availability of several IIR design programs. Usually, FIRs are designed either by windowing techniques or by computer optimization algorithms. This section summarizes some of the more common design techniques.

* Reference 3.

† It is customary to refer to these as "digital" filters, although at the design stage they really are discrete-time filters.

IIR Filters

In the following discussion, $h_a(t)$ and $H_a(j\Omega)$ denote the impulse response and frequency response of an analog prototype, respectively. Similarly, $h(n)$ and $H(e^{j\omega})$ denote the unit pulse response and the frequency response of the digital filter to be designed. The objective is to obtain $H(e^{j\omega})$ (or $h(n)$) from $H_a(j\Omega)$ (or $h_a(t)$) so that the desirable features of the prototype are preserved.

Impulse Invariance—A digital filter is produced that has a unit pulse response which is exactly equal to the impulse response of the analog filter at the sampling instants; i.e., $h(n) \equiv h_a(t)\big|_{t=nT}$. The frequency responses are related by

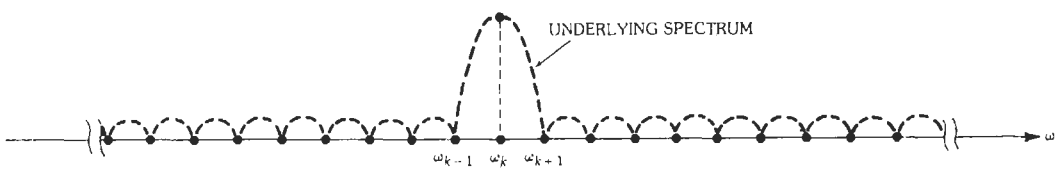
$$H\left(e^{j\Omega T}\right) = \sum_{k=-\infty}^{+\infty} H_a\left(j(\Omega + k2\pi/T)\right) \quad \text{(Eq. 18)}$$

Hence, this technique preserves the frequency response when $H_a(j\Omega)$ is band-limited, and T is chosen to satisfy the Nyquist criterion.

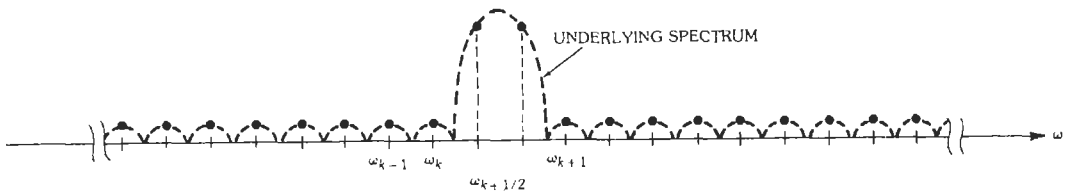
The design procedure is: Design the prototype to obtain $H_a(s)$. Then expand $H_a(s)$ into partial fractions (assuming the multiplicity of each pole is unity), i.e.

$$H_a(s) = \sum_{k=1}^{N} \left[A_k / (s - s_k)\right] \quad \text{(Eq. 19)}$$

Each real A_k has a real s_k, which generates a first-order section in the digital filter. For every complex A_k with pole s_k, there is a conjugate term A_k^* with pole s_k.* These can be combined to generate a second-order section in the digital filter that has only real coefficients. If



(A) FFT of a windowed sinusoid with frequency $\omega_k = 2\pi k/N$.



(B) Leakage for a nonharmonic sinusoidal component.

Fig. 5. Picket-fence effect.

there are M real poles and L complex conjugate pairs, the resulting digital filter becomes

$$H(z) = \sum_{l=1}^{M}\left[a_l/\left(1+b_l z^{-1}\right)\right] + \sum_{k=1}^{L}\left[\left(c_{k0}+c_{k1}z^{-1}\right)\left(1+d_{k1}z^{-1}+d_{k2}z^{-2}\right)\right] \quad \text{(Eq. 20)}$$

where

$$a_l = A_l \text{ (real)}$$
$$b_l = -e^{\alpha_l T}$$
$$c_{k0} = -2T \operatorname{Re}\{A_k\}$$
$$c_{k1} = -2T\, e^{\alpha_k T} \operatorname{Re}\{A_k\, e^{-j\beta_k T}\}$$
$$d_{k1} = -2\, e^{\alpha_k T} \cos(\beta_k T)$$
$$d_{k2} = e^{2\alpha_k T} \quad \text{(Eq. 21)}$$

and $s_k = \alpha_k + j\,\beta_k$ is the kth pole of $H_a(s)$. Note that $H(z)$ is completely defined in terms of a_k, s_k, and T.

Features:

(1) Good only for band-limited $H_a(j\Omega)$.
(2) Results initially in a parallel form.
(3) $\omega = \Omega T \rightarrow$ linear relationship between the analog and digital frequency variables.
(4) The impulse invariant technique is not an algebraic mapping; i.e., $H(z)$ cannot be obtained from $H_a(s)$ by a substitution of variable.

Example: The magnitude of the frequency response is shown in Fig. 6 for a fourth-order IIR digital filter designed by the impulse invariant technique with a sampling frequency off = 16 kHz. The analog prototype is a fourth-order Butterworth low-pass function with a –3 dB cutoff frequency of f_c = 2000 Hz.

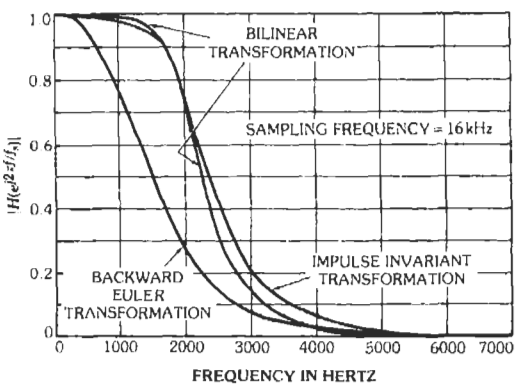


Fig. 6. Frequency response of fourth-order Butterworth analog prototype with f_c = 2000 Hz transformed to digital filters by various methods.

Bilinear z-Transformation—A digital filter is produced by substituting $s = (2/T)[(1 - z^{-1})](1 + z^{-1})]$ into $H_a(s)$ to produce $H(z)$. The relation between the analog frequency variable, Ω, and the digital frequency variable, ω, is given by

$$\omega = 2 \arctan [\Omega T/2] \quad \text{(Eq. 22)}$$

which implies that the entire analog frequency axis $-\infty < \Omega < \infty$ is mapped into the interval $-\pi < \omega < \pi$ so there is no aliasing distortion. Fig. 7 shows the important features of how the s-plane is mapped into the z-plane: (A) the $j\Omega$ axis is mapped into the unit circle in the z-plane; (B) the left half s-plane is mapped inside the unit circle; and (C) the right half z-plane is mapped outside the unit circle. Since the bilinear z-transform warps the frequency axis, it is necessary to prewarp the analog prototype so that the critical frequencies occur at the right places. Suppose the final digital filter has N critical frequencies (corner frequencies, band edges, zeros, etc.), denoted ω_i, $i = 1, \ldots, N$. The prewarped analog frequencies, Ω_i, $i = 1, \ldots, N$ are generated by

$$\Omega_i = (2/T) \tan [\omega_i/2],\ i = 1, \ldots, N \quad \text{(Eq. 23)}$$

and are then used to design the analog prototype.

Features:

(1) Eliminates aliasing distortion, but causes nonlinear warping of the frequency axis.
(2) Requires prewarping of the analog prototype.
(3) Transformation is algebraic, preserves the prototype order, and can be applied to $H_a(s)$ in any form (parallel, cascade, direct, ladder, etc.).
(4) Particularly useful for wideband filters with piecewise constant magnitude specifications.

Example: Fig. 6 shows the magnitude of the frequency response for a fourth-order Butterworth IIR filter designed with the bilinear z-transform for a sampling frequency f_s = 16 kHz. Prewarping has caused the –3 dB cutoff of the digital filter to occur at 0.707. The bilinear z-transform design does not exhibit aliasing distortion, and hence its transition regions fall off faster than for the impulse invariant design.

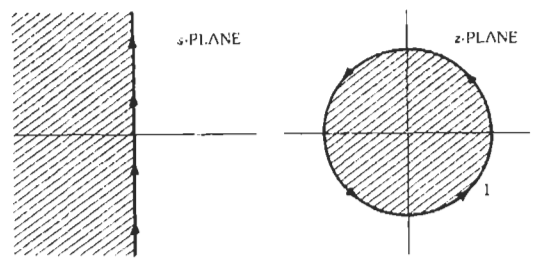

Fig. 7. Mapping of the s-plane into the z-plane by the bilinear z-transformation.

Euler Transformations—Although the Euler transformations are, in general, inferior to the above two design techniques for digital filters, they are mentioned here because they occur frequently for the discrete-time solution of differential equations. The backward and forward Euler transformations are algebraic transformations characterized in the frequency domain by $s = (1/T)(1 - z^{-1})$ and $s = (1/T)(z - 1)$, respectively. The backward Euler transformation results from a backward difference approximation to the first derivative, whereas the forward Euler transformation results from a forward difference approximation.* Both of the Euler transformations are known to distort the frequency response unless the sampling rate is very high with respect to the upper band edge of the analog prototype. The backward Euler transformation always maps stable analog prototypes into stable digital filters. In contrast, the forward Euler transformation has the potential to map a stable prototype into an unstable digital filter unless the sampling rate is chosen sufficiently high.

In Fig. 6, a backward Euler design for the fourth-order Butterworth IIR example is shown for the sampling rate $f_s = 16$ kHz. It is apparent that the backward Euler design results in considerable distortion in comparison with the other two designs.

Nonlinear Optimization Methods—Digital filter design techniques exist which treat the design as a nonlinear optimization problem. In particular, Deczky's method is often used.† Nonlinear design methods are more complicated than transformation of an analog prototype filter via the methods described above. However, direct nonlinear optimization allows much more freedom in the frequency responses that are designed and the accompanying optimization criteria.

FIR Filters

Two general approaches are available for the design of FIR digital filters: (1) designs by windowing techniques and (2) optimal designs by computer optimization techniques. In general, window designs can be carried out with the aid of a hand calculator and a table of well-known window functions. In contrast, computer optimization requires a sophisticated computer program and a considerable amount of computer time. Filters obtained by method 2 are, in general, higher quality filters. Also, more elaborate filter specifications can be approximated because the computer does most of the work.

Window Designs—Let $h(n)$ be the unit pulse response that corresponds to some desired frequency response, $H(e^{j\omega})$. If $H(e^{j\omega})$ has sharp discontinuities, such as the low-pass example shown in Fig. 8, then $h(n)$ will represent an IIR function. The objective is to time-limit $h(n)$ in such a way as to not disturb $H(e^{j\omega})$ any more than necessary. If $h(n)$ is simply truncated, a ripple‡ occurs around discontinuities, resulting in a distorted filter, as illustrated in Fig. 8.

Suppose that $\omega(n)$ is a window function that time-limits $h(n)$ to create an FIR approximation, $\hat{h}(n)$; i.e., $\hat{h}(n) = \omega(n)h(n)$. Then if $W(e^{j\omega})$ is the spectrum of $w(n)$, $\hat{h}(n)$ has a Fourier transform given by $\hat{H}(e^{j\omega}) = W(e^{j\omega}) \circledast H(e^{j\omega})$. From this it can be seen that the ripples in $\hat{H}(e^{j\omega})$ result from the side lobes of $W(e^{j\omega})$. Ideally, $W(e^{j\omega})$ should be similar to an impulse so that $\hat{H}(e^{j\omega}) \cong H(e^{j\omega})$.

Special case (simple FIRs): Let $h(n) = \cos n\omega_0$, $-\infty < n < +\infty$. Then $\hat{h}(n) = \omega(n) \cos n\omega_0$, and

$$\hat{H}(e^{j\omega}) = (1/2)\, W(e^{j\omega+\omega_0}) + (1/2)\, W(e^{j\omega-\omega_0})$$

as depicted in Fig. 9. For this simple class, the center of the passband is controlled by ω_0, and both the shape of the passband and the side-lobe structure are strictly determined by the choice of the window. While this simple class of FIRs does not allow very flexible designs, it is a simple technique for obtaining relatively good low-pass, bandpass, and high-pass FIRs.

General case (design procedure): Specify an ideal frequency response, $H(e^{j\omega})$, and choose samples from the curve. Use a long inverse FFT of length $\hat{N}$ to find

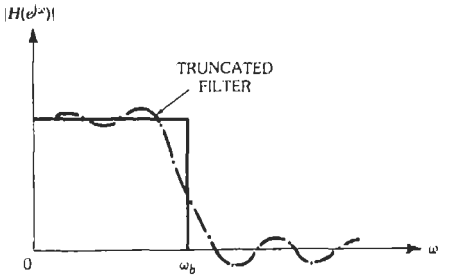

Fig. 8. Gibbs effect in a low-pass filter caused by truncating the unit pulse response.

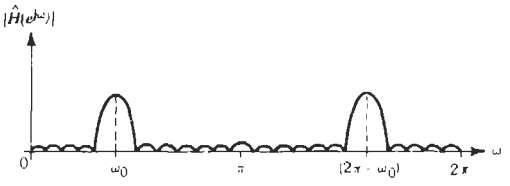

Fig. 9. Design of a simple FIR filter by windowing.

* Reference 25.

† Reference 6

‡ This ripple, known as the Gibbs phenomenon, occurs around points of discontinuity due to the truncation of the Fourier series expansion of $H(e^{j\omega})$.

an approximation to $h(n)$, where if N is the desired length of the FIR, then $\hat{N} >> N$. Then use a carefully selected window to truncate $h(n)$ according to $\hat{h}(n) = \omega(n)h(n)$. Finally, use an FFT of length $\hat{N}$ to find $\hat{H}(e^{j\omega})$. If $\hat{H}(e^{j\omega})$ is a satisfactory approximation to $H(e^{j\omega})$, the design is finished. If not, choose a new $H(e^{j\omega})$ or a new $\omega(n)$ and repeat. Throughout the procedure, it is important to choose $\hat{N} = kN$, with k an integer in the range [4, . . . , 10]. The k should be made as large as possible within the limits of the computer resources. This design technique is a trial-and-error procedure. The quality of the result will depend to some degree on the skill and experience of the designer.

Table 4 lists a few well-known window functions that can be used in this procedure. An extensive list of windows and their figures of merit has been published in Reference 12.

Computer Design by Equiripple Approximation—There are quite a few publications and numerous computer programs that deal with optimized designs for FIRs using equiripple approximations in the frequency domain. One popular program that has been widely distributed is the one published by McClellan, et. al.* This program is capable of designing bandpass (including low-pass and high-pass), differentiator, and Hilbert-transform FIR filters under the constraint of linear phase. Fig. 10 illustrates an equiripple approximation for an ideal low-pass response. In the program, the order, N, of the equiripple approximation (also the resulting order of the FIR design) is fixed by the designer. Also, the designer specifies the transition band, which is treated as a "don't care" interval during the computer optimization; i.e., the optimization is unconstrained in this interval. This particular program uses the Remez Exchange Algorithm to find the best equiripple approximation to the specified response, returning to the user the FIR coefficients and the stopband and passband ripple factors. If the result is unsatisfactory, the user can change the order, N, the transition width or the relative weighting factors in the various bands to improve the result. In general, this design program is easy to use, executes efficiently, and produces excellent results. In certain circumstances, the design for multiple-band bandpass filters results in undesirable resonance peaks in the "don't-care" bands, a problem that has been addressed in the literature. Fig. 11 shows a 64th-order dual bandpass FIR filter that was designed with the program of McClellan, et. al.†

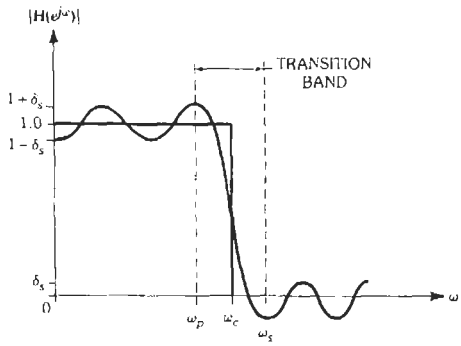

Fig. 10. Equiripple approximation to an ideal low-pass response.

DIGITAL-FILTER IMPLEMENTATION

The fundamental building blocks for implementing digital filters are multipliers, adders, unit delay registers, and semiconductor memories. This section addresses some of the issues concerning the selection of a network topology, arithmetic number codes, and the analysis of quantization effects in digital signal processors. Much of the discussion is directed toward IIR digital filters, because the feedback in IIR structures causes the performance to be rather sensitive to network topology and the effects of quantization error.

Network Structures

The generic building block for IIR filters is the second-order section (Fig. 12). The canonical-form second-order section requires two delay registers, five multipliers, and four adders and is capable of realizing a pair of complex poles and complex zeros with real-valued multiplier coefficients. It is well known that the sensitivity of the zeros of a polynomial with respect to incremental changes in the coefficients grows large rapidly as the polynomial order increases. Therefore, with respect to transfer function sensitivity and round-off error accumulation, it is always preferable to decompose a high-order transfer function into lower-order subsystems. This results in a parallel or cascade‡ realization.

In the parallel realization, $H(z)$ is expanded as a partial fraction expansion of the form

$$H(z) = \sum_{k=0}^{M-1} c_k z^{-k} + \sum_{j=1}^{L} H_j(z) \qquad \text{(Eq. 24)}$$

where the first M terms are called the feed-forward terms, and each $H_j(z)$ has a first-order numerator and a second-order denominator of the form

$$H_j(z) = (\gamma_{0j} + \gamma_{1j} z^{-1})/(1 + b_{1j} z^{-1} + b_{2j} z^{-2})$$

* Reference 22.

Note that this program has been integrated into many commercially available DSP software design tools.

† Reference 22.

‡ Some references call this form a "series" realization, although "cascade" is now more commonly used.

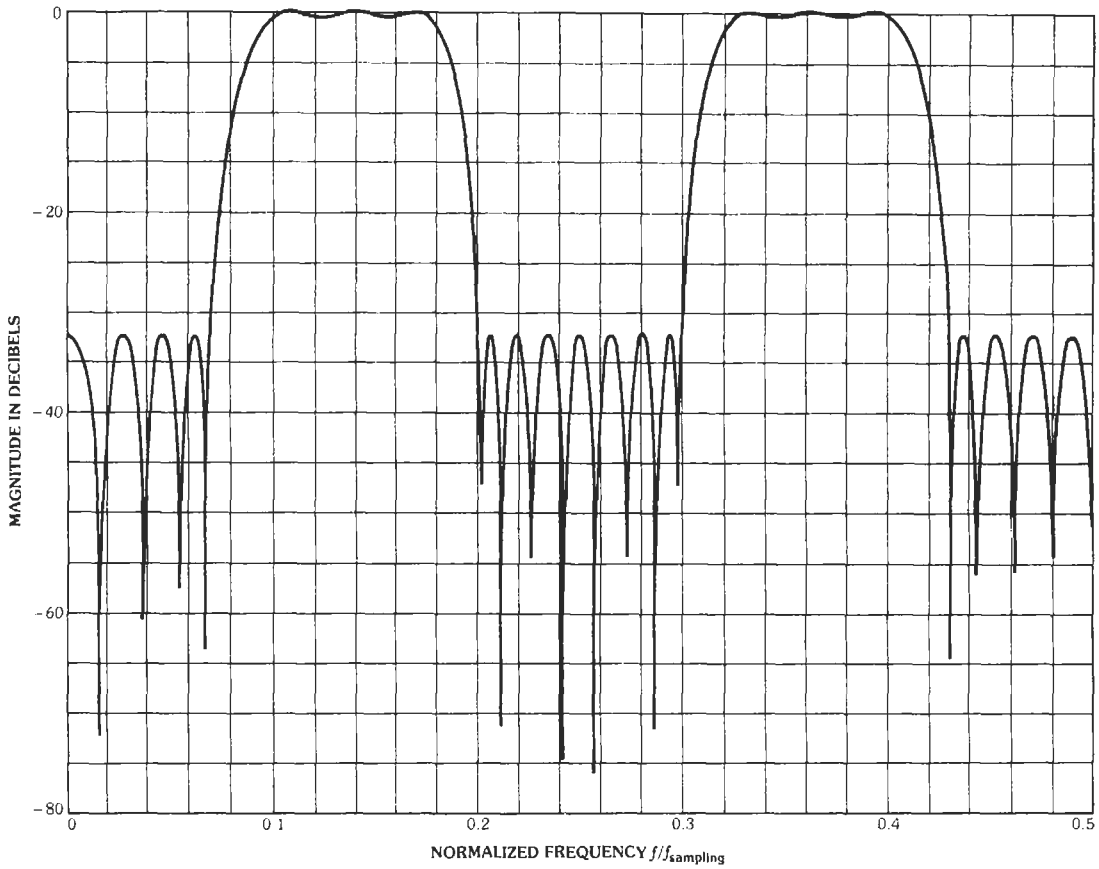

Fig. 11. Magnitude response of a 64th-order dual passband FIR digital filter.

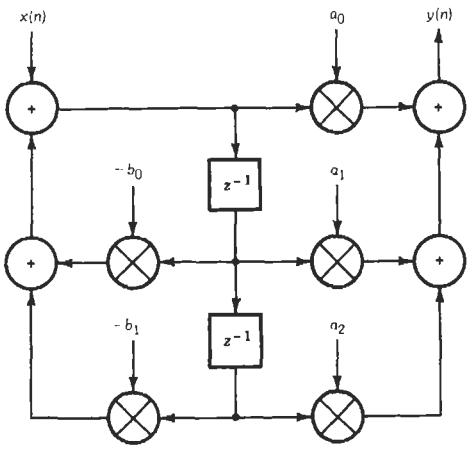

Fig. 12. Second-order section.

The network structure takes the form shown in Fig. 13. The c_k's result by dividing the denominator of $H(z)$ into the numerator until the remainder is in proper form to expand into partial fractions.

In the cascade realization, $H(z)$ is factored into numerator and denominator factors that are at most second order, i.e.

$$H(z) = H_1(z) \cdot H_2(Z) \ldots H_L(Z) \qquad \text{(Eq. 25)}$$

where each factor has the form

$$H_j(z) = (a_{0j} + a_{1j} z^{-1} + a_{2j} z^{-2})/(1 + b_{1j} z^{-1} + b_{2j} z^{-2})$$

The cascade structure is shown in Fig. 14.

Both the parallel and cascade structures are convenient for multiplexing the hardware of one second-order section. Also, in general, the two forms require the same number of multiplications because the feedforward multiplies make up for the lower-order numerators of the parallel second-order sections. In certain types of filter functions (elliptic), it is found that $a_{0j} = a_{2j}$, so that one multiply can be eliminated. This feature, together with the fact that extra adders are required at the output of the parallel structure, has resulted in more popularity of the cascade structure.

The order in which the factors in Eq. 25 are implemented, as well as the pairing of the numerator and denominator factors, greatly affects quantization error accumulation and represents an additional design

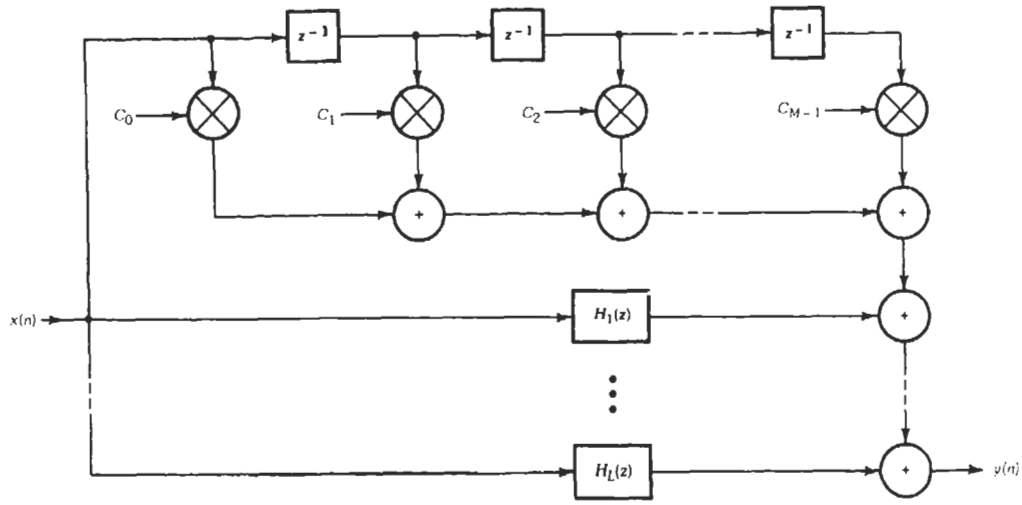

Fig. 13. Parallel realization.

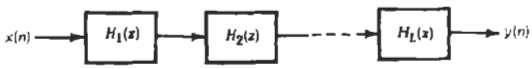

Fig. 14. Cascade realization.

parameter for cascade filters. The problem has been called pole-zero pairing, and at the present time there does not appear to be a known analytical technique to determine the correct pairing for minimum-error performance.

Two other realizations for the second-order section have been proposed for special situations. The coupled-form second-order section, shown in Fig. 15, realizes a complex pair of poles, $P_k = re^{\pm j\omega}$ with the transfer function

$$H(z) = r \sin\theta\, z^{-1}/[1 - (2r\cos\theta)z^{-1} + r^2 z^{-2}] \quad \text{(Eq. 26)}$$

The coupled form is a low-sensitivity second-order section that is preferable for very narrow-band low-pass filters, which are well known to be quite sensitive with respect to coefficient quantization. A second structure that has gained popularity in many applications is a multiplierless ROM-accumulator realization that was popularized by Peled and Liu.* Assume that the second-order section is characterized by the difference equation

$$y(n) = a_0x(n) + a_1x(n-1) + a_2x(n-2) - b_1y(n-1) - b_2y(n-2) \quad \text{(Eq. 27)}$$

and that each data sample is encoded as a $(b+1)$-bit two's-complement binary word, e.g.

$$x(n) = -x^0(n) + \sum_{j=1}^{b} x^j(n)2^{-j} \quad \text{(Eq. 28)}$$

* Reference 27.

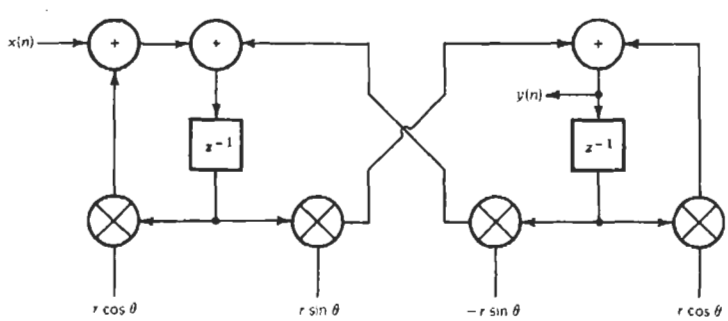

Fig. 15. A coupled-form second-order section.

If Eq. 28 is used in Eq. 27 for both the $x(n)$'s and the $y(n)$'s and the order of summations is interchanged, the output of the section can be expressed as

$$y(n) = \sum_{j=1}^{b} 2^{-j} \phi\left(A_j(n)\right) - \phi\left(A_0(n)\right) \quad \text{(Eq. 29)}$$

where $A_j(n) = x^j(n), x^j(n-1), x^j(n-2), y^j(n-1), y^j(n-2)$ is a five-bit binary address that is used to address the stored function

$$\phi(A_j(n)) = a_0 x^j(n) + a_1 x^j(n-1) + a_2 x^j(n-2) - b_1 y^j(n-1) - b_2 y^j(n-2)$$

The structure for the resulting filter is shown in Fig. 16. The output, $y(n)$, is computed by a sequence of memory fetches, shifts, and adds. Therefore, multiplication has been entirely eliminated. This architecture is very appealing for high-speed real-time operation, as well as for filters that may be integrated as part of a VLSI system implementation. For a second-order section, the ROM must have 32 words of memory, and the generation of each $y(n)$ requires $b + 1$ memory fetches and b add-shift cycles. The major disadvantage of this structure is that the filter coefficients are fixed in the ROM according to the function $\phi(\cdot)$. Although several ROMs can be used to select among a predetermined set of filter functions, the ROM-accumulator structure is not well suited for adaptive filters, where the a_i's and b_i's are changed in a continual time-varying fashion. This is due to the fact that a change of only a few coefficients would require a complete recalculation of the stored $\phi(\cdot)$ function, thereby nullifying the efficiencies of using a stored function in the first place.

The most common network structure for FIR filters is shown in Fig. 17. A length-N filter requires N multipliers, $N - 1$ delay registers, and $N - 1$ two-input adders. Normally, one hardware multiplier and one adder are time-multiplexed to minimize hardware costs, resulting in a low-cost/low-speed realization.

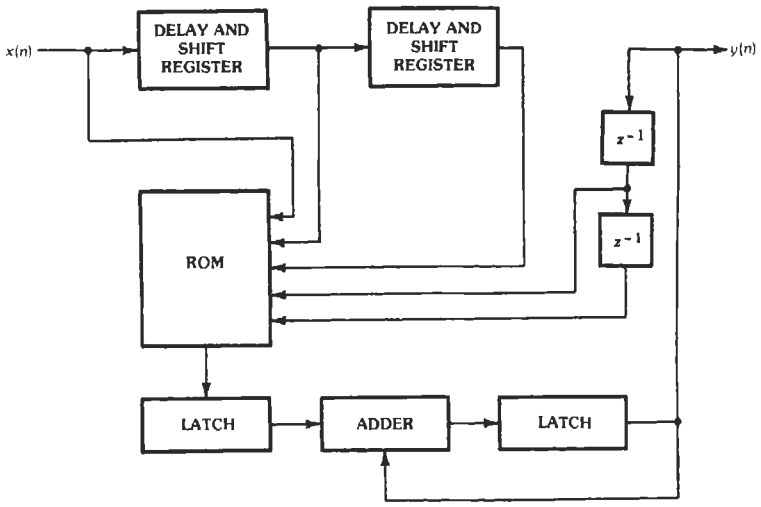

Fig. 16. ROM-accumulator realization of a second-order section.

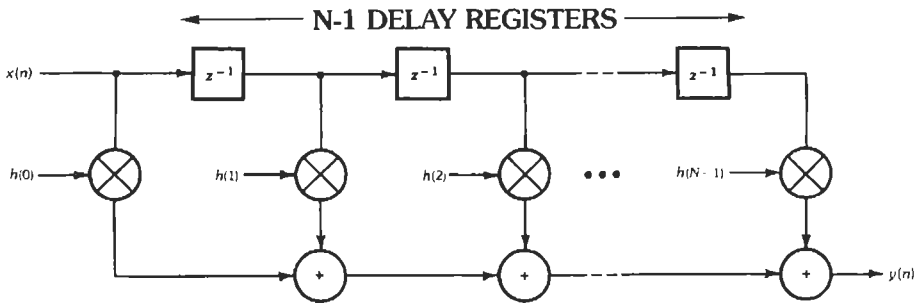

Fig. 17. Common FIR filter structure.

When higher speed is required, more computational elements are used in a pipelined configuration, resulting in a high-speed/high-cost realization. Since there is no feedback, limit cycles cannot occur, and quantization error in the output is simply the additive result of all the quantization error in the multipliers.

Finite Wordlength Effects

Three basic sources of quantization error occur in digital filters: (1) errors due to quantizing an input signal in the A/D converter; (2) errors introduced by rounding during arithmetic operations; and (3) errors in the filter response due to a finite number of bits used in the filter coefficients. The following describes quantization in fixed-point systems.

Input Error—Quantization that occurs in the A/D converter does not corrupt the filter itself, but rather acts as an additive noise component at the input of the ideal system. This noise cannot cause filter instabilities, although it does create inaccuracy in the time-domain response. A common model for A/D quantization noise is shown in Fig. 18, where $e(n)$ is usually assumed to be white noise that is uncorrelated with the signal, $x_a(nT)$, and which is uniformly distributed over the smallest quantization interval. If the probability density function has the form shown in Fig. 19, then the mean and variance of the noise at the filter input are $m_e = 0$ and $\sigma_e^2 = [2^{-2b}/12]$. Then the mean and variance of the noise in the filter output, $\epsilon(n)$, are given by

$$m_\epsilon = 0$$

$$\sigma_\epsilon^2 = \left[2^{-2b}/12\right] \sum_{n=-\infty}^{+\infty} |h(n)|^2$$

$$= \left[2^{-2b}/24\pi\right] \int_{-\pi}^{\pi} \left|H\left(e^{j\omega}\right)\right|^2 d\omega$$

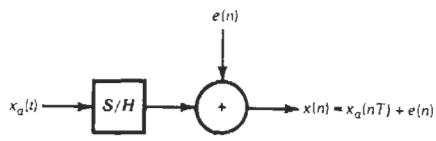

Fig. 18. Noise model for A/D quantization error.

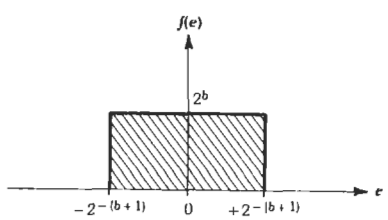

Fig. 19. PDF for rounded A/D quantization.

where $h(n)$ is the unit pulse response and $H(e^{j\omega})$ is the frequency response of the DT system. The statistics of $e(n)$ depend on the specific hardware details of the A/D converter; *i.e.*, different assumptions would be made depending on whether the quantization is implemented by rounding or truncation, and whether the digital code is one's-complement, two's-complement, or sign-magnitude.

Coefficient Error—Filter coefficients are represented by a finite number of bits, commonly in the range of 8 to 16 bits. This results in the implementation of a filter that differs slightly from the original design. The effect is particularly noticeable in IIR filters, mainly because the poles are moved when the coefficients are quantized. If the unquantized design has a pole very close to the unit circle (or on the unit circle, as in an iterative sine generator), slight coefficient changes may move a pole across the unit circle, causing instability. Pole movement also affects frequency response, so the final result must be carefully checked to ensure that coefficient quantization does not cause intolerable magnitude (phase) distortion.

Coefficient errors are fixed at the time of implementation. These errors have no inherently random properties, although one technique of predicting their effect is to treat them as random variables. This approach has been quite successful in predicting the number of bits required to keep the frequency response between specified tolerance limits.

Uncorrelated Roundoff Errors—A product resulting from the multiplication of two $b + 1$ bit twos-complement numbers requires $2b + 1$ bits for its representation. Therefore, a product must be rounded (truncated) to maintain a $b + 1$ bit data stream. Roundoff is an inherently random process when viewed over many computations. It has been rather successfully modeled as a random noise entering the system through a summation node immediately following a multiplier. If the assumption holds that the error from each multiplier is a white-noise source that is uncorrelated with other quantization errors in the structure, roundoff simply causes a jitter in the output, which can be well described by a statistical noise analysis.*

For example, a second-order section with two real poles at $z = 1/2$ and $z = 1/3$ is shown in Fig. 20 as a cascade of two first-order sections. The errors $e_1(n)$, $e_2(n)$, and $e_3(n)$ are assumed to be uncorrelated white-noise sources that represent the quantization errors due to the multipliers 1/2, –5/6, and 1/3. (Note that multiplication by 2 does not require quantization.) If it is also assumed that the number code is two's-complement with $b + 1$ bits and that the quantization is rounding, then the statistics are $m_{e_i} = 0$ and $\sigma_{e_i}^2 = [2^{-2b}/12]$, for $i = 1, 2$, and 3. If the e_i's are uncorrelated with the data stream, the output can be expressed *as* $\hat{y}(n) = \hat{y}(n) + \epsilon(n)$ with

$$m_\epsilon = 0$$

* Reference 25

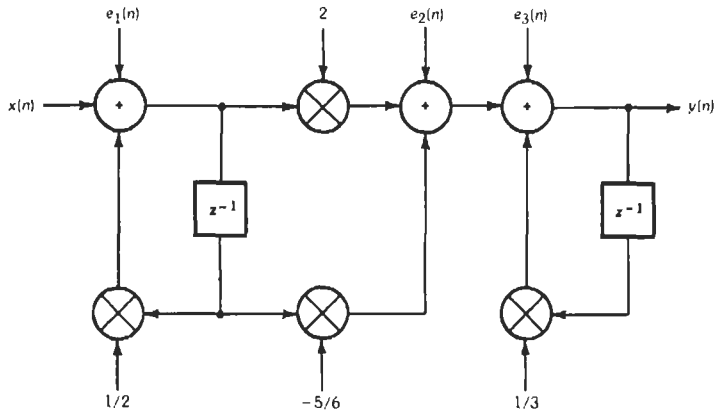

Fig. 20. Second-order section with roundoff error sources $e_1(n)$, $e_2(n)$, and $e_3(n)$.

and

$$\sigma_\epsilon^2 = \sigma_{e_1}^2 \sum_{n=0}^{\infty} |h(n)|^2 + \left(\sigma_{e_2}^2 + \sigma_{e_3}^2\right) \sum_{n=0}^{\infty} |h_2(n)|^2$$

where

$h(n) = [(1/2)^n + (1/3)^n]u(n)$ is the overall system unit pulse response,
$h_2(n) = (1/3)^n u(n)$ is the unit pulse response of the second section.

Furthermore, it is found that $\sigma_\epsilon^2 = [7.26/12]2^{-2b}$. If the order of the sections is interchanged, a similar analysis reveals that $\sigma_\epsilon^2 = [9.89/12]2^{-2b}$. This demonstrates that the error accumulation in the output of a cascade filter depends on the ordering of the sections, and that in general there is a preferred ordering (the first in this case).

This general approach to the analysis of arithmetic quantization errors can be extended to higher-order filters realized in any configuration, provided the transfer functions (unit pulse responses) from each noise source to the filter output can be determined. Noise analysis is particularly well suited for computer-aided analysis routines that obtain the required transfer function as a step during a frequency-domain analysis. Figs. 21 and 22 show the roundoff noise spectrum at the output of a fourth-order Butterworth filter realized with 18-bit two's-complement arithmetic in the parallel and cascade form. The noise spectrum for the parallel structure is somewhat smaller than that of the cascade structure, although for this filter the difference is not very great.

In filters implemented with floating-point arithmetic, a roundoff error can also occur during addition. When two floating-point numbers are added, the exponents must be made equal, usually by scaling the smaller exponent until it equals the larger. This requires a right shift of the mantissa, resulting in a loss of bits on the lower end of the word and the necessity

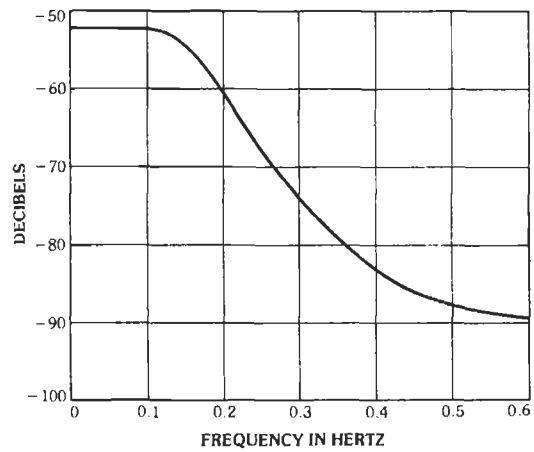

Fig. 21. Roundoff noise spectrum for fourth-order Butterworth low-pass filter in cascade form.

for rounding (truncating). Adder roundoff can also be modeled as a random process, although there is evidence that the process is not zero mean, and elementary statistical assumptions are more difficult to justify than in the case of multiplicative roundoff error.

There arise situations in which roundoff errors become correlated. This often occurs during zero input response, when all internal states are decaying toward the zero state. Roundoff forces the filter states to take on one of a finite number of distinct levels. Forcing the state into these unnatural quanta by the nonlinear quantization scheme often results in limit cycles. These small amplitude limit cycles, which have been called *deadbands*, are a manifestation of highly correlated roundoff errors. In most filters using fixed-point hardware, and in some using floating-point hardware, these deadbands result in idle channel noise, which can be unsatisfactory. Since it is a tedious job to discover all

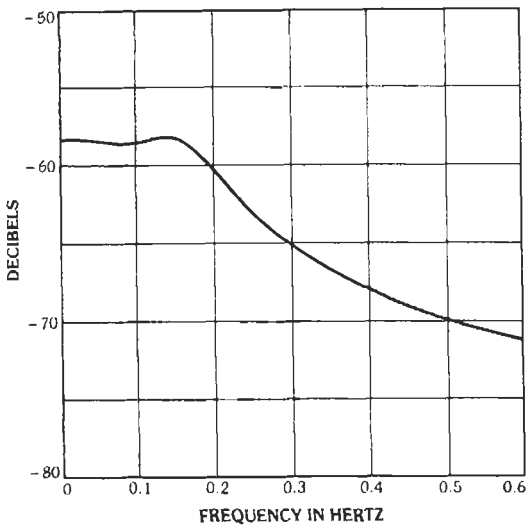

Fig. 22. Roundoff noise spectrum for fourth-order Butterworth low-pass filter in parallel form.

possible limit cycles, a great amount of attention has been focused on the computation of an absolute bound that is tight enough to be useful, and yet which bounds all possible limit cycles.

Overflow Oscillations—If a filter is not scaled properly or if a large unexpected transient should occur at the input, some of the internal states might grow too large for the dynamic range of the filter. In the two's-complement system, a number that grows too large reenters the dynamic range as a large negative number. This phenomenon occurs because the range of a two's-complement system forms a closed ring, as illustrated in Fig. 23. The transfer function of a

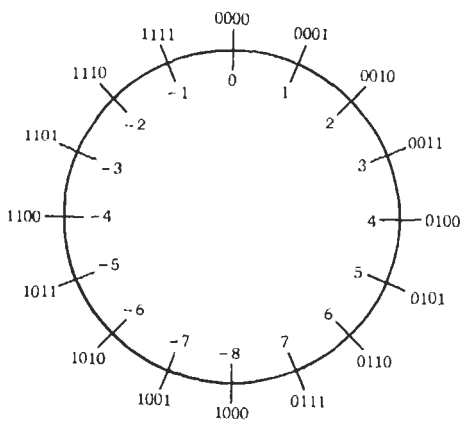

Fig. 23. Dynamic range of two's-complement number system.

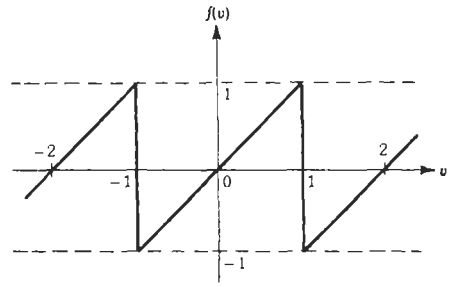

Fig. 24. The transfer function of a two's-complement adder.

two's-complement adder is shown in Fig. 24, where the adder performs $[x + y] = f(x + y)$ and $[\cdot]$ means the actual machine result. The sudden change in sign due to range overflow can result in large self-sustained limit cycles, which are called *overflow oscillations*. These oscillations are characterized as being large and disabling, contrary to the deadband effect, which is usually small and primarily a source of annoyance.

Overflow oscillations cannot be tolerated. One way to prevent them is to scale the input so that overflow at internal summation points cannot occur. A second method is to alter the adders as shown in Fig. 25 so that they saturate (or zero) when the result is outside the dynamic range. Such a scheme, called saturating (or zeroing) arithmetic, will stop overflow oscillations. Generalized forms of saturation arithmetic have been reported that allow $f(v)$ to take on a continuum of different shapes, although there appears to be no practical application of these generalizations to date.

ADAPTIVE DIGITAL SIGNAL PROCESSING

Adaptive digital signal processing is a subject that has attracted increasing attention in recent years due to demands for improved performance in high data rate digital communication systems and in wideband image/video processing systems. Adaptive system identification, adaptive noise cancellation, adaptive linear prediction, and adaptive channel equalization

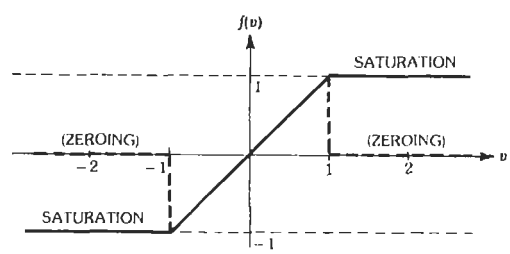

Fig. 25. Modified two's-complement adder.

are just a few of the important applications areas that have been significantly advanced with adaptive signal processing techniques. Much of the recent success in adaptive signal processing has been facilitated by improvements in VLSI digital signal processor (DSP) integrated circuit technology, which currently provides large amounts of digital signal processing power in a convenient and reliable form. Since many improvements in integrated circuit technology are still to come in the future, it is expected that adaptive techniques will assume an even more important role for high performance electronic systems of the future.

This discussion is limited to the simplest and most widely used adaptive systems, i.e., linear adaptive digital filters based on the Least Mean Square (LMS) algorithm.* Although adaptive analog filters are effective in certain applications, adaptive digital filters are far more common because of the efficiency and accuracy of DSP technology. Adaptive filters are self-designing in the sense that they continually adjust their own characteristics by means of a real-time recursive algorithm so that the filter is constantly optimized in some statistical sense while in actual operation.

The LMS Algorithm for FIR Adaptive Filters

An adaptive FIR filter consists of a digital tapped delay line with variable multiplier coefficients that are adjusted by an adaptive algorithm. The adaptive algorithm attempts to minimize a cost function that is designed to provide an instantaneous on-line estimate of how closely the adaptive filter achieves a prescribed optimum condition. The cost function most frequently used is an approximation to the expected value of the squared error, $E\{e^2(n)\}$, where $e(n) = d(n) - y(n)$ is the difference between a training signal $d(n)$ and the filter output $y(n)$, and $E\{\cdot\}$ denotes the expected value. The training signal $d(n)$ is obtained by different means in different applications, some of which are described later in the context of system identification, adaptive noise cancellation, adaptive linear prediction, and adaptive equalization.

The input vector and the coefficient weight vector of the adaptive filter at the nth iteration are defined as $\mathbf{X}(n) = [x(n), x(n-1), \ldots, x(n-N+1)]^t$ and $\mathbf{W}(n) = [w_0(n), w_1(n), \ldots, w_{N-1}(n)]^t$, respectively, where the superscript t denotes vector transpose. The nth output is then given by

$$y(n) = \mathbf{W}^t(n)\mathbf{X}(n) = \sum_{k=0}^{N-1} w_k(n)x(n-k) \qquad \text{(Eq. 30)}$$

In the following discussion, the training signal $d(n)$ and the input signal $x(n)$ are assumed to be stationary and ergodic. An adaptive filter uses an iterative method by which the tap weights $\mathbf{W}(n)$ are made to converge to the optimal solution $\mathbf{W}^*$ that minimizes the cost function. It is well known that $\mathbf{W}^*$, referred to in the literature as the Wiener solution, is given by

$$\mathbf{W}^* = \mathbf{R}_{xx}^{-1}\mathbf{R}_{xd} \qquad \text{(Eq. 31)}$$

where $\mathbf{R}_{xx} = E\{\mathbf{X}(n)\mathbf{X}^t(n)\}$ is the autocorrelation matrix of the input and $\mathbf{R}_{xd} = E\{\mathbf{X}(n)d(n)\}$ is the cross correlation vector between the input and the desired response. The most common iterative approach is to update each tap weight according to a steepest descent strategy; i.e., the tap weight vector is incremented in proportion to the gradient $\nabla\mathbf{w}$ according to

$$\mathbf{W}(n+1) = \mathbf{W}(n) - \mu\nabla\mathbf{w} \qquad \text{(Eq. 32)}$$

where μ is the step size, $\nabla\mathbf{w} = [\nabla_{w0}(n), \ldots, \nabla_{wN-1}(n)]^t$, and $\nabla_{wk}(n) = \delta E\{e^2(n)\}/\delta w_k$ is the partial derivative of the cost function with respect to $w_k(n)$, for $k = 0, \ldots, N-1$. However, the precise value of the cost function is not known, nor is the gradient known explicitly, so it is necessary to make some simplifying assumptions that allow gradient estimates to be computed on-line. Different approaches to estimating the cost function and/or the gradient lead to different adaptive algorithms, such as the Least Mean Squares (LMS), the Recursive Least Squares (RLS), and the quasi-Newton (q-N) algorithms.†

The LMS algorithm‡ makes the simplifying assumption that the expected value of the squared error is approximated by the squared error itself:

$$E\{e^2(n)\} \approx e^2(n)$$

In deriving the algorithm, the error squared is differentiated with respect to $\mathbf{W}$ to give a term that approximates the true gradient. Differentiating the squared error with respect to each filter coefficient w_k yields

$$\nabla_{wk}(n) \approx \delta[e^2(n)]/\delta_{wk} = -2e(n)x(n-k) \qquad \text{(Eq. 33)}$$

for each $k = 0, \ldots, N-1$. Thus in vector notation the complete LMS update relation becomes

$$W(n+1) = W(n) + 2\mu e(n)\mathbf{X}(n) \qquad \text{(Eq. 34)}$$

The value of μ, usually determined experimentally, greatly affects both the convergence rate of the adaptive process and the minimum mean squared error after convergence. To ensure stability and guarantee convergence of both the coefficients and the mean squared error estimate, μ must satisfy the condition

$$0 < \mu < 1/NE\{x^2(n)\}$$

where $E\{x^2(n)\} = (1/N)tr[R_{xx}]$ is the average input signal power, which can be determined directly from the input signal, or can be calculated from R_{xx} if the input autocorrelation matrix is known. When μ is properly chosen, the weight vector converges to an estimate of

* Reference 35.

† Reference 18.

‡ Reference 35.

the Wiener solution. In practice, because of gradient noise, the weight vector converges to a solution that constantly fluctuates about $\mathbf{W}^*$. It has been shown that the estimate of $\mathbf{W}^*$ achieved by the LMS algorithm is an unbiased estimate of the true Wiener solution.

The LMS Algorithm for IIR Adaptive Filters

The MSE approximation that led to the conventional LMS algorithm for FIR filters has also been applied to the general class of IIR filter.* Recall that a direct form IIR digital filter is characterized by a difference equation,

$$y(n)=\sum_{k=0}^{N_a} b_k x(n-k)+\sum_{k=1}^{N_a} a_k y(n-k) \qquad \text{(Eq. 35)}$$

where the b_ks are the coefficients that define the zeros of the filter and the a_ks define the poles. The LMS adaptive algorithm for IIR filters is derived in a similar manner as in the FIR case, although the recursive relation of Eq. 35 is used instead of the convolutional sum to characterize the input-output relationship of the filter. The IIR derivation is more complicated because the recursive terms on the right side of Eq. 35 depend on past values of the filter coefficients.

If the derivatives of the squared error function are calculated using the chain rule, so that all first order dependencies are taken into account, the result is

$$\begin{aligned}\nabla_{E[e^2]} &= \left[\frac{\partial\left(e^2(n)\right)}{\partial \boldsymbol{a}}, \frac{\partial\left(e^2(n)\right)}{\partial \boldsymbol{b}}\right]^t \\ &= \left[2e(n)\frac{\partial e(n)}{\partial \boldsymbol{a}}, 2e(n)\frac{\partial e(n)}{\partial \boldsymbol{b}}\right]^t \\ &= \left[-2e(n)\frac{\partial y(n)}{\partial \boldsymbol{a}}, -2e(n)\frac{\partial y(n)}{\partial \boldsymbol{b}}\right]^t\end{aligned}$$

where

$$\frac{\partial y(n)}{\partial b_k} = x(n-k)+\sum_{j=1}^{N} a_j(n)\frac{\partial y(n-j)}{\partial b_k}$$

$$k=0,\ldots,N_b \qquad \text{(Eq. 36a)}$$

and

$$\frac{\partial y(n)}{\partial a_k} = y(n-k)+\sum_{j=1}^{N} a_j(n)\frac{\partial y(n-j)}{\partial a_k}$$

$$k=0,\ldots,N_a \qquad \text{(Eq. 36b)}$$

This procedure does not generate a closed form expression for the gradient as it did in the FIR case, but it does result in a mechanism by which the gradient can be generated recursively using Eq. 36. Note that Eq. 36a consists of N_b "all-pole" filters, where the input to the k-th filter is simply the input signal shifted by k time steps; similarly, Eq. 36b represents a similar bank of filters, but where the input to the k-th filter is the shifted output signal $y(n-k)$. Strictly speaking, Eqs. 36a and b require $N_a + N_b$ distinct filters, one for each of the gradient terms. However, in practice it is usually assumed that the filter coefficients are slowly varying in comparison to the signal frequency content, so that within a shift of N_a or N_b time samples, the filters can be treated as though they are time-invariant. With this assumption all of the gradient components represented by Eq. 36a can be generated by a single all-pole gradient filter whose input is x(n).

Similarly, the gradient terms in Eq. 36b can be produced with a second filter that is identical to the first, but which uses $y(n)$ as the input signal. Then time-shifted outputs from these filters will serve as accurate approximations to the true gradient components represented by Eqs. 36a and b. This assumption of "stationarity" in the input and output gradient filters is justified by imposing slow parameter variation by choosing a small step size. In the adaptive filtering literature, the filter represented by Eq. 36a is typically called the input gradient filter, whereas the one represented by Eq. 36b is the output gradient filter. Similar concepts are found in the fields of automatic control and analog circuit theory, where such filters are typically called input and output sensitivity filters

It is known that the use of the output error in the formulation of the cost function prevents bias in the solution due to noise in the desired signal. However, the effect of this recursion is to make the problem nonlinear in terms of the coefficient parameters. The current filter parameters now depend upon previous filter coefficients, which are time-varying. This can lead to MSE surfaces that are not quadratic in nature. There are many examples in the literature for which the MSE surface demonstrates one or more local minima, in addition to the global minimum. In these cases the LMS algorithm, being a gradient search technique, may converge to a local minimum, resulting in poor performance when used in practical applications. Therefore, in general, practicing engineers are often reluctant to use the LMS IIR adaptive filter in practical applications due to its uncertain performance.

Generic Applications of Adaptive Methods

There are four basic configurations in which adaptive filters are typically used to solve practical engineering problems:†

System Identification Configuration—An adaptive filter is said to be used in the system identification configuration when both the adaptive filter and an unknown system are excited by the same input signal $x(n)$, the system outputs are compared to form the

* Reference 35.

† Reference 13.

error signal $e(n) = d(n) - y(n)$, and the parameters of the adaptive filter are iteratively adjusted to minimize some specified function of the error $e(n)$. In the system identification configuration, shown in Fig. 26, the desired signal is produced as the output of an unknown plant whose input is accessible for excitation. When the minimum of the cost function is achieved and the adaptive filter parameters have converged to stable values, the adaptive filter provides a model of the unknown system, in the sense that the adaptive process has formed the best approximation it can in the MSE sense using the structure imposed by the adaptive system. The converged coefficients provide good estimates of the model parameters.

In order for the adaptive system to form a good model of the unknown system at all frequencies, it is important that the input signal have sufficiently rich spectral content. For example, if the adaptive filter is an FIR filter structure with N adjustable coefficients, the input signal must contain at least N distinct frequency components in order to uniquely determine the set of coefficients that minimizes the MSE. A white noise input signal is ideal because it excites all frequencies with equal power. A broadband colored noise input will also provide a good excitation signal, in the sense of driving the adaptive filter to the minimum MSE solution. Although, in general, the convergence rate of the learning process will be slower than for white noise inputs because the frequencies that are excited with small power levels will converge slowly. Many adaptive algorithms attempt to normalize (or whiten) the input power spectrum in order to improve the convergence rate of the learning process.*

The system identification configuration is a fundamental adaptive filtering concept that underlies many applications of adaptive filters. The major attraction of the system identification configuration is that the training signal is automatically generated as the output of the unknown system. The disadvantage is that the input of the unknown system must be accessible to be excited by an externally applied input noise signal. In some applications obtaining a model of the unknown system is the desired result, and the accuracy of the adaptive coefficients is a primary concern. In other applications it is not necessary that the unknown system be identified explicitly, but rather that the adaptive filter is required to model the unknown system only to generate accurate estimates of its output signal. This leads to the next configuration called adaptive noise cancellation, which is really a variation on the fundamental theme of system identification.

Adaptive Noise Cancelling Configuration—A block diagram for an adaptive noise canceller is shown in Fig. 27, where it is seen that the unknown system in this configuration is not shown explicitly, nor is it desired to identify the implicit unknown system in a direct way. The primary signal is assumed to be the sum of an information bearing signal $s(n)$ and an additive noise component $N_0(n)$, which is uncorrelated with $s(n)$. The primary signal is used to train the adaptive noise canceller, so that $d(n) = s(n) + N_0(n)$ and the error signal becomes $e(n) = d(n) - y(n) = s(n) + N_0(n) - y(n)$. The reference signal, which is used as the input to the adaptive filter, should be a reference noise $N_1(n)$ that is uncorrelated to $s(n)$, but which is correlated in an unknown way with $N_0(n)$. The adaptive filter forms an estimate of $N_0(n)$ and subtracts this estimate from the primary input signal, thereby forming in a good estimate of the information signal at the output of the noise canceller. Note that

$$E\left[|e(n)|^2\right] = E\left[|s(n)|^2\right] + E\left[|N_0(n) - y(n)|^2\right] \quad \text{(Eq. 37)}$$

so that minimizing $E[|e(n)|^2]$ will also minimize $E[|N_0(n) - y(n)|^2]$ because the first term in Eq. 37 is dependent only on the information signal $s(n)$ and its mean squared value cannot be affected by the adaptive filter as long as $s(n)$ and $N_1(n)$ are uncorrelated. After

* Reference 13.

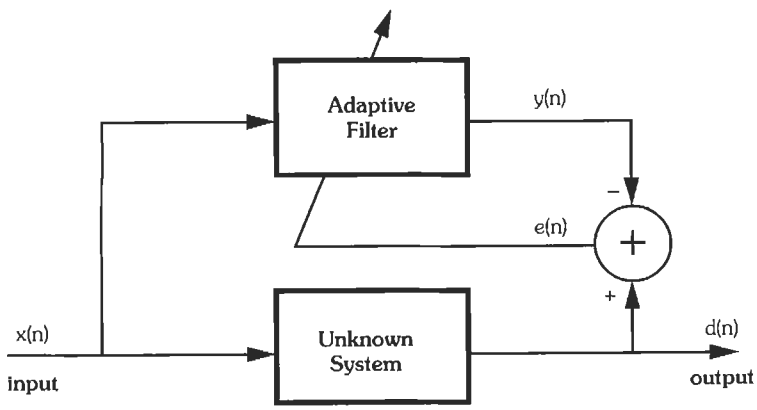

Fig. 26. System identification configuration.

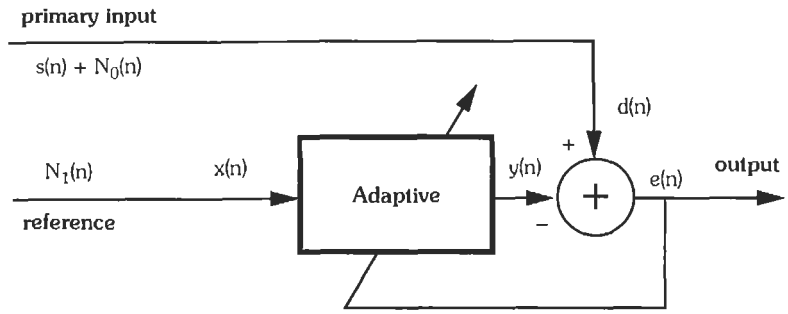

Fig. 27. Noise cancelling configuration.

the adaptive filter converges $y(n)$ becomes the best estimate of $N_0(n)$ according to the MSE criterion.

Since the unknown system in the adaptive noise-cancelling configuration is implicit, there is no need for access to its input in this configuration. However, it is necessary to find a suitable reference signal that does not contain any significant amount of the information signal s(n). If the reference contains even small levels of $s(n)$, then some part of the primary signal $s(n)$ will be canceled and the overall signal-to-noise ratio will degrade.

Adaptive Linear Prediction Configuration—Adaptive linear prediction is a very important and well developed subject that spans many different areas of engineering. A block diagram of this configuration is shown in Fig. 28. In this configuration the input vector is delayed, usually by one time sample, and the delayed input vector $\mathbf{x}(n-1) = [x(n-1), x(n-2), \ldots, x(n-N)]^T$ is then used to predict $x(n)$, the current value of the input. The *prediction error* is given by $e(n) = d(n) - y(n) = x(n) - y(n)$. Sometimes the entire system of Fig. 28 from the input $x(n)$ to output 1 is considered to be a single complete system, in which case it is referred to as a *prediction error filter*. Whenever the mean squared prediction error is minimized $e(n)$ will become uncorrelated with $x(n)$, while $y(n)$ remains highly correlated with $x(n)$. Therefore, since $d(n) = y(n) + e(n)$, the prediction filter decomposes the input signal into two components, one that is uncorrelated to the input and one that is highly correlated to the input. In this sense the linear predictor is a type of correlation filter.

Note that two distinct outputs, output 1 and output 2, are labeled in Fig. 28 to give access to both the correlated and uncorrelated components. Output 1 is used in applications such as adaptive linear predictive coding (LPC) for speech analysis and synthesis, and in adaptive differential pulse code modulation (ADPCM) for speech (and image) waveform compression. Since the prediction error is a difference between the actual value of $x(n)$ and its predicted value $y(n)$, the dynamic range needed for accurately encoding $e(n)$ is usually much smaller than $x(n)$ itself. This is the fundamental mechanism by which a linear prediction filter is able to compress waveforms. Alternately, output 2 produces a filtered version of $x(n)$ with the uncorrelated noise component removed. When used in this mode, the adaptive linear predictor becomes a *line enhancer*, which is capable of removing broadband noise from a narrow band information signal, a function frequently needed in communication systems.

The linear predictor described above is called a *forward prediction filter* because it uses the N "past" samples contained in $x(n-1)$ to predict the "future" sample $x(n)$. In this case the prediction error is called the *forward prediction error*, denoted by $e_f(n)$, and the overall filter from the input to output 1 is called a *for-*

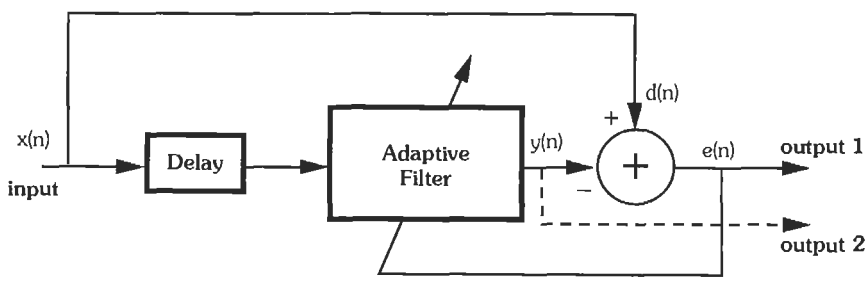

Fig. 28. Linear prediction configuration.

ward prediction error filter. The linear prediction problem can also be formulated as backward linear prediction, in which case the filter is used to estimate the sample $x(n-N)$ from the N "future" samples contained in $x(n) = [x(n), x(n-1), \ldots, x(n-N+1)]^T$. In this case, the prediction filter is called the *backward prediction filter*, the prediction error is called the *backward prediction error*, denoted $e_b(n)$, and the overall filter is called the *backward prediction error filter*. A combination of forward and backward prediction is used in the conventional adaptive lattice filters, where the uncorrelated properties of the prediction error leads to excellent learning characteristics.*

Inverse System Configuration—The fourth adaptive filtering configuration is the inverse system configuration shown in Fig. 29. In this configuration the adaptive filter is placed in series with an unknown system and the output $y(n)$ is driven by the adaptive algorithm to form the best MSE approximation to a delayed copy of the input signal. When the adaptive filter reaches convergence, the series combination of the unknown and adaptive systems forms an overall frequency response that approximates a pure delay, i.e., the overall system approximates a flat magnitude response and a linear phase characteristic across the usable bandwidth of the excited spectrum. In this case the adaptive filter estimates $H^{-1}(j\omega)$, where $H(j\omega)$ is the frequency response of the unknown system. The inverse system configuration is the basis for adaptive equalization, in which non-ideal communication channels are equalized in order to reduce dispersion and to eliminate intersymbol interference in high-speed digital communications (see Reference 10). The adaptive equalizer forms an essential component of most state-of-the-art modems today, where the equalization function is required to maintain acceptable bit error rates when binary information is transmitted across narrowband (4 kHz) telephone channels. Equalizers have also been used to equalize the dispersive channel that a computer faces when transferring high-speed digital data to a magnetic recording medium (disk or tape). It has been shown that properly designed equalizers will permit symbols to be more densely written on the magnetic recording medium due to the reduction in intersymbol interference. This methodology has attracted the attention of many disk manufacturers due to its ability to effectively increase the capacity of the disk.

The training of an adaptive equalizer in the inverse system configuration raises a number of problems that are unique to this configuration. Note that by the nature of the network configuration, the input to the adaptive filter has already been filtered by the unknown system. Hence in most situations the input to the equalizer cannot be a white noise signal, and depending on the severity of the channel imperfections, the equalizer may experience trouble converging quickly. In a communication system, the transmitter and the receiver are typically located at separate physical locations, so it may not be a simple matter to provide a training signal that is an exact delayed copy of the transmitted waveform. For this reason, channel equalizers are often trained during prescribed "hand shaking" intervals, during which time a pseudorandom binary sequence with known spectral characteristics is transmitted. Once the equalizer has converged to equalize the present characteristics of the unknown channel, the parameters of the equalizer are frozen and held at their converged values during the data transfers that follow.

Due to the difficulty in obtaining a suitable training reference, there has been a great deal of interest in combining certain blind equalization schemes with decision feedback equalizers. In these cases the blind equalization technique is used to bring the equalizer into the neighborhood of proper convergence, at which point the scheme is switched over to a decision feedback algorithm which works very well as long as the

* Reference 13.

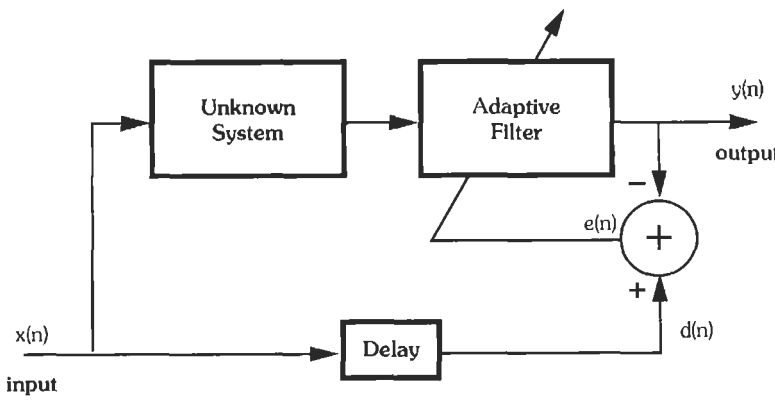

Fig. 29. Inverse system configuration.

equalizer remains in the neighborhood of its optimum solution.

Fig. 30 shows an adaptive filter used for channel equalization. The idea behind this application is that the degrading effects of a linear dispersive communications channel can be removed by using the adaptive filter to approximate the inverse of the channel characteristics. In this application, a delayed replica of the transmitted signal must be available as a training sequence, and the approximate delay Δ in the channel must be known. When the adaptive filter is adjusted properly, the frequency response of the combined channel and adaptive equalizer will have an approximately flat spectrum with a linear phase characteristic. The linear phase models the combined delay in the channel and the equalizer. Fig. 31 shows a computer simulation of an adaptive equalizer designed to operate with the LMS algorithm. Note that the impulse

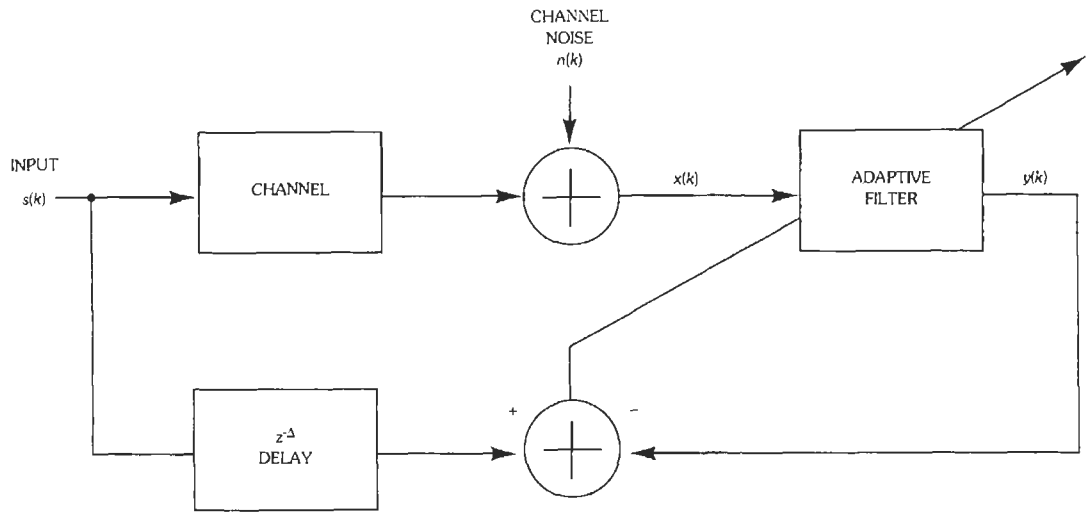

Fig. 30. An adaptive filter used for channel equalization.

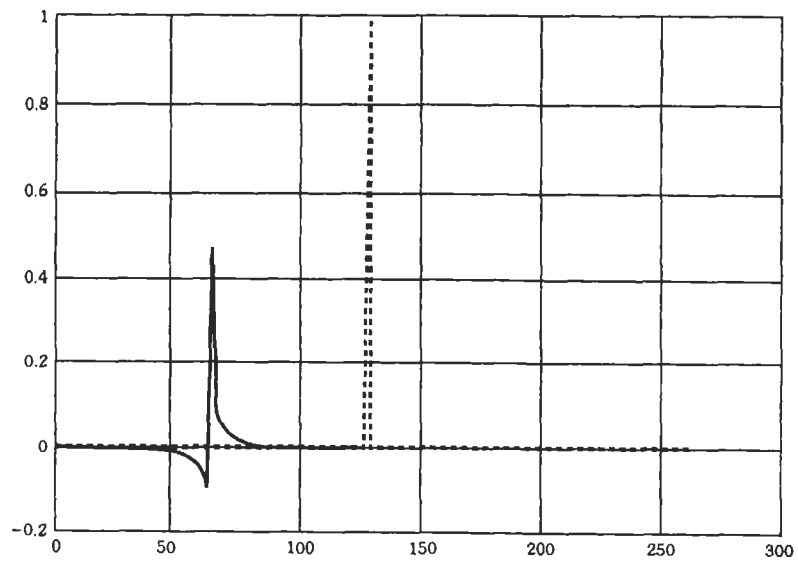

Fig. 31. Computer simulation of adaptive equalization. **Solid line:** impulse response of the unequalized channel. **Dashed line:** impulse response of the equalized channel.

response of the channel model (solid line) in Fig. 31 shows a broadening of the pulse and loss of height at the peak due to channel dispersion. The simulated impulse response of the equalized channel (dashed line) shows a much sharper impulse with a higher peak. Adaptive channel equalizers are now found in high-data-rate state-of-the-art communications equipment, such as high speed modems used for computer communications and in certain communication channels that link computer CPUs to magnetic disk storage devices.

DISCRETE-TIME ANALOG TECHNOLOGIES

The most obvious implementation of discrete-time filters is with digital technology. However, filters operating at very large bandwidths can require very high computational rates, and digital implementations become very expensive in terms of cost, size, and power consumption. Several discrete-time analog technologies have been developed which compute discrete-time filters via analog means, thus avoiding explicit analog-to-digital conversion. Although they lack some of the flexibility of a digital implementation, these technologies have found application in a number of specialized cost-sensitive or high-bandwidth applications. Filter coefficients for these technologies are obtained by using the filter design methods described earlier. The basic filtering operation can also accomplish other tasks such as radar pulse detection and compression, communication channel equalization, signal generation, and pattern matching.

Two discrete-time analog technologies are discussed in this section. Switched Capacitor Filters (SCF), which implement IIR filters at relatively low bandwidths (up to about 10 MHz), are often a cost-effective alternative to an all-digital implementation. SCFs inherently sample the analog signal and thus exhibit spectral aliasing. Surface Acoustic Wave (SAW) devices implement FIR filters with nonadjustable coefficients at very high bandwidths, and are widely used in very high frequency systems such as radars and televisions. SAW devices process the continuous signal without sampling and thus produce no aliasing errors, but the filter is discrete and the frequency response exhibits spectral periodicity.

The following subsections provide an overview of these two discrete-time analog technologies and their operating characteristics; devices are most likely to be purchased from a manufacturer specializing in these technologies, since a number of proprietary techniques are involved in manufacturing high-quality SCF or SAW devices. However, it is important that the system designer know the capabilities and limits of these technologies to evaluate whether these technologies are attractive for a given application. Table 5 summarizes some of the key parameters of the various technologies at the present time.

Switched Capacitor Circuits

Switched capacitor (SC) circuits became popular with circuit designers and IC technologists when it was discovered that SC techniques could be used for the design and manufacture of high precision monolithic filters. SC circuits are designed to depend only on capacitor ratios, which can be controlled quite accurately in MOS technology to realize high precision circuits.

Widespread interest in SC circuits developed during the mid 1970s, although a patent by Baker* in 1967 already had established that a filter characteristic could be specified entirely in terms of capacitor ratios. Baker's patent disclosure described circuits containing only switches, capacitors, and op amps, although his invention did not directly combine the concept with MOS IC technology. It now seems clear that much of the new interest that sprang up in the mid 1970s did not result so much from new advancements in either

* Reference 2.

TABLE 5. KEY PARAMETERS OF DISCRETE-TIME FILTER TECHNOLOGIES

	Technologies

Stopband rejection	—	80 dB	60 dB
Dynamic range	A/D limited	80 dB	70 dB

circuit theory or IC technology alone, but rather from coupling these two areas in an effective way.

Basic Principles of SC Circuits—The earliest SC filter designs were derived from active filters by means of resistor replacement. The three SC circuits shown in Fig. 32 represent different types of discrete-time integrators that result by replacing the input resistor in an RC active integrator with a series, parallel, or "toggled" switched capacitor, respectively. The concept of resistor replacement is easily understood by considering a linear capacitor C as it is charged by a voltage V that is held approximately constant during each interval of a clock sequence of period T. The voltage V causes the charge on the plates to change by the amount Δq during the time interval T. Since the capacitor obeys the linear law $\Delta q = CV$, or $\Delta q/T = C/TV$, it is easily shown that the term on the left represents the average current that flows in the capacitor terminals during the interval T. Thus the switched capacitor obeys the approximate relation $i = (C/T)V$. As long as the clock frequency is high enough relative to the signal frequency content so that the constant voltage assumption holds, the switched capacitor behaves

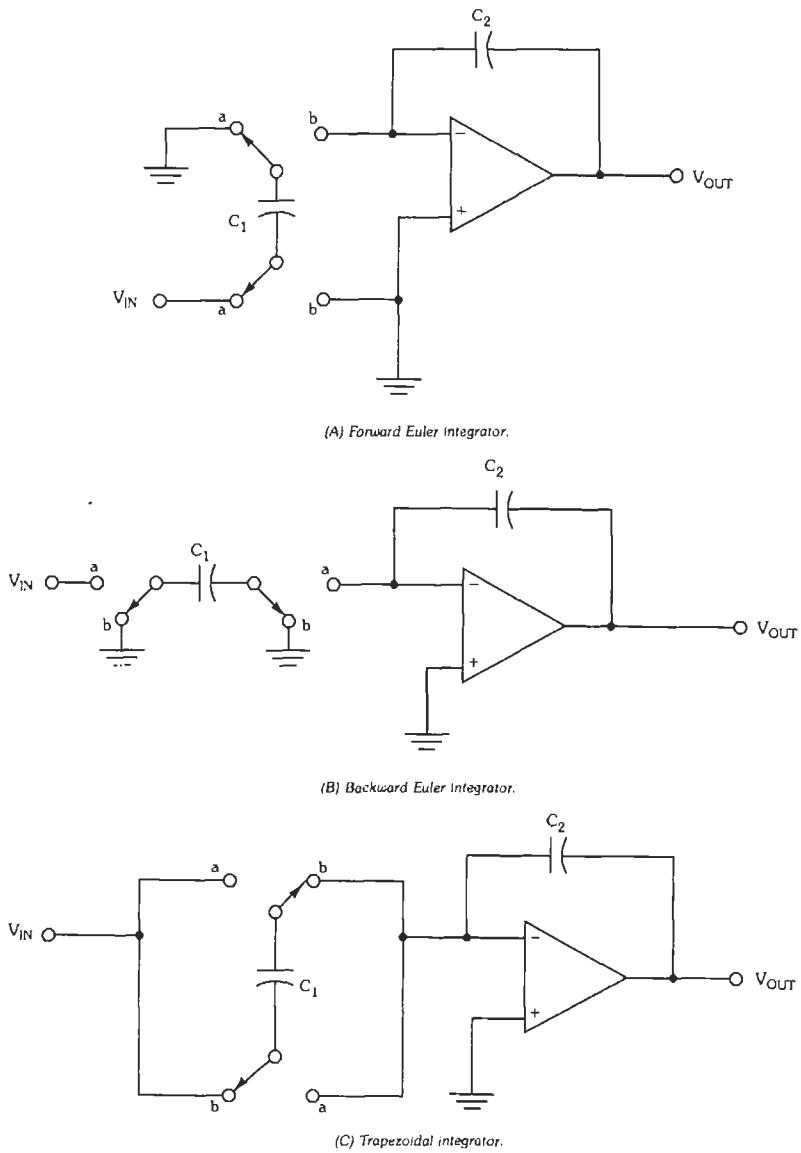

Fig. 32. SC integrators obtained by resistor replacement.

approximately like a resistor of value $R_{eq} = (T/C)$. When the frequency of the clock approaches the Nyquist limit relative to the signal bandwidth, this approximation begins to break down, and it is necessary to consider the details of the switch phasing in order to determine an accurate model for the performance of the SC circuit.

As it became better understood that resistor replacement techniques are inaccurate for switching rates near the Nyquist limit, SC circuit designers began to characterize charge transfer relationships in SC circuits with discrete-time difference equations and to apply the theory of discrete time systems to analyze performance. It was learned that if the output voltage is sampled on the "a" switch phase, then the network shown in Fig. 32a behaves as a forward Euler integrator, the network of Fig. 32b as a backward Euler integrator, and that of Fig. 32c as a trapezoidal integrator. Subsequently, Broderson et. al.* showed how high quality SC filters can be derived from the "leapfrog" active filter structure, a particular form of a doubly terminated LC ladder, by using SC integrator replacements.

If a toggled switched capacitor, like the one used to replace the input resistor in the trapezoidal integrator of Fig. 32c, is used to replace every resistor in an arbitrary RC active filter, the analog structure is transformed into an SC structure according to the bilinear-z transformation discussed earlier. If each phase of the biphase clock has period T, the effective sampling rate becomes $2/T$ because the toggle switched capacitor has identical behavior on each phase.

In MOS transistors, there normally is a rather large nonlinear parasitic capacitance C_s between the bottom plate and the substrate, as well as a considerably smaller parasitic capacitance C_p between the top plate and the substrate. C_s can be as much as 20% of the fabricated capacitor, and is rather difficult to predict or compensate. C_p is normally an order of magnitude smaller, although its presence can disturb a sensitive design significantly. It is important for SC circuits to be designed with the bottom plate of all capacitors grounded or switched between a voltage source and ground so that excess charge accumulated by the parasitic during the charging phase is harmlessly discharged to ground and does not affect the characteristics of the circuit. It is clear that a toggled switched capacitor cannot be made parasitic insensitive in general, since the top and bottom plates must perform the same function on alternate phases. Despite efforts to compensate for parasitics in the "bilinear switched capacitor," it was largely rejected by IC technologists as impractical because it led to too much uncontrolled variation in the characteristics of the final SC circuits.

Note that the forward and backward Euler integrators of Fig. 32 are insensitive with respect to both the top plate and bottom plate parasitics. For this reason these types of integrators became more successful than the bilinear integrator, and were subsequently used in many design methods that were eventually published. Broderson et al.† described a set of practical considerations for MOS implementation of SC circuits that became standard rules of thumb for SC circuit designers: (1) switched capacitor "resistors" should not close an on amp feedback path; (2) there should be no floating nodes; (3) at least one plate of every capacitor should be connected to a voltage source or switched between voltage sources; and (4) the noninverting op amp input should be kept at a constant voltage (usually grounded) or switched between voltage sources. Although these should be guidelines rather than strict rules, they have withstood the test of time in the sense that most IC technologists tend to reject designs that violate these conditions. The later book by Ghausi and Laker‡ incorporated these rules into the design procedure, representing a change of philosophy from the resistor and integrator replacement techniques that dominated earlier designs.

Switched Capacitor Filters for Voice Quality CODECs—One successful application of switched capacitor circuit technology has been in the realization of analog pre- and post-filters required for digital voice transmission in modern telephone channels. The A/D and D/A conversion, as well as some additional signal conditioning (companding, etc.), is implemented with an IC referred to as a CODEC (coder-decoder). A single IC contains the "transmit" filter to handle transmission in the forward direction, the "receive" filters to handle the returned voice signal, as well as other circuits required for signal conditioning. The industry standard for the digital sampling rate is 8 kHz, which is designed to prevent aliasing on a 4-kHz telephone channel. Prior to SC circuit technology, the transmit and receive filtering was done with an active filter that was implemented with expensive hybrid fabrication techniques. With switched capacitor circuit techniques, the goal of integrating the transmit and receive filters together with the CODEC, while meeting the rather strict system specifications, became reachable. The philosophy is to switch the SC filters at a very high rate (usually 256 kHz) relative to the 8-kHz sampling rate of the CODEC so that sampled data effects in the SC circuits are negligible, and for all intents and purposes the SC pre- and post-filters function as analog filters. The transmit filter must have a low-pass characteristic within a 0±0.01 dB tolerance in the passband up to a ripple cutoff frequency of 3.4 kHz. In the receive channel, a post-filter is required following the D/A converter to smooth the staircase waveform that results from the reconstruction process. The receive filter is a low-pass filter with a cutoff at 3.4 kHz, which is essentially the same as the antialiasing transmit filter.

The SC ladder structure shown in Fig. 33 is capable of realizing the low-pass characteristic required in a CODEC by means of a fifth order elliptic low-pass design. (The example presented here is for the idealized low-pass filter alone; i.e., the design does not include the transmit notch and receive sin x/x compensation.) This circuit is a variation of a state variable ladder derived by an LD1 (lossless discrete integrator) transformation, although certain switches have been rearranged to guarantee a parasitic insensitive circuit. It can be seen from Fig. 33 that this design approximates the desired response very accurately. Although many different SC circuits have been designed that meet the CODEC requirements, the state variable ladder is a preferred design because of its low sensitivities to variations in capacitor ratios.

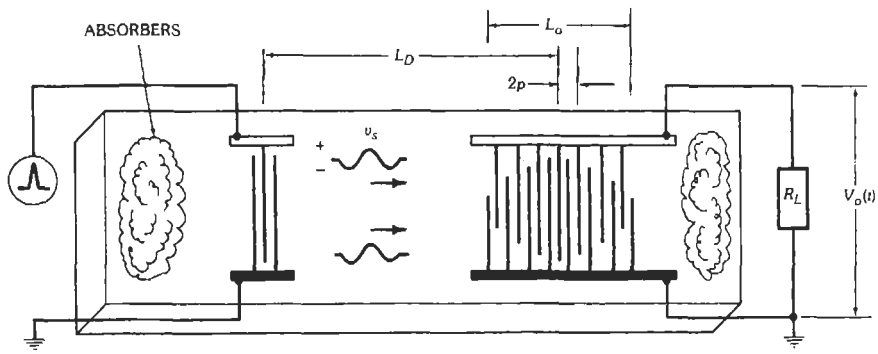
(B) Frequency response.

Fig. 33. A fifth order elliptic low-pass state variable ladder realization of a CODEC antialiasing filter. (Same filter is used as the D/A analog post-filter.)

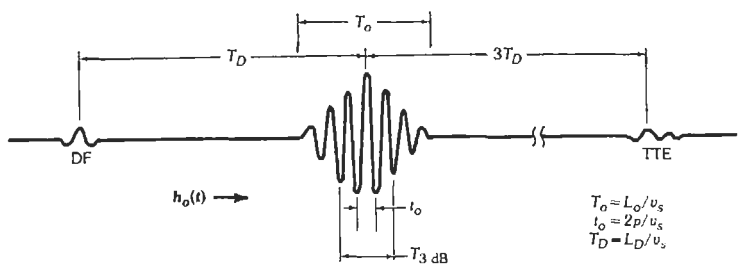
Surface-Acoustic-Wave Filters

A surface-acoustic-wave (SAW) filter consists of an input transducer that generates a surface-acoustic-wave replica of the signal, a polished piezoelectric substrate that acts as the propagation path for the waves, and an output transducer that converts the delayed acoustic waves back to an electrical signal. The input and output transducers each have an impulse response with a finite duration, and the construction is such that the transducer electrodes have a one-to-one correspondence with individual cycles in the impulse response. The impulse response center frequency is set by electrode spacing, and its envelope is set by the electrode length. The frequency-dependent transfer function of each transducer is the Fourier transform of its impulse response. The surface-acoustic-wave device connected between a voltage source and a low-impedance load operates as a filter with an overall transfer function that is the product of the input and output transducer frequency responses and a delay proportional to the separation between the centers of the transducers.

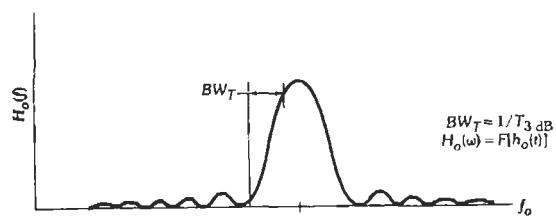
Consider the SAW device shown in Fig. 34, which uses a single electrode placed between a pair of grounded electrodes as the SAW generation transducer. When a pulse is applied, it creates a uniform



(A) Structure.



(B) Impulse response.



(C) Frequency response.

Fig. 34. Surface-acoustic-wave FIR filter.

wavefront acoustic disturbance that propagates along the surface both to the left and to the right. The wave propagating to the left is absorbed, to prevent it from bouncing back and creating an echo. Since the substrate is piezoelectric, the disturbance propagating to the right carries an electric field with it. The output transducer in this example consists of seven electrode pairs with center-to-center spacing p. The electrodes vary in length and are connected interdigitally to two bus bars, one of which is grounded and the other connected to a load. As the SAW pulse passes through the output transducer, it creates an oscillating impulse response, $h_0(t)$, with an overall duration, T_0, equal to the output transducer length, L_0, divided by the SAW velocity, v_s (Fig. 34B). The center frequency, f_0, is equal to the SAW velocity divided by the electrode-to-electrode spacing, p, and the amplitude of each cycle, h_i, is proportional to the corresponding transducer electrode length, l_i. The delay, T_D, is equal to the center-to-center distance of the input and output transducers, L_D, divided by the SAW velocity. The frequency response of the output transducer, $H_0(f)$, is equal to the Fourier transform of the impulse response (Fig. 34C). The device has a transition bandwidth, BW_T that is approximately equal to the reciprocal of the impulse response duration as measured at the 3-dB points, T_{3dB}.

Response—Operation of SAW filters is limited to a specific range of frequencies, fractional bandwidths, transition bandwidths, and delays because the SAW propagation velocity is approximately 3000 meters per second (plus or minus 20 percent) for most useful materials.

Frequency: The highest center frequency achievable with the SAW device is dependent on the ability to print fine lines. If an electrode-to-electrode spacing of 0.75 micron can be achieved, then the devices will operate with a 2-GHz center frequency. At low frequencies, the wavelengths become very long (3 mm at 1 MHz). Since the device must be hundreds or thousands of wavelengths in length and be much thicker than a wavelength, SAW devices become impractical below 5 MHz.

Delay: The substrate size for practical devices is limited to approximately 6 cm, which means that the maximum usable delay is in the order of 20 microseconds. If the application calls for very long delays and cost is not a particularly strong consideration, then delays can be expanded to the 100-microsecond range by using long substrates. The problem of achieving very short delays is the problem of getting the transducers physically close to each other. The minimum possible delay that can be achieved in a filter is twice the reciprocal of the transition bandwidth.

Transition Bandwidth: The impulse response duration is limited by substrate size to periods less than 10 microseconds so that transition bandwidths are limited to values greater than 100 kHz.

Inband Ripple: The SAW devices are designed with the same mathematical techniques used to design digital FIR filters. In the case of SAW devices, the design is realized by adjusting the length and position of the electrodes, and this can be done with an accuracy of approximately one percent. In addition, internally generated echoes add ripples to the frequency response. The measured amplitude-vs-frequency response of SAW bandpass filters generally matches the theoretical design specifications within ±0.5 dB. In special cases where the application can tolerate higher insertion losses and warrants extra development costs, the response deviations can be reduced to ±0.2 dB.

Out-of-Band Rejection: The SAW out-of-band rejection depends on the accuracy with which the transducers are implemented and the transducer isolation built into the device. Typical state of the art SAW filters provide approximately 50–70 dB of out-of-band rejection. In certain circumstances, the out-of-band rejection can be raised to 80 dB. It is also possible to cascade SAW filters to improve rejection, if the cost, losses, and inband deviations of two filters can be tolerated.

Echo Levels: The main source of SAW-filter-generated noise is signals (called echoes) that precede and/or follow the main impulse response of the device. The two echoes in a SAW filter are the direct feed signals that are coupled directly to the output without any delay and the triple-transit echo that emerges with a delay three times that of the main signal. These echoes are highly dependent on the method by which the devices are interfaced into the supporting electronic circuitry and are typically 45 dB below the main signal.

Temperature Dependence: Both the center frequency and the delay of SAW filters are temperature dependent because the substrate dimensions and the SAW velocity vary with temperature. These two effects are combined into a single term called the SAW *temperature coefficient of delay* (TCD). The temperature coefficient of delay is approximately 90 ppm/°C (parts per million per degree Celsius) for the $LiNbO_3$ substrates used in large-percentage-bandwidth devices, and less than I ppm/°C for the quartz material used in low-percentage-bandwidth filters.

Dynamic Range: A 50–70-dB dynamic range is typical, and it can be expanded to 100 dB in certain cases. The largest possible signal is limited by burnout, and the smallest input signal that a SAW device can process is limited by the transducer losses and the thermal noise generated in the load.

Noise Figure: The noise figure of a SAW filter is equal to the noise figure of the output amplifier plus the device insertion loss. The effective noise figure is high (typically 15–35 dB), and that is the reason SAW devices are presently being used primarily in the IF sections of receivers.

SAW Filters for IS-95 Compatible CDMA Digital Receivers*

Standing Acoustic Wave (SAW) filters are commonly used as band-pass filters at the intermediate frequency in wideband superheterodyne receivers due to their sharp magnitude characteristics and excellent linear phase response. These SAW filters are one of the largest and most expensive components at the front end of the receiver, making them less desirable for portable, consumer applications. Studies have shown that minimum phase, finite impulse response SAW filters (FIRs) can obtain similar performance with fewer tap weights than their linear phase counterparts. They also lead to the shortest possible propagation, or energy, delays. In SAW filters a minimum phase design has an additional advantage that the magnitude response is less sensitive to errors in the tap weights. Therefore the potential exists for reducing overall size and cost by selecting a minimum phase design. However, the phase response of a minimum phase FIR filter is nonlinear and does not meet linear phase constraints required by IS-95 CDMA specifications. This phase non-linearity can be controlled by using an adaptive all-pass phase equalizer that maintains overall phase linearity when the center frequency drifts due to environmental temperature variations.

Minimum Requirements for SAW Performance

Commercially available transversal bandpass SAW filters meet stringent stability requirements and are widely used as the IF filter in superheterodyne digital receivers. They are designed to have a very flat magnitude and linear-phase frequency response over the bandpass region. Two commercially available SAW filters which meet specifications for the IS-95-A spread spectrum standard are the Thomson Microsonics FB E872 [32] and the SAWTEK 855292 [28]. In the following discussion, the specifications of these components, as summarized in Table 6, are to represent those of a typical SAW filter.

TABLE 6. MINIMUM MAGNITUDE RESPONSE SPECIFICATIONS

–5 dB one-sided bandwidth	≥ 630 kHz
–33 dB one-sided bandwidth	≤ 900 kHz
Amplitude ripple within ± 300 kHz	≤ 0.6 dB_p
Phase linearity within ± 630 kHz	± 3° rms

Because the center frequency of a SAW filter depends on the physical dimensions of the quartz substrate, it drifts slightly over the operating temperature range of –30 to 80°C. To compensate for this drift, SAW filters are designed to have a two-sided –5 dB bandwidth greater than the minimum requirement of 2 · 630 kHz given in the table above. Thus, data signals will pass through the filter even though the IF local oscillator frequency does not exactly match the center frequency fc of the SAW filter.

Fig. 35 illustrates the difference between the impulse responses of two SAW filters with identical magnitude responses, where one has a minimum phase characteristic, and the other, linear phase. For SAW filters, the minimum phase design has the additional advantage that the magnitude response is less sensitive to errors in the tap weights. Therefore, the potential exists for reducing the overall cost of the SAW filter, as well as its size by using a minimum phase SAW filter.

Fig. 36 shows the frequency response of a minimum phase SAW filter which meets the magnitude response specifications given in Table 6. But Fig. 37 illustrates that the rms phase is outside of those specifications, regardless of the center frequency of the filter.

Note that the degree of phase nonlinearity changes with respect to f_c. Therefore, an equalizer that adjusts with changes in f_c is necessary to maintain the maximum SNR over variations in temperature.

An IIR adaptive phase equalizer is capable of providing enough non-linear phase compensation to meet the IS-95-A linear phase constraints. Examples presented in Reference 36 showed learning characteristics of one-section IIR phase equalizers trained with both the decision-directed algorithm (DDA) and the constant modulus algorithm (CMA) adaptive phase equalizers, respectively. Both were able to minimize their corresponding cost functions, achieving local minima that brought the cascade combination of the minimum phase SAW filter and the first order IIR adaptive equalizer into compliance with the magnitude and phase specifications of Table 6. It was seen that the DDA demonstrates considerably faster learning characteristics than the CMA, providing the probability of error is low and correct decisions are made most of the time. The CMA learning characteristics showed a slower learning (convergence) rate, and a large minimum mean square error. Fig. 38 shows phase characteristic of the combined minimum phase SAW filter ($f_c = 0$) and the allpass IIR equalizing filter using six first order all-pass IIR sections. The equalized minimum phase filter has a slightly larger propagation delay than the unequalized minimum phase SAW filter, but it achieves a much smaller propagation delay than the linear phase SAW filter at a greatly reduced cost. This example demonstrates how analog and digital signal processing technologies can be combined to achieve efficient mixed mode solutions to certain practical problems.

29 Transmission Lines

Revised by
Tatsuo Itoh

The equations and charts of this chapter are for transmission lines operating in the TEM mode.* At the beginning of several of the sections (e.g., "Fundamental Quantities and Line Parameters," "Voltage and Current," "Impedance and Admittance," "Voltage Reflection Coefficient and Standing-Wave Ratio") there are accurate equations, according to conventional transmission-line theory. These are applicable from the lowest power and communication frequencies, including direct current, up to the frequency where a higher mode begins to appear on the line.

Following the accurate equations are others that are specially adapted for use in radio-frequency problems. In cases of small attenuation, the terms α^2x^2 and higher powers in the expansion of $\exp\alpha x$, etc., are neglected. Thus, when $\alpha x = (\alpha/\beta)\theta = 0.1$ neper (or about 1 decibel), the error in the approximate equations is of the order of 1 percent.

Much of the information is useful also in connection with special lines that function in a quasi-TEM mode (e.g., microstrip).

It should be observed that Z_0 and Y_0 are complex quantities and the imaginary part cannot be neglected in the accurate equations, unless preliminary examination of the problems indicates the contrary. Even when attenuation is small, $Z_0 = 1/Y_0$ must often be taken at its complex value, especially when the standing-wave ratio is high. In the first few pages of equations, the symbol R_0 is used frequently. However, in later charts and special applications, the conventional symbol Z_0 is used where the context indicates that the quadrature component need not be considered for the moment.

RULE OF SUBSCRIPTS AND SIGN CONVENTIONS

The equations for voltage, impedance, etc., are generally for the quantities at the input terminals of the line in terms of those at the output terminals (Fig. 1). In case it is desired to find the quantities at the output in terms of those at the input, it is simply necessary to interchange the subscripts 1 and 2 in the equations and to place a minus sign before x or θ. The minus sign may then be cleared through the hyperbolic or circular functions; thus

$$\sinh(-\gamma x) = -\sinh\gamma x$$

and so on.

SYMBOLS

Voltage and current symbols usually represent the alternating-current complex sinusoid, with magnitude equal to the root-mean-square value of the quantity.

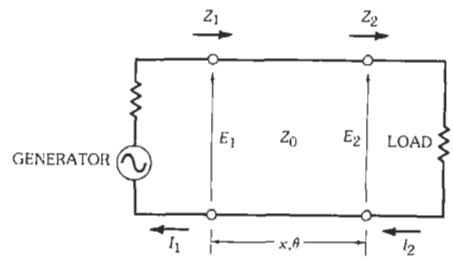

Fig. 1. Transmission line with generator and load.

Certain quantities, namely C, c, f, L, T, v, and ω are shown with an optional set of units in parentheses. Either the standard units or the optional units may be used, provided the same set is used throughout. (For the physical significance of C, G, L, and R, refer to Fig. 2.)

A = $10\log_{10}(1/\eta)$ = dissipation loss in a length of line in decibels
A_0 = $8.686\alpha x$ = normal or matched-line attenuation of a length of line in decibels
B_0 = susceptive component of Y_0 in mhos
C = capacitance of line in farads/unit length (microfarads/unit length)
c = velocity of light in vacuum in units of length/second (units of length/microsecond). See table of physical constants in Chapter 3.

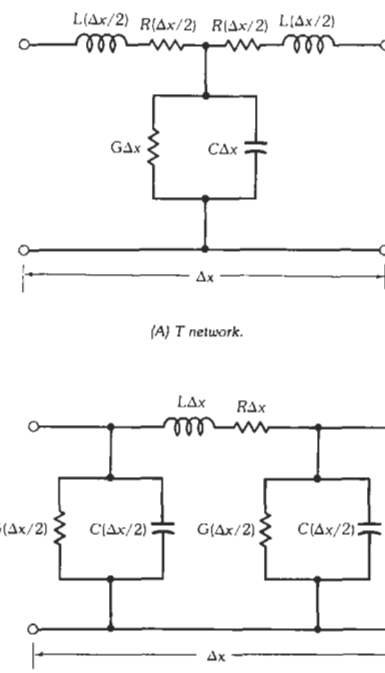

Fig. 2. Equivalent networks of a short section, Δx, of a transmission line.

* The information through the section "Length of Transmission Line" (page 29-21) is valid for single-mode waveguides in general, except for equations where the symbols R, L, G, or C per unit length are involved.

E = voltage (root-mean-square complex sinusoid) in volts
${}_fE$ = voltage of forward wave, traveling toward load
${}_rE$ = voltage of reflected wave
$|E_{flat}|$ = root-mean-square voltage when standing-wave ratio = 1.0
$|E_{max}|$ = root-mean-square voltage at crest of standing wave
$|E_{min}|$ = root-mean-square voltage at trough of standing wave
e = instantaneous voltage
$F_p = G/\omega C$ = power factor of dielectric
f = frequency in hertz (megahertz)
G = conductance of line in mhos/unit length
G_0 = conductive component of Y_0 in mhos
$g_a = Y_a/Y_0$ = normalized admittance at voltage standing-wave maximum
$g_b = Y_b/Y_0$ = normalized admittance at voltage standing-wave minimum
I = current (root-mean-square complex sinusoid) in amperes
${}_fI$ = current of forward wave, traveling toward load
${}_rI$ = current of reflected wave
i = instantaneous current
L = inductance of line in henrys/unit length (microhenrys/unit length)
P = power in watts
R = resistance of line in ohms/unit length
R_0 = resistive component of Z_0 in ohms
$r_a = Z_a/Z_0$ = normalized impedance at voltage standing-wave maximum
$r_b = Z_b/Z_0$ = normalized impedance at voltage standing-wave minimum
$S = |E_{max}/E_{min}|$ = voltage standing-wave ratio
T = delay of line in seconds/unit length (microseconds/unit length)
v = phase velocity of propagation in units of length/second (units of length/microsecond)
X_0 = reactive component of Z_0 in ohms
x = distance between points 1 and 2 in units of length (also used for normalized reactance $= X/Z_0$)
$Y_1 = G_1 + jB_1 = 1/Z_1$ = admittance in mhos looking toward load from point 1
$Y_0 = G_0 + jB_0 = 1/Z_0$ = characteristic admittance of line in mhos
$Z_1 = R_1 + jX_1$ = impedance in ohms looking toward load from point 1
$Z_0 = R_0 + jX_0$ = characteristic impedance of line in ohms
Z_{oc} = input impedance of a line open-circuited at the far end
Z_{sc} = input impedance of a line short-circuited at the far end
α = attenuation constant = nepers/unit length = 0.1151 × decibels/unit length
β = phase constant in radians/unit length
$\gamma = \alpha + j\mathrm{B}$ = propagation constant
ϵ = base of natural logarithms = 2.718; or dielectric constant of medium (relative to air), according to context
$\eta = P_2/P_1$ = efficiency (fractional)
$\theta = \beta x$ = electrical length or angle of line in radians
$\theta^\circ = 57.3\theta$ = electrical angle of line in degrees
λ = wavelength in units of length
λ_0 = wavelength in free space
$\rho = |\rho| \angle 2\psi$ = voltage reflection coefficient
$\rho\mathrm{dB} = -20 \log_{10}(1/\rho)$ = voltage reflection coefficient in decibels
ϕ = time phase angle of complex voltage at voltage standing-wave maximum
ψ = half the angle of the reflection coefficient = electrical angle to nearest voltage standing-wave maximum on the generator side
$\omega = 2\pi f$ = angular velocity in radians/second (radians/microsecond).

FUNDAMENTAL QUANTITIES AND LINE PARAMETERS

$$dE/dx = -(R + j\omega L)I$$

$$d^2E/dx^2 = \gamma^2 E$$

$$dI/dx = -(G + j\omega C)E$$

$$d^2I/dx^2 = \gamma^2 I$$

$$\gamma = \alpha + j\beta = [(R + j\omega L)(G + j\omega C)]^{1/2}$$

$$= j\omega(LC)^{1/2} \times [(1 - jR/\omega L)(1 - jG/\omega C)]^{1/2}$$

$$\alpha = (\tfrac{1}{2}\{[(R^2 + \omega^2 L^2)(G^2 + \omega^2 C^2)]^{1/2} + RG - \omega^2 LC\})^{1/2}$$

$$\beta = (\tfrac{1}{2}\{[(R^2 + \omega^2 L^2)(G^2 + \omega^2 C^2)]^{1/2} - RG + \omega^2 LC\})^{1/2}$$

$$Z_0 = 1/Y_0 = [(R + j\omega L)/(G + j\omega C)]^{1/2}$$

$$= (L/C)^{1/2}\,[(1 - jR/\omega L)/(1 - jG/\omega C]^{1/2}$$

$$= R_0(1 + jX_0/R_0)$$

$$Y_0 = 1/Z_0 = G_0(1 + jB_0/G_0)$$

$$\alpha = \tfrac{1}{2}(R/R_0 + G/G_0)$$

$$\beta\, B_0/G_0 = \tfrac{1}{2}(R/R_0 - G/G_0)$$

$$R_0 = [M/2(G^2 + \omega^2 C^2)]^{1/2}$$

$$G_0 = [M/2(R^2 + \omega^2 L^2)]^{1/2}$$

$$B_0/G_0 = -X_0/R_0 = (\omega RC - \omega LG)/M$$

where

$$M = [(R^2 + \omega^2L^2)(G^2 + \omega^2C^2)]^{1/2} + RG + \omega^2LC$$

$$1/T = v = f\lambda = \omega/\beta$$

$$\beta = \omega/v = \omega T = 2\pi/\lambda$$

$$\gamma x = \alpha x + j\beta x = (\alpha/\beta)\theta + j\theta$$

$$\theta = \beta x = 2\pi x/\lambda = 2\pi fTx$$

$$\theta^\circ = 57.3\theta = 360x/\lambda = 360fTx$$

(A) Special case—distortionless line: When $R/L = G/C$, the quantities Z_0 and α are independent of frequency.

$$X_0 = 0$$

$$\alpha = R/R_0$$

$$Z_0 = R_0 + j_0 = (L/C)^{1/2}$$

$$\beta = \omega(LC)^{1/2}$$

(B) For small attenuation: $R/\omega L$ and $G/\omega C$ are small.

$$\gamma = j\omega(LC)^{1/2}\{1 - j[(R/2\omega L) + (G/2\omega C)]\}$$

$$= j\beta(1 - j\alpha/\beta)$$

$$\beta = \omega(LC)^{1/2} = \omega L/R_0 = \omega CR_0$$

$$T = 1/v = (LC)^{1/2} = R_0C$$

$$\alpha/\beta = (R/2\omega L) + (G/2\omega C) = (R/2\omega L) + \tfrac{1}{2}F_p$$

$$= (Rv/2\omega R_0) + \tfrac{1}{2}F_p$$

$$=$$ attenuation in nepers/radian

$$=$$ (decibels per 100 feet)(wavelength in line in meters)/1663

$$\alpha = \tfrac{1}{2}R(C/L)^{1/2} + \tfrac{1}{2}G(L/C)^{1/2}$$

$$= (R/2R_0) + \pi(F_p/\lambda)$$

$$= (R/2R_0) + \tfrac{1}{2}(F_p\beta)$$

where R and G vary with frequency, while L and C are nearly independent of frequency.

$$Z_0 = 1/Y_0$$

$$= (L/C)^{1/2}\{1 - j[(R/2\omega L) - (G/2\omega C)]\}$$

$$= R_0(1 + jX_0/R_0)$$

$$= 1/[G_0(1 + j\,B_0/G_0)]$$

$$= (1/G_0)(1 - jB_0/G_0)$$

$$R_0 = 1/G_0 = (L/C)^{1/2}$$

$$B_0/G_0 = -(X_0/R_0) = (R/2\omega L) - \tfrac{1}{2}F_p = (\alpha/\beta) - F_p$$

$$X_0 = -[R/2\omega(LC)^{1/2}] + (G/2\omega C)(L/C)^{1/2}$$

$$= -(R\lambda/4\pi) + (\tfrac{1}{2}F_p)R_0$$

(C) With certain exceptions, the following few equations are for ordinary lines (e.g., not spiral delay lines) with the field totally immersed in a uniform dielectric of dielectric constant ϵ (relative to air). The exceptions are all the quantities not including the symbol ϵ, these being good also for special types such as spiral delay lines, microstrip, etc.

$$L = 1.016R_0(\epsilon^{1/2}) \times 10^{-3}$$ microhenrys/foot

$$= \tfrac{1}{3}R_0(\epsilon^{1/2}) \times 10^{-4}$$ microhenrys/centimeter

$$C = 1.016[(\epsilon^{1/2})/R_0] \times 10^{-3}$$ microfarads/foot

$$= [(\epsilon^{1/2})/3R_0] \times 10^{-4}$$ microfarads/centimeter

$$v/c = 1016/R_0C' = \epsilon^{-1/2}$$

$$=$$ velocity factor (with capacitance C' in picofarads/foot)

$$\lambda = \lambda_0 v/c = c/f(\epsilon^{1/2}) = \lambda_0/(\epsilon^{1/2})$$

$$T = 1/v = R_0C' \times 10^{-6} = 1.016 \times 10^{-3}/(v/c)$$

$$= 1.016 \times 10^{-3}\epsilon^{1/2}$$ microseconds/foot (with capacitance c' in picofarads/foot)

The line length is

$$x/\lambda = xf(\epsilon^{1/2})/984$$ wavelengths

$$\theta = 2\pi x/\lambda = xf(\epsilon^{1/2})/156.5$$ radians

where xf is the product of feet times megahertz.

VOLTAGE AND CURRENT

$$E_1 = {}_fE_1 + {}_rE_1 = {}_fE_2\epsilon^{\gamma x} + {}_rE_2\epsilon^{-\gamma x}$$

$$= E_2\{[(Z_2 + Z_0)/2Z_2]\epsilon^{\gamma x} + [(Z_2 - Z_0)/2Z_2]\epsilon^{-\gamma x}\}$$

$$= \tfrac{1}{2}(E_2 + I_2Z_0)\epsilon^{\gamma x} + \tfrac{1}{2}(E_2 - I_2Z_0)\epsilon^{-\gamma x}$$

$$= E_2[\cosh\gamma x + (Z_0/Z_2)\sinh\gamma x]$$

$$= E_2\cosh\gamma x + I_2 Z_0 \sinh\gamma x$$

$$= [E_2/(1+\rho_2)](\epsilon^{\gamma x} + \rho_2\epsilon^{-\gamma x})$$

$$I_1 = {}_fI_1 + {}_rI_1 = {}_fI_2\epsilon^{\gamma x} + {}_rI_2\epsilon^{-\gamma x}$$

$$= Y_0({}_fE_2\epsilon^{\gamma x} - {}_rE_2\epsilon^{-\gamma x})$$

$$= I_2\{[(Z_0 - Z_2)/2Z_0]\epsilon^{\gamma x} + [(Z_0 + Z_2)/2Z_0]\epsilon^{-\gamma x}\}$$

$$= \tfrac{1}{2}(I_2 + E_2 Y_0)\epsilon^{\gamma x} + \tfrac{1}{2}(I_2 - E_2 Y_0)\epsilon^{-\gamma x}$$

$$= I_2[\cosh\gamma x + (Z_2/Z_0)\sinh\gamma x]$$

$$= I_2\cosh\gamma x + E_2 Y_0 \sinh\gamma x$$

$$= [I_2/(1-\rho_2)](\epsilon^{\gamma x} - \rho_2\epsilon^{-\gamma x})$$

$$E_1 = AE_2 + BI_2$$

$$I_1 = CE_2 + DI_2$$

where the general circuit parameters are $A = \cosh\gamma x$, $B = Z_0\sinh\gamma x$, $C = Y_0\sinh\gamma x$, and $D = \cosh\gamma x$.

Refer to section entitled "Matrix Algebra" in Chapter 47.

(A) When point 2 is at a voltage maximum or minimum, x' is measured from voltage maximum and x'' from voltage minimum (similarly for currents).

$$E_1 = E_{max}(\cosh\gamma x' + S^{-1}\sinh\gamma x')$$

$$= E_{min}(\cosh\gamma x'' + S\sinh\gamma x'')$$

$$I_1 = I_{max}(\cosh\gamma x' + S^{-1}\sinh\gamma x')$$

$$= I_{min}(\cosh\gamma x'' + S\sinh\gamma x'')$$

When attenuation is neglected

$$E_1 = E_{max}(\cos\theta' + jS^{-1}\sin\theta')$$

$$= E_{min}(\cos\theta'' + jS\sin\theta'')$$

(B) Letting Z_l = impedance of load, l = distance from load to point 2, and x_l = distance from load to point 1

$$E_1 = E_2\frac{\cosh\gamma x_l + (Z_0/Z_l)\sinh\gamma x_l}{\cosh\gamma l + (Z_0/Z_l)\sinh\gamma l}$$

$$I_1 = I_2\frac{\cosh\gamma x_l + (Z_l/Z_0)\sinh\gamma x_l}{\cosh\gamma l + (Z_l/Z_0)\sinh\gamma l}$$

(C) $e_1 = \sqrt{2}\,|{}_fE_2|\,\epsilon^{\alpha x}\sin\omega t + 2\pi(x/\lambda) - \psi_2 + \phi] + \sqrt{2}\,|{}_rE_2|\,\epsilon^{-\alpha x}\sin[\omega t - 2\pi(x/\lambda) + \psi_2 + \phi]$

$$i_1 = \sqrt{2}\,|{}_fI_2|\,\epsilon^{\alpha x}\times\sin[\omega t + 2\pi(x/\lambda) - \psi_2 + \phi + \tan^{-1}(B_0/G_0)] + \sqrt{2}\,|{}_rI_2|\,\epsilon^{-\alpha x}\times\sin[\omega t - 2\pi(x/\lambda) + \psi_2 + \phi + \tan^{-1}(B_0/G_0)]$$

(D) For small attenuation

$$E_1 = E_2\{[1 + (Z_0/Z_2)\alpha x]\cos\theta + j[(Z_0/Z_2) + \alpha x]\sin\theta$$

$$I_1 = I_2\{[1 + (Z_2/Z_0)\alpha x]\cos\theta + j[(Z_2/Z_0) + \alpha x]\sin\theta\}$$

(E) When attenuation is neglected

$$E_1 = E_2\cos\theta + jI_2 Z_0\sin\theta$$

$$= E_2[\cos\theta + j(Y_2/Y_0)\sin\theta]$$

$$= {}_fE_2\epsilon^{j\theta} + {}_rE_2\epsilon^{-j\theta}$$

$$I_1 = I_2\cos\theta + jE_2 Y_0\sin\theta$$

$$= I_2[\cos\theta + j(Z_2/Z_0)\sin\theta]$$

$$= Y_0({}_fE_2\epsilon^{j\theta} - {}_rE_2\epsilon^{-j\theta})$$

General circuit parameters are

$$A = \cos\theta$$

$$B = jZ_0\sin\theta$$

$$C = jY_0\sin\theta$$

$$D = \cos\theta$$

IMPEDANCE AND ADMITTANCE

$$\frac{Z_1}{Z_0} = \frac{Z_2\cosh\gamma x + Z_0\sinh\gamma x}{Z_0\cosh\gamma x + Z_2\sinh\gamma x}$$

$$\frac{Y_1}{Y_0} = \frac{Y_2\cosh\gamma x + Y_0\sinh\gamma x}{Y_0\cosh\gamma x + Y_2\sinh\gamma x}$$

(A) The input impedance of a line at a position of maximum or minimum voltage has the same phase angle as the characteristic impedance.

$$Z_1/Z_0 = Z_b/Z_0 = Y_0/Y_b = r_b + j0 = S^{-1}$$

at a voltage minimum (current maximum).

$$Y_1/Y_0 = Y_a/Y_0 = Z_0/Z_a = g_a + j0 = S^{-1}$$

at a voltage maximum (current minimum).

(B) When attenuation is small

$$\frac{Z_1}{Z_0} = \frac{[(Z_2/Z_0) + \alpha x] + j[1 + (Z_2/Z_0)\alpha x] \tan\theta}{[1 + (Z_2/Z_0)\alpha x] + j[(Z_2/Z_0) + \alpha x] \tan\theta}$$

For admittances, replace Z_0, Z_1, and Z_2 by Y_0, Y_1, and Y_2, respectively.

(C) When attenuation is neglected

$$\frac{Z_1}{Z_0} = \frac{Z_2/Z_0 + j\tan\theta}{1 + j(Z_2/Z_0)\tan\theta} = \frac{1 - j(Z_2/Z_0)\cot\theta}{Z_2/Z_0 - j\cot\theta}$$

and similarly for admittances.

(D) When attenuation $\alpha x = \theta\alpha/\beta$ is small and the standing-wave ratio is large (say > 10)(*Note:* The complex value of Z_0 or Y_0 must be used in computing the resistive component of Z_1 or Y_1.): For θ measured from a voltage minimum

$$Z_1/Z_0 = [r_b + (\alpha/\beta)\theta](1 + \tan^2\theta) + j\tan\theta$$

$$= [r_b + (\alpha/\beta)\theta](\cos^2\theta)^{-1} + j\tan\theta$$

(See Note 1)

$$Z_0/Z_1 = Y_1/Y_0$$

$$= [r_b + (\alpha/\beta)\theta](1 + \cot^2\theta) - j\cot\theta$$

$$= [r_b + (\alpha/\beta)\theta](\sin^2\theta)^{-1} - j\cot\theta$$

(See Note 2)

For θ measured from a voltage maximum

$$Z_0/Z_1 = Y_1/Y_0 = [g_a + (\alpha/\beta)\theta](1 + \tan^2\theta) + j\tan\theta$$

(See Note 1)

$$Z_1/Z_0 = [g_a + (\alpha/\beta)\theta](1 + \cot^2\theta) - j\cot\theta$$

(See Note 2)

Note 1: Not valid when $\theta \approx \pi/2$, $3\pi/2$, etc., due to approximation in denominator $1 + (r_b + \theta\alpha/\beta)^2 \tan^2\theta = 1$ (or with g_a in place of r_b).

Note 2: Not valid when $\theta \approx 0$, π, 2π, etc., due to approximation in denominator $1 + (r_b + \theta\alpha/\beta)^2 \cot^2\theta = 1$ (or with g_a in place of r_b). For open- or short-circuited line, valid at $\theta = 0$.

(E) When x is an integral multiple of $\lambda/2$ or $\lambda/4$: For $x = n\lambda/2$, or $\theta = n\pi$

$$\frac{Z_1}{Z_0} = \frac{(Z_2/Z_0) + \tanh n\pi(\alpha/\beta)}{1 + (Z_2/Z_0)\tanh n\pi(\alpha/\beta)}$$

For $x = n\lambda/2 + \lambda/4$, or $\theta = (n + \frac{1}{2})\pi$

$$\frac{Z_1}{Z_0} = \frac{1 + (Z_2/Z_0)\tanh(n + \frac{1}{2})\pi(\alpha/\beta)}{(Z_2/Z_0) + \tanh(n + \frac{1}{2})\pi(\alpha/\beta)}$$

(F) For small attenuation, with any standing-wave ratio: For $x = n\lambda/2$, or $\theta = n\pi$, where n is an integer

$$\frac{Z_1}{Z_0} = \frac{(Z_2/Z_0) + n\pi(\alpha/\beta)}{1 + (Z_2/Z_0)n\pi(\alpha/\beta)}$$

$$g_{a1} = \frac{g_{a2} + \alpha n\lambda/2}{1 + g_{a2}\alpha n\lambda/2} = S_1^{-1}$$

For $x = (n + \frac{1}{2})\lambda/2$, or $\theta = (n + \frac{1}{2})\pi$, where n is an integer or zero

$$\frac{Z_1}{Z_0} = \frac{1 + (Z_2/Z_0)(n + \frac{1}{2})\alpha(\lambda/2)}{(Z_2/Z_0) + (n + \frac{1}{2})\alpha(\lambda/2)}$$

$$g_{b1} = \frac{1 + g_{a2}(n + \frac{1}{2})(\alpha/\beta)\pi}{g_{a2} + (n + \frac{1}{2})(\alpha/\beta)\pi} = S_1$$

Subscript a refers to the voltage-maximum point and b to the voltage minimum. In the above equations, subscripts a and b may be interchanged, and/or r may be substituted in place of g, except for the relationships to standing-wave ratio.

LINES OPEN- OR SHORT-CIRCUITED AT THE FAR END

Point 2 is the open- or short-circuited end of the line, from which x and θ are measured.

(A) Voltages and Currents: Use the equations of the "Voltage and Current" section, with the following conditions.

Open circuited line:

$$\rho_2 = 1.00 \angle 0° = 1.00$$

$${}_rE_2 = {}_jE_2 = E_2/2$$

$${}_rI_2 = -{}_jI_2$$

$$I_2 = 0$$

$$Z_2 = \infty$$

Short-circuited line:

$$\rho_2 = 1.00 \angle 180° = -1.00$$

$${}_rE_2 = -{}_jE_2$$

$$E_2 = 0$$

$${}_rI_2 = {}_jI_2 = I_2/2$$

$$Z_2 = 0$$

(B) Impedances and admittances:

$$Z_{oc} = Z_0 \coth \gamma x$$

$$Z_{sc} = Z_0 \tanh \gamma x$$

$$Y_{oc} = Y_0 \tanh \gamma x$$

$$Y_{sc} = Y_0 \coth \gamma x$$

(C) For small attenuation: Use the equations for large swr in **(D)** of the preceding section, with the following conditions.

Open-circuited line:

$$g_a = 0$$

Short-circuited line:

$$r_b = 0$$

(D) When attenuation is neglected:

$$Z_{oc} = -jR_0 \cot\theta$$

$$Z_{sc} = jR_0 \tan\theta$$

$$Y_{oc} = jG_0 \tan\theta$$

$$Y_{sc} = -jG_0 \cot\theta$$

(E) Relationships between Z_{oc} and Z_{sc}:

$$(Z_{oc}Z_{sc})^{1/2} = Z_0$$

$$\pm(Z_{sc}/Z_{oc})^{1/2} = \tanh \gamma x$$

$$\pm(Z_{oc}/Z_{sc})^{1/2} = \coth \gamma x$$

(F) When attenuation is small (except for $\theta \approx n\pi/2$, $n = 1, 2, 3, \cdots$)

$$\pm(Z_{sc}Z_{oc})^{1/2} = \pm(Y_{oc}/Y_{sc})^{1/2}$$

$$= \pm j[-(C_{oc}/C_{sc})]^{1/2}$$

$$\times [1 - j\tfrac{1}{2}(G_{oc}/\omega C_{oc} - G_{sc}/\omega C_{sc})]$$

where $Y_{oc} = G_{oc} + j\omega C_{oc}$ and $Y_{sc} = G_{sc} + j\omega C_{sc}$. The + sign is to be used before the radical when C_{oc} is positive, and the − sign when C_{oc} is negative.

(G) $R/|X|$ component of input impedance of low-attenuation nonresonant line:

Short-circuited line (except when $\theta \approx \pi/2, 3\pi/2$, etc.)

$$R_1/|X_1| = G_1/|B_1|$$

$$= |(\alpha/\beta)\theta(\tan\theta + \cot\theta) + (B_0/G_0)|$$

$$= |(\alpha/\beta)(2\theta/\sin 2\theta) + (B_0/G_0)|$$

Open-circuited line (except when $\theta \approx \pi, 2\pi$, etc.)

$$R_1/|X_1| = G_1/|B_1|$$

$$= |(\alpha/\beta)\theta(\tan\theta + \cot\theta) - (B_0/G_0)|$$

$$= |(\alpha/\beta)(2\theta/\sin 2\theta) - (B_0/G_0)|$$

VOLTAGE REFLECTION COEFFICIENT AND STANDING-WAVE RATIO

$$\rho = {}_rE/{}_fE = -{}_rI/{}_fI = (Z - Z_0)/(Z + Z_0)$$

$$= (Y_0 - Y)/(Y_0 + Y) = |\rho| \angle 2\psi$$

where ψ is the electrical angle to the nearest voltage maximum on the generator side of the point where ρ is measured (Figs. 3 and 4).

$$\rho_1 = \rho_2 \epsilon^{-2\alpha x} \angle -2\theta$$

$$|\rho_1| = |\rho_2| / 10^{A_0/10}$$

Voltage reflection coefficient in decibels

$$\rho_{dB} = -20 \log_{10} |1/\rho|$$

The minus sign is frequently omitted.

$$|\rho_{dB} \text{ at input}| = |\rho_{dB} \text{ at load}| + 2A_0$$

These two relationships and standing-wave ratio ver-

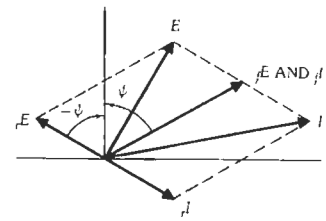

Fig. 3. Voltages and currents at time $t = 0$ at point ψ electrical degrees toward the load from a voltage standing-wave maximum.

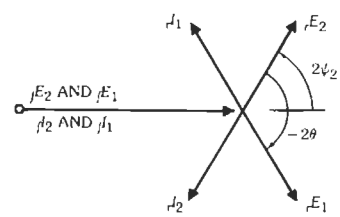

Fig. 4. Abbreviated diagram of a line with zero attenuation.

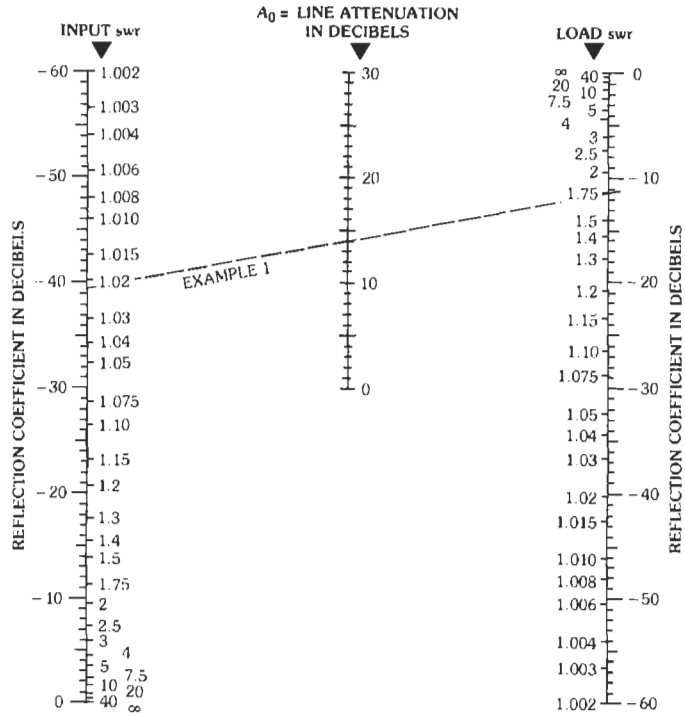

Fig. 5. Line attenuation and voltage reflection coefficient for low swr.

sus reflection coefficient in decibels are shown in Figs. 5 and 6.

$$Z = E/I = ({}_fE + {}_rE)/({}_fI + {}_rI)$$

$$= Z_0[(1 + \rho)/(1 - \rho)]$$

$$Z/Z_0 = (1 + \rho)/(1 - \rho)$$

$$= \frac{1 + jS\cot\psi}{S + j\cot\psi}$$

$$S = |E_{max}/E_{min}| = |I_{max}/I_{min}|$$

$$= \frac{|{}_fE| + |{}_rE|}{|{}_fE - |{}_rE|} = \frac{|{}_fI + |{}_rI|}{|{}_fI| - |{}_rI|}$$

$$= \frac{1 + |\rho|}{1 - |\rho|} = r_a = {g_a}^{-1} = g_b = {r_b}^{-1}$$

$$|\rho| = (S - 1)/(S + 1)$$

$$1/S_1 = \tanh[\alpha x + \tanh^{-1}(1/S_2)]$$

$$= \tanh[0.1151A_0 + \tanh^{-1}(1/S_2)]$$

(A) For high standing-wave ratio: When the ratio S_1 is greater than 6/1, then with 1 percent accuracy or better

$$1/S_1 = 1/S_2 + \alpha x = 1/S_2 + 0.115A_0$$

$$|\rho_{dB}| = 17.4/S$$

Subject to the conditions below, the standing-wave ratio is given by one or the other of

$$S \approx (1 + x^2)/r$$

$$S \approx (1 + b^2)/g$$

where

$$r + jx = Z/Z_0 = (1/R_0)[R - (B_0/G_0)X + jX]$$

$$g + jb = Y/Y_0 = (1/G_0)[G + (B_0/G_0)B + jB]$$

Conditions, for 1-percent accuracy

$$r < 0.1\ |x + 1/x| \quad \text{when } |x| > 0.3$$

$$g < 0.1\ |b + 1/b| \quad \text{when } |b| > 0.3$$

The boundary of the 1-percent-error region can be plotted on the Smith chart (Fig. 7) by use of the equation (for impedances)

$$|\cot\psi| = 0.1S^2/(S^2 - 1)^{1/2}$$

The same boundary line on the chart holds when reading admittances. The area outside the solid heart-shaped curve is where the swr equation is accurate to within 1 percent. The area outside the dashed curve is where the reciprocal of $r + jx$ lies in the permitted region.

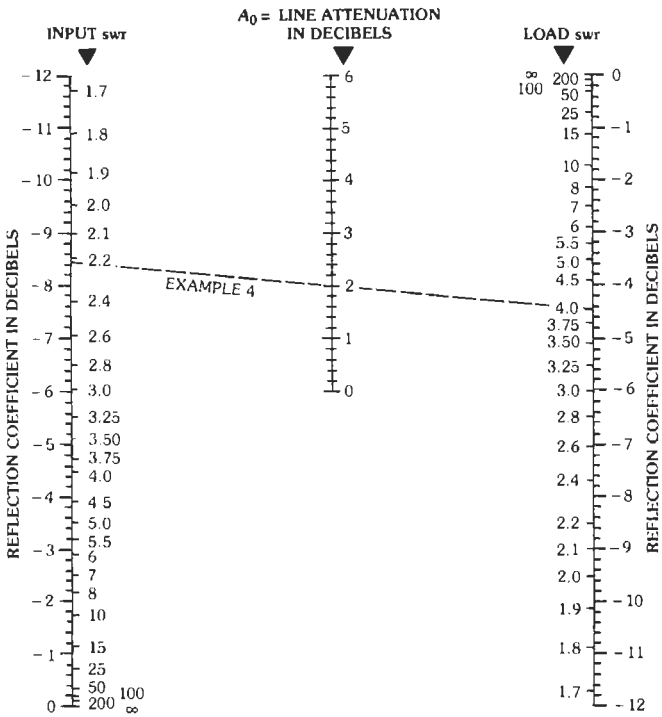

Fig. 6. Line attenuation and voltage reflection coefficient for high swr.

POWER AND EFFICIENCY

The net power flowing toward the load is

$$P = |_fE|^2 G_0[1 - |\rho|^2 + 2|\rho|\ (B_0/G_0)\ \sin 2\psi]$$

(A) When the angle B_0/G_0 of the characteristic admittance is negligibly small, the net power flowing toward the load is given by

$$P = G_0(|_fE|^2 - |_rE|^2)$$

$$= |_fE|^2\ G_0(1 - |\rho|^2)$$

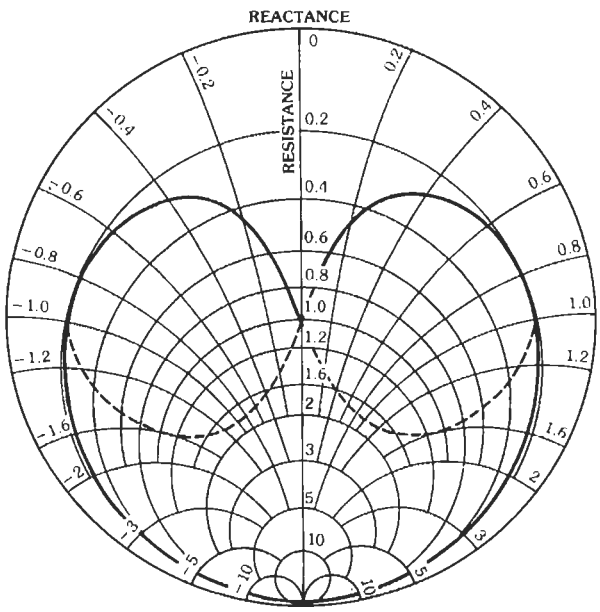

Fig. 7. Permitted region for use of equation $S \approx (1 + x^2)/r$. (*From W. W. Macalpine, "Computation of Impedance and Efficiency of Transmission Line with High Standing-Wave Ratio,"* Trans. of the AIEE, *Vol. 72, Part 1, p. 336, Fig. 2; July 1953.*)

$$= |E_{max}E_{min}|/R_0$$

$$P_1 = |_fE_2|^2\, G_0(\epsilon^{2(\alpha/\beta)\theta} - |\rho_2|^2\epsilon^{-2(\alpha/\beta)\theta})$$

(B) Efficiency, when B_0/G_0 is negligibly small:

$$\eta = P_2/P_1 = \frac{1 - |\rho_2|^2}{\epsilon^{2(\alpha/\beta)\theta} - |\rho_2|^2\epsilon^{-2(\alpha/\beta)\theta}}$$

$$= \eta_{max}\,\frac{1 - |\rho_2|^2}{1 - |\rho_2|^2\eta_{max}^2} = \frac{1 - |\rho_2|^2}{1 - |\rho_1|^2}\epsilon^{-2\alpha x}$$

$$= \frac{1/|\rho_2| - |\rho_2|}{1/|\rho_1| - |\rho_1|} = \frac{S_1 - 1/S_1}{S_2 - 1/S_2}$$

The maximum error in the above expressions is

$$\pm\ 100(S_2 - 1/S_2)B_0/G_0 \quad \text{percent}$$

$$\pm\ 4.34(S_2 - 1/S_2)B_0/G_0 \quad \text{decibels}$$

When the ratio S_1 is greater than 6/1:

$$\eta \approx S_1/S_2 \approx (1 + 0.115A_0S_2)^{-1}$$

When the load matches the line, $\rho_2 = 0$ and the efficiency is accurately

$$\eta_{max} = \exp[-2(\alpha/\beta)\theta] = \exp(-2\alpha x) = 10^{-A_0/10}$$

$$A - A_0 = 10\log_{10}(\eta_{max}/\eta)$$

Fig. 8 is drawn from the expressions in this paragraph.

(C) Efficiency, when swr is high:

$$\eta = \frac{P_2}{P_1} = \frac{R_2}{R_1}\left(\frac{1 + x_1^2}{1 + x_2^2}\right) = \frac{G_2}{G_1}\left(\frac{1 + b_1^2}{1 + b_2^2}\right)$$

$$= \frac{R_2}{R_0^2G_1}\left(\frac{1 + b_1^2}{1 + x_2^2}\right) = \frac{R_0^2G_2}{R_1}\left(\frac{1 + x_1^2}{1 + b_2^2}\right)$$

where R is the ohmic resistance and x is the normalized reactance, and similarly for G and b. It is important that the Rs and Gs be computed properly, using equations in the following section, headed "Transformation of Impedance on Lines with High SWR." Note the identity of the efficiency equations with the left-hand terms of the impedance equations. The conditions for accuracy are the same as stated for the impedance equations for high standing-wave ratio.

Example: Physical significance of the equation for efficiency at high standing-wave ratio: Subject to stated conditions, approximately, $x = \cot\psi$ and $I = I_{max}\sin\psi$.

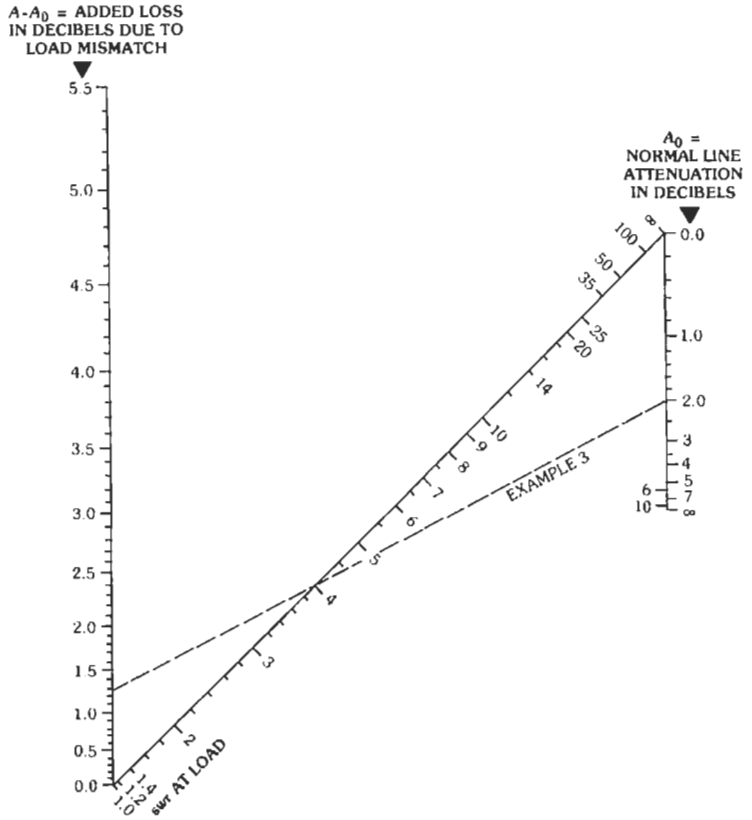

Fig. 8. Standing-wave loss factor. Due to load mismatch, an increase of loss in decibels as read from this figure must be added to normal line attenuation to give total dissipation loss in the line. This does not include mismatch loss due to any difference of line *input* impedance from the conjugate of the generator impedance [Paragraph **(B)** in section headed "Power and Efficiency"].

I_{max} = current standing-wave maximum, practically constant along line when standing-wave ratio > 6. Then

$$P = I^2R = I_{max}^2R/(1 + x^2)$$

When line length is greater than $\frac{1}{3}$ wavelength, then

$$\eta \approx [1 + 0.115A_0(1 + x_2^2)\,(R_0/R_2)]^{-1}$$

(D) Loss in nepers = $\frac{1}{2}\log_\epsilon(P_1/P_2) = 0.1151 \times$ (loss in decibels).

For a matched line, loss = attenuation = $(\alpha/\beta)\theta = \alpha x$ nepers.

Loss in decibels = $10\log_{10}(P_1/P_2) = 8.686 \times$ (loss in nepers).

When $2(\alpha/\beta)\theta$ is small

$$P_1/P_2 = 1 + 2(\alpha/\beta)\theta\,\frac{1 + |\rho_2|^2}{1 - |\rho_2|^2}$$

and

decibels/wavelength

$$= 10\log_{10}\left(1 + 4\pi(\alpha/\beta)\,\frac{1 + |\rho_2|^2}{1 - |\rho_2|^2}\right)$$

(E) For the same power flowing in a line with standing waves as in a matched or "flat" line:

$$P = |E_{flat}|^2/R_0$$

$$|E_{max}| = |E_{flat}|\,S^{1/2}$$

$$|E_{min}| = |E_{flat}|\,/S^{1/2}$$

$$|_fE| = \tfrac{1}{2}\,|E_{flat}|\,(S^{1/2} + S^{-1/2})$$

$$|_rE| = \tfrac{1}{2}\,|E_{flat}|\,(S^{1/2} - S^{-1/2})$$

When the loss is small, so that S is nearly constant over the entire length, then per half wavelength

$$\text{(power loss)/(loss for flat line)} \approx \tfrac{1}{2}(S + 1/S)$$

(F) The power dissipation per unit length, for unity standing-wave ratio, is

$$\Delta P_d/\Delta x = 2\alpha P$$

$$\frac{\text{(dissipation in watts/foot)}}{\text{(line power in kilowatts)}} = 2.30\ \text{(decibels/100 feet)}$$

where the decibels/100 feet is the normal attenuation for a matched line.

When swr > 1, the dissipation at a current maximum is S times that for swr = 1, assuming the attenuation to be due to conductor loss only. The multiplying factor for local heating reaches a minimum value equal to $(S + 1/S)/2$ all along the line when conductor loss and dielectric loss are equal.

(G) Further considerations on power and efficiency are given in the section headed "Mismatch and Transducer Loss" (p. 29-13).

TRANSFORMATION OF IMPEDANCE ON LINES WITH HIGH SWR*

When standing-wave ratio is greater than 10 or 20, resistance cannot be read accurately on the Smith chart, although it is satisfactory for reactance.

Use the equation (Fig. 9)

$$R_1 = R_2\,\frac{1 + x_1^2}{1 + x_2^2} + R_0(1 + x_1^2)$$

$$\times\left[(\alpha/\beta)\theta + (B_0/G_0)\left(\frac{x_1}{1 + x_1^2} - \frac{x_2}{1 + x_2^2}\right)\right]$$

where,

R = ohmic resistance,
$x = X/R_0$ = normalized reactance.

When admittance is given or required, similar equations can be written with the aid of the following tabulation. The top row shows the terms in the above equation.

R_1	R_2	x_1^2	x_2^2	R_0	x_1	$-x_2$
G_1	G_2	b_1^2	b_2^2	$1/R_0$	$-b_1$	b_2
R_1	$G_2R_0^2$	x_1^2	b_2^2	R_0	x_1	b_2
G_1	R_2/R_0^2	b_1^2	x_2^2	$1/R_0$	$-b_1$	$-x_2$

For transforming R to G or vice versa:

$$R = R_0^2G\,|x/b|$$

where x and b are read on the Smith chart in the usual manner for transforming impedances to admittances.

* W. W. Macalpine, "Computation of Impedance and Efficiency of Transmission Lines with High Standing-Wave Ratio," *Transactions of the AIEE*, Vol. 72, Part I, pp. 334–339; July 1953; also *Electrical Communication*, Vol. 30, pp. 238–246; September 1953.

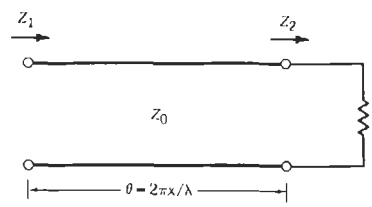

Fig. 9. Transmission-line impedances.

The conditions for roughly 1-percent accuracy of the equations are:

Standing-wave ratio is greater than 6/1 at input; $|B_0/G_0| < 0.1$; $r + jx$ or $g + jb$ (whichever is used, at each end of line) meet the requirements stipulated in paragraph (A) of the section headed "Voltage Reflection Coefficient and Standing-Wave Ratio" (p. 29-8); and the line parameters and given impedance are known to 1-percent accuracy.

When line length is greater than $\frac{1}{3}$ wavelength, then

$$R_1 \approx R_2[(1 + x_1^2)/(1 + x_2^2)] + 0.115A_0R_0(1 + x_1^2)$$

$$\frac{R_1/R_0}{1 + x_1^2} \approx \frac{R_2/R_0}{1 + x_2^2} + (\alpha/\beta)\theta$$

The equation for resistance transformation is derived from expressions for high swr in paragraph (A), just referred to.

Example: A load of $0.4 - j2000$ ohms is fed through a length of RG-218/U cable at a frequency of 2.0 megahertz. What are the input impedance and the efficiency for a 24-foot length of cable and for a 124-foot length?

For RG-218/U, the attenuation at 2.0 megahertz is 0.095 decibel/100 feet (see Fig. 29). The dielectric constant $\epsilon = 2.26$, and F_p is negligibly small. Then, by equations in (**B**) and (**C**), p. 29-5:

$$B_0/G_0 = \alpha/\beta = (\text{dB}/100\text{ ft})\ (\lambda_{\text{meters}})/1663$$

$$= [0.095 \times 150/(2.26)^{1/2}]/1663 = 0.0057$$

$$x/\lambda = xf\epsilon^{1/2}/984 = 24 \times 2.0 \times 1.5/984 = 0.073$$

$$\theta = 2\pi x/\lambda = 0.46 \text{ radian for 24-foot length}$$

while

$$x/\lambda = 0.38 \text{ and } \theta = 2.4 \text{ for 124-foot length}$$

$$Z_2/Z_0 \approx (0.4 - j2000)/50 = 0.008 - j40$$

For the 24-foot length, by the Smith chart

$$x_1 = X_1/Z_0 = -1.9, \text{ or } X_1 \approx -95 \text{ ohms}$$

The conditions for accuracy of the resistance transformation equation are satisfied. Now

$$1 + x_1^2 = 1 + (1.9)^2 = 4.6$$

$$1 + x_2^2 = 1 + (40)^2 = 1600$$

$$R_1 = 0.4(4.6/1600) + 50 \times 4.6 \times 0.0057 \times [0.46 - (1.9/4.6) + (40/1600)]$$

$$= 0.0012 + 0.105 = 0.106 \text{ ohm}$$

The efficiency equation in paragraph (**C**) on p. 29-11 gives

$$\eta = 0.0012/0.106 = 0.0113, \text{ or } 1.1 \text{ percent}$$

where the 0.0012 figure is taken directly from the first quantity on the right-hand side of the computation of the value of R_1.

Similarly, for the 124-foot length, $x_1 = 1.1$, $X_1 = 55$ ohms, $1 + x_1^2 = 2.21$, $R_1 = 0.00055 + 1.83 = 1.83$ ohms

$$\eta = 0.00055/1.83 = 3.1 \times 10^{-4}, \text{ or } 0.03 \text{ percent}$$

Tabulating the results,

Length (feet)	Input Impedance (ohms)	Efficiency (%)	Loss (dB)
24	$0.106 - j95$	1.1	19.6
124	$1.8 + j55$	0.03	35

The considerably greater loss for 124 feet compared with 24 feet is because the transmission passes through a current maximum where the loss per unit length is much higher than at a current minimum.

MISMATCH AND TRANSDUCER LOSS

Figs. 5, 6, and 8, plus the equations in this section, permit the calculation of loss when impedance mismatch exists in a transmission-line system; also, the change in standing-wave ratio along a line due to attenuation can be determined.

One End Mismatched

When either generator or load impedance is mismatched to the Z_0 of the line and the other is matched (Fig. 10)

$$(\text{mismatch loss}) = P_m/P$$

$$= 1/(1 - |\rho|^2) = (S + 1)^2/4S \qquad \text{(Eq. 1)}$$

where,

P = power delivered to load,
P_m = power that would be delivered were system matched,

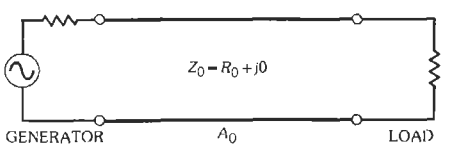

Fig. 10. Transmission line with generator and load.

S = standing-wave ratio of mismatched impedance referred to Z_0.

Compared with an ideal transducer (ideal matching network between generator and load)

$$(\text{transducer loss}) = A_0 + 10 \log_{10}(P_m/P) \text{ decibels} \quad \text{(Eq. 2)}$$

where A_0 = normal attenuation of line.

Generator and Load Mismatched

$$|X_0/R_0| \ll 1$$

When mismatches exist at both ends of the system (Fig. 11)

$$(\text{mismatch loss at input}) = P_m/P = [(R_g + R_1)^2 + (X_g + X_1)^2]/4R_gR_1 \quad \text{(Eq. 3)}$$

$$(\text{transducer loss}) = (A - A_0) + A_0 + 10 \log_{10}(P_m/P) \text{ decibels} \quad \text{(Eq. 4)}$$

where $(A - A_0)$ = standing-wave loss factor obtained from Fig. 8 for S = standing-wave ratio at load.

Notes on Equation (3)

Equation (3) reduces to Eq. (1) when X_g and/or X_1 is zero.

In Eq. (3), the impedances can be either ohmic or normalized with respect to any convenient Z_0.

When determining input impedance $R_1 + jX_1$ on a Smith chart, adjust the radius arm for S at the input, determined from that at the output by the aid of Figs. 5 and 6.

For the junction of two admittances, use Eq. (3) with G and B substituted for R and X, respectively.

Equation (3) is valid for a junction in any linear passive network. The same is true of Eq. (1) when at least one of the impedances concerned is purely resistive. Determine S as if one impedance were that of a line.

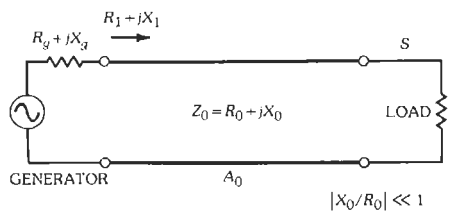

Fig. 11. Transmission line with mismatch at both ends.

Examples

Example 1: The swr at the load is 1.75, and the line has an attenuation of 14 decibels. What is the input swr?

Using Fig. 5, set a straightedge through the 1.75 division on the "load swr" scale and the 14-decibel point on the middle scale. Read the answer on the "input swr" scale, which the straightedge intersects at 1.022.

Example 2: Readings on a reflectometer show the reflected wave to be 4.4 decibels below the incident wave. What is the swr?

Using Fig. 6, locate the reflection coefficient 4.4 (or −4.4) decibels on either outside scale. Beside it, on the same horizontal line, read swr = 4.0+.

Example 3: A 50-ohm line is terminated with a load of 200 + *j*0 ohms. The normal attenuation of the line is 2.00 decibels. What is the loss in the line?

Using Fig. 8, align a straightedge through the points $A_0 = 2.0$ and swr = 4.0. Read $A - A_0 = 1.27$ decibels on the left-hand scale. Then the transmission loss in the line is

$$A = 1.27 + 2.00 = 3.27 \text{ decibels.}$$

This is the dissipation, or heat loss, as opposed to the mismatch loss at the input (example 4).

Example 4: In the preceding example, suppose the generator impedance is 100 + *j*0 ohms, and the line is 5.35 wavelengths long. What is the mismatch loss between the generator and the line?

According to example 3, the load swr = 4.0 and the line attenuation is 2.0 decibels. Then, using Fig. 6, the input swr is found to be 2.22. On the Smith chart, locate the point corresponding to 0.35 wavelength toward the generator from a voltage maximum, and swr = 2.22. Read the input normalized impedance as 0.62 + *j*0.53 with respect to Z_0 = 50 ohms. Now the mismatch loss at the input can be determined by use of Eq. (3). However, since the generator impedance is nonreactive, Eq. (1) can be used if desired. Refer to the following paragraph and to the "Notes on Equation (3)" above.

With respect to 100 + *j*0 ohms, the normalized impedance at the line input is 0.31 + *j*0.265, which gives swr = 3.5 according to the Smith chart. Then by Eq. (1), $P_m/P = 1.45$, giving a mismatch loss of 1.62 decibels. The transducer loss is found by using the results of examples 3 and 4 in Eq. (4). This is

$$1.27 + 2.00 + 1.62 = 4.9 \text{ decibels}$$

ATTENUATION AND RESISTANCE OF TRANSMISSION LINES AT ULTRAHIGH FREQUENCIES

The normal or matched-line attenuation in decibels/100 feet is

$$A_{100} = 4.34R_t/Z_0 + 2.78f\epsilon^{1/2}F_p$$

where the total line resistance/100 feet (for perfect surface conditions of the conductors) is, for copper coaxial line

$$R_t = 0.1(1/d + 1/D)f^{1/2}$$

and for copper 2-wire open line

$$R_t = (0.2/d)f^{1/2}$$

where,

D = diameter of inner surface of outer coaxial conductor in inches,
d = diameter of conductors (coaxial-line center conductor) in inches,
f = frequency in megahertz,
ϵ = dielectric constant relative to air,
F_p = power factor of dielectric at frequency f.

For other conductor materials, the resistance of a conductor of diameter d (and similarly for D) is

$$0.1(1/d)\ (f\mu_r\rho/\rho_{Cu})^{1/2} \text{ ohms/100 feet}$$

where,

μ_r = relative permeability of material (1 for nonmagnetic materials),
ρ = resistivity of material at any temperature,
ρ_{Cu} = resistivity of copper at 20 °C (1.724 microhms-centimeter),
f = frequency in megahertz.

RESONANT LINES

Symbols:

f_0 = resonance frequency in megahertz
G_a = conductance load in mhos at voltage standing-wave maximum, equivalent to some or all of the actual loads
k = coefficient of coupling
n = integral number of quarter wavelengths
$p = k^2Q_{1s}Q_{2s}$ = load transfer coefficient or matching factor
P_c = power converted into heat in resonator
P_m = power available from generator in watts $= E_{oc}^2/4R_{gen}$
P_x = power transferred when load is directly connected to generator (for single resonators); or an analogous hypothetical power (for two coupled resonators)
Q = figure of merit of a resonator as it exists, whether loaded or unloaded
Q_d = doubly loaded Q (all loads being included)
Q_s = singly loaded Q (all loads included except one). For a pair of coupled resonators, Q_{1s} is the value for the first resonator when isolated from the other. (Similarly for Q_{2s})
Q_u = unloaded Q
R_b = resistance load in ohms at voltage standing-wave minimum, equivalent to some or all of the actual loads
R_u = resistance similar to R_b except for unloaded resonator
R_1 = generator resistance, referred to short-circuited end
R_2 = load resistance
$S_x = R_1/R_2$ or R_2/R_1 = mismatch factor between generator and load
Z_{10} = characteristic impedance of the first of a pair of resonators
θ_1 = electric angle from a voltage standing-wave minimum point

(A) Q of a resonator (electrical, mechanical, or any other) is

$$Q = 2\pi \frac{\text{(energy stored)}}{\text{(energy dissipated per cycle)}}$$

$$= 2\pi f \frac{\text{(energy stored)}}{\text{(power dissipation)}}$$

In a freely oscillating system, the amplitude decays exponentially.

$$I = I_0 \exp(-\pi ft/Q)$$

(B) Unloaded Q of a resonant line:

$$Q_u = \beta/2\alpha$$

the line length being n quarter-wavelengths, where n is a small integer. The losses in the line are equivalent to those in a hypothetical resistor at the short-circuited end (**D**) in the section headed "Impedance and Admittance")

$$R_u = n\pi Z_0/4Q_u$$

(C) Loaded Q of a resonant line (Fig. 12):

$$Q^{-1} = Q_u^{-1} + (4R_b/n\pi Z_0) + (4G_a/n\pi Y_0)$$

$$= (4/n\pi Z_0)\ (R_u + R_b + G_a/Y_0^2)$$

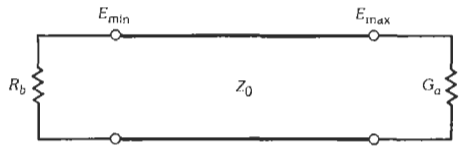

Fig. 12. Quarter-wave line with loadings at nominal short-circuit and open-circuit points.

All external loads can be referred to one end and represented by either R_b or G_a as in Fig. 13.

The total loading is the sum of all the individual loadings.

General conditions:

$$R_b/Z_0 = G_a/Y_0 << 1.0$$

or, roughly, $Q > 5$.

(D) Input admittance and impedance:

The converse of the equations for Fig. 13 can be used at the resonance frequency. Then R or G is the input impedance or admittance, while

$$R_b = n\pi Z_0/4Q_s$$

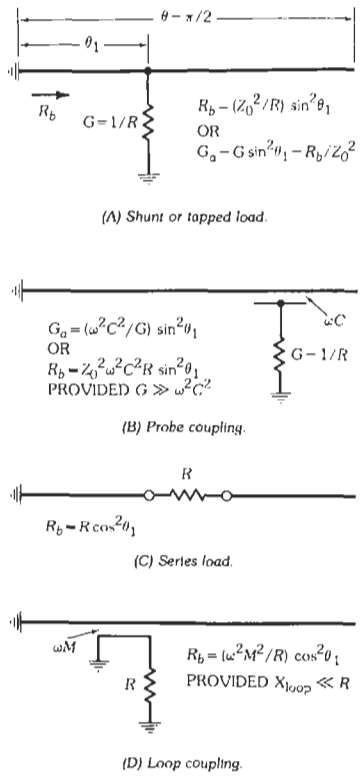

Fig. 13. Typical loaded quarter-wave sections with apparent R_b equivalent to the loading at distance θ_1 from voltage-minimum point of the line. Outer conductor not shown.

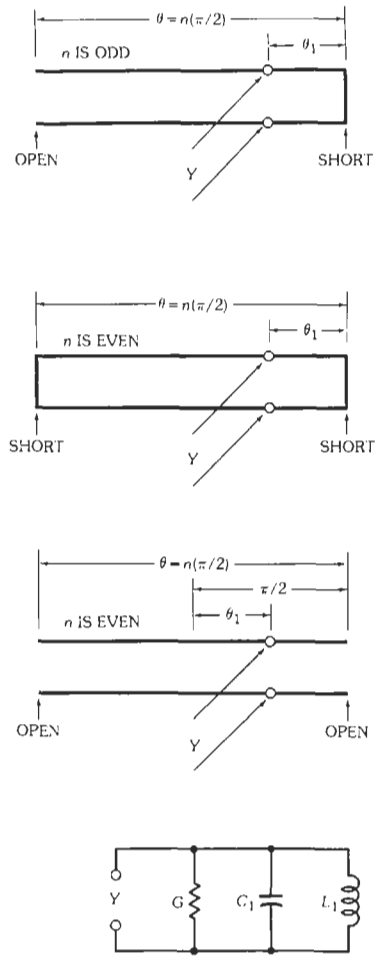

Fig. 14. Resonant transmission lines and their equivalent lumped circuit.

where Q_s = singly loaded Q with the losses and all the loads considered except that at the terminals where input R or G is being measured.

In the vicinity of the resonance frequency, the input admittance when looking into a line at a tap point θ_1 in Fig. 14 is approximately

$$Y = G + jB = \frac{n\pi Y_0}{4 \sin^2\theta_1}\left(Q_s^{-1} + j2\frac{f - f_0}{f_0}\right)$$

provided

$$|f - f_0|/f_0 << 1.0$$

and

$$|[\theta(f - f_0)/f_0] \cot\theta_1| << 1.0$$

where $\theta = n\pi/2$ = length of line at f_0. The equation is

not valid when $\theta_1 \approx 0$, π, 2π, etc., except that it is good near the short-circuited end when $f - f_0 \approx 0$.

Such a resonant line is approximately equivalent to a lumped *LCG* parallel circuit, where

$$\omega_0^2 L_1 C_1 = (2\pi f_0)^2 L_1 C_1 = 1$$

Admittance of the equivalent circuit is

$$Y = G + j[\omega C_1 - (1/\omega L_1)]$$

$$\approx \omega_0 C_1 \{Q_s^{-1} + j2[(f - f_0)/f_0]\}$$

Then, subject to the conditions stated above

$$L_1 = (4 \sin^2\theta_1)/n\pi\omega_0 Y_0$$

$$C_1 = n\pi Y_0/(4\omega_0 \sin^2\theta_1) = nY_0/(8f_0 \sin^2\theta_1)$$

$$G = n\pi Y_0/(4Q_s \sin^2\theta_1)$$

$$Q_s = \omega_0 C_1/G = 1/\omega_0 L_1 G$$

Similarly, the input impedance at a point in series with the line (Figs. 13C and D) is

$$Z = R + jX = \frac{n\pi Z_0}{4 \cos^2\theta_1}\left(Q_s^{-1} + j2\frac{f - f_0}{f_0}\right)$$

provided

$$|f - f_0|/f_0 \ll 1.0$$

and

$$|\theta[(f - f_0)/f_0] \tan\theta_1| \ll 1.0$$

The equation is not valid when $\theta_1 \approx \pi/2$, $3\pi/2$, etc.

The voltage standing-wave ratio at resonance, on the generator (Fig. 15), is

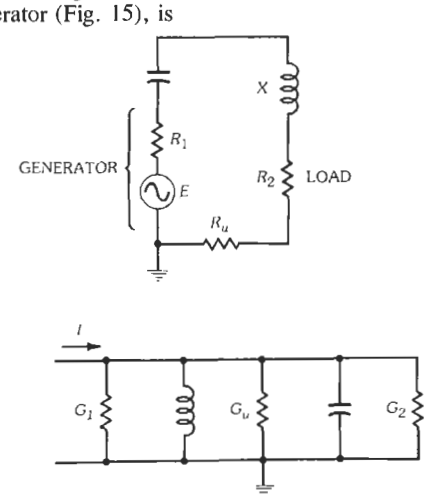

Fig. 15. Equivalent circuits of a resonant line (or a lumped tuned circuit) as seen at the short-circuited and open-circuited ends. All the power equations are good for either lumped or distributed parameters.

$$S = (R_2 + R_u)/R_1$$

$$= \frac{(R_2/R_1)Q_u + Q_d}{Q_u - Q_d}$$

When $R_1 = R_2$

$$S = \frac{1 + Q_d/Q_u}{1 - Q_d/Q_u}$$

$$\rho = Q_d/Q_u$$

(E) Insertion loss (Fig. 15): At resonance, for either a distributed or a lumped-constant device

(dissipation loss)

$$= 10 \log_{10}(P_x/P_{out})$$

$$= 20 \log_{10}[1/(1 - Q_d/Q_u)]$$

$$\approx 20 \log_{10}(1 + Q_d/Q_u)$$

$$\approx 8.7 Q_d/Q_u \text{ decibels}$$

(mismatch loss)

$$= 10 \log_{10}(P_m/P_x)$$

$$= 10 \log_{10}[(1 + S_x)^2/4S_x] \text{ decibels}$$

The dissipation loss also includes a small additional mismatch loss due to the presence of the resonator. The error in the form $20 \log_{10}(1 + Q_d/Q_u)$ is about twice that of the form $8.7Q_d/Q_u$. The last expression $(8.7Q_d/Q_u)$ is in error compared with the first, $20\log_{10}[1/(1 - Q_d/Q_u)]$, by roughly $-50(Q_d/Q_u)$ percent for $(Q_d/Q_u) < 0.2$.

The selectivity is given on page 8-7, where $Q = Q_d$. That equation is accurate over a smaller range of $(f - f_0)$ for a resonant line than it is for a single tuned circuit.

At resonance*

$$P_{out}/P_{in} = R_2/(R_u + R_2)$$

$$= \frac{Q_u - Q_d}{Q_u + (R_1/R_2)Q_d} = 1 - Q_s/Q_u$$

where Q_s is for the resonator loaded with R_2 only.

The maximum power transfer, for fixed Q_u, Q_d, and Z_0 occurs when $R_1 = R_2$. Then

* When the line is resonated by a reactive load ($\theta \neq n\pi/2$), it is frequently preferable to use the resistance form of the equation. Compute R_u by the method in the section "Transformation of Impedance on Lines With High SWR," or the section "Impedance and Admittance," where $Z_0 = R_0(1 - jB_0/G_0)$.

$$P_{out}/P_{in} = (Q_u - Q_d)/Q_u + Q_d) = 1 - Q_s/Q_u$$

$$P_{out}/P_m = (1 - Q_d/Q_u)^2$$

$$P_{in}/P_m = 1 - (Q_d/Q_u)^2$$

When the generator R_1 or G_1 is negligibly small (then $Q = Q_s = Q_d$)

$$(P_{in}/P_{out})_s = Q_u/(Q_u - Q)$$

(F) Power dissipation (= P_c):

$$P_c/P_m = \frac{4(Q_d/Q_u)\,(1 - Q_d/Q_u)}{1 + R_2/R_1}$$

For matching input and output ($R_1 = R_2$)

$$P_c/P_m = 2(Q_d/Q_u)(1 - Q_d/Q_u)$$

$$\approx 2Q_d/Q_u \quad (\text{for } Q_d << Q_u)$$

$$P_c/P_{out} = 2Q_d/(Q_u - Q_d)$$

$$P_c/P_{in} = 2Q_d/(Q_u + Q_d)$$

For generator matched by load plus cavity

$$P_c/P_m = 2Q_d/Q_u$$

When the generator R_1 or G_1 is negligibly small

$$(P_c/P_{out})_s = Q/(Q_u - Q)$$

$$(P_c/P_{in})_s = Q_s/Q_u$$

(G) Voltage and current: At the current-maximum point of an n-quarter-wavelength resonant line

$$I_{sc} = 4\left[\frac{P_m Q_d(1 - Q_d/Q_u)}{(1 + R_2/R_1)n\pi Z_0}\right]^{1/2}, \text{ rms amperes}$$

$$= 4\left[\frac{P_m Q_d}{\{1 + [(R_2 + R_u)/R_1]\}n\pi Z_0}\right]^{1/2}$$

When the generator R_1 or G_1 is negligibly small

$$I_{sc} = 2\left[\frac{P_s Q_s}{n\pi Z_0(R_2 + R_u)/R_s}\right]^{1/2}$$

where,

P_s = rated power of generator,
R_s = rated load impedance as transformed into current-maximum point of cavity.

$$I = I_{sc}\cos\theta_1$$

$$E = Z_0 I_{sc}\sin\theta_1$$

The voltage and current are in quadrature time phase. When $R_1 = R_2 + R_u$ and $n = 1$

$$I_{sc} \approx (8P_m Q_d/\pi Z_0)^{1/2}$$

In a lumped-constant tuned circuit

$$I = 2\left[\frac{P_m Q_d(1 - Q_d/Q_u)}{(1 + R_2/R_1)X}\right]^{1/2}$$

(H) Pair of coupled resonators (Fig. 16):

With inductive coupling near the short-circuited end of a pair of quarter-wave resonant lines

$$k = (4/\pi)\omega M/(Z_{10}Z_{20})^{1/2}$$

For coupling through a lossless quarter-wavelength line, inductively coupled near the short-circuited ends of the resonators (Fig. 16D):

$$k = \frac{4\omega^2 M_1 M_2}{\pi Z_0(Z_{10}Z_{20})^{1/2}}$$

Probe coupling near top (Fig. 16C):

$$k = (4/\pi)\omega C_{12}(Z_{10}Z_{20})^{1/2}\sin\theta_1\sin\theta_2$$

For lumped-constant coupled circuits, p and k are defined on pp. 8-6 and 8-2, respectively.

In either lumped or distributed resonators

(dissipation loss)

$$= 10\log_{10}(P_x/P_{out})$$

$$= 10\log_{10}[1/(1 - Q_{1s}/Q_{1u})\,(1 - Q_{2s}/Q_{2u})]$$

$$\approx 20\log_{20}[1/(1 - Q_s/Q_u)]$$

$$\approx 20\log_{10}(1 + Q_s/Q_u)$$

$$\approx 8.7Q_s/Q_u \text{ decibels}$$

where

$$Q_s/Q_u = [(Q_{1s}/Q_{1u})\,(Q_{2s}/Q_{2u})]^{1/2}$$

provided (Q_{1s}/Q_{1u}) and (Q_{2s}/Q_{2u}) do not differ by a ratio of more than 4 to 1, and neither exceeds 0.2.

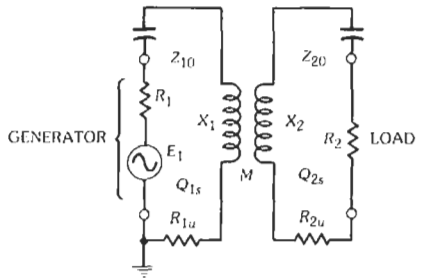
(mismatch loss at f_0)

$$= 10\log_{10}(P_m/P_x)$$

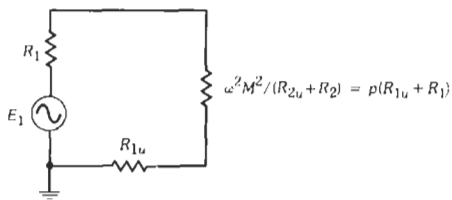
$$= 10\log_{10}[(1 + p)^2/4p]\text{decibels}.$$

Equations and curves for selectivity are given on pp. 8-7 and 8-8, where $Q = Q_s$.

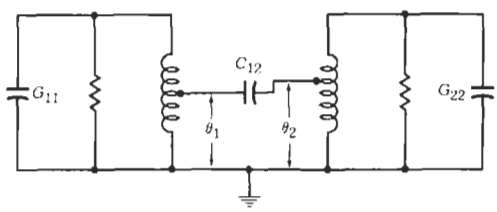
At the peaks, when $p \geq 1$, the mismatch loss is zero,



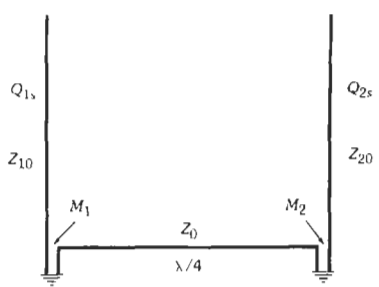
(A) Equivalent circuit with resistances as seen at the short-circuited end.



(B) Equivalent circuit of first resonator at resonance frequency.



(C) Probe-coupled or aperture-coupled resonators.



(D) Quarter-wavelength line coupling.

Fig. 16. Two coupled resonators.

except for some that is included in the dissipation loss.

Input voltage standing-wave ratio at f_0 for equal or unequal resonators:

$$S = \frac{p + Q_{1s}/Q_{1u}}{1 - Q_{1s}/Q_{1u}}$$

At the peak frequencies ($p \geq 1$) for equal or nearly equal resonators:

$$S = \frac{1 + Q_{1s}/Q_{1u}}{1 - Q_{1s}/Q_{1u}}$$

Similar equations, using subscript 2 instead of 1, apply at the output.

When the resonators are isolated, each one presents to the generator or load an swr of

$$S = (Q_u/Q_s) - 1$$

The power dissipation in either lumped or distributed (quarter-wave) devices, where the two resonators are not necessarily identical, but $Q_s << Q_u$, is

$$P_{1c} = I_{1sc}{}^2 R_{1u}[4/(1 + p)^2]P_m Q_{1s}/Q_{1u}$$

$$P_{2c} = [4p/(1 + p)^2]P_m Q_{2s}/Q_{2u}$$

These equations and those below for the currents assume that P_m is concentrated at f_0.

The currents in quarter-wave resonant lines, when $Q_s << Q_u$.

$$I_{1sc} = [4/(1 + p)](P_m Q_{1s}/\pi Z_{10})^{1/2}$$

$$I_{2sc}/I_{1sc} = (pZ_{10}Q_{2s}/Z_{20}Q_{1s})^{1/2}$$

Similarly, for a pair of tuned circuits at resonance, when $Q_s << Q_u$.

$$I_1 = [2/(1 + p)]\,(P_m Q_{1s}/X_1)^{1/2}$$

$$I_2/I_1 = (pX_1Q_{2s}/X_2Q_{1s})^{1/2}$$

QUARTER-WAVE MATCHING SECTIONS

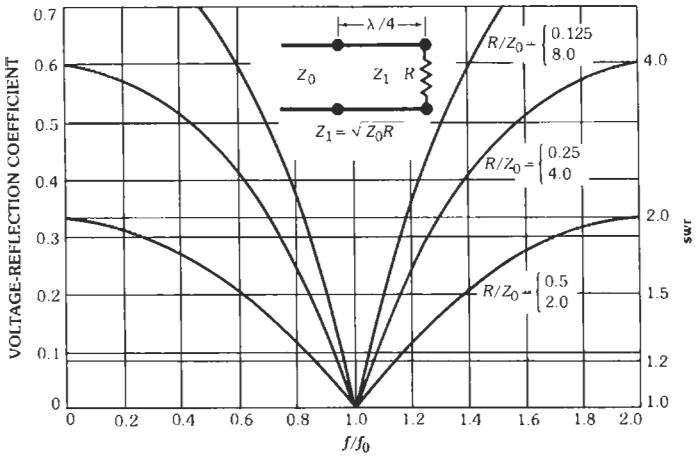
Fig. 17 shows how voltage-reflection coefficient and standing-wave ratio (swr) vary with frequency f when quarter-wave matching lines are inserted between a line of characteristic impedance Z_0 and a load of resistance R. The symbol f_0 represents the frequency for which the matching sections are exactly one-quarter wave-length ($\lambda/4$) long.

IMPEDANCE MATCHING WITH SHORTED STUB

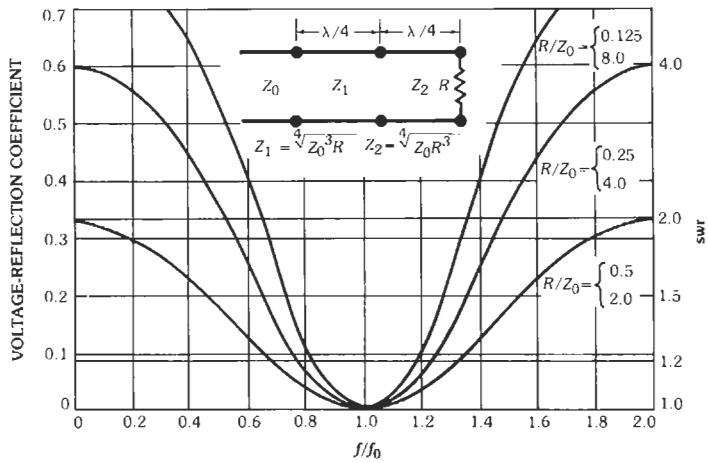
The use of a shorted stub for impedance matching is illustrated in Fig. 18.

IMPEDANCE MATCHING WITH OPEN STUB

The use of an open stub for impedance matching is illustrated in Fig. 19.



(A) One section.



(B) Two sections.

Fig. 17. Quarter-wave matching sections.

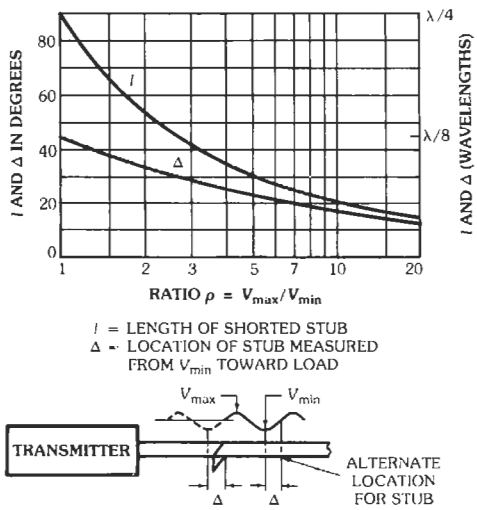


Fig. 18. Impedance matching with shorted stub.

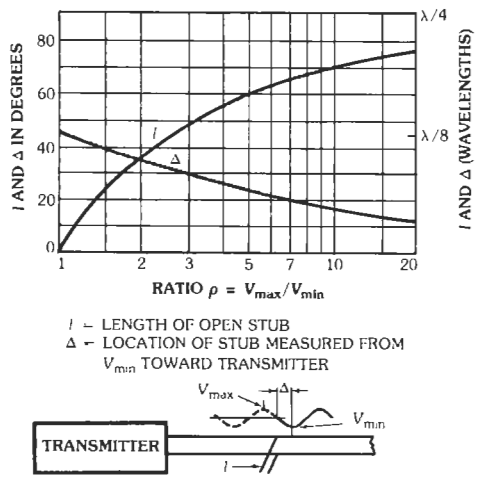

Fig. 19. Impedance matching with open stub.

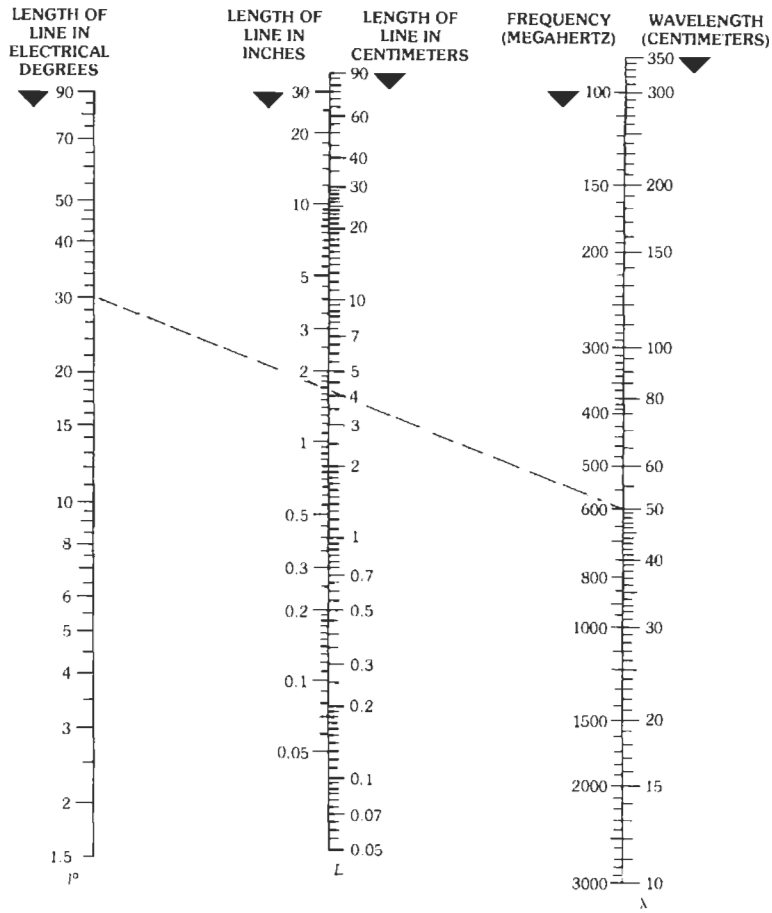

Fig. 20. Determination of length of transmission line.

LENGTH OF TRANSMISSION LINE

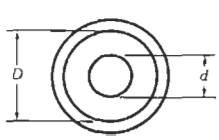
Fig. 20 relates the actual length of line in centimeters and inches to the length in electrical degrees and the frequency, provided that the velocity of propagation on the transmission line is equal to that in free space. The length is given on the L-scale intersection by a line between λ and l°, where

$$l^\circ = \frac{360L \text{ in centimeters}}{\lambda \text{ in centimeters}}$$

Example: $f = 600$ megahertz, $l^\circ = 30$, length $L = 1.64$ inches or 4.2 centimeters.

CHARACTERISTIC IMPEDANCE OF LINES

A. Single coaxial line (See also Fig. 21.)



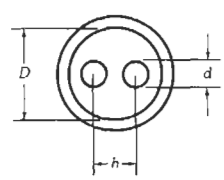
$$Z_0 = (138/\epsilon^{1/2}) \log_{10} (D/d)$$

$$= (60/\epsilon^{1/2}) \log_e (D/d)$$

ϵ = dielectric constant

= 1 in air

B. Balanced shielded line



For $D >> d$, $h >> d$

$$Z_0 = (276/\epsilon^{1/2}) \log_{10}\{2\nu[(1 - \sigma^2)/(1 + \sigma^2)]\}$$

$$= (120/\epsilon^{1/2}) \log_e\{2\nu[(1 - \sigma^2)/(1 + \sigma^2)]\}$$

$\nu = h/d \qquad \sigma = h/D$

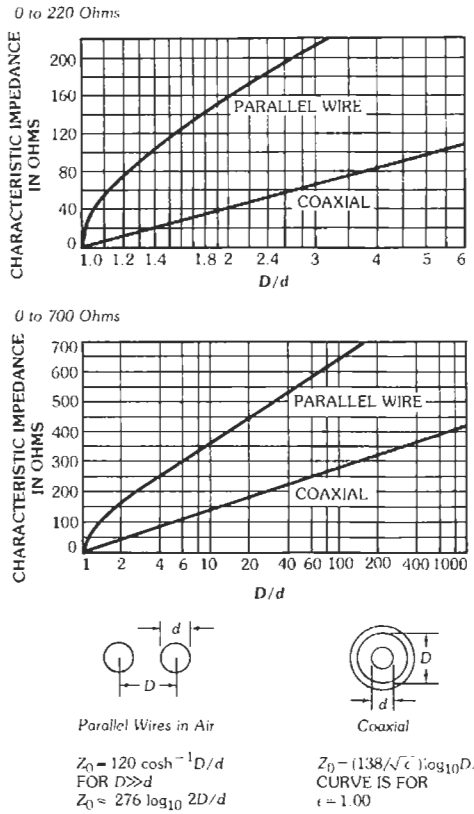


Fig. 21. Characteristic impedance of transmission lines.

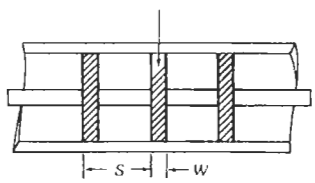
C. Beads—dielectric ϵ_1

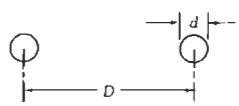


For lines *A* and *B*, if insulating beads are used at frequent intervals, call new characteristic impedance Z_0'

$$Z_0' = Z_0/\{1 + [(\epsilon_1/\epsilon) - 1](W/S)\}^{1/2}$$

$$W \ll S \ll \lambda/4$$

D. Open two-wire line in air (See also Fig. 21.)

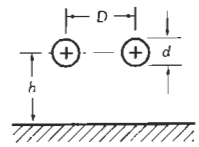


$$Z_0 = 120 \cosh^{-1}(D/d)$$

$$\approx 276 \log_{10}(2D/d)$$

$$\approx 120 \log_e(2D/d)$$

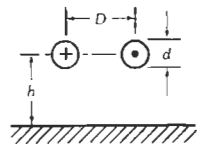
E. Wires in parallel, near ground



For $d \ll D$, h

$$Z_0 = (69/\epsilon^{1/2}) \log_{10}\{(4h/d)[1 + (2h/D)^2]^{1/2}\}$$

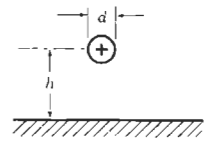
F. Balanced, near ground



For $d \ll D$, h

$$Z_0 = (276/\epsilon^{1/2}) \log_{10}\{(2D/d)\,[1 + (D/2h)^2]^{-1/2}\}$$

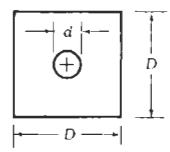
G. Single wire, near ground



For $d \ll h$

$$Z_0 = (138/\epsilon^{1/2}) \log_{10}(4h/d)$$

H. Single wire, square enclosure



$$Z_0 \approx [138 \log_{10}\rho + 6.48 - 2.34A - 0.48B - 0.12C]\epsilon^{-1/2}$$

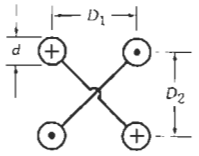
where $\rho = D/d$

$$A = (1 + 0.405\rho^{-4})/(1 - 0.405\rho^{-4})$$

$$B = (1 + 0.163\rho^{-8})/(1 - 0.163\rho^{-8})$$

$$C = (1 + 0.067\rho^{-12})/(1 - 0.067\rho^{-12})$$

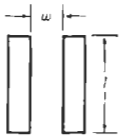
I. Balanced 4-wire



For $d \ll D_1, D_2$

$$Z_0 = (138/\epsilon^{1/2}) \log_{10}\{(2D_2/d)[1 + (D_2/D_1)^2]^{-1/2}$$

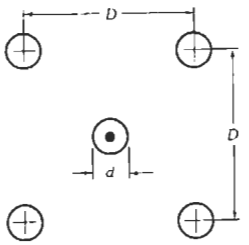
J. Parallel-strip line



$$w/l < 0..1$$

$$Z_0 \approx 377(w/l)$$

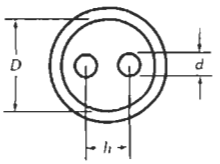
K. Five-wire line



For $d \ll D$

$$Z_0 = (173/\epsilon^{1/2}) \log_{10}(D/0.933d)$$

L. Wires in parallel—sheath return



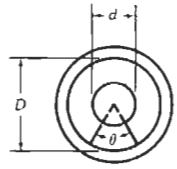
For $d \ll D, h$

$$Z_0 = (69/\epsilon^{1/2}) \log_{10}[(\nu/2\sigma^2)(1 - \sigma^4)]$$

$$\sigma = h/D$$

$$\nu = h/d$$

M. Air coaxial with dielectric supporting wedge

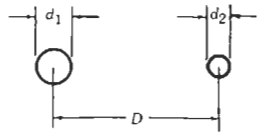


$$Z_0 \approx \frac{138 \log_{10}(D/d)}{[1 + (\epsilon - 1)(\theta/360)]^{1/2}}$$

ϵ = dielectric constant of wedge

θ = wedge angle in degrees

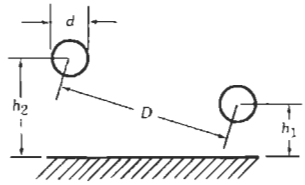
N. Balanced 2-wire—unequal diameters



$$Z_0 = (60/\epsilon^{1/2}) \cosh^{-1}N$$

$$N = \tfrac{1}{2}[(4D^2/d_1d_2) - (d_1/d_2) - (d_2/d_1)]$$

O. Balanced 2-wire near ground



For $d \ll D, h_1, h_2$

$$Z_0 = (276/\epsilon^{1/2}) \log_{10}\{(2D/d)[1 + (D^2/4h_1h_2)]^{-1/2}\}$$

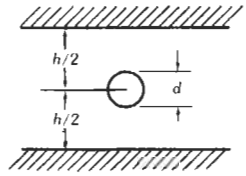
Holds also in either of the following special cases:

$$D = \pm(h_2 - h_1)$$

or

$$h_1 = h_2 \text{ (see } F \text{ above)}$$

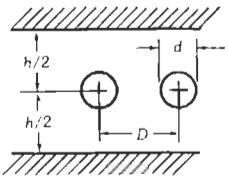
P. Single wire between grounded parallel planes—ground return



For $d/h < 0.75$

$$Z_0 = (138/\epsilon^{1/2}) \log_{10}(4h/\pi d)$$

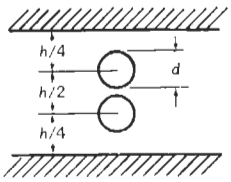
Q. Balanced line between grounded parallel planes



For $d \ll D, h$

$$Z_0 = (276/\epsilon^{1/2}) \log_{10}\left(\frac{4h \tanh(\pi D/2h)}{\pi d}\right)$$

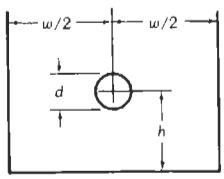
R. Balanced line between grounded parallel planes



For $d \ll h$

$$Z_0 = (276/\epsilon^{1/2}) \log_{10}(2h/\pi d)$$

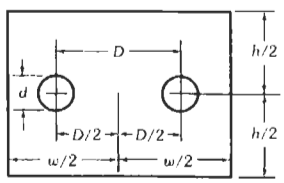
S. Single wire in trough



For $d \ll h, w$

$$Z_0 = (138/\epsilon^{1/2}) \log_{10}\left(\frac{4w \tanh(\pi h/w)}{\pi d}\right)$$

T. Balanced 2-wire line in rectangular enclosure



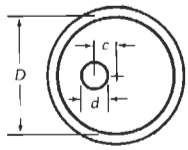
For $d \ll D, w, h$

$$Z_0 = (276/\epsilon^{1/2}) \left[\log_{10}\left(\frac{4h \tanh(\pi D/2h)}{\pi d}\right) - \sum_{m=1}^{\infty} \log_{10}\left(\frac{1 + u_m^2}{1 - v_m^2}\right)\right]$$

where

$$u_m = \frac{\sinh(\pi D/2h)}{\cosh(m\pi w/2h)} \qquad v_m = \frac{\sinh(\pi D/2h)}{\sinh(m\pi w/2h)}$$

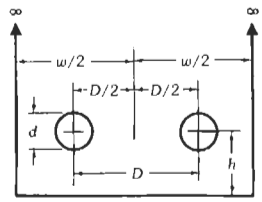
U. Eccentric line



$$Z_0 = (60/\epsilon^{1/2}) \cosh^{-1} U$$

$$U = \tfrac{1}{2}\left[(D/d) + (d/D) - (4c^2/dD)\right]$$

V. Balanced 2-wire line in semi-infinite enclosure



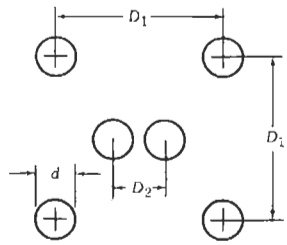
For $d \ll D, w, h$

$$Z_0 = (276/\epsilon^{1/2}) \log_{10}[2w/\pi d(A^{1/2})]$$

where

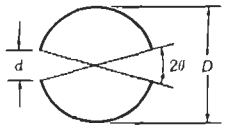
$$A = \operatorname{cosec}^2(\pi D/w) + \operatorname{cosech}^2(2\pi h/w)$$

W. Outer wires grounded, inner wires balanced to ground



$$Z_0 \approx (276/\epsilon^{1/2}) \left\{\log_{10}(2D_2/d) - \left[\log_{10}\frac{1 + (1 + D_2/D_1)^2}{1 + (1 - D_2/D_1)^2}\right]^2 \left[\log_{10}(2D_1\sqrt{2}/d)\right]^{-1}\right\}$$

X. Split thin-walled cylinder



$$Z_0 \approx \frac{129}{\log_{10}[\cot\frac{1}{2}\theta + (\cot^2\frac{1}{2}\theta - 1)^{1/2}]}$$

For θ small:

$$Z_0 \approx 129/\log_{10}(4D/d)$$

Courtesy of Electronic Engineering

Y. Slotted air line

When a slot is introduced into an air coaxial line for measuring purposes, the increase in characteristic impedance in ohms, compared with a normal coaxial line, is less than

$$\Delta Z = 0.03\theta^2$$

where θ is the angular opening of the slot in radians.

MICROSTRIP LINES

Microstrip line consists of a conductor strip placed on a dielectric substrate (relative dielectric constant ϵ_r), which is in turn backed by a conducting ground plane (Fig. 22). At lower microwave frequencies, the modal field is considered almost TEM. However, as the frequency is increased, the dispersion effect becomes more obvious, and the characteristic impedance and the phase velocity defined under the quasi-TEM analysis must be modified.

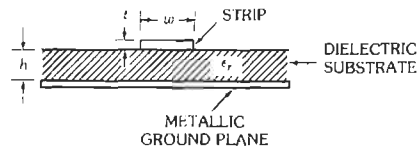


Fig. 22. Cross section of microstrip line.

Quasi-TEM Characteristics*

The characteristic impedance Z_0 and the effective dielectric constant ϵ_e are functions of structure and the dielectric constant ϵ_r.

$$Z_0(w, t, h, \epsilon_r) = Z_{01}(U_r)/[\epsilon_e(U_r, \epsilon_r)]^{1/2}$$

$$\beta = \frac{Z_{01}(U_1)}{Z_{01}(U_r)}\,[\epsilon_e(U_r, \epsilon_r)]^{1/2}\,\omega/c$$

where,

$$Z_{01}(x) = (376.73/2\pi)\,\ln\left\{\frac{f(x)}{x} + [1 + (2/x)^2]^{1/2}\right\}$$

$$f(x) = 6 + (2\pi - 6)\exp\left[-(30.666/x)^{0.7528}\right]$$

$$\epsilon_e(x, \epsilon_r) = [(\epsilon_r + 1)/2] + [(\epsilon_r - 1)/2](1 + 10/x)^y$$

$$y = -a(x)b(\epsilon_r)$$

$$a(x) = 1 + (1/49)\,\ln\left[\frac{x^4 + (x/52)^2}{x^4 + 0.432}\right] + (1/18.7)\,\ln\left[1 + (x/18.1)^3\right]$$

$$b(\epsilon_r) = 0.564\,[(\epsilon_r - 0.9)/(\epsilon_r + 3)]^{0.053}$$

* These formulas are from E. Hammerstadt and O. Jensen, *1980 IEEE International Microwave Symposium Digest*, pp. 407–409, June 1980. For the effects of an additional ground plane over the structure, see S. March, *Microwaves*, pp. 83–94, December 1981.

x is either

$$U_r = w/h + (t/\pi) \ln \left[1 + \frac{4 \exp(1)}{t \coth^2 (6.517\ w/h)^{1/2}}\right] \left[1 + 1/\cosh (\epsilon_r - 1)^{1/2}\right]/2$$

or

$$U_1 = w/h + (t/\pi) \ln \left[1 + \frac{4 \exp(1)}{t \coth^2 (6.517\ w/h)^{1/2}}\right]$$

depending on which is called for in the above equations. Note that $t \to 0$, both U_r and U_1 approach w/h.

Fig. 23 shows Z_0 as a function of w/h.

Attenuation

Dielectric loss (dB/unit length)

$$\alpha_D = 4.34\ \beta \tan\delta/[1 + (1/\epsilon_r)(F - 1)/(F + 1)]$$

$$F = (1 + 10h/w)^{1/2}$$

The factor $\tan\delta$ is the loss tangent of the substrate material.** The formula for β is given in the preceding subsection, "Quasi-TEM Characteristics."

Conductor loss is†

** M. V. Schneider, "Dielectric Loss in Hybrid Integrated Circuits," *Proc. IEEE*, Vol. 57, pp. 1206–1207, 1969.

† R. A. Pucel, D. J. Massé, and C. P. Hartwig, "Losses in Microstrip," *IEEE Trans. Microwave Theory and Techniques*, Vol. MTT-16, pp. 342–350, 1968.

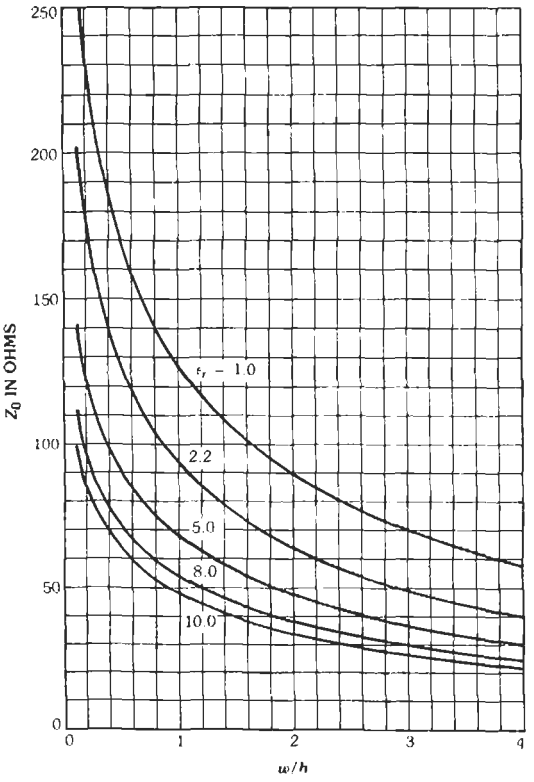

Fig. 23. Characteristic impedance of microstrip line. Calculated from quasi-tem formulas by Hammerstadt and Jensen. (Curves assume t is negligible; *i.e.*, $U_r = U_e = w/h$.)

$$\alpha_c = (4.34R_s/\pi hZ_0)[1 - (w'/4h)^2]\{1 + h/w' + (h/\pi w')[\ln(4\pi w/t + 1) - (1 - t/w)/(1 + t/4\pi w)]\}$$

$$w/h \leq 1/2\pi$$

$$= (4.34R_s/\pi hZ_0)[1 - (w'/4h)^2]\{1 + h/w' + (h/\pi w')[\ln(2h/t + 1) - (1 + t/h)/(1 + t/2h)]\}$$

$$1/2\pi < w/h \leq 2$$

$$= \frac{8.68\,R_s\left[\frac{w'}{h} + \frac{w'/\pi h}{w'/2h + 0.94}\right]}{hZ_0\{w'/h + (2/\pi)\ln[2\pi\epsilon\,(w'/2h + 0.94)]\}^2}\{1 + h/w' + (h/\pi w')[\ln(2h/t + 1) - (1 + t/h)/(1 + t/2h)]\}$$

$$w/h > 2$$

where

$$w' = w + \Delta w$$

and for $2t/h < w/h$, $1/2\pi$

$$\Delta w = (t/\pi)\ln(4\pi w/t + 1)$$

$$w/h \leq 1/2\pi$$

$$= (t/\pi)\ln(2h/t + 1)$$

$$w/h \geq 1/2\pi$$

The quantity Z_0 is the characteristic impedance discussed before, and R_s is the surface resistivity. Typically, $R_s = 2.61 \times 10^{-7}\sqrt{f}$ for copper.

Frequency-Dependent Characteristics

As the microstrip mode is not purely TEM, both Z_0 and ϵ_e are functions of frequency.‡

$$Z_0(f) = Z_0(0)[\epsilon_e(0)/\epsilon_e(f)]^{1/2}[\epsilon_e(f) - 1]/[\epsilon_e(0) - 1]$$

$$\epsilon_e(f) = \epsilon_r - [\epsilon_r - \epsilon_e(0)]/[1 + G(f/f_p)^2]$$

where,

$f_p = Z_0(0)/(2\mu_0 h)$
μ_0 = free-space permeability.

$$G = (\pi^2/12)[(\epsilon_r - 1)/\epsilon_e(0)][Z_0(0)/60]^{1/2}$$

In the above, $Z_0(0)$ and $\epsilon_e(0)$ are dc values and are obtained from the formulas in "Quasi-TEM Characteristics."

‡ E. Hammerstadt and O. Jensen, *1980 IEEE International Microwave Symposium Digest*, pp. 407–409, June 1980.

Power-Handling Capacity

For a microstrip line composed of a strip 7/32-inch wide on a Teflon-impregnated fiberglass base 1/16-inch thick:

(A) At 3000 megahertz with 300 watts cw, the temperature under the strip conductor has been measured at 50° Celsius rise above 20° Celsius ambient.

(B) Under pulse conditions, corona effects appear at the edge of the strip conductor for pulse power of roughly 10 kilowatts at 9000 megahertz.

STRIP TRANSMISSION LINES*

Strip transmission lines differ from microstrip in that a second ground plane is placed above the strip and the space between the two ground planes is filled completely with a homogeneous dielectric (Fig. 24). The characteristic impedance is shown in Fig. 25 and the attenuation in Fig. 26.

Dielectric loss in decibels/unit length

$$\alpha_d = 27.3F_p(\epsilon_r)^{1/2}/\lambda_0$$

where,

λ_0 = free-space wavelength,
F_p = power factor or loss angle.

Conductor loss in decibels/unit length

$$\alpha_c = (\gamma/b)(f_{GHz}\epsilon_r\mu_r\rho/\rho_{Cu})^{1/2}$$

* S. B. Cohn, "Problems in Strip Transmission Lines," *Transactions of the IRE Professional Group on Microwave Theory and Techniques*, Vol. MTT3, pp. 119-126, March 1955. Other papers on strip-type lines also appear in that issue of the journal.

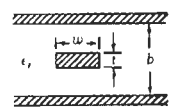

Fig. 24. Cross section of a strip transmission line.

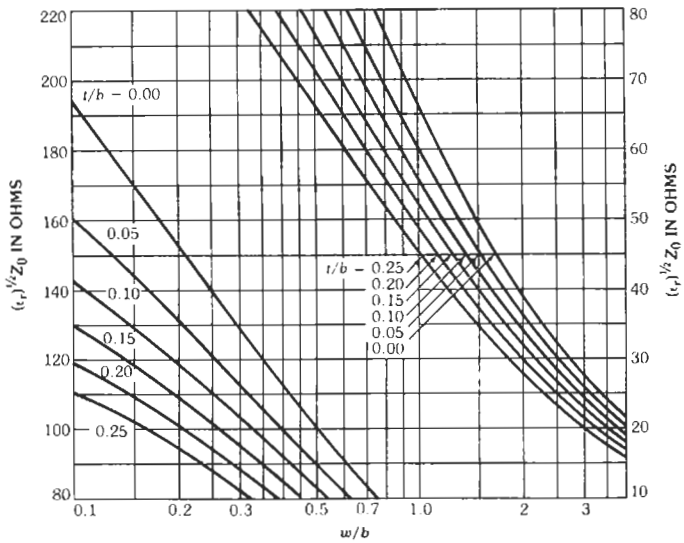

Fig. 25. Plot of strip-transmission-line Z_0 versus w/b for various values of t/b. For lower-left family of curves, refer to left-hand ordinate values; for upper-right curves, use right-hand scale. (*Courtesy of Transactions of the IRE Professional Group on Microwave Theory and Techniques.*)

where,

y = ordinate from Fig. 26,
ρ/ρ_{Cu} = resistivity relative to copper.

The unit of length in α_d is that of λ_0, and in α_c it is that of b.

COPLANAR TRANSMISSION LINES

A quasi-TEM propagation takes place in a coplanar transmission line (Fig. 27). When $t = 0$, the phase constant and the characteristic impedance under the quasi-TEM approximation are**

$$\beta = \sqrt{\epsilon_e}\ \omega/c$$

$$Z_0 = (30\pi/\sqrt{\epsilon_e})\ K_r$$

$$K_r = (1/\pi)\ \ln\ [2(1 + \sqrt{k})/(1 - \sqrt{k})]$$

$$0.707 \leq k \leq 1$$

$$K_r = \pi/\ln\ [2(1 + \sqrt{k'})/(1 - \sqrt{k'})]$$

$$0 \leq k \leq 0.707$$

** An approximation for a ratio of complete elliptic integrals by W. Helberg, "From Approximation to Exact Relations for Characteristic Impedances," *IEEE Trans. Microwave Theory and Technique*, Vol. MTT-17, pp. 259–265, 1969, is used in the original expression for Z_0 by C.P. Wen, "Coplanar Waveguide: A Surface Strip Transmission Line Suitable for Non-Reciprocal Gyromagnetic Device Applications," *IEEE Trans. Microwave Theory and Techniques*. Vol. MTT-17, pp. 1087–1090, 1969.

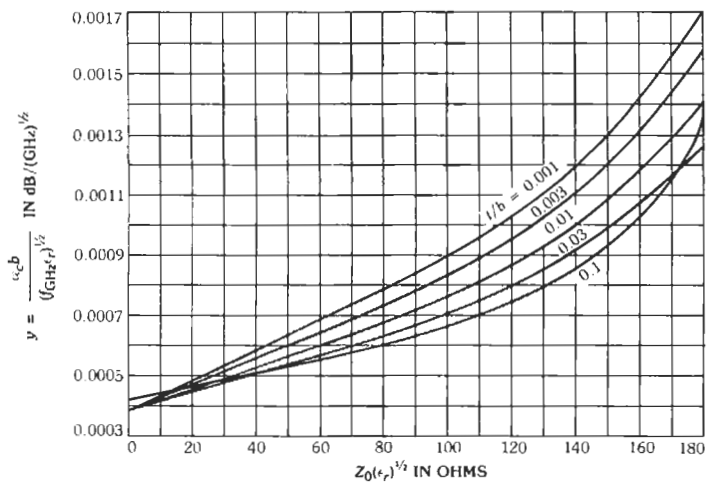

Fig. 26. Theoretical attenuation of copper-shielded strip transmission line in dielectric medium ϵ_r. (*Courtesy of Transactions of the IRE Professional Group on Microwave Theory and Techniques.*)

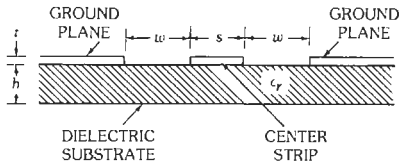

Fig. 27. Cross section of coplanar transmission line.

$$k = s/(2w + s)$$

$$k' = (1 - k^2)^{1/2}$$

where for the range of practical interest $1 \leq h/w < \infty$. The value of ϵ_e is given by†

$$\epsilon_e = [(\epsilon_r + 1)/2]\,\{\tanh[0.775 \ln (h/w) + 1/75]$$

$$+ k(w/h)[0.04 - 0.7k + 0.01(1 - 0.1\epsilon_r)(0.25 + k)]\}$$

If t is not negligible, k and ϵ_e in the exprcssions for $t = 0$ must be replaced with†

$$k^e = k + (1 - k^2)\,(1.25t/2w\pi)[1 + \ln (4\pi s/t)]$$

$$\epsilon_e^l = \epsilon_e - 0.7(\epsilon_e - 1)\,(t/w)/(K_r + 0.7t/w)$$

Fig. 28 is a graph of characteristic impedance calculated from the formulas in this section for $t = 0$.

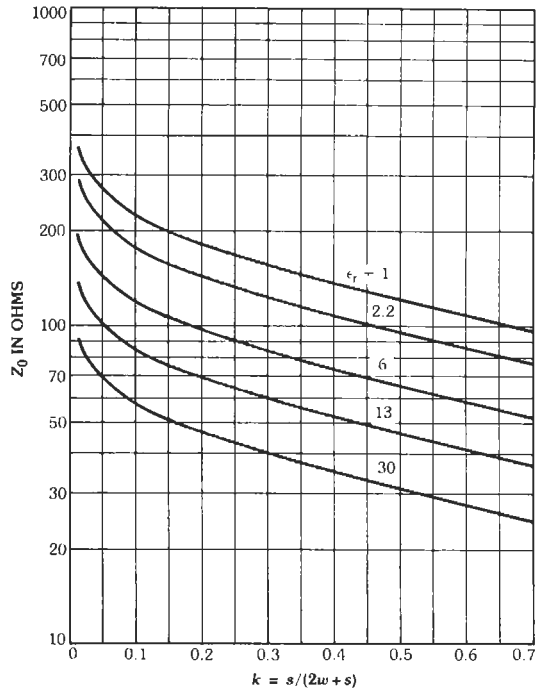

Fig. 28. Graph showing characteristic impedance of coplanar transmission line.

ATTENUATION AND POWER RATING OF LINES AND CABLES

Attenuation

Fig. 29 illustrates the attenuation of general-purpose radio-frequency lines and cables up to their practical upper frequency limit. Most of these are coaxial-type lines, but waveguide and microstrip are included for comparison.

The following notes are applicable to this figure.

(A) For the RG-type cables, only the number is given (for instance, the curve for RG-218/U is labeled 218. Refer to the table of radio-frequency cables.) The data on RG-type cables are taken mostly from "RF Transmission Lines and Fittings," MIL-HDBK-216, 4 January 1962, revised 18 May 1965, and from "Solid Dielectric Transmission Lines," Electronic Industries Association Standard RS-199, December 1957.

Some approximation is involved in order to simplify the figure. Thus, where a single curve is labeled with several type numbers, the actual attenuation of each individual type may be slightly different from that shown by the curve.

(B) The curves for rigid copper coaxial lines are labeled with the diameter of the line only, as 7/8"C. These have been computed for the lines listed in "Rigid Coaxial Transmission Lines, 50 Ohms," Electronic Industries Association Standard RS–225, August 1959. The computations considered the copper losses only, on the basis of a resistivity $\rho = 1.724$ microhm-centimeters; a derating of 20 percent has been applied to allow for imperfect surface, presence of fittings, etc., in long installed lengths. Relative attenuations of the different sizes are

$$A_{6\frac{1}{8}"} \approx 0.13A_{\frac{7}{8}"}$$

$$A_{3\frac{1}{8}"} \approx 0.26A_{\frac{7}{8}"}$$

$$A_{1\frac{5}{8}"} \approx 0.51A_{\frac{7}{8}"}$$

(C) Typical curves are shown for three sizes of 50-ohm semirigid cables such as Styroflex, Spiroline, Heliax, Alumispline, etc. These are labeled by size in inches, as 7/8"S.

(D) The microstrip curve is for Teflon-impregnated fiberglass dielectric 1/16-inch thick and conductor strip 7/32-inch wide.

(E) Shown for comparison is the attenuation in the $TE_{1,0}$ mode of five sizes of brass waveguide. The resistivity of brass was taken as $\rho = 6.9$ microhm-

† K. C. Gupta, et. al., *Microstrip Lines and Slotlines*, (Dedham, Mass.: Artech House, 1969).

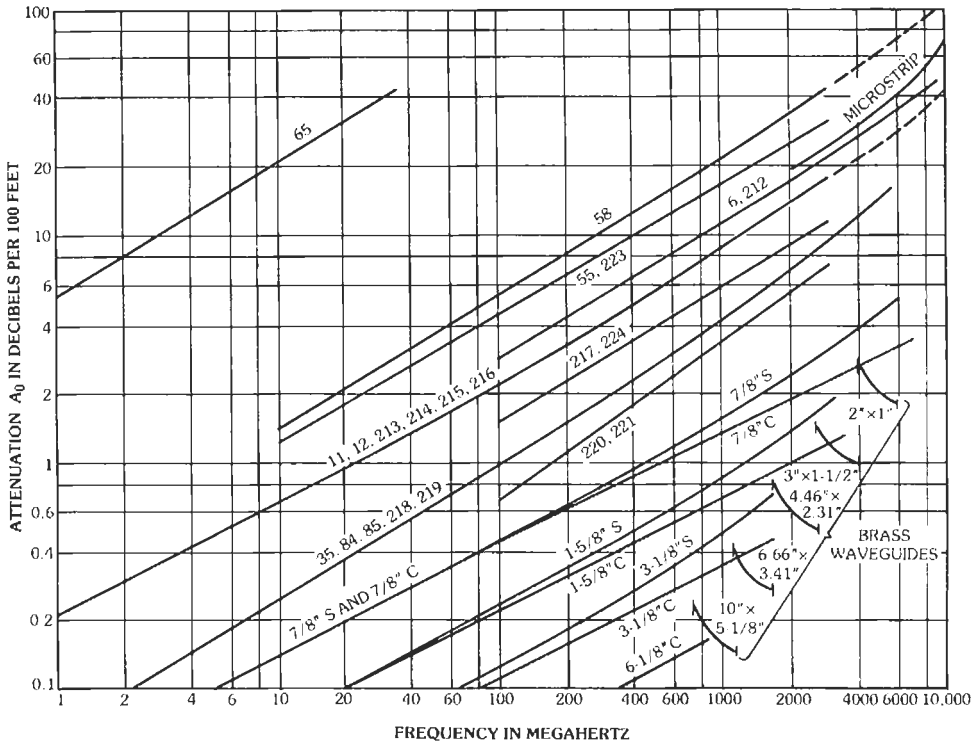

Fig. 29. Attenuation of cables.

centimeters, and no derating was applied. For copper or silver, attenuation is about half that for brass. For aluminum, attenuation is about two-thirds that for brass.

Power Rating

Fig. 30 shows the approximate power transmitting capabilities of various coaxial-type lines. The following notes are applicable.

(A) Identification of the curves for the RG-type cables is the same as in Fig. 29. The data for these cables are from the same sources. For polyethylene cables, an inner-conductor maximum temperature of 80 degrees Celsius is specified (**G**). For high-temperature cables (types 211, 228; 225, 227) the inner-conductor temperature is 250 degrees Celsius.

(B) The curves for 50-ohm rigid coaxial line are labeled with the diameter of the line only, as ⅞"*C*.

ARMY-NAVY LIST OF PREFERRED

Class of Cables		JAN Type RG-	Inner Conductor†	Dielectric Material (Note 1)	Nominal Diameter of Dielectric (in.)	Shielding Braid
50 ohms	Single braid	58C/U	19/0.0071" tinned copper	A	0.116	Tinned copper
		213/U	7/0.0296" copper	A	0.285	Copper
		215/U	7/0.0296" copper	A	0.285	Copper
		218/U	0.195" copper	A	0.680	Copper

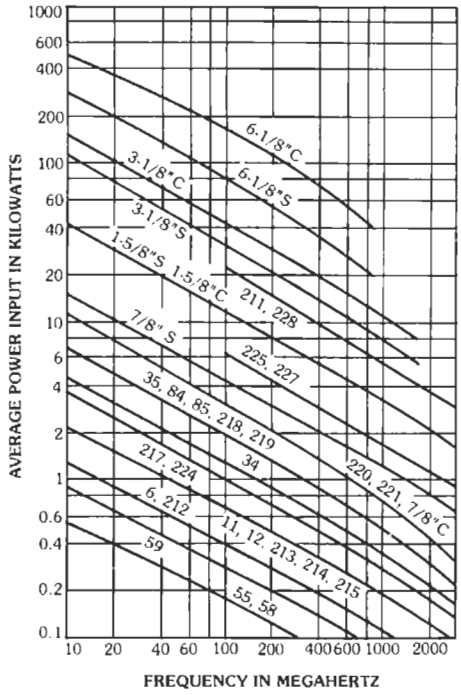

Fig. 30. Power rating of cables.

These are rough estimates based largely on miscellaneous charts published in catalogs.

(C) For Styroflex, Spiroline, Heliax, Alumispline, etc., cables, refer to **(C)** above.

(D) The curves are for unity voltage standing-wave ratio. Safe operating power is inversely proportional to swr expressed as a numerical ratio greater than unity. Do not exceed maximum operating voltage (see table of radio-frequency cables).

TABLE 1. DERATING FACTOR

Ambient Temperature (°C)	Maximum Allowable Center-Conductor Temperature (°C)			
	80	75	70	65
40	1.0	0.86	0.72	0.59
50	0.72	0.59	0.46	0.33
60	0.46	0.33	0.22	0.10
70	0.20	0.09	0	—
80	0	—	—	—

(E) An ambient temperature of 40 degrees Celsius is assumed.

(F) The four curves meeting the 100-watt ordinate may be extrapolated: at 3000 megahertz for 55, 58, power is 28 watts; for 59, power is 44 watts; and for 6, 212, power is 58 watts.

(G) Electronic Industries Association Standard RS-199 states that operation of a polyethylene dielectric cable at a center-conductor temperature in excess of 80 degrees Celsius is likely to cause permanent damage to the cable. Where practicable, and particularly where continuous flexing is required, it is recommended that a cable be selected which, in regular operation, will produce a center-conductor temperature not greater than 65 degrees Celsius. Rating factors for various operating temperatures are given in Table 1. Multiply points on the power-rating curve by the factors in the table to determine power rating at operating reset above to add one line conditions.

30 Waveguides and Resonators

Revised by
Tatsuo Itoh

PROPAGATION OF ELECTROMAGNETIC WAVES IN HOLLOW WAVEGUIDES

For propagation of energy at microwave frequencies through a hollow metal tube under fixed conditions, the following different types of waves are available.

TE Waves: Transverse-electric waves, sometimes called H waves, characterized by the fact that the electric vector (E vector) is always perpendicular to the direction of propagation. This means that

$$E_z \equiv 0$$

where z is the direction of propagation.

TM Waves: Transverse-magnetic waves, also called E waves, characterized by the fact that the magnetic vector (H vector) is always perpendicular to the direction of propagation. This means that

$$H_z \equiv 0$$

where z is the direction of propagation.

Note—TEM Waves: Transverse-electromagnetic waves. These waves are characterized by the fact that both the electric vector (E vector) and the magnetic vector (H vector) are perpendicular to the direction of propagation. This means that

$$E_z \equiv H_z \equiv 0$$

where z is the direction of propagation. This is the mode commonly excited in coaxial and open-wire lines. It cannot be propagated in a waveguide.

The solutions for the field configurations in waveguides are characterized by the presence of the integers m and n, which can take on separate values from 0 or 1 to infinity. Only a limited number of these different m,n modes can be propagated, depending on the dimensions of the guide and the frequency of excitation. For each mode there is a definite lower limit or cutoff frequency below which the wave is incapable of being propagated. Thus, a waveguide is seen to exhibit definite properties of a high-pass filter.

The propagation constant, $\gamma_{m,n}$, determines the amplitude and phase of each component of the wave as it is propagated along the length of the guide. With z = (direction of propagation) and $\omega = 2\pi \times$ (frequency), the factor for each component is

$$\exp[j\omega t - \gamma_{m,n} z]$$

Thus if $\gamma_{m,n}$ is real, the phase of each component is constant, but the amplitude decreases exponentially with z. When $\gamma_{m,n}$ is real, it is said that no propagation takes place. The frequency is considered below cutoff. Actually, propagation with high attenuation does take place for a small distance, and a short length of guide below cutoff is often used as a calibrated attenuator.

When $\gamma_{m,n}$ is imaginary, the amplitude of each component remains constant, but the phase varies with z. Hence, propagation takes place. The value of $\gamma_{m,n}$ is purely imaginary only in a lossless guide. In the practical case, $\gamma_{m,n}$ usually has both a real part, $\alpha_{m,n}$, which is the attenuation constant, and an imaginary part, $\beta_{m,n}$, which is the phase propagation constant. Then $\gamma_{m,n} = \alpha_{m,n} + j\beta_{m,n}$.

RECTANGULAR WAVEGUIDES

Fig. 1 shows a rectangular waveguide and a rectangular system of coordinates, disposed so that the origin falls on one of the corners of the waveguide; z is the direction of propagation along the guide, and the cross-sectional dimensions are y_0 and x_0.

For the case of perfect conductivity of the guide walls with a nonconducting interior dielectric (usually air), the equations for the $TM_{m,n}$ or $E_{m,n}$ waves in the dielectric are

$$E_x = -A \frac{\gamma_{m,n}}{\gamma_{m,n}^2 z + \omega^2 \mu\epsilon} (m\pi/x_0) \sin[(n\pi/y_0)y] \times \cos[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n} z)$$

$$E_y = -A \frac{\gamma_{m,n}}{\gamma_{m,n}^2 z + \omega^2 \mu\epsilon} (n\pi/y_0) \cos[(n\pi/y_0)y] \times \sin[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n} z)$$

$$E_z = A \sin[(n\pi/y_0)y] \sin[(m\pi/x_0)x] \times \exp(j\omega t - \gamma_{m,n} z)$$

$$H_x = -A \frac{j\omega\epsilon}{\gamma_{m,n}^2 z + \omega^2 \mu\epsilon} (n\pi/y_0) \cos[(n\pi/y_0)y] \times \sin[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n} z)$$

$$H_y = A \frac{j\omega\epsilon}{\gamma_{m,n}^2 z + \omega^2 \mu\epsilon} (m\pi/x_0) \sin[(n\pi/y_0)y] \times \cos[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n} z)$$

$$H_z \equiv 0$$

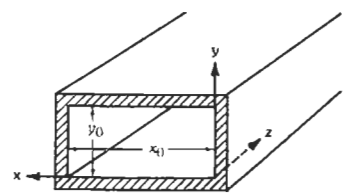

Fig. 1. Rectangular waveguide.

where ϵ is the dielectric constant and μ the permeability of the dielectric material in meter-kilogram-second (rationalized) units.

Constant A is determined solely by the exciting voltage. It has both amplitude and phase. Integers m and n may individually take values from 1 to infinity. No TM waves of the 0,0 type or 1,0 type are possible in a rectangular guide, so neither m nor n may be 0.

Equations for the $TE_{m,n}$ waves or $H_{m,n}$ waves in a dielectric are

$$E_x = -B \frac{j\omega\mu}{\gamma_{m,n}z + \omega^2\mu\epsilon} (n\pi/y_0) \sin[(n\pi/y_0)y] \times \cos[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n}z)$$

$$E_y = B \frac{j\omega\mu}{\gamma_{m,n}z + \omega^2\mu\epsilon} (m\pi/x_0) \cos[(n\pi/y_0)y] \times \sin[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n}z)$$

$$E_z \equiv 0$$

$$H_z = B \frac{\gamma_{m,n}}{\gamma_{m,n}z + \omega^2\mu\epsilon} (m\pi/x_0) \cos[(n\pi/y_0)y] \times \sin[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n}z)$$

$$H_y = B \frac{\gamma_{m,n}}{\gamma_{m,n}z + \omega^2\mu\epsilon} (n\pi/y_0) \sin[(n\pi/y_0)y] \times \cos[(m\pi/x_0)x] \exp(j\omega t - \gamma_{m,n}z)$$

$$H_z = B \cos[(n\pi/y_0)y] \cos[(m\pi/x_0)x] \times \exp(j\omega t - \gamma_{m,n}z)$$

Constant B depends only on the original exciting voltage and has both magnitude and phase; m and n individually may assume any integer value from 0 to infinity. The 0,0 type of wave where both m and n are 0 is not possible; all other combinations are.

As stated previously, propagation takes place only when propagation constant $\gamma_{m,n}$ is imaginary.

$$\gamma_{m,n} = [(m\pi/x_0)^2 + (n\pi/y_0)^2 - \omega^2\mu\epsilon]^{1/2}$$

This means, for any m,n mode, propagation takes place when

$$\omega^2\mu\epsilon > (m\pi/x_0)^2 + (n\pi/y_0)^2$$

or, in terms of frequency f and velocity of light c, when

$$f > \frac{c}{2\pi(\mu_1\epsilon_1)^{1/2}} [(m\pi/x_0)^2 + (n\pi/y_0)^2]^{1/2}$$

where μ_1 and ϵ_1 are the relative permeability and relative dielectric constant, respectively, of the dielectric material with respect to free space.

The wavelength in the air-filled waveguide is always greater than the wavelength in free space. The wavelength in the dielectric-filled waveguide may be less than the wavelength in free space. If λ is the wavelength in free space and the medium filling the waveguide has a relative dielectric constant ϵ,

$$\lambda_{g(m,n)} = \frac{\lambda}{[\epsilon - (m\lambda/2x_0)^2 - (n\lambda/2y_0)^2]^{1/2}}$$

$$= \frac{\lambda}{[\epsilon - (\lambda/\lambda_c)^2]^{1/2}}$$

where $(1/\lambda_c)^2 = (m/2x_0)^2 + (n/2y_0)^2$.

The phase velocity within the guide is also always greater than in an unbounded medium. The phase velocity, v, and group velocity, u, are related by

$$u = c^2/v$$

where the phase velocity is given by $v = c\lambda_g/\lambda$, and the group velocity is the velocity of propagation of the energy.

To couple energy into waveguides, it is necessary to understand the configuration of the characteristic electric and magnetic lines. Fig. 2 shows the field configuration for a $TE_{1,0}$ wave. Fig. 3 shows the instantaneous field configuration for a higher mode, a $TE_{2,1}$ wave.

In Fig. 4 are shown only the characteristic E lines for the $TE_{1,0}$, $TE_{2,0}$, $TE_{1,1}$, and $TE_{2,1}$ waves. The arrows on the lines indicate their instantaneous relative directions. To excite a TE wave, it is necessary to insert a probe to coincide with the direction of the E lines. Thus, for a $TE_{1,0}$ wave, a single probe projecting from the side of the guide parallel to the E lines would be sufficient to couple into it. Two ways of coupling from a coaxial line to a rectangular waveguide to excite the $TE_{1,0}$ mode are shown in Fig. 5. With structures such as these, it is possible to make the standing-wave ratio due to the junction less than 1.15 over a 10- to 15-percent frequency band.

Fig. 6 shows the instantaneous configuration of a $TM_{1,1}$ wave; Fig. 7 shows the instantaneous field configuration for a $TM_{2,1}$ wave. Coupling to this type of wave may be accomplished by inserting a probe that is parallel to the E lines, or by means of a loop oriented to link the lines of flux.

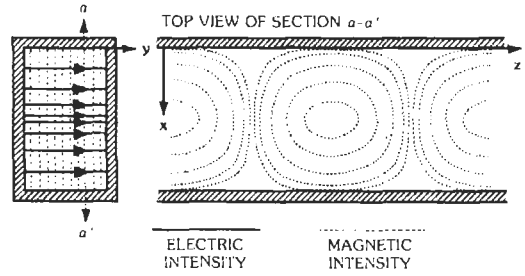

Fig. 2. Field configuration for a $TE_{1,0}$ wave.

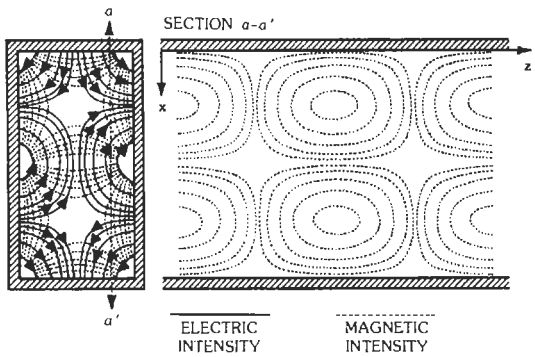

Fig. 3. Field configuration for a $TE_{2,1}$ wave.

CIRCULAR WAVEGUIDES

The usual coordinate system is ρ, θ, z, where ρ is the radial direction, θ is the angle, and z is in the longitudinal direction.

TM Waves (*E* Waves): $H_z \equiv 0$

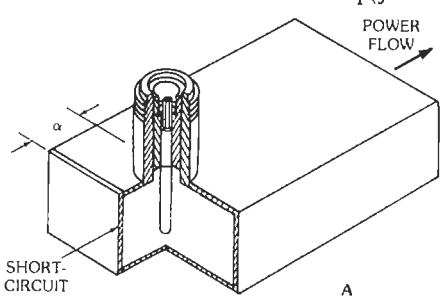
$$E_\rho = H_\theta \eta(\lambda/\lambda_{g(m,n)}) \exp(j\omega t - \gamma_{m,n}z)$$

$$E_\theta = -H_\rho \eta(\lambda/\lambda_{g(m,n)}) \exp(j\omega t - \gamma_{m,n}z)$$

$$E_z = AJ_n(k_{m,n}\rho) \cos n\theta \exp(j\omega t - \gamma_{m,n}z)$$

$$H_\rho = -jA(2\pi n/\lambda k_{m,n}{}^2 \eta\rho)J_n(k_{m,n}\rho) \sin n\theta$$

$$\times \exp(j\omega t - \gamma_{m,n}z)$$



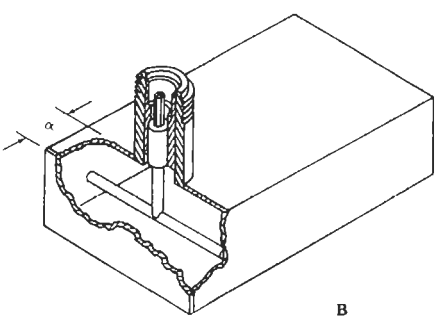


Fig. 5. Methods of coupling to $TE_{1,0}$ mode ($\alpha \approx \lambda_g/4$).

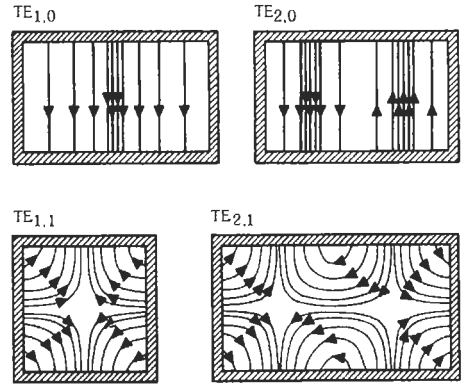

Fig. 4. Characteristic *E* lines for TE waves.

$$H_\theta = -jA(2\pi/\lambda k_{m,n}\eta)J_n'(k_{m,n}\rho) \cos n\theta$$

$$\times \exp(j\omega t - \gamma_{m,n}z)$$

where $\eta = (\mu/\epsilon)^{1/2}$, with μ and ϵ in absolute units.

By the boundary conditions, $E_z = 0$ when $\rho = a$, the radius of the guide. Thus, the only permissible values of k are those for which $J_n(k_{m,n}a) = 0$, because E_z must be zero at the boundary.

The numbers m,n take on all integral values from zero to infinity. The waves are seen to be characterized by the numbers m and n, where n gives the order of the Bessel functions, and m gives the order of the root of $J_n(k_{m,n}a)$. The Bessel function has an infinite number of roots, so there are an infinite number of k's that make $J_n(k_{m,n}a) = 0$.

TE Waves (*H* Waves): $E_z \equiv 0$

$$E_\rho = jB(2\pi n\eta/\lambda k_{m,n}{}^2\rho)J_n(k_{m,n}\rho) \sin n\theta$$

$$\times \exp(j\omega t - \gamma_{m,n}z)$$

$$E_\theta = jB(2\pi\eta/\lambda k_{m,n})J_n'(k_{m,n}\rho) \cos n\theta$$

$$\times \exp(j\omega t - \gamma_{m,n}z)$$

$$H_\rho = -E_\theta(\lambda_{g(m,n)}/\eta\lambda) \exp(j\omega t - \gamma_{m,n}z)$$

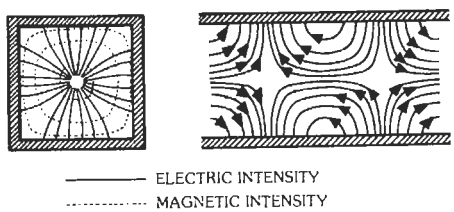

Fig. 6. Instantaneous field configuration, $TM_{1,1}$ wave.

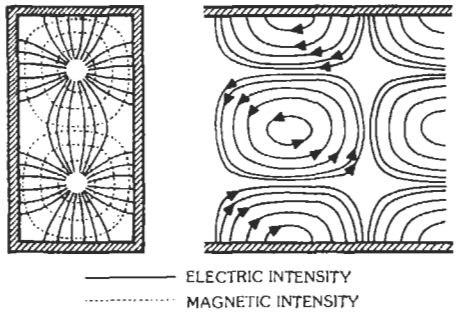

Fig. 7. Instantaneous field configuration, $TM_{2,1}$ wave.

$$H_\theta = E_\rho(\lambda_{g(m,n)}/\eta\lambda) \exp(j\omega t - \gamma_{m,n}z)$$

$$H_z = BJ_n(k_{m,n}\rho) \cos n\theta \exp(j\omega t - \gamma_{m,n}z)$$

Again, n takes on integral values from zero to infinity. The boundary condition $E_\theta = 0$ when $\rho = a$ still applies. To satisfy this condition, k must be such as to make $J_n'(k_{m,n}a)$ equal to zero [where the superscript indicates the derivative of $J_n(k_{m,n}a)$]. It is seen that m takes on values from 1 to infinity, since there are an infinite number of roots of $J_n'(k_{m,n}a)$.

For circular waveguides, the cutoff frequency for the m,n mode is

$$f_{c(m,n)} = ck_{m,n}/2\pi$$

where c = velocity of light, and $k_{m,n}$ is evaluated from the roots of the Bessel functions.

$$k_{m,n} = U_{m,n}/a \text{ or } U_{m,n}'/a$$

where a = radius of guide or pipe, and $U_{m,n}$ is the root of the particular Bessel function of interest (or its derivative).

The wavelength in any guide filled with a homogeneous dielectric ϵ (relative) is

$$\lambda_g = \lambda_0/[\epsilon - (\lambda_0/\lambda_c)^2]^{1/2}$$

where λ_0 is the wavelength in free space, and λ_c is the free-space cutoff wavelength for any mode under consideration.

Tables 1 and 2 are useful in determining the values of k. For TE waves, the cutoff wavelengths are given in Table 1, and for TM waves the cutoff wavelengths are given in Table 2, where n is the order of the Bessel function and m is the order of the root.

TABLE 1. TE WAVES, VALUES OF λ_c/a (WHERE a = RADIUS OF GUIDE)

Fig. 8 shows λ_0/λ_g as a function of λ_0/λ_c. From this, λ_g may be determined when λ_0 and λ_c are known.

The pattern of magnetic force of TM waves in a circular waveguide is shown in Fig. 9. Only the maximum lines are indicated. To excite this type of pattern, it is necessary to insert a probe along the length of the waveguide and concentric with the H lines. For instance, in the $TM_{0,1}$ type of wave, a probe extending down the length of the waveguide at its very center would provide the proper excitation. This method of excitation is shown in Fig. 10. Corresponding methods of excitation may be used for the other types of TM waves shown in Fig. 9.

Fig. 11 shows the patterns of electric force for TE waves. Again, only the maximum lines are indicated. This type of wave may be excited by an antenna that is parallel to the electric lines of force. The $TE_{1,1}$ wave may be excited by means of an antenna extending across the waveguide. This is illustrated in Fig. 12.

Propagating E waves have a minimum attenuation at $(3)^{1/2}f_c$. The $H_{1,1}$ wave has minimum attenuation at the frequency $2.6\ (3)^{1/2}\ f_c$.

The $H_{0,1}$ wave has the interesting and useful property that attenuation decreases as the frequency increases. This has made the $H_{0,1}$ mode exceedingly useful in the transmission of microwave signals over long distances.

Table 3 presents some of the important equations for various guides.

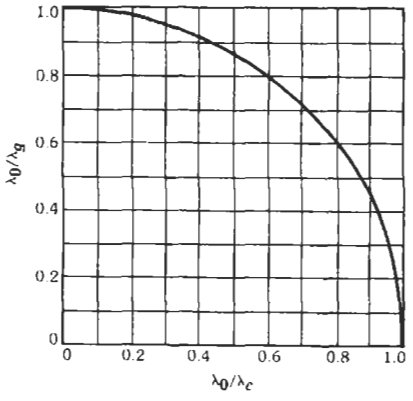

Fig. 8. Chart for determining guide wavelength.

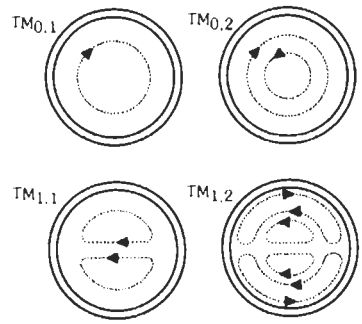

Fig. 9. Patterns of magnetic force of TM waves in circular waveguides.

SQUARE WAVEGUIDES

Waveguide having interior dimensions $x_0 = y_0$ (Fig. 1) has found increasingly important application in dual-polarized horn feeds and waveguide multiplexers. Usually these involve simultaneous propagation of the orthogonally oriented dominant modes, $TE_{1,0}$ and $TE_{0,1}$. These modes are theoretically capable of propagation without cross coupling, at the same frequency, in lossless waveguide of square cross section. In practice, wall losses, surface irregularities, and unequal transverse interior dimensions give rise to $TE_{1,0}$ and $TE_{0,1}$ mode cross-conversion. This occurs continually along the waveguide so that unless special care is taken, long lengths of dual-polarized waveguide exhibit a deteriorated mode isolation as a function of length of guide.

Most important in establishing the initial mode isolation is proximity of the operating frequency to the cutoff frequency of the $TE_{1,0}$ mode in the square waveguide so that the total operating frequency band is above $TE_{1,0}$ cutoff and well below $TE_{1,1}$ cutoff. The lowest operating frequency should be approximately 25% above the $TE_{1,0}$ cutoff frequency. Thus, a dual-polarized feed propagating a 4400-MHz signal should use a square waveguide having internal dimensions of about 1.68 inches. If the internal dimensions are arrived at by using the 1.87 internal dimension of WR 187 waveguide, the dual-mode isolation will probably not exceed 35 dB. By operating about 25% above the $TE_{1,0}$ mode cutoff frequency and well below $TE_{1,1}$ cutoff, the isolation can exceed 50 dB.*

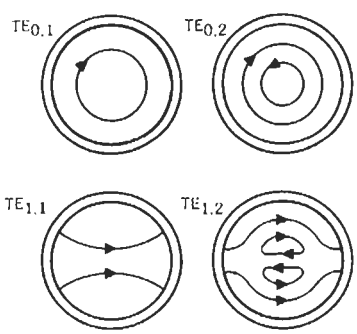

Fig. 11. Patterns of electric force of TE waves in circular waveguides.

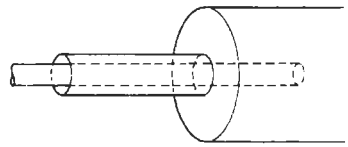

Fig. 10. Method of coupling to circular waveguide for $TM_{0,1}$ wave.

ATTENUATION IN A WAVEGUIDE BEYOND CUTOFF

When a waveguide is used at a wavelength greater than the cutoff wavelength, there is no real propagation and the fields are attenuated exponentially. The attenuation, L, in a length, d, is given by

$$L = 54.5(d/\lambda_c)[1 - (\lambda_c/\lambda)^2]^{1/2} \text{ decibels}$$

where λ_c = cutoff wavelength and λ = operating wavelength.

Note that for $\lambda >> \lambda_c$, attenuation is essentially independent of frequency and

$$L = 54.5d/\lambda_c \text{ decibels}$$

where λ_c is a function of geometry.

STANDARD WAVEGUIDES

Table 4 lists some properties and dimensions of standard rectangular waveguides. For other than theoretical vacuum performance, consider the relative value of ϵ for sea level, 20° C air, as approximately 1.0006. Rounded inner corners also modify performance slightly.†

TABLE 3. CUTOFF WAVELENGTHS AND ATTENUATION FACTORS*

Type of Guide (Copper)†	Cutoff Wavelength λ_c $f_c = (c/\lambda_c)$	Attenuation Constant α (dB/100 ft)
Coaxial line‡ TEM 	0	$\frac{3.58 \times 10^{-6}(f)^{1/2}(1/b)[1 + (b/a)]}{\ln (b/a)}$ Note: Fig. 29 in Chapter 29 includes a derating factor of 20% applied to calculated α.
Rectangular pipe $TE_{m,0}$ or $H_{m,0}$ 	$2a/m$	$\frac{1.107}{a^{3/2}} \times \frac{1/2(a/b)\,(f/f_c)^{3/2} + (f/f_c)^{-1/2}}{[(f/f_c)^2 - 1]^{1/2}}$
Circular pipe: 		
$TM_{0,1}$ or $E_{0,1}$	$2.613a$	$\frac{0.485}{a^{3/2}} \times \frac{(f/f_c)^{3/2}}{[(f/f_c)^2 - 1]^{1/2}}$
$TE_{1,1}$ or $H_{0,1}$	$3.412a$	$\frac{0.423}{a^{3/2}} \times \frac{(f/f_c)^{-1/2} + (1/2.38)\,(f/f_c)^{3/2}}{[(f/f_c)^2 - 1]^{1/2}}$
$TE_{0,1}$ or $H_{0,1}$	$1.640a$	$\frac{0.611}{a^{3/2}} \times \frac{(f/f_c)^{-1/2}}{[(f/f_c)^2 - 1]^{1/2}}$

* Dimensions are in inches and frequencies in hertz; vacuum dielectric.
† For other metals multiply α by the square root of ratio of resistivity relative to that of copper.
‡ Inner and outer conductors same material.

RIDGED WAVEGUIDES

To lower the cutoff frequency of a waveguide for use over a frequency band wider than normal, ridges may be used. By proper choice of dimensions, it is possible to obtain as much as a 4:1 ratio between cutoff frequencies for the $TE_{2,0}$ and $TE_{1,0}$ modes.

Tables 5 and 6 and Figs. 13 and 14 give the essential characteristics of single- and double-ridged guides. Figs. 15 and 16 show the relationship between the cutoff wavelength and the critical dimensions. Figs. 17 and 18 describe the bandwidth (ratio of cutoff wavelengths of the 0,1 and 0,2 modes). The price paid for increased bandwidth is an increase in attenuation relative to the equivalent rectangular guide (Figs. 19 and 20).

Coaxial line can be coupled to either the single- or double-ridged guide by partly inserting the probe into the open space between the ridge and the opposite wall or ridge (Fig. 5A) or connecting it directly across the gap.

FLEXIBLE WAVEGUIDES

Flexible waveguide is used to join rigid sections or components that cannot be accurately dimensioned, positioned, or rendered immobile in space. Thus, rather than attempt to specify and hold precisely every bend,

‡ Fig. 14B in these frequency ranges only.

twist, and straight section of a long waveguide run between fixed points, it is often adequate to leave a short run or bend to be filled by a flexible guide insert. Flexible sections are also used to permit thermally induced relative movement and to insulate portions of a waveguide run from shock and vibration. Flexible waveguide should not be treated as a link between a cabinet and its frequently opened doors and drawers, unless the cabinet is specified and/or designed for that type of service. Most flexible-waveguide structures are susceptible to cracking under these conditions if flexure is repeated often.

Flexible waveguide is available in many different forms. It may be made from flat ribbons wound on a rectangular mandrel with the edges convoluted or folded in and interlocked. The convoluted guide may be soldered or unsoldered, since the bending and twisting results from a flexure of each turn and not from a relative sliding as in the case of the interlocked guide. If soldered, it is more difficult to flex and essentially loses twist capability.

Corrugated flexible guide may be made by properly shaping thin-wall seamless rectangular tubing, or by bending and soldering corrugated sheet metal (with due consideration to current flow so that a low-loss joint results).

A bellows-type guide is produced from a group of radial chokes in tandem configuration and made of a flexible alloy.

Vertebral guide is made from a tandem chain of choke-cover sections contained within a neoprene or rubber jacket.

In general, all types except the seamless corrugated waveguide should be jacketed with neoprene or rubber. The unsoldered convoluted, interlocking, and vertebral guide must be jacketed to be pressurized.

Table 7 gives the properties of soldered convoluted flexible waveguide.

The wide variety of manufacturing techniques, the jacketing material and thickness, the length dependence, and other characteristics make it impossible to limit the (±) stretch, twist, and center-line displacement ranges of flexible waveguide. These are usually described in terms of maximum acceptable vswr or loss of the section as a function of the (±) stretch, twist, or displacement, and are best established on advice from the manufacturer selected.

WAVEGUIDE LOSSES

Hollow, enclosed single-conductor waveguides, propagating in the interior space, exhibit losses via dissipation in the waveguide walls and the dielectric material filling the space, leakage through the walls and connections to the guide, and localized power absorption (and heating) at the connections (flanges) because of poor contact or fabrication. The following discussion assumes that the dielectric is air, with zero loss tangent, and that the depth of penetration into the walls is very much less than the wall thickness, so that no appreciable wall leakage occurs.

Waveguide Material and Modes

Fig. 21 shows attenuation as a function of percent conductivity for WR-112 waveguide at 9.0 GHz.* Table 8 relates material composition and percent conductivity.

To obtain the lowest attenuation where a choice of waveguide size and cross section is possible, consideration should be given to mode selection. Fig. 22 shows

the relation among various waveguides for different modes and cross sections over a broad frequency band. Fig. 23 relates the attenuation rates of several circular and square guides (in the $TE_{0,1}$, $TE_{1,1}$, and $TE_{1,0}$ modes) over a limited frequency band.

Waveguide Flange Leakage*

It is extremely difficult to apply quantitative measurements to flange leakage without direct reference to a specific set of measuring procedures, equipment, and test environment. However, in general, measurements of flange fields, made with a probe at the flanges, have indicated that the leakage fields exhibit sharp peaks distributed around the edge of the flange connection. The levels of the peaks are of the order of −130 decibels relative to the guide power, and may be higher or lower depending on the bolt tension and RFI gaskets employed.

Flange Resistance and Bolt Torque†

The equivalent series resistance of a die-cast sealed rectangular aluminum *S*-band flange pair as a function of bolt torque (each bolt) is shown in Fig. 24, as an indication of the importance of proper bolt tightening at a flange connection. Table 9 gives the bolt torque for several bolt sizes to meet the recommended value of about 1000 lb/linear inch of flange connection, which is estimated to give a satisfactory waveguide seal for high-power applications.

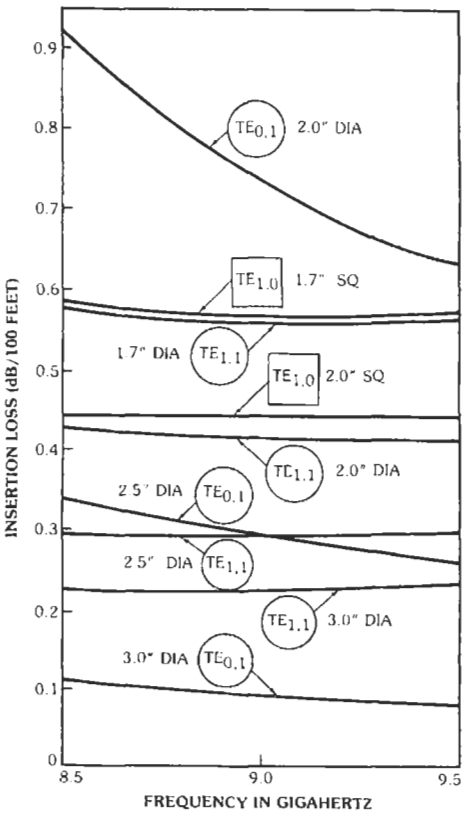

Fig. 23. Attenuation curves for various square and circular waveguides in range 8.5–9.5 GHz. (*From R. M. Cox and W. E. Rupp, "Fight Waveguide Losses 5 Ways,"* Microwaves, *Vol. 5, No. 8, August 1966; p. 37.*)

** Tension (lb) = torque (lb-in)/ 0.2×diameter of bolt (in).

Flange Insertion Loss**

The relationship between the flange resistance and insertion loss is

$$L(\text{decibels}) = 10 \log(1 - R_F/Z_0)$$

where R_F = radio-frequency flange resistance (measured), and

$$Z_0 = 593\ b/a[1 - (f_c/f)^2]^{-1/2}\ (\text{ohms})‡$$

The approximate value of flange insertion loss calculated from the above equation may be scaled to other flange sizes and frequencies by

$$R_{F1}/R_{F2} \sim (A_1/A_2)(f_1/f_2)^{1/2}$$

where A = flange area, f = frequency, and the subscripts refer to the two conditions.

Losses and Noise Temperature

In radio telescopes, satellite ground antennas, and other loss-sensitive waveguide systems, the noise-temperature contributions must be controlled and accounted for in the system design. The waveguide losses may be converted to noise temperature* by

$$T = T_R(1 - a)$$

where,

* A. J. Giger, S. Pardee, Jr., and P. R. Wickliffe, Jr., "The Ground Transmitter and Receiver." *Bell System Technical Journal*, Vol. 42, No. 4, Part 1, July 1963, p. 1096.

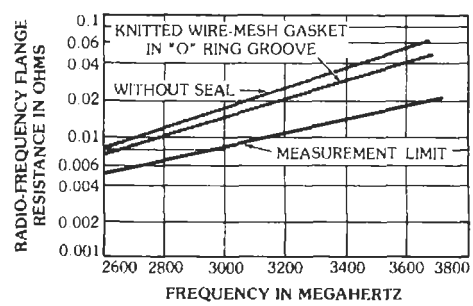

Fig. 25. Typical flange resistance as a function of frequency for choke-cover combination (UG-53/U plus UG-54/U, measured). *From Handbook Catalog W5460,* Waveguide Flange and EMI Sealing, Culver City, Calif.: *Parker Seal Co., © 1967.*)

** S. Galagan. *Electrical Characteristics of Waveguide Seals with EMI Supplement.* Unpublished report prepared for the Parker Seal Co., Culver City, Cal.; January 1964.

‡ This is the characteristic impedance, defined as the maximum transverse voltage divided by the total longitudinal current.

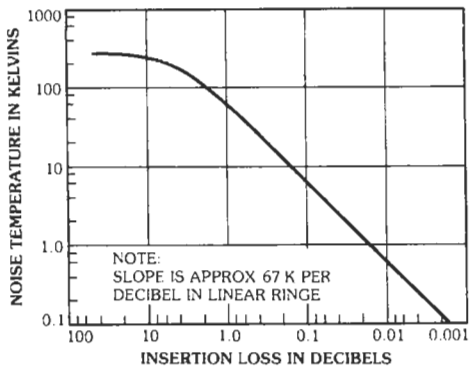

Fig. 26. Noise temperature as a function of insertion loss (290 K ambient).

T = temperature in kelvins,
T_R = temperature of the lossy insert in kelvins,
a = power transmission coefficient.

For A (decibels) $= -10 \log_{10} a$

$$T = T_R(1 - 10^{-A/10})$$

Fig. 26 relates the noise temperature added to a lossless waveguide system at 290 K by inserting a 290 K pad having A decibels of loss between the measuring point (or input to the receiver) and a 0 K load, as a function of insertion loss A (decibels).

Some typical values of insertion loss measured for a specific configuration are:

23-decibel directional coupler*	0.03 decibel
Flexible waveguide*	0.023 decibel
Flanges (UG-53/U plus UG-53/U)†	0.0017 decibel

WAVEGUIDE CIRCUIT ELEMENTS‡

Just as at low frequencies, it is possible to shape metallic or dielectric pieces to produce local concentrations of magnetic or electric energy within a waveguide and thus produce what are, essentially, lumped inductances or capacitances over a limited frequency bandwidth.

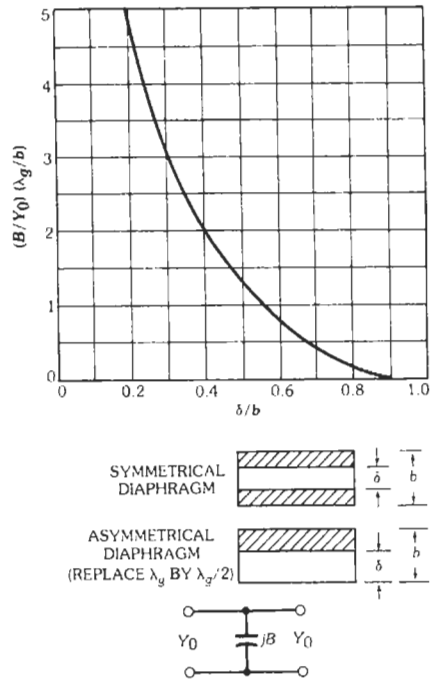

Fig. 27. Normalized susceptance of capacitive diaphragms.

This behavior as a lumped element will be evident only at some distance from the obstacle in the guide, since the fields in the immediate vicinity are disturbed.

Capacitive elements are formed from electric-field concentrating devices, such as screws or thin diaphragms inserted partially along electric-field lines. These are susceptible to breakdown under high power. Fig. 27 shows the relative susceptance, B/Y_0, for symmetrical and asymmetrical diaphragms for small b/λ_g.

A common form of shunted lumped inductance is the diaphragm. Figs. 28 and 29 show the relative susceptance, B/Y_0, for symmetrical and asymmetrical diaphragms in rectangular waveguides. These are computed for infinitely thin diaphragms. Finite thicknesses result in an increase in B/Y_0.

Another form of shunt inductance that is useful because of mechanical simplicity is a round post completely across the narrow dimension of a rectangular guide (for $TE_{1,0}$ mode). Fig. 30 gives the normalized values of the elements of the equivalent four-terminal network for several post diameters.

Frequency dependence of waveguide susceptances may be given approximately as

$$\text{Inductive} = B/Y_0 \propto \lambda_g$$

$$\text{Capacitive} = B/Y_0 \propto 1/\lambda_g \text{ (distributed)}$$

$$= B/Y_0 \propto \lambda_g/\lambda^2 \text{ (lumped)}$$

---

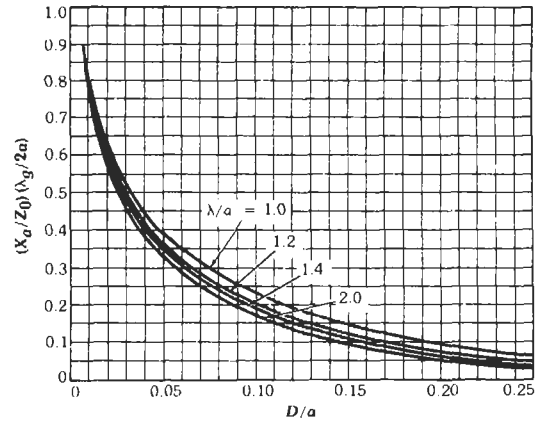
Distributed capacitances are found in junctions and slits, whereas tuning screws act as lumped capacitances.

HYBRID JUNCTIONS*

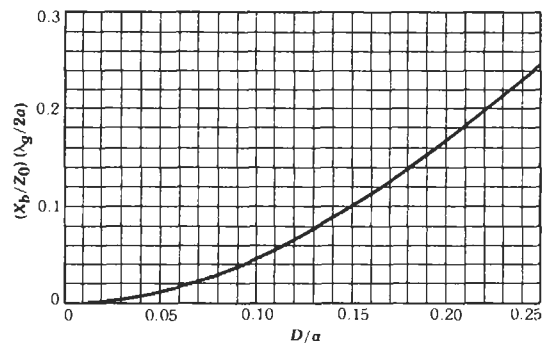
The hybrid junction is illustrated in various forms in Fig. 31. An ideal junction is characterized by the fact that there is no direct coupling between arms 1 and 4 or between 2 and 3. Power flows from 1 to 4 only by virtue of reflections in arms 2 and 3. Thus, if arm 1 is excited, the voltage arriving at arm 4 is

$$E_4 = \tfrac{1}{2}E_1[\Gamma_2 \exp(j2\theta_2) - \Gamma_3 \exp(j2\theta_3)]$$

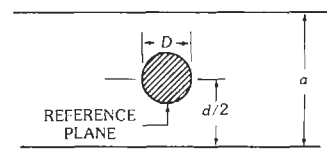
* C. G. Montgomery, R. H. Dicke, and E. M. Purcell. *Principles of Microwave Circuits*. New York: McGraw-Hill Book Co., 1948; Chapter 9.



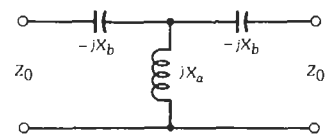
(A) Shunt reactance characteristic.



(B) Series reactance characteristic.



(C) Physical dimensions.



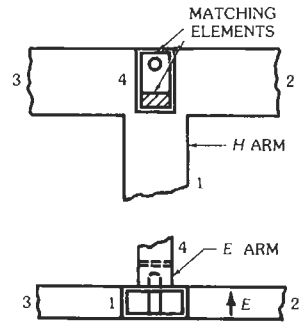
(D) Electrical equivalent.

Fig. 30. Equivalent circuit for inductive cylindrical post.

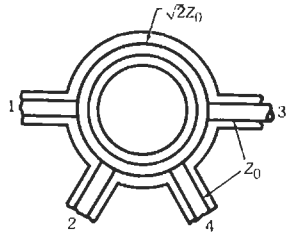
and the reflected voltage in arm 1 is

$$E_{r1} = \tfrac{1}{2}E_1[\Gamma_2 \exp(j2\theta_2) + \Gamma_3 \exp(j2\theta_3)]$$

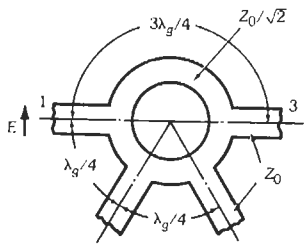
where,



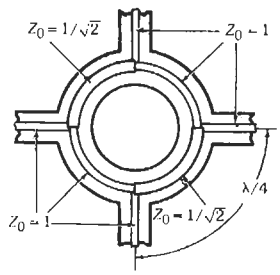
(A) Waveguide hybrid junction (magic T).



(B) Shunt coaxial hybrid ring.



(C) E-plane waveguide hybrid ring.



(D) Symmetrical coaxial hybrid.

Fig. 31. Hybrid junctions.

E_1 is the amplitude of the incident wave,
Γ_2 and Γ_3 are the reflection coefficients of the terminations of arms 2 and 3,
θ_2 and θ_3 are the respective distances of the terminations from the junctions.

In the case of the rings, θ is the distance between the arm-and-ring junction and the termination.

If the decoupled arms of the hybrid junction are independently matched and the other arms are terminated in their characteristic impedances, then all four arms are matched at their inputs.

RESONANT CAVITIES

A cavity enclosed by metal walls has an infinite number of natural frequencies at which resonance will occur. One of the more common types of cavity resonators is a length of transmission line (coaxial or waveguide) short-circuited at both ends.

Resonance occurs when

$$2h = l(\lambda_g/2)$$

where,

l = an integer,
$2h$ = length of the resonator,
λ_g = guide wavelength in resonator
$= \lambda/[\epsilon - (\lambda/\lambda_c)^2]^{1/2}$
λ = free-space wavelength,
λ_c = guide cutoff wavelength,
ϵ = relative dielectric constant of medium in cavity.

For $TE_{m,n}$ or $TM_{m,n}$ waves in a rectangular cavity with cross section a, b

$$\lambda_c = 2/[(m/a)^2 + (n/b)^2]^{1/2}$$

where m and n are integers.

For $TE_{m,n}$ waves in a cylindrical cavity

$$\lambda_c = 2\pi a/U_{m,n}'$$

where a is the guide radius and $U_{m,n}'$ is the mth root of the equation $J_n'(U) = 0$.

For $TM_{m,n}$ waves in a cylindrical cavity

$$\lambda_c = 2\pi a/U_{m,n}$$

where a is the guide radius and $U_{m,n}$ is the mth root of the equation $J_n(U) = 0$.

For TM waves, $l = 0, 1, 2, \ldots$.

For TE waves, $l = 1, 2, \ldots$, but not 0.

Rectangular Cavity of Dimensions *a, b, 2h*

$$\lambda = 2/[(l/2h)^2 + (m/a)^2 + (n/b)^2]^{1/2}$$

where only one of l, m, n may be zero.

Cylindrical Cavities of Radius *a* and Length 2*h*

$$\lambda = 1/[(l/4h)^2 + (1/\lambda_c)^2]^{1/2}$$

where λ_c is the guide cutoff wavelength.

Spherical Resonators of Radius *a*

$\lambda = 2\pi a/U_{m,n}$ for a TE wave

$\lambda = 2\pi a/U_{m,n}'$ for a TM wave

Values of $U_{m,n}$:

$$U_{1,1} = 4.5,\ U_{2,1} = 5.8,\ U_{1,2} = 7.64$$

Values of $U_{m,n}'$:

$U_{1,1}' = 2.75$ = lowest-order root

Additional Cavity Equations

Note that resonant modes are characterized by three subscripts in the mode designations of Table 10, Chart 1, and Fig. 32.

Fig. 32 is a mode chart for a right-circular-cylindrical resonator, showing the distribution of resonant modes with frequency as a function of cavity shape. With the aid of such a chart, the various possible resonances can be predicted as the length ($2h$) of the cavity is varied by a movable piston.

Effect of Temperature and Humidity on Cavity Tuning

The resonant frequency of a cavity changes with temperature and humidity (due to changes in dielectric constant of the atmosphere) and with thermal expansion of the cavity. A homogeneous cavity made of one kind of metal will have a thermal-tuning coefficient equal to the linear coefficient of expansion of the metal (Table 11), since the frequency is inversely proportional to the linear dimension of the cavity.

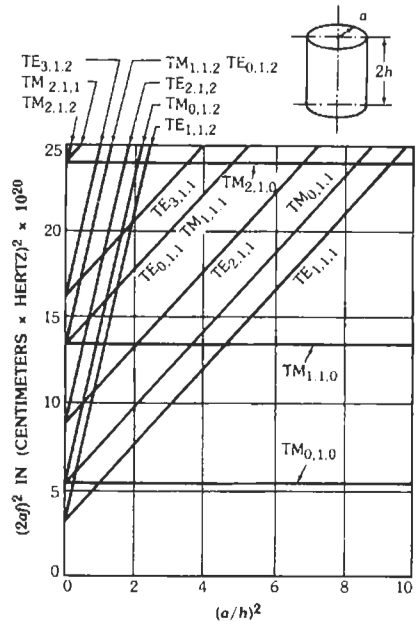


Fig. 32. Mode chart for right-circular-cylindrical cavity. (*Reprinted from* Techniques of Microwave Measurements, *by Carol G. Montgomery, 1st ed., 1947; by permission, McGraw-Hill Book Co., N.Y.*)

The relative dielectric constant of air (vacuum = 1) is given by

$$k_e = 1 + 210 \times 10]^{-6}(P_a/T) + 180 \times 10^{-6}[1 + (5580/T)](P_w/T)$$

where P_a and P_w are partial pressures of air and water vapor in millimeters of mercury and T is the absolute temperature. Fig. 33 is a nomograph showing change of cavity tuning relative to conditions at 25 degrees Celsius and 60 percent relative humidity (expansion is not included).

Invar	1.1 × 10^{-6}

Coupling to Cavities and Loaded Q

Near resonance, a cavity may be represented as a simple shunt-resonant circuit, characterized by a loaded $Q = Q_l$, where $1/Q_l = (1/Q_0) + (1/Q_{ext})$, Q_0 is the unloaded Q characteristic of the cavity itself, and $1/Q_{ext}$ is the loading due to the external circuits. The variation of Q_{ext} with size of the coupling is approximately as given in Table 12.

Equations for Coupling Through a Cavity

Table 13 summarizes some of the useful relationships in a four-terminal cavity (transmission type) for three conditions of coupling: matched input (input resistance at resonance equals Z_0 of input line), equal coupling $(1/Q_{in} = 1/Q_{out})$, and matched output (resistance seen looking into output terminals at resonance equals output-load resistance). A matched generator is assumed.

In the table, g_c' is the apparent conductance of the cavity at resonance, with no output load; the transmission T is the ratio of the actual output-circuit power delivered to the available power from the matched generator. The loaded Q is Q_l and unloaded Q is Q_0.

Cavity Coupling Techniques*

To couple power into or out of a resonant cavity, either waveguide or coaxial loops, probes, or apertures may be used.

The essentially inductive loop (a certain amount of electric-field coupling exists) is inserted in the resonator at a desired point where it can couple to a strong magnetic field. The degree of coupling may be con-

TABLE 13. COUPLING THROUGH A CAVITY

	Matched Input	Equal Coupling	Matched Output
Input Standing-Wave Ratio	1	$1+g_c' = 2(T^{-1/2}-1)$	$1+2g_c'$
Transmission Ratio = T	$1-g_c' = 1-2\rho$	$(1+g_c'/2)^{-2} = (1-\rho)^2$	$(1+g_c')^{-1} = 1-2\rho$
$Q_l/Q_0 = \rho$	$\frac{1}{2}g_c' = \frac{1}{2}(1-T)$	$[g_c'/(2+g_c')] = 1-(T^{1/2})$	$[g_c'/2(1+g_c')] = \frac{1}{2}(1-T)$

trolled by rotating the loop so that more or less loop area links this field. For a fixed location of the loop, the loaded Q of a loop-coupled coaxial resonator varies as the square of the effective loop area and inversely as the square of the distance of the loop center from the resonator axis of revolution.

The off-resonance input impedance of the loop is low, a feature that sometimes is helpful in series connections.

The capacitive probe is inserted in the resonator at a point where it is parallel to and can couple to strong electric fields. The degree of coupling is controlled by adjusting the length of the probe relative to the electric field.

The off-resonance input impedance of the probe-coupled resonator is high; this property is useful in parallel connections.

Aperture coupling is suitable when coupling wave-

guides to resonators or in coupling resonators together. In this case, the aperture must be located and shaped to excite the proper propagating modes.

For all means of coupling, the input impedance at resonance and the loaded Q may be adjusted by proper selection of the point of coupling and the degree of coupling.

Simple Waveguide Cavity*

A cavity may be made by enclosing a section of waveguide between a pair of large shunt susceptances, as shown in Fig. 34. Its loaded Q is given by

$$Q_l = \tfrac{1}{4}(\lambda_g/\lambda)^2(b^4 + 4b^2)^{1/2}\tan^{-1}(2/b)$$

and the resonant guide wavelength, λ_{g0}, is obtained from

$$2\pi l/\lambda_{g0} = \tan^{-1}(2/b)$$

Resonant Irises

Resonant irises may be used to obtain low values of loaded Q (< 30). The simplest type is shown in Fig. 35. It consists of an inductive diaphragm and a capacitive screw located in the same plane across the waveguide. For $Q_l < 50$, the losses in the resonant circuit may be ignored and

$$1/Q_l \approx 1/Q_{ext}$$

To a good approximation, the loaded Q (matched load and matched generator) is given by

$$Q_l = (B_l/2Y_0)(\lambda_{g0}/\lambda)^2$$

where B_l is the susceptance of the inductive diaphragm. This value may be taken from charts such as Figs. 28 and 29 as a starting point, but because of the proximity of the elements, the susceptance value is modified. Exact Qs must be obtained experimentally. Other resonant structures are given in Figs. 36 and 37. These are often designed so that the capacitive gap will break down under high power levels for use as transmit-receive (TR) switches in radar systems.

SURFACE-WAVE TRANSMISSION LINE*

The surface-wave transmission line is a single-conductor line having a relatively thick dielectric sheath

* G. L. Ragan, *Microwave Transmission Circuits*, New York: McGraw-Hill Book Co., 1948; Chapter 10.

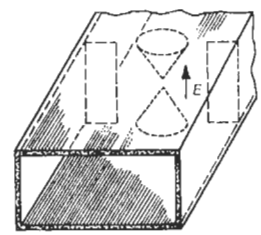

Fig. 37. Resonant structure consisting of cones with capacitive gap between apexes and thin symmetrical inductive diaphragm.

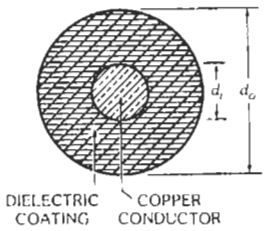

Fig. 38. Cross section of surface-wave transmission line.

(Fig. 38). The sheath diameter is often three or more times the conductor diameter. A mode of propagation that is practically nonradiating is excited on the line by means of a conical horn at each end as shown in Fig. 39. The mouth of the horn is roughly one-quarter to one wavelength in diameter. Losses are about half those of a two-wire line, but the surface-wave line has a practical lower frequency limit of about 50 megahertz. Design charts are given in Figs. 40, 41, and 42.

Fig. 39. Surface-wave transmission line with launchers at each end. (*Courtesy* Electronics.)

The losses in the two launchers combined vary from less than 0.5 decibel to a little more than 1.0 decibel, according to their design.

Conductor loss L_c by the equation below is 5 percent over the theoretical value for pure copper. Dielectric loss L_p for polyethylene at 100 megahertz is shown in Fig. 41. For other dielectrics and frequencies, find L_i by the equation.

$$L_c = 0.455 f^{1/2} / Z d_i \text{ decibels/100 feet}$$

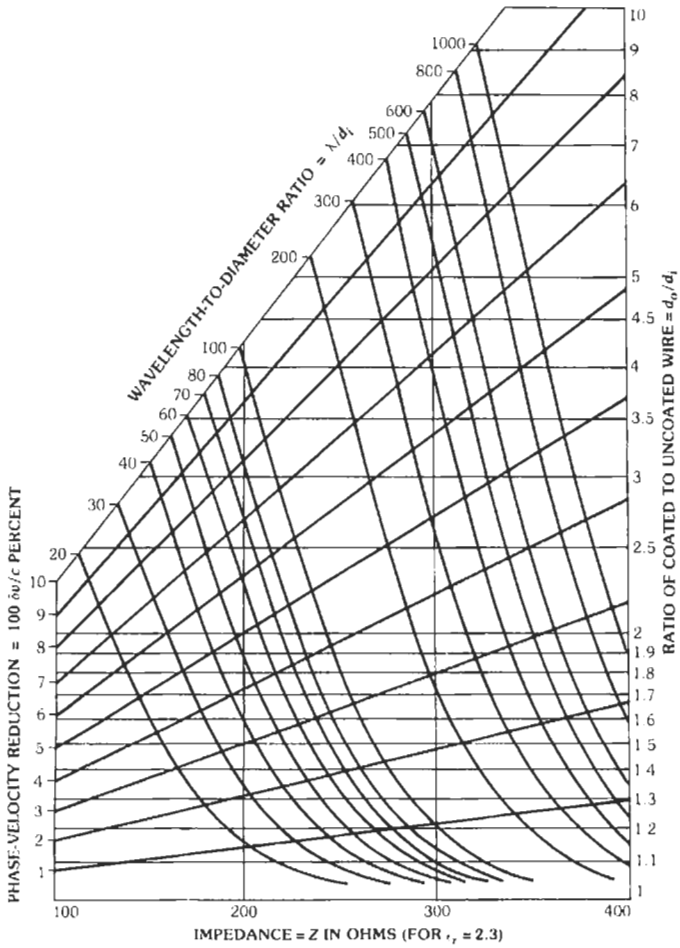

Fig. 40. Relationship among wire diameter, dielectric layer, phase-velocity reduction, and impedance (for brown polyethylene). (*Courtesy* Electronics.)

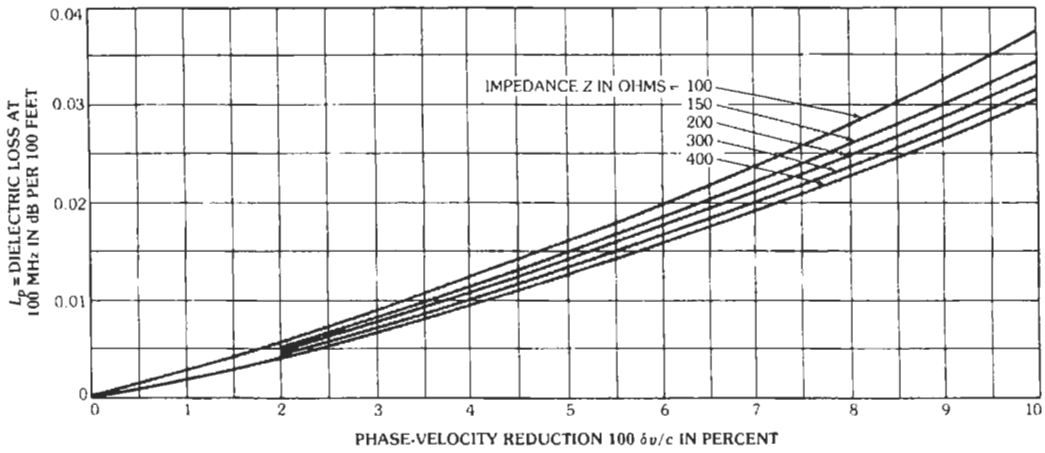

Fig. 41. Dielectric loss at 100 MHz for brown polyethylene ($\epsilon_r = 2.3$ and $F_p = 5 \times 10^{-4}$). (*Courtesy* Electronics.)

$$L_i = 26 f F_p L_p/(\epsilon_r - 1) \text{ decibels/100 feet}$$

$$L_i = L_p f/100$$

for brown polyethylene (Fig. 41).

Symbols

c = velocity of propagation in free space
d_i = diameter of the conductor (inches in equation for L_c)
d_o = outside diameter of the dielectric coating
f = frequency in megahertz
F_p = power factor of dielectric
L_c = conductor loss in decibels/100 feet
L_i = dielectric loss in decibels/100 feet
L_p = dielectric loss shown in Fig. 41
Z = waveguide impedance in ohms
δv = reduction in phase velocity
ϵ_r = dielectric constant relative to air
λ = free-space wavelength

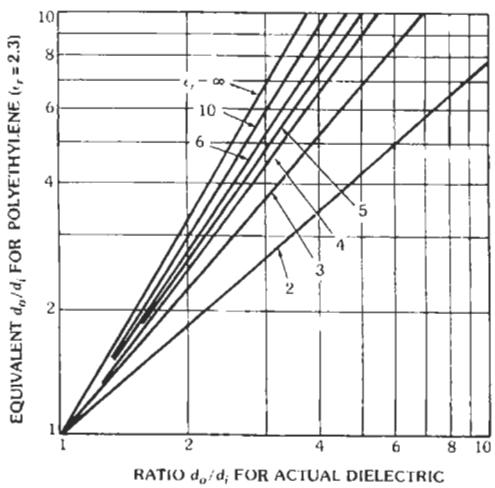

Fig. 42. Conversion chart for dielectric other than polyethylene. (*Courtesy* Electronics.)

Example: At 900 megahertz ($\lambda = 0.333$ meter), a 200-foot line is required having a permissible loss of 1.0 decibel/100 feet (not including the launcher losses). What are its dimensions?

If 20 percent is allowed for dielectric loss, the conductor loss would be $L_c = 0.8$ decibel/100 feet. Assuming $Z = 250$ ohms as a first approximation, the formula for L_c gives $d_i = 0.068$ inch. Use No. 14 AWG wire ($d_i = 0.064$ and $\lambda/d_i = 204$). Now going to Fig. 40 and assuming that $100\delta v/c = 6$ percent is adequate, we find that $d_o/d_i = 3$ and $Z = 270$ ohms.

Recomputing, $L_c = 0.79$ decibel/100 feet. By Fig. 41, $L_p = 0.017$ at 100 megahertz for brown polyethylene. For the same material at 900 megahertz, the loss is $L_i = 0.15$ decibel/100 feet.

For 200 feet, the combined conductor and dielectric loss is 1.9 decibels, to which must be added the loss of 0.5 to 1.0 decibel total for the two launchers.

Dielectric Other Than Polyethylene

Determine Z and $\delta v/c$ for polyethylene ($\epsilon_r = 2.3$) from Fig. 40. Then use Fig. 42 to find the value of d_o/d_i required for the same performance with actual dielectric constant ϵ_r. Make a computation of the new dielectric loss, using Fig. 41 and the equation for L_i.

DIELECTRIC-ROD WAVEGUIDES

The dielectric-rod waveguide has applications in antenna structures, laser devices, fiber optics, and millimetric-wave techniques.

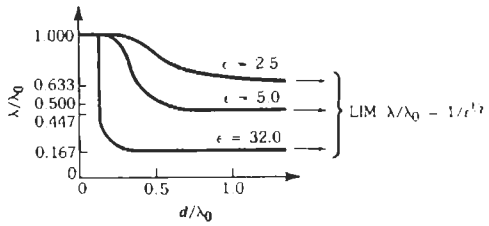

Fig. 43. Wavelength of $HE_{1,1}$ mode as a function of d/λ_0. (*From D. G. Kieley, "Dielectric Aerials,"* Methuen's Monographs on Physical Subjects. *New York: John Wiley & Sons, Inc., 1953; p. 27.*)

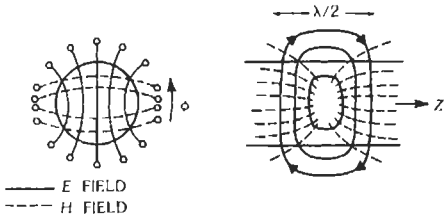

Fig. 44. $HE_{1,1}$ mode, field distribution. (*From D. G. Kieley, "Dielectric Aerials,"* Methuen's Monographs on Physical Subjects. *New York: John Wiley & Sons, Inc., 1953; p. 27.*)

The field structures for the nonradiating modes fall into two classes—circularly symmetric and nonsymmetric modes. The cutoff wavelengths (λ_c) for symmetric modes are (for the $E_{0,m}$ and $H_{0,m}$ modes)*

$$\lambda_c = \pi d(\epsilon - 1)^{1/2}/j_{0,m}$$

where,

d = rod diameter,
ϵ = relative dielectric constant,
$j_{0,m}$ = mth root of $J_0(X)$.

Analysis of the field equations reveals the necessary coexistence of an E wave with an H wave to obtain a nonsymmetric field structure.†

These modes are described as HE if the H mode is predominant, and as EH if the E mode predominates. The special case of the $HE_{1,1}$ mode, referred to as the "dipole" mode because of the resemblance of the transverse-electric-field pattern to that of the electrostatic dipole, is of special interest because it has zero cutoff frequency.‡

Fig. 43 describes the relation between λ/λ_0 and d/λ_0 for rods of different ϵ (λ = operating wavelength, λ_0 = free-space wavelength, d = rod diameter), and the field structure is shown in Fig. 44.

The attenuation of the $HE_{1,1}$ mode, for material having relatively low loss,§ is found from

$$\alpha = 27.3(\epsilon/\lambda_0)R \tan\delta \text{ (dB/cm)}$$

where,

ϵ = relative dielectric constant,
$\tan\delta$ = loss tangent of dielectric,
R = attenuation factor (dimensionless).

Note that this closely resembles the expression for TEM-mode propagation in a low-loss dielectric medium,** given by

$$\alpha = [27.3(\epsilon)^{1/2}/\lambda] \tan\delta \text{ (dB/cm)}$$

For d/λ_0 larger than 0.8, $R \approx [1/(\epsilon)^{1/2}]$. For other values see Elsasser.§

The HE_{11}-mode waveguide is impractical for many frequencies in the UHF and lower bands because of the size of the rod and field spread adjacent to the rod outside of the dielectric. At higher microwave and millimeter-wave frequencies, lack of suitable material prevents use of this rod waveguide for transmission over long distances. Some attempts are being made to use this structure as a flexible waveguide by covering the rod with a cladding dielectric having a lower dielectric constant and further with a lossy jacket. The structure then resembles that of an optical fiber.

The optical fiber is now widely used in practice due to its extremely low propagation loss. More detailed information on optical fibers can be found in Chapter 22.

RECTANGULAR DIELECTRIC GUIDES AND IMAGE GUIDES

Rectangular dielectric waveguides (Fig. 45) find use in integrated optics and in millimeter-wave integrated circuits. In the latter case, image guides (Fig. 46) are more frequently used. Modes are classified into E^y_{pq} and E^x_{pq}. The former has a principal E field in the y direction and the latter in the x direction. The subscripts p and q indicate the number of transverse field maxima in the x and y directions.

For a well-guided mode, approximate expressions for these modes in the guide in Fig. 45 are††

$$\beta = \{\epsilon_1 k^2 - (p\pi/a)^2/(1 + 2A_3/\pi a)^2 - (q\pi/b)^2/[1 + (\epsilon_2 A_2 + \epsilon_3 A_3)/\epsilon_1 \pi b]^2\}^{1/2}$$

for the E^y_{pq} mode; $p, q = 1, 2 \ldots$

$$\beta = \{\epsilon_1 k^2 - (p\pi/a)^2/(1 + 2\epsilon_3 A_3/\epsilon_1 \pi a)^2 - (q\pi/b)^2/[1 + (A_2 + A_3)/\pi b]^2\}^{1/2}$$

for the E^x_{pq} mode; $p, q = 1, 2 \ldots$

where,

$A_2 = \lambda_0/2\sqrt{\epsilon_1 - \epsilon_2}$

$A_3 = \lambda_0/2\sqrt{\epsilon_1 - \epsilon_3}$

λ_0 is the free space wavelength,
ϵ_1, ϵ_2, and ϵ_3 are the relative dielectric constants of the materials involved.

Dispersion characteristics are provided for a rectangular guide created in a glass substrate in normalized form (Fig. 47). These curves were derived with the above equations.

The above formulas are not very accurate near the cutoff frequencies. More accurate data are obtainable by using a number of techniques, the simplest of which is the effective dielectric constant (EDC) method.**

As the image guide is usually surrounded by air and is considered one half of the dielectric rod in free space for the dominant E^y_{11} mode, the formulas given above and the EDC can be used for dispersion characteristics. Results calculated by the EDC are given in Fig. 48 for various dielectric materials when the aspect ratio is $a/b = 2$.

DIELECTRIC RESONATORS

A dielectric resonator usually consists of a high dielectric material such as barium-tetratitanate formed into a pillbox shape. The dominant resonant mode is $TE_{01\delta}$ and has magnetic fields in the radial and axial directions and an electric field in the circumferential direction. The fields do not vary in the circumferential direction for this mode.

The resonant frequencies have been calculated by several methods. Fig. 49 shows resonant frequency (in the form of the relationship of the resonant wavelength to the radius) versus the structural profile for the

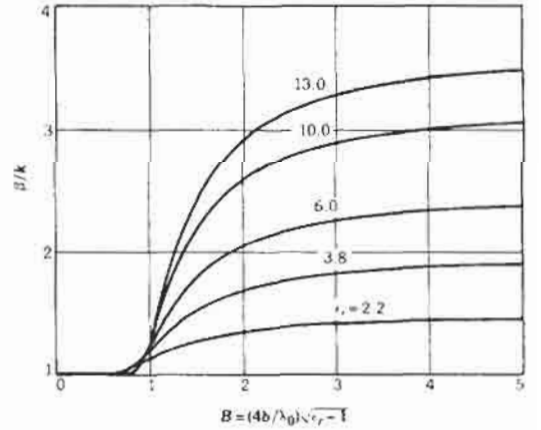

Fig. 48. Dispersion characteristics of image guide.

resonator immersed in free space.* Unloaded Q on the order of several thousands has been obtained.†

SLOT LINES

Slot line consists of a narrow gap (or slot) in a conductive coating on a dielectric substrate, as shown in Fig. 50. The slot line normally uses a dielectric substrate of sufficiently high permittivity (e.g., $\epsilon_r = 16$) that the guide wavelength is much smaller than the free-space wavelength, and the fields are closely confined to the slot with negligible radiation loss. The nature of the slot-mode configuration is such that the electric field extends across the slot while the magnetic field is in a plane perpendicular to the slot and forms closed loops at half-wave intervals.

* Calculated by the method reported by T. Itoh and R. Rudokus in "New Method for Computing the Resonant Frequencies of Dielectric Resonators," *IEEE Trans. Microwave Theory and Techniques*, Vol. MTT-25, Jan. 1977, pp. 32–54.

† For the resonant frequencies and Q of the dielectric resonator placed in a microwave integrated circuit configuration, see M. Dydyk, "Apply High-Q Resonators to mm-Wave Microstrip," *Microwaves*, Vol. 19, Dec. 1980, pp. 62–63.

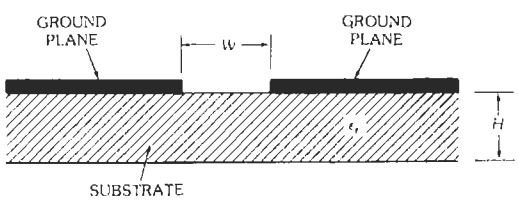

Fig. 50. Cross section of slot line.

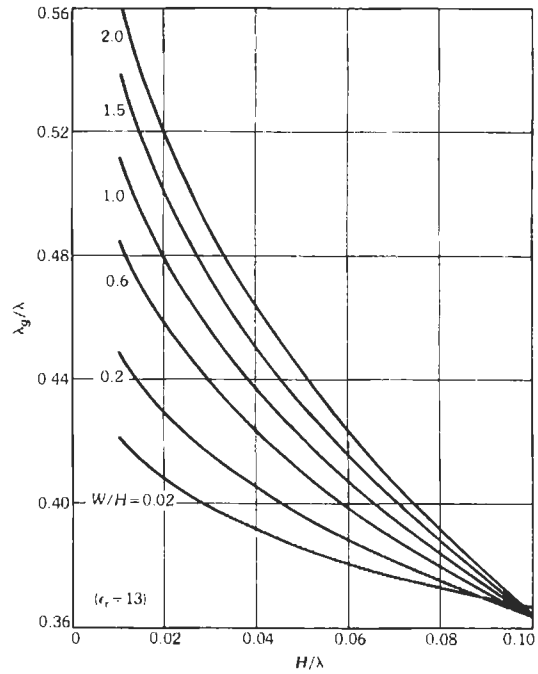
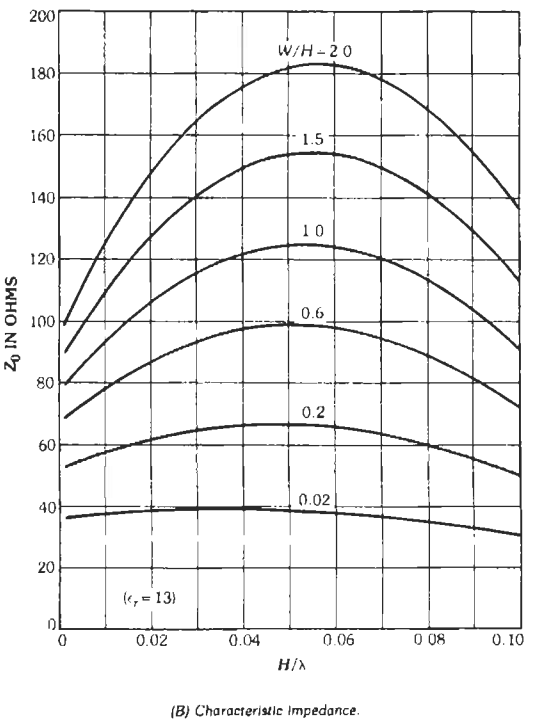


(A) Relative guide wavelength.



(B) Characteristic impedance.

Fig. 51. Characteristics of slot line.

Since the slot mode is a non-TEM wave, the definition of characteristic impedance is not unique. One definition could be

$$Z_0 = V^2/2P$$

where,

V is the peak voltage amplitude across the slot,
P is the average power flow of the wave.

For the intervals given by $9.6 \leq \epsilon_r \leq 20$, $0.02 \leq W/H \leq 2.0$, and $0.015 \leq H/\lambda \leq 0.08$ and an infinitesimally thin ground plane, a closed-form approximation to λ_g/λ (where λ_g is the guide wavelength and λ is the free-space wavelength) can be expressed as*

$$\lambda_g/\lambda = f_1(\epsilon_r)\{f_2(W/h) + f_3(W/h)(H/\lambda)^{f_4(W/H)} + f_5(W/H)\}$$

Hofmann, "Calculation of Quasi-Planar Lines for mm-Wave Application,"* 1977 IEEE MTT-S International Microwave Symposium Digest, *June 1977, pp. 381–384. © 1977 IEEE.*)

$$f_1(\epsilon_r) = 3.549\ \epsilon_r^{-0.56}$$

$$f_2(W/H) = 0.5632\ (W/H)^{0.104(W/H)^{0.266}}$$

$$f_3(W/H) = -0.8777\ (W/H)^{0.81} + 0.4233\ (W/H)^{-0.2492}$$

$$f_4(W/H) = -1.269 \times 10^{-2}\ [\ln(50\ W/H)]^{1.7} + 0.0674 \ln(50\ W/H) + 0.20$$

$$f_5(W/H) = 1.906 \times 10^{-3}\ [\ln(50\ W/H)]^{2.9} - 7.203 \times 10^{3} \ln(50\ W/H) + 0.1223$$

The accuracy of the expression is ±3.7%

A closed-form approximation for Z_0 is

$$Z_0 = (11/\epsilon_r)^{p(W/H,H/\lambda)}\ g(W/H,\ H/\lambda)$$

$$p(W/H,H/\lambda) = [-30.21 \ln(W/H) - 46.03](H/\lambda)^2 + [0.5073 \ln(W/H) + 3.358\ (W/H) + 6.492]\ (H/\lambda) - 2.013 \times 10^{-2} \ln(W/H) - 0.1374(W/H) + 0.2365$$

$$g(W/H,H/\lambda) = [-1.176 \times 10^{4}\ (W/H)^{0.502} - 6.311 \times 10^{3}\ (W/H) - 162.7]\ (H/\lambda)^2 + [900.5(W/H)^{0.28} + 1262(W/H) - 123.8]\ (H/\lambda) + 1.637 \ln(50\ W/H) + 40.99(W/H)^{0.46} + 30.96$$

Over the same parameter ranges as above, the accuracy of Z_0 is ±14.5%. For $W/H \geq 0.2$, it is better than 4%. Data calculated by these formulas are plotted in Fig. 51.

FIN-LINES

Fin-lines (Fig. 52) consist of fins separated by a gap printed on one or both sides of a dielectric substrate that is in turn placed at the center of a rectangular waveguide along its *E*-plane. Therefore, fin-lines are considered printed versions of ridged waveguides and have single-mode operating bandwidth wider than the one for an enclosing waveguide itself. Fin-lines are widely used for millimeter-wave integrated circuits in the frequency range from 26.5 GHz to 100 GHz.

The effective dielectric constant, $\epsilon_{eff} = (\lambda/\lambda_g)^2$, and the characteristic impedance, Z_L, have been computed by a number of authors. Those by H. Hofmann are reproduced in Fig. 53 for K_a-band (26.5–40 GHz) application.* The characteristic impedance is defined as the ratio of the voltage across the slot to the current on the fins and is believed useful for small values of substrate thickness and gap width. Negative values of S indicate the overlap of fins in the antipodal fin-lines. The waveguides supporting the fins of Fig. 53 are WR-28 (a = 7.112 mm, b = 3.556 mm).

31 Scattering Matrices

Georges A. Deschamps and John D. Dyson

Microwave structures are characterized by dimensions that are of the order of the wavelength of the propagated signal. The notions of current, voltage, and impedance, useful at lower frequencies, have been successfully extended to these structures, but these quantities are not as directly available for measurement; there are no voltmeters or ammeters and no apparent "terminal pair" between which to connect them. The electromagnetic field itself, distributed throughout a region, becomes the relevant quantity.

Within uniform structures, which are the usual form of waveguides, the *power flow* and the *phase* of the field at a cross section are the quantities of importance. The most usual form of measurement, that of the standing-wave pattern in a slotted section, is easily interpreted in terms of *traveling* waves and gives directly the *reflection coefficient*. The scattering description of waveguide junctions was introduced* to express this point of view. It is not, however, restricted to microwaves; a low-frequency network can be considered as a "waveguide junction" between transmission lines connected to its terminal pairs, and the scattering matrix is a useful complement to the impedance and admittance descriptions.

AMPLITUDE OF A TRAVELING WAVE

In a uniform transmission line a traveling wave is characterized, for a given mode and frequency, by the electromagnetic-field distribution in a transverse cross section and by a propagation constant h. The field in any other cross section, at a distance z in the direction of propagation, has the same pattern but is multiplied by $\exp(-jhz)$. A wave propagating in the opposite direction, for the same mode and frequency, varies with z as $\exp(jhz)$. When losses are negligible, h is real.

The *amplitude* of a traveling wave, at a given cross section in the waveguide, is a complex number a defined as follows. The square $|a|^2$ of the magnitude of a is the power flow,** that is, the integral of the Poynting vector over the waveguide cross section. The phase angle of a is that of the transverse field in the cross section.†

The amplitude of a given traveling wave varies with z as $\exp(-jhz)$.

The wave amplitude has the dimensions of the square root of a power. The meter-kilogram-second unit is therefore the $(\text{watt})^{1/2}$.

* C. G. Montgomery, R. H. Dicke, and E. M. Purcell, *Principles of Microwave Circuits* (New York: McGraw-Hill Book Co., 1948).

** The amplitude is sometimes defined to make the power flow equal to $\frac{1}{2}|a|^2$ rather than to $|a|^2$. This would correspond to the use of peak values instead of root-mean-square values.

† This phase is well defined for a pure mode, since the field has the same phase everywhere in the cross section.

REFLECTION COEFFICIENT

Definition

At a cross section in a waveguide, the reflection coefficient W (also often represented by Γ) is the ratio of the amplitudes of the waves traveling respectively in the negative and positive directions.

The positive direction must be specified and is usually taken as toward the load. To give a definite phase to the reflection coefficient, a convention is necessary that describes how the phases of waves traveling in opposite directions are to be compared. The usual convention is to compare in the two waves the phases of the transverse electric-field vectors.‡

For a short-circuit, produced, for instance, by a perfect conducting plane placed across the waveguide, the reflection coefficient is $W = -1$. For an open circuit, it is $W = +1$; and for a matched load, it is $W = 0$.

When the cross section is displayed by z in the positive direction, the reflection coefficient W becomes

$$W' = W \exp(2jhz) \qquad \text{(Eq. 1)}$$

Measurement

In a slotted waveguide equipped with a sliding voltage probe,* the position of a maximum is one where the phase of the reflection coefficient is zero.

The ratio of the maximum to the minimum (the standing-wave ratio, or swr) is

$$(\text{swr}) = (1 + |W|)/(1 - |W|)$$

Therefore

$$W = [(\text{swr}) - 1]/[(\text{swr}) + 1] \qquad \text{(Eq. 2)}$$

is the value of W at the position of a maximum. At the position of a minimum, which is easier to locate in practice, the reflection coefficient is $[1 - (\text{swr})]/[1 + (\text{swr})]$.

At any other position, the value of W is obtained by applying Eq. (1). If the reflection coefficient is wanted in some waveguide connected to the slotted section, a good match must obtain at the transition, or a correction must be applied as explained later in problems A and B (pages 31-6 to 31-8).

Reflectometers that give the reflection coefficient by direct reading, or display it on a Smith chart, are in current use.

‡ The dual convention, based on the magnetic-field vector, would give the "current" reflection coefficient, equal to minus the "voltage" reflection coefficient. The latter is used almost exclusively, and the "voltage" is implicit.

* A probe that gives a reading proportional to the electric field.

SCATTERING MATRIX OF A JUNCTION

Definition

To define accurately the waves incident on a waveguide junction and those reflected (or scattered) from it, some reference locations must be chosen in the waveguides. These locations are called the ports† of the junction. In a waveguide that can support several propagating modes, there should be as many ports as there are modes. (These ports may or may not have the same physical location in the multimode waveguide.)

At each port i of a junction, consider the amplitude a_i of the incident wave traveling toward the junction, and the amplitude b_i of the scattered wave, traveling away from it. As a consequence of Maxwell's equations, there exists a linear relation between the b_i and the a_i. Considering the a_i (where i varies from 1 to n) as the components of a vector **a,** and the b_i as the components of a vector **b,** this relation can be expressed by

$$\mathbf{b} = \mathbf{Sa}$$

where $\mathbf{S} = (s_{ij})$ as an $n \times n$ matrix called the *scattering matrix* of the junction.

The s_{ii} is the *reflection coefficient* looking into port i, and s_{ij} is the *transmission coefficient* from j to i, all other ports being terminated in matching impedances.

Properties

For a *reciprocal* junction, the transmission coefficient from i to j equals that from j to i; the matrix **S** is symmetrical.

$$\mathbf{S} = \tilde{\mathbf{S}}$$

where $\tilde{\mathbf{S}}$ denotes the transpose of **S.**

The total power incident on the junction is

$$|\mathbf{a}|^2 = \sum_{i=1}^{n} |a_i|^2$$

The total power scattered is

$$|\mathbf{b}|^2 = \sum_{i=1}^{n} |b_i|^2$$

For a lossless junction, these two powers are equal

$$|\mathbf{a}|^2 = |\mathbf{b}|^2$$

This implies that the matrix **S** is unitary (see "Matrix Algebra" in Chapter 47).

$$\mathbf{S}\dagger = \mathbf{S}^{-1}$$

For a *passive* junction with losses, $|\mathbf{b}|^2 < |\mathbf{a}|^2$, hence the matrix $\mathbf{1} - \mathbf{SS}\dagger$ is positive definite.

Change of Terminal Plane

If the port in arm i is moved away from the junction by ϕ_i electrical radians, the scattering matrix becomes

$$\mathbf{S}' = \Phi\mathbf{S}\Phi \qquad \text{(Eq. 3)}$$

where

$$\Phi = \begin{bmatrix} e^{-j\phi_1} & 0 & 0 & 0 & \cdots \\ 0 & e^{-j\phi_2} & 0 & 0 & \cdots \\ 0 & 0 & e^{-j\phi_3} & 0 & \cdots \\ \cdot & \cdot & \cdot & \cdot & \cdots \\ \cdot & \cdot & \cdot & \cdot & \cdots \\ \cdot & \cdot & \cdot & \cdot & \cdots \end{bmatrix} \qquad \text{(Eq. 4)}$$

TWO-PORT JUNCTIONS

The two-port junction includes the case of an obstacle or discontinuity placed in a waveguide as well as that of two essentially different waveguides connected to each other.

If reciprocity applies, the scattering matrix

$$\mathbf{S} = \begin{bmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{bmatrix} \qquad \text{(Eq. 5)}$$

is symmetrical

$$s_{21} = s_{12}$$

For a lossless junction, the scattering coefficients can be expressed by

$$s_{11} = + \tanh(u/2) \exp(-2j\alpha)$$

$$s_{22} = - \tanh(u/2) \exp(-2j\beta)$$

$$s_{12} = + \operatorname{sech}(u/2) \exp[-j(\alpha + \beta)] \qquad \text{(Eq. 6)}$$

in terms of three parameters, u, α, and β.

This corresponds to the representation of the junction by an ideal transformer with transformer ratio $n = \exp(-u/2)$, of hyperbolic amplitude u, placed between two sections of transmission line with electrical lengths α and β, respectively.

The quantity $-20 \log_{10} |s_{12}|$ is the insertion loss.

TRANSFORMATION MATRIX

To find the effect of successive obstacles in a waveguide or to combine two-port junctions placed in cascade, it is convenient to introduce the wave transformation matrix **T.** This matrix **T** relates the traveling

† At lower frequencies, for a network connecting transmission lines, a port is a terminal pair.

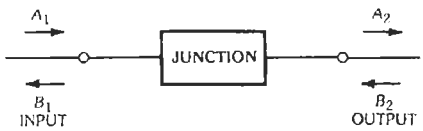

Fig. 1. Convention for wave transformation matrix T.

waves on one side of the junction to those on the other side. Using the notations of Fig. 1

$$\begin{bmatrix} A_1 \\ B_1 \end{bmatrix} = T \begin{bmatrix} A_2 \\ B_2 \end{bmatrix} \quad \text{(Eq. 7)}$$

The 2 × 2 transformation matrix **T** may be deduced from the scattering matrix **S**

$$\mathbf{T} = s_{21}^{-1} \begin{bmatrix} 1 & -s_{22} \\ s_n & -\det \mathbf{S} \end{bmatrix} \quad \text{(Eq. 8)}$$

Conversely, if $\mathbf{T} = (t_{ij})$, the scattering matrix is

$$\mathbf{S} = t_{11}^{-1} \begin{bmatrix} t_{21} & \det \mathbf{T} \\ 1 & -t_{12} \end{bmatrix} \quad \text{(Eq. 9)}$$

When reciprocity applies to the junction

$$\det \mathbf{T} = s_{12}/s_{21} \quad \text{(Eq. 10)}$$

becomes unity.

The input reflection coefficient $W' = B_1/A_1$ is related to the load reflection coefficient $W = B_2/A_2$ by

$$W' = (t_{21} + t_{22}W)/(t_{11} + t_{12}W) \quad \text{(Eq. 11)}$$

$$= s_{11} + [s_{12}^2 W/(1 - s_{22}W)] \quad \text{(Eq. 12)}$$

When a number of junctions, 1, 2, 3, are placed in cascade (Fig. 2), the output port of each of them being the input port of the following one, the resulting junction has the transformation matrix

$$\mathbf{T} = \mathbf{T}_1\mathbf{T}_2\mathbf{T}_3$$

If n similar junctions with transformation matrix **T** are placed in cascade, the resulting transformation matrix is $\mathbf{T}^n$.

Letting trace $\mathbf{T} = t_{11} + t_{22} = 2 \cos \theta$

$$\mathbf{T}^n = (\sin n\theta/\sin \theta)\,\mathbf{T} - [\sin (n-1)\,\theta/\sin \theta] \quad \text{(Eq. 13)}$$

MEASUREMENT OF THE SCATTERING MATRIX

The measurement of the scattering parameters of the junction by conventional techniques is covered in Chapter 12. However, there may be occasions when it is not possible, or not desirable, to connect equipment to the

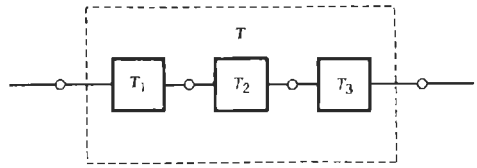

Fig. 2. Junctions in cascade.

output ports for the measurement of the transmission coefficients s_{ij}. Under these conditions, it is still possible to determine the coefficients s_{ii} and s_{ij} from measurements of the reflection coefficient at one port.

For any load with reflection coefficient W, placed on side 2 of a junction, the input reflection coefficient W' on side 1 can be measured. Coefficient W' is called the *image* of W, and they are related by the transformation

$$W' = s_{11} + [s_{12}s_{21}W/(1 - s_{22}W)] \quad \text{(Eq. 14)}$$

The measurement of the images of three known loads, W_1, W_2, W_3, will provide sufficient information to determine, either analytically or graphically, the coefficients s_{11} and s_{22} and the product $s_{12}s_{21}$.

Considering an analytical approach first, Eq. 14 can be expressed as:

$$W_i' = s_{11} + W_iW_i's_{22} - W_i\Delta s \quad \text{(Eq. 15)}$$

where,

$$\Delta s = s_{11}s_{22} - s_{12}s_{21}$$
$$i = 1, 2, 3$$

Equation 15 represents three linear equations in s_{11}, s_{22}, and Δs with solutions:

$$s_{11} = [W'_1 W_2 W_3 (W'_2 - W'_3) + W'_2W_3W_1 (W'_3 - W'_1) + W'_3W_1 W_2(W'_1 - W'_2)]/D$$

$$s_{22} = -[W_1 (W'_2 - W'_3) + W_2 (W'_3 - W'_1) + W_3 (W'_1 - W'_2)]/D$$

$$\Delta s = -[W'_1 W_1 (W'_2 - W'_3) + W'_2W_2(W'_3 - W'_1) + W'_3 W_3 (W'_1 - W'_2)]/D$$

$$D = [W_2W_3(W'_2 - W'_3) + W_3W_1(W'_3 - W'_1) + W_1W_2(W'_1 - W'_2)] \quad \text{(Eq. 16)}$$

Once s_{11}, s_{22}, and $s_{12}s_{22}$ are known, the reflection coefficient W_L of an unknown termination can be determined from the measured image W_M by rewriting Eq. (14):

$$W_L = (W_M - s_{11})/[s_{12}s_{21} + s_{22}(W_M - s_{11})] \quad \text{(Eq. 17)}$$

Solutions to Eq. 14 can also be obtained graphically.* Doing so provides an insight into the transformation of W into its image W'. The images of various known loads can be plotted on a reflection chart and the scattering coefficients deduced by the following procedures.

(A) With a matched load, one obtains directly s_{11} plotted as O' on Fig. 3. Point O' is called the iconocenter.

(B) With a sliding short-circuit on side 2, or any variable reactive load, the input reflection coefficient describes a circle Γ', image of the unit circle Γ. This circle can be deduced from three or more measurements. Let C be its center and R its radius (Fig. 3). The magnitudes of the scattering coefficients result:

$$|s_{11}| = OO'$$

$$|s_{22}| = O'C/R$$

$$|s_{12}|^2 = R(1 - |s_{22}|^2) \qquad \text{(Eq. 18)}$$

The phases of these coefficients all follow from one more measurement as described in **(C)**.

(C) The input reflection coefficient is measured with an open-circuit load placed at port 2, or for a short-circuit placed a quarter wave away from it. This may be one of the measurements taken in step **(B)**. It gives (Fig. 4) the point P', image of the point $P(W = +1)$.

A point P'' is constructed by projecting P' through O' onto Q on Γ', then Q through C onto P'' on Γ' (Fig. 4). Then

$$\text{Phase of } s_{11} = \text{angle } (OP, OO')$$

$$\text{Phase of } s_{22} = \text{angle } (O'C, CP'')$$

$$\text{Phase of } s_{12} = \tfrac{1}{2} \text{ angle } (OP, CP'') \qquad \text{(Eq. 19)}$$

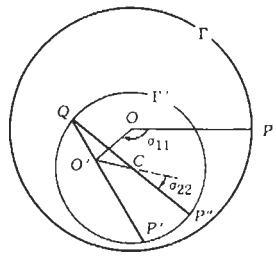

Fig. 4. Construction for the phases of the scattering coefficients.

(D) When no matched load is available, as was assumed in **(A)**, the iconocenter O' may be obtained as in Fig. 5. Let P_1, P_2, P_3, P_4 represent the input reflection coefficients when a short circuit is placed successively at port 2 and at distances $\lambda/8$, $\lambda/4$, and $3\lambda/8$ from it. These points define the circle Γ' [as in **(B)**], and the intersection I (the crossover point) of P_1P_3 and P_2P_4 may be used to find O': draw perpendiculars to CI at points C and I up to their intersections with Γ' and get C' and I'; then O' is the intersection of CI and $C'I'$.

The point P_3 is identical to P' in **(C)** above; hence the four measurements give the complete scattering matrix by constructing P'' and applying Eqs. 18 and 19.

(E) The construction of O' in **(D)** above is valid with any sliding load not necessarily reactive. Taking a load with small standing-wave ratio increases the accuracy of the construction.

(F) When exact measurements of the displacements of the sliding load are difficult to make, for instance if the wavelength is very short, the point O' may be obtained as follows. Using a reactive load, construct the circle Γ' as in **(B)** above; then using a sliding load as in **(E)** above, construct a circle Γ'' (see Fig. 6). The iconocenter O' is the hyperbolic midpoint of the diameter of Γ'' (through C) with respect to Γ'. It may be constructed by means of the hyperbolic protractor*

(Fig. 8) or by means of the dotted-line construction (Fig. 5).

GEOMETRY OF REFLECTION CHARTS

The following brief outline is complemented by the section on hyperbolic trigonometry contained in Chapter 47.

Conformal Charts

A reflection coefficient can be represented by a point in a plane just as any complex number is represented on the Argand diagram.

The passive loads, $|W| \leq 1$, are represented by points inside a unit circle Γ. Inside this circle, the lines of constant resistance and reactance (Smith chart) or the lines of constant magnitude and phase of the impedance (Carter chart) may be drawn.

The transformation from a load reflection coefficient W to its image W' through a two-port junction is bilinear as in Eq. 11 or 12. On the reflection chart, this transformation maps circles into circles and preserves the angle between curves and the cross ratio of four points; if

$$[W_1, W_2, W_3, W_4] = \frac{W_1 - W_3}{W_1 - W_4} : \frac{W_2 - W_3}{W_2 - W_4}$$

denotes the cross ratio of four reflection coefficients W_1, W_2, W_3, and W_4, then

$$[W_1', W_2', W_3', W_4'] = [W_1, W_2, W_3, W_4]$$

The transformation through a lossless junction preserves also the unit circle Γ and therefore leaves invariant the *hyperbolic distance* defined in Chapter 47. The hyperbolic distance to the origin of the chart is the *mismatch,* that is, the standing-wave ratio expressed in decibels. It may be evaluated by means of the proper graduation on the radial arm of the Smith chart. For two arbitrary point W_1, W_2, the hyperbolic distance between them may be interpreted as the mismatch that results from the load W_2 seen through a lossless network that matches W_1 to the input waveguide.

Projective Chart

The reflection coefficient W is represented by the point $\bar{W}$ (Fig. 7) on the same radius of the circle Γ but at a distance

$$O\bar{W} = 2OW/(1 + OW^2) \qquad \text{(Eq. 20)}$$

from the origin.

This is equivalent to using the standing-wave ratio squared instead of the direct ratio:

$$\bar{W}J/\bar{W}I = (WJ/WI)^2 \qquad \text{(Eq. 21)}$$

The transformation of Eqs. 11, 12, when the junction is lossless, is represented on this chart by a projective transformation, that is, one that maps straight lines into straight lines and preserves the cross ratio of four points on a straight line. It therefore preserves the hyperbolic distance defined in Chapter 47.

EVALUATION OF HYPERBOLIC DISTANCE

On the projective chart, the hyperbolic distance $\langle AB \rangle$ between two points A and B inside the circle Γ can be evaluated by means of a hyperbolic protractor as shown in Fig. 8. The line AB is extended to its intersections I and J with Γ. The protractor is placed so that the sides OX, OY of the right angle go through I and J. (This can be done in many ways but does not affect the result.) The numbers read on the radial lines of the protractor going through A and B, respectively, are added if A and B are on opposite sides of the radial line marked O; they are subtracted otherwise. This result divided by 2 is the distance $\langle AB \rangle$. In Fig. 8, for instance

$$\langle AB \rangle = \tfrac{1}{2}(12 + 4) = 8 \text{ decibels}$$

Problem A

A slotted line with 100-ohm characteristic impedance is used to make measurements on a 60-ohm

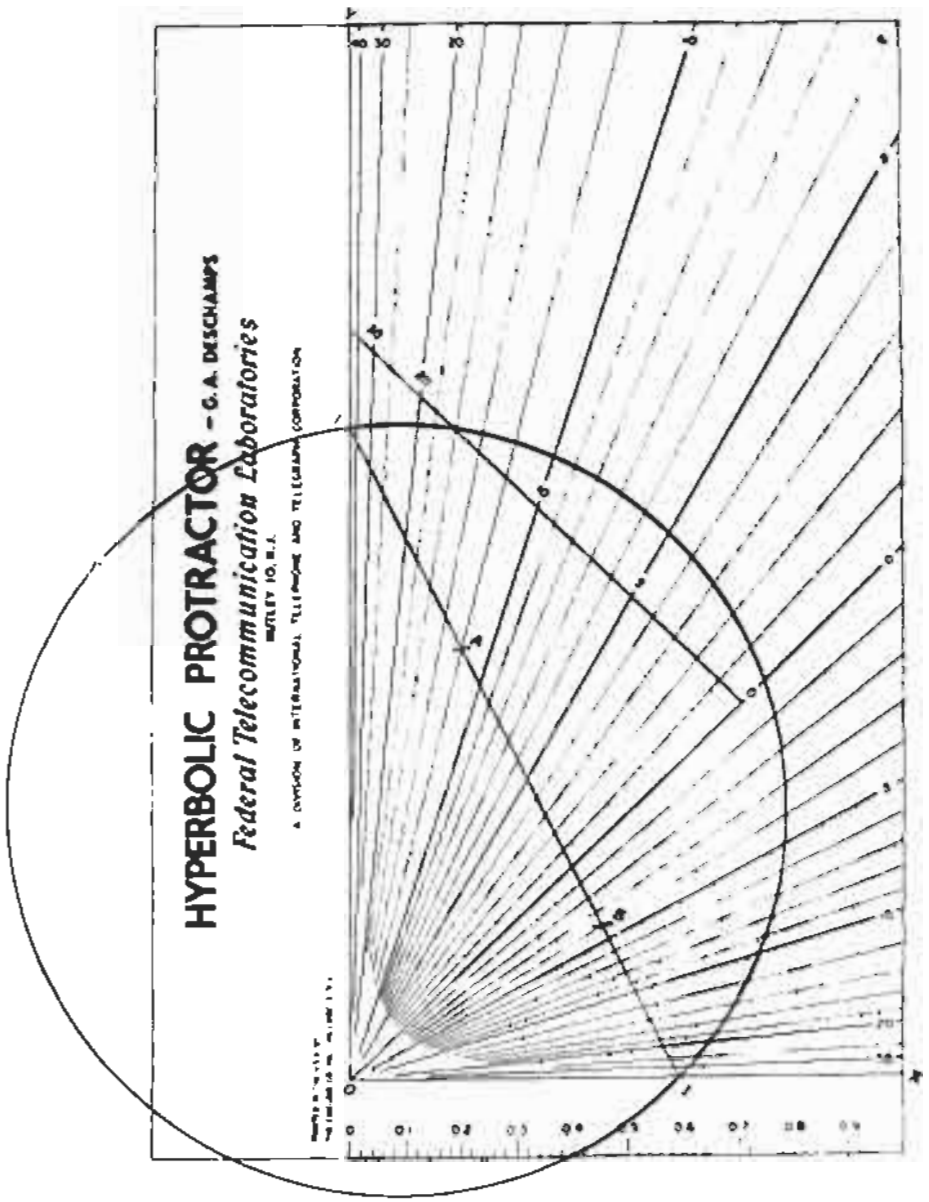

Fig. 8. Definition and evaluation of hyperbolic distance $\langle AB \rangle$ using hyperbolic protractor.

coaxial line. The transition acts as an ideal transformer. Find the reflection coefficient W of an obstacle placed in the coaxial line, knowing that it produces a reflection coefficient

$$W' = 0.5 \exp(j\pi/2)$$

in the slotted line.

A match in the coaxial line appears in the slotted line as a normalized impedance of 0.6; hence the mismatch (standing-wave ratio in decibels) is 4.5 decibels. The corresponding point $\overline{O}'$ is plotted on the projective chart as in Fig. 9 at the distance $\langle O\overline{O}' \rangle = 4.5$. (On the Smith chart drawn inside the same unit circle Γ, the point would be O'.)

The point $\overline{W}'$ representing the unknown load is plotted at the hyperbolic distance

$$20 \log_{10}[(1 + 0.5)/(1 - 0.5)] = 9.5 \text{ decibels}$$

from the origin in the direction $+90°$. The hyperbolic distance

$$\langle \overline{O}'\overline{W}' \rangle = 11 \text{ decibels}$$

is measured with the protractor. This is the mismatch produced by the obstacle in the coaxial line. It corresponds to a magnitude of the reflection coefficient of 0.56.

The phase of this reflection coefficient is the elliptic angle $\langle \overline{O}'P, \overline{O}'\overline{W}' \rangle$. It is evaluated as explained in Chapter 47: extend QO' up to R on Γ and measure the arc

$$PR = 56°$$

The answer is

$$W = 0.56 \angle 56°$$

Problem B

If the transition between the slotted line and the waveguide is not an ideal transformer as in problem A, its properties may be found by the method described earlier in this chapter. In particular, if the transition has no losses (the circle Γ' coincides with Γ), the point O' may be found as in **(A), (D), (E),** or **(F),** above, the point P' as in **(C)** or **(D),** above, and this completes the calibration.

For any load placed in the waveguide and producing the reflection coefficient W' in the slotted line, the corrected standing-wave ratio in decibels is the hyperbolic distance $[O'W']$. This is evaluated by constructing $\overline{O}'$, $\overline{W}'$ on the projective chart and measuring $\langle \overline{O}'\overline{W}' \rangle$ with the protractor. The phase angle is the elliptic angle $\langle \overline{O}'P', \overline{O}'\overline{W}' \rangle$ (see Chapter 47).

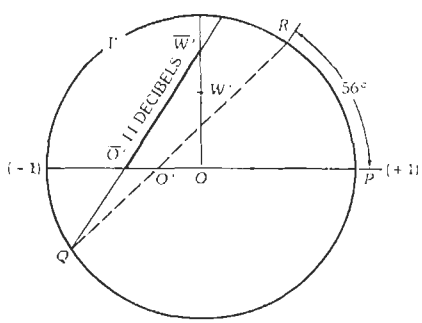

Fig. 9. Measurement of reflection coefficient with a mismatched slotted line.

Problem C

A section of coaxial line 90 electrical degrees in length and with 100-ohm characteristic impedance is inserted between a 50-ohm coaxial line on one side and a 70-ohm coaxial line on the other (Fig. 10). Find the transformer ratio $n = \exp(-u/2)$ and the electrical lengths α, β of the representation [Eqs. (6)].

The two discontinuities are assumed to act as ideal transformers with hyperbolic amplitudes

$$20 \log_{10} \frac{100}{50} = 6 \text{ decibels} = 0.67 \text{ neper}$$

and

$$20 \log_{10} \frac{70}{100} = -3.1 \text{ decibels} = -0.36 \text{ neper}$$

The characteristic polygon* on the projective chart is

* G. A. Deschamps, *Hyperbolic Protractor for Microwave Impedance Measurements and Other Purposes* (New York: International Telephone and Telegraph Corp., 1953; pp. 15–16 and p. 41).

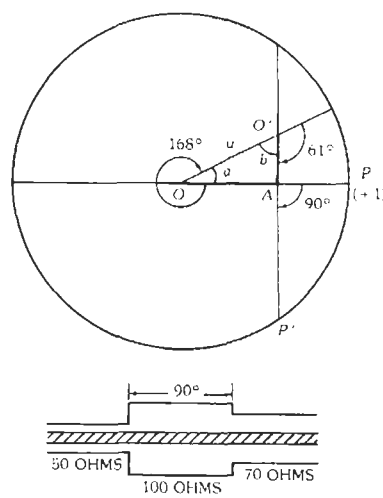

Fig. 10. Solution for transformation in transmission line.

a triangle OAO' with right angle A; hence, $u = \langle OO' \rangle$ is given by

$$\cosh u = \cosh 0.69 \cosh 0.36$$

$$u = 0.78 \text{ neper} = 6.8 \text{ decibels}$$

$$n = \exp(-u/2) = 1/1.48$$

The lengths of line α and β can be deduced from evaluating the elliptic angles $\langle OA, OO' \rangle = a$ and $\langle O'A, O'O \rangle = b$

$$\tan a = \tanh 0.36/\sinh 0.69 = 0.46$$

$$a = 24.7°$$

$$\tan b = \tanh 0.69/\sinh 0.36 = 1.62$$

$$b = 58.4°$$

$$\alpha = \tfrac{1}{2}(360° - 24.7°) = 167.6°$$

$$\beta = \tfrac{1}{2}(180° - 58.4°) = 60.8°$$

The resulting equivalent network is shown in Fig. 11. It could also have been obtained by geometrical evaluation of the distance $\langle OO' \rangle$ with the hyperbolic protractor and the elliptic angles a and b by constructions (page 31-7 and Chapter 47).

CORRESPONDENCES WITH CURRENT, VOLTAGE, AND IMPEDANCE VIEWPOINTS

Normalized Current and Voltage

In a waveguide, at a point where the amplitudes of the waves traveling in the positive and negative directions are, respectively, a and b, the normalized voltage v and the normalized current i are defined by the expressions

$$v = a + b$$

$$i = a - b \qquad \text{(Eq. 22)}$$

The *net power flow* at that point in the positive direction is

$$|a|^2 - |b|^2 = \text{Re } vi^* \qquad \text{(Eq. 23)}$$

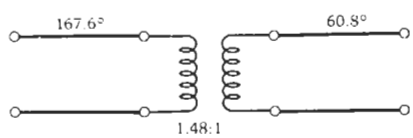

Fig. 11. Equivalent circuit for Fig. 10.

Current and Voltage Not Normalized

A more general definition for current and voltage becomes possible when a meaning has been assigned to the characteristic impedance Z_0 of the waveguide

$$V = vZ_0^{1/2}$$

$$I = iY_0^{1/2} \qquad \text{(Eq. 24)}$$

where,

$Y_0 = 1/Z_0$ is the characteristic admittance,
v and i are the normalized values defined above.

Conversely, if by some convention the voltage (or the current) has been defined, a characteristic impedance will result from Eqs. (24). This is the case for a two-conductor waveguide supporting the tem mode; the characteristic impedance is the ratio of voltage to current in a traveling wave.

If V and I are the voltage and the current at a point in a waveguide of characteristic impedance $Z_0 = 1/Y_0$, the amplitudes of the waves traveling in both directions at that point are

$$a = \tfrac{1}{2}(V Y_0^{1/2} + IZ_0^{1/2})$$

$$b = \tfrac{1}{2}(V Y_0^{1/2} + IZ_0^{1/2}) \qquad \text{(Eq. 25)}$$

Normalized Impedance and Admittance

At a point in a waveguide, the normalized impedance is $Z = v/i$, and the normalized admittance is the inverse, $Y = 1/Z$.

They are related to the reflection coefficient $W = b/a$ by

$$Z = (1 + W)/(1 - W)$$

$$Y = (1 - W)/(1 + W) \qquad \text{(Eq. 26)}$$

hence

$$W = (1 - Y)/(1 + Y) = (Z - 1)/(Z + 1) \qquad \text{(Eq. 27)}$$

Impedance and Admittance Matrix of a Junction

The $\mathbf{Z}$ and $\mathbf{Y}$ matrices of a junction are defined in terms of the scattering matrix $\mathbf{S}$ by

$$\mathbf{Y} = (\mathbf{1} - \mathbf{S})(\mathbf{1} + \mathbf{S})^{-1}$$

$$\mathbf{Z} = (\mathbf{1} + \mathbf{S})(\mathbf{1} - \mathbf{S})^{-1} \qquad \text{(Eq. 28)}$$

The matrices $\mathbf{Y}$ and $\mathbf{Z}$ do not always exist, since $\mathbf{S}$ may have eigenvalues $+1$ or -1, which means that det $(\mathbf{1} - \mathbf{S})$ or det $(\mathbf{1} + \mathbf{S})$ may be zero.

Conversely

$$\mathbf{S} = (\mathbf{1} - \mathbf{Y})(\mathbf{1} + \mathbf{Y})^{-1} = (\mathbf{Z} - \mathbf{1})(\mathbf{Z} + \mathbf{1})^{-1} \qquad \text{(Eq. 29)}$$

These equations may be used as definitions for the scattering matrix of lumped-constant networks with n terminal pairs. This is equivalent to considering the network as a junction between n transmission lines of unit characteristic impedance.

If the network or the junction is reciprocal, $\mathbf{Y}$ and $\mathbf{Z}$ are purely imaginary.

For a two-port junction, Eq. 28 becomes

$$\mathbf{Y} = (\mathbf{1} - \mathbf{S})(\mathbf{1} + \mathbf{S})^{-1}$$

$$= [\det (\mathbf{1} + \mathbf{S})]^{-1} \times \begin{bmatrix} 1 - \det \mathbf{S} + (s_{22} - s_{11}) & -2s_{12} \\ -2s_{21} & 1 - \det \mathbf{S} - (s_{22} - s_{11}) \end{bmatrix} \qquad \text{(Eq. 30)}$$

and

$$\mathbf{Z} = (\mathbf{1} + \mathbf{S})(\mathbf{1} - \mathbf{S})^{-1}$$

$$= [\det (\mathbf{1} - \mathbf{S})]^{-1} \times \begin{bmatrix} 1 - \det \mathbf{S} - (s_{22} - s_{11}) & 2s_{12} \\ 2s_{21} & 1 - \det \mathbf{S} + (s_{22} - s_{11}) \end{bmatrix} \qquad \text{(Eq. 31)}$$

$$\det (\mathbf{1} + \mathbf{S}) = 1 + \operatorname{tr} \mathbf{S} + \det \mathbf{S}$$

$$= 1 + (s_{11} + s_{22}) + (s_{11}s_{22} + s_{12}s_{21})$$

$$\det (\mathbf{1} - \mathbf{S}) = 1 - \operatorname{tr} \mathbf{S} + \det \mathbf{S}$$

$$= 1 - (s_{11} + s_{22}) + (s_{11}s_{22} - s_{12}s_{21})$$

The matrices $\mathbf{Y}$ and $\mathbf{Z}$ relate normalized voltages and currents at both ports (Fig. 12) as follows:

$$\begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \mathbf{Z} \begin{bmatrix} i_1 \\ i_2 \end{bmatrix}$$

$$\begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \mathbf{Y} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}$$

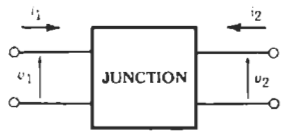

Fig. 12. Sign convention for defining the impedance and admittance of a two-port junction.

TRANSFORMATION MATRIX

A transformation matrix useful for composing two-port junctions in cascade relates the voltage and current on one side of the junction to the same quantities on the other side. With the notation in Fig. 13

$$\begin{bmatrix} v' \\ i' \end{bmatrix} = \mathbf{U} \begin{bmatrix} v \\ i \end{bmatrix} \qquad \text{(Eq. 32)}$$

The matrix $\mathbf{U}$, sometimes called the *ABCD* matrix, has the same properties as $\mathbf{T}$ described earlier.

For a series element that has a normalized impedance Z

$$\mathbf{U} = \begin{bmatrix} 1 & Z \\ 0 & 1 \end{bmatrix}$$

and for a shunt element with normalized admittance Y

$$\mathbf{U} = \begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix}$$

A product of matrices of these types gives the transformation matrix for any ladder network.

For the shunt element Y, the scattering matrix is

$$\mathbf{S} = (2 + Y)^{-1} \begin{bmatrix} -Y & 2 \\ 2 & -Y \end{bmatrix} \qquad \text{(Eq. 33)}$$

hence

$$s_{11} = s_{22}$$

$$s_{12} = 1 + s_{11} \qquad \text{(Eq. 34)}$$

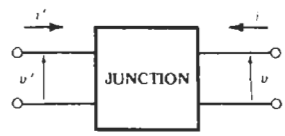

Fig. 13. Sign convention for voltages and currents related by the transformation matrix.

For the series element Z, the scattering matrix is

$$\mathbf{S} = (2 + Z)^{-1} \begin{bmatrix} Z & 2 \\ 2 & Z \end{bmatrix} \qquad \text{(Eq. 35)}$$

hence

$$s_{11} = s_{22}$$

$$s_{12} = 1 - s_{11} \qquad \text{(Eq. 36)}$$

Relations 34 and 36 are characteristic, respectively, of a shunt and a series obstacle in a waveguide.

The matrix $\mathbf{T}$ can be deduced from $\mathbf{U}$ and vice versa:

$$\mathbf{T} = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \mathbf{U} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

$$= \frac{1}{2}\begin{bmatrix} u_{11}+u_{12}+u_{21}+u_{22} & u_{11}-u_{12}+u_{21}-u_{22} \\ u_{11}+u_{12}-u_{21}-u_{22} & u_{11}-u_{12}-u_{21}+u_{22} \end{bmatrix}$$

(Eq. 37)

A similar equation will transform $\mathbf{T}$ into $\mathbf{U}$, since

$$\mathbf{U} = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \mathbf{T} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \qquad \text{(Eq. 38)}$$

32 Antennas

Robert C. Hansen

GENERAL

Introduction

The field of antennas is sufficiently broad to be beyond the scope of this chapter, even for succinct design information. Thus the intent is to be eclectic rather than inclusive. Fortunately, several excellent books on antennas are available. For more detailed design data, the reader should consult the two-volume *Handbook of Antenna Design* edited by Rudge et al.* Thorough texts on antenna theory, including extensive coverage of the powerful geometric theory of diffraction (GTD) and moment method analytical approaches, as well as exemplary computer programs, are by Balanis† and by Stutzman and Thiele.‡ A third excellent text, which has extensive coverage on fixed beam array design, is by Elliott.§ Finally, the most extensive treatment of phased arrays (electronic scanning) is *Phased Array Antennas* by Hansen;" another useful book is still the three-volume *Microwave Scanning Antennas* by Hansen.#

Six parts comprise this chapter. Basic antenna behavior, including definitions, fields, near-field power density, antenna noise temperature, and polarization coupling are in the general part. The next two parts cover, respectively, low- and medium-gain antennas, where dipoles, slots, loops, and microstrip patches are low gain, and horns, Yagi–Udas, helices, spirals, and log-periodics are medium-gain. Arrays of all types are covered next. Aperture distributions, because of their common importance, occupy an entire part. Finally, reflector-type antennas are the subject of the last part. Some old favorites have been left out, and this reflects somewhat the changing antenna usage.

Because of the power and ready availability of calculators and computers, tables of calculated functions have largely been omitted. Instead, key performance indices have been quantified, with design formulas given so that the designer can implement them directly.

Definitions

Directivity and gain are measures of how well energy is concentrated in a given direction. Directivity is the ratio of power density (PD) in that direction to the power density that would be produced if the power were radiated isotropically. The reference can be linearly or circularly polarized, and directivity is often given in dBi, decibels above isotropic. Some early literature refers to gain above a dipole; this usage is deprecated, as it is confusing and unnecessary. Directivity, then, is given by

$$D = 4\pi PD \Big/ \sqrt{\frac{\varepsilon}{\mu}} \int\int |E|^2 \, d\Omega$$

Gain includes antenna losses; thus gain is the field intensity produced in the given direction by a fixed input power to the antenna. Gain is related to directivity by efficiency η, and is

$$G = D\eta$$

$$G = 4\pi PD/P_{\text{in}}$$

Through reciprocity, directivity is independent of transmission or reception, as is gain. Gain, as widely used in the industry, includes the impedance mismatch factor. However, the academic gain does not.

Effective area is defined by:

$$A_e = \lambda^2 G/4\pi$$

where λ is the free-space wavelength. (All through this chapter, commonly used symbols are employed.) For an antenna matched to a load, the load power is $P_{\text{load}} = PD \cdot A_e$, where PD is the power density at the antenna in watts per square meter.

Path loss is part of the range equation, where received power is related to transmitted power as

$$P_r = P_t G_t G_r \lambda^2/(4\pi R)^2$$

The distance between antennas is R, and the path loss is given by

$$\text{Path loss} = (4\pi R/\lambda)^2$$

Effective length relates the ability of a receiving antenna to produce open-circuit voltage. It is

$$l_e = V/E$$

where V is the open-circuit voltage for an incident field strength E. The early usage "effective height," is deprecated, as it also has a meaning for antennas over the earth. For any antenna, the preceding parameters are related through

$$30\pi l_e^2 = R_r A_e$$

Here, R_r is radiation resistance, where the radiated power of a current-driven antenna is $P_r = I^2 R_r$. Table 1 gives often used parameters for short dipoles and for half-wave dipoles. Dipole half-length and monopole lengths are h, and θ_3 is the half-power beamwidth, i.e., the width of the pattern between –3–dB points. For loops, the diameter is d, N is the number of turns, $k = 2\pi/\lambda$, and μ_e is the effective permeability.

TABLE 1. LOW-GAIN-ANTENNA PARAMETERS

Type	D	l_e	A_e	θ_1	R_r
Isotropic	1	—	$\lambda^2/4\pi = 0.0796\lambda^2$	360°	—
Short Dipole	1.5	h	$3\lambda^2/8\pi = 0.1194\lambda^2$	90°	$20k^2h^2$
$\lambda/2$ Dipole	1.6409	λ/π	$30\lambda^2/\pi R_r = 0.1306\lambda^2$	78.078°	73.13
$\lambda/4$ Monopole	3.2818	λ/π	$30\lambda^2/\pi R_r = 0.2612\lambda^2$	78.078°	36.56
Small Loop	1.5	$\pi Nkd^2\ \mu_c/4$	$3\lambda^2/8\pi = 0.1194\lambda^2$	90°	$5\pi^2N^2k^4d^4\mu_c^2/4$

Bandwidth may be defined through pattern characteristics, efficiency, impedance, etc. The latter is often used, with the bandwidth being the range between the two frequencies where the radiated power falls to half (the 3–dB, or half-power, bandwidth) or where the VSWR reaches a fixed value, e.g., 2. Note that half-power bandwidth occurs when the input $R = |X|$, and for VSWR = 5.828. Since the product of antenna Q and fractional bandwidth, BW, is:

$$Q \cdot BW = (\text{VSWR} - 1)/\sqrt{\text{VSWR}}$$

the bandwidth at one VSWR is related to that at another VSWR by:

$$BW_1/BW_2 =$$

$$[(\text{VSWR}_1 - 1)/(\text{VSWR}_2 - 1)](\text{VSWR}_2/\text{VSWR}_1)^{1/2}$$

For example, the 3–dB bandwidth is 2.828 times larger than the VSWR = 2 bandwidth. These results include the effect of a matched load (generator); for half-power $Q \cdot BW = 2$.

Field regions must be defined carefully, as the early optical terms are inadequate for modern antennas. The terms Fraunhofer and Fresnel, which refer to specific field integral approximations in optics, are obsolete and deprecated. For example, with focused antennas, a Fraunhofer-type pattern may exist well within the usual D^2/λ near-far field boundary distance, while a Fresnel-type field may exist for smaller and for larger distances. Some antennas have no Fraunhofer-type fields anywhere, as they have no phase center, e.g., some horns and annular slots. Finally, the Fresnel approximation itself is unambiguous only in one dimension; for the more common and useful area sources, the Fresnel results vary widely with coordinate system and formulation.*

Thus, the following definitions have evolved. Space is divided into three regions as follows. That region of space immediately surrounding the antenna in which the reactive components predominate is known as the *reactive near-field region*. The size of this region varies for different antennas. For most antennas, however, the outer limit is on the order of a few wavelengths or less. For the particular case of an electrically small dipole, the reactive field predominates to a distance of approximately $\lambda/2\pi$, where the radiating and reactive fields are equal. Beyond the reactive near-field region, the radiating field predominates. The radiating region is divided into two subregions, the *radiating near-field region* and the *far-field region*. In the radiating near-field region, the relative angular distribution of the field (the usual radiation pattern) is dependent on the distance from the antenna. The reason for this behavior is twofold: the relative phase relationship of field contributions from different elements of the antenna changes with distance, and the relative amplitudes of these field contributions also change with distance. As the observation point in space moves away from the antenna, the amplitude of the field first oscillates and then decays monotonically. This variation in the limit is given by the reciprocal of the first power of distance. Furthermore, the relative phase and amplitude relationships between the field contributions from different elements of the antenna asymptotically approach a fixed relationship, and the relative angular distribution of the field becomes independent of the distance. This occurs in the far-field region; patterns are essentially independent of distance. For most antennas, the transition distance is D^2/λ, where D is the width of the equivalent uniformly excited aperture. Precision gain measurements or measurements of nulls may require a distance of $2D^2/\lambda$ or more. Low-sidelobe antennas will require multiples of D^2/λ, depending on the sidelobe level and allowable error.† Fig. 1 shows the reactive near-field boundary at $R = \lambda$ and the D^2/λ far-field boundary for several planar apertures.

Small Antennas

Antennas that are small in wavelength are conceptually simple, and difficult to use, as will appear below. It has been observed by Wheeler‡ that all small antennas are dipoles, loops, or combinations of these two canonical types. When the dipole (or monopole over a large ground plane) is short, the current is essentially

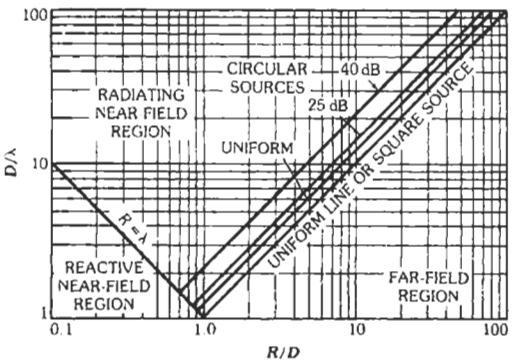

Fig. 1. Field regions.

linear from feed to end, and the fields produced, when the dipole is along the z-axis of a standard spherical coordinate system, are

$$E_\theta = j\,60\pi h I_0 e^{-jkr} \sin\theta/r\lambda,$$

$$H_\Phi = -jhI_0 e^{-jkr} \sin\theta/2r\lambda$$

The radiation resistance is $R_r = 20k^2h^2$, where $k = 2\pi/\lambda$ and h is the dipole half-length. Similarly, a small loop of diameter d carries essentially a constant current, and the fields with the loop axis along z are analogously

$$E_\Phi = 30\pi^3 d^2 I_0 e^{-jkr} \sin\theta/r\lambda^2$$

$$H_\theta = -\pi^2 d^2 I_0 e^{-jkr} \sin\theta/4r\lambda^2$$

The radiation resistance is given by:

$$R_r = (5/4)\pi^2 N^2 k^4 d^4 \mu_e^2$$

See the section on low-gain antennas for details of μ_e. When $h << \lambda$ or $d << \lambda$, the radiation resistance is very small, often smaller than the loss resistance of the conductors. Efficiency then can be small, and although the directivity is 1.5, the gain is also small. Reactance, on the other hand, is high; for short dipoles it varies as $1/kh$, whereas for small loops it varies as $\sim kd$. The Q is therefore high, and the bandwidth, which is approximately $(h/\lambda)^3$ for $Q >> 1$, is small. It is useful to know what bandwidth can be achieved; the Wheeler papers referred to above give practical answers. A theoretical fundamental limitation was derived by Chu* and refined by Harrington† and Collin.‡ See also Hansen.§

for a discussion of fundamental limitations in antennas. Since any radiating field can be written as a sum of spherical modes, the antenna, of whatever type it happens to be, is enclosed in a sphere of radius a. The radiated power can be calculated from propagating modes within the sphere. All modes contribute to the reactive power. When the sphere is sufficiently large to support several propagating modes, this approach is of little value because the modal coefficients are difficult to calculate. With only one propagating mode, the radiated power arises primarily from that mode. The utility of the Chu work becomes apparent when the sphere is too small to allow a propagating mode; all modes are then evanescent (below cutoff), and the Q becomes large, as the evanescent modes contribute little real power. Note that, unlike the case of a closed waveguide, there is a real part of each evanescent mode. Each mode has a Q based on the ratio of stored energy to radiated energy, and the Q rises rapidly when kr drops below the mode number. For all modes well below cutoff, the result is

$$Q = (1 + k^2a^2)/[k^3a^3]$$

When the antenna contains loss, the Q is reduced by the efficiency, η. Fig. 2 gives fundamental limitation curves for several values of efficiency. This Q is for the

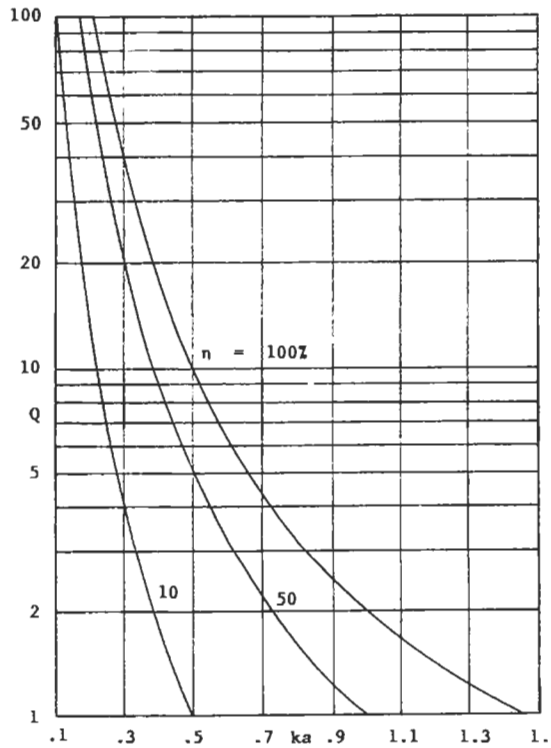

Fig. 2. Chu–Harrington fundamental limitations for single-mode antenna, various efficiencies.

§ Hansen, R. C. "Fundamental Limitations in Antennas." *Proc. IEEE*, Vol. 69, February 1981, pp. 170–182.

lowest TM mode. When both a TM mode and a TE mode are excited, the value of Q is halved. The importance of the Chu result is that it relates the lowest achievable Q to the maximum dimension of an electrically small antenna, and this result is independent of the art that is used to construct the antenna within the hypothetical sphere, except in determining whether a pure TE or pure TM mode, or both, is excited. Since the Q grows rapidly (inverse cube) as size decreases, this indeed represents a fundamental limit that has only been approached but never equaled, much less exceeded. Bandwidth is derived from Q by assuming that the antenna equivalent is a resonant circuit with fixed values. Then the fractional bandwidth is

$$\text{Bandwidth} = \frac{f_{\text{upper}} - f_{\text{lower}}}{f_{\text{center}}} \simeq 1/Q$$

A matched load is not included here, but use of it halves the Q. For $Q >> 1$ this relationship is meaningful, as the fixed resonant circuit is a good approximation to the antenna. But for $Q < 2$, the representation is no longer accurate. However, the curves are still useful for low Q even though imprecise. Since most small antennas are loops or dipoles, which do not use the spherical volume efficiently, an octave antenna is large, often larger than $\lambda/2$.

Antenna bandwidth can be increased by use of one or more matching networks. The maximum improvement possible was derived by Fano, and his results have been implemented by Matthaei et al.* From their formulas, the bandwidth improvement factors for VSWR = 2 and for the half-power case are as shown in Table 2.

Electrically small antennas can be broadbanded by introducing loss as indicated,† or by utilization of a large mismatch. A small loop with a very low-impedance preamplifier at its terminals or a short monopole (dipole) with a high-impedance preamplifier at its terminals is called an "aperiodic loop" or "aperiodic monopole." The term "integrated antenna" has been used, but it is confusing and is now obsolete. If the amplifier impedance is much larger than the monopole reactance at the lowest frequency of interest, the output signal is nearly constant over a bandwidth of one or more octaves. The large mismatch reduces the signal and external noise. Aperiodic antennas are useful at those frequencies where the external noise is so large that even after the large mismatch loss the antenna noise is still larger than the preamp noise; thus the system is external-noise limited. Let the ratio of preamp input resistance to lowest antenna reactance be $\alpha = R/X_1$, and use F_{ant} as the ratio of external antenna noise temperature to $T_0 = 290\ K$, and F_N as the preamp noise figure. A key system performance factor, γ, is the ratio of actual s/n to s/n if the system were external-noise limited. That is, γ determines s/n degradation compared to a narrow-band matched antenna-preamp system at frequency f. The s/n degradation factor for a monopole that is short over the band of interest is‡

$$\gamma = \frac{\left(2\alpha F_{\text{ant}} f^2/f_1^2\right)/\left(\alpha^2 + f_1^2/f^2\right)}{\left[2\alpha\left(F_{\text{ant}} - 1\right)f^2/f_1^2\right]/\left(\alpha^2 + f_1^2/f^2\right) + 3AF_N/k_1^3h^3}$$

In this result, $A = 1n(h/a) - 1$, and h and a are the monopole length and radius. Even with F_N in the 2-dB range, there can be significant s/n degradation in using an aperiodic monopole unless the upper frequency is close to the lower, f_1.

Superconducting Antennas

High T_c superconducting materials offer advantages for millimeter arrays, both waveguide and microstrip types. For superdirective arrays, and for electrically small dipole antennas, efficiency improvements are significant only when the radiation resistance is such that the Q is unacceptably high, typically greater than 1000. However, these antennas have low radiation resistance and high reactance which present a very high VSWR. A transmission-line match or lumped circuit with matched loss L has an apparent loss L_a that is greatly increased due to the VSWR or V:

$$L_a = [(V+1)^2L^2 - (V-1)^2]/4VL$$

Thus, the superconducting material is needed in the matching networks. Electrically small loop antennas can realize efficiency improvements, but without the leavening effect of loss resistance the Q is often unusably high. For a review of superconducting antennas, see Hansen.§

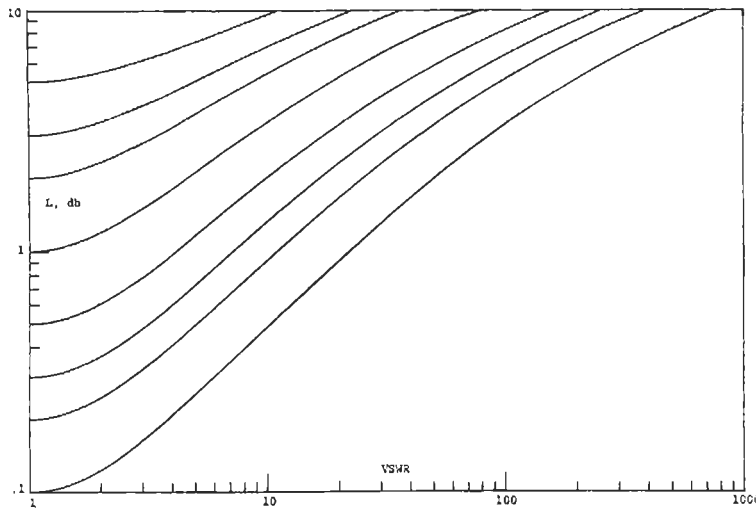

Fig. 2a. Line loss with mismatch.

Near-Field Power Density

Personnel and equipment electromagnetic radiation safety have made the understanding of radiated power density important. For points in the far-field region, the power density is given simply by

$$PD = P_r G/4\pi r^2$$

where

P_r is radiated power in watts,
r is distance in meters,
PD is in W/m^2

To convert to mW/cm^2, divide by 10. When the point of interest is within $\lambda/2$ of a low-gain transmitting antenna, such as a single vertical tower, the near-field dipole formulas can be used for approximate results. For dipoles at greater distances, $PD = 30P_r/\pi R_r r^2$.

Near fields of larger antennas can be accurately estimated if the aperture (or array) distribution is known. Both line sources and planar apertures will be discussed, because the near-field behavior of these two is quite different. For a line source, the beam is usually designed to be narrow in one plane while it is broad or omnidirectional in the other plane. In the near field, the phase errors degrade the pencil beam pattern, effectively decollimating it so that $1/r$ of the field intensity variation with distance is effectively canceled. The other $1/r$ still remains, with the result that near-field power density for a line source oscillates about a $1/r$ variation. The oscillations are reduced for tapered amplitude distributions, and there is, of course, a transition region from the far-field $1/r^2$ behavior to the near-field $1/r$. Because most high-power antennas are planar sources instead of line sources, only limited information is given on line sources. For uniform excitation the near-field power density is*

$$PD = (4.05/\Delta)[C^2\,(1/2\sqrt{\Delta}) + S^2\,(1/2\sqrt{\Delta})]$$

Here, the distance from the antenna is normalized in terms of $2L^2/\lambda$, where $\Delta = r/(2L^2/\lambda)$; C and S are conventional Fresnel integrals. For a square uniformly excited aperture, the power density is

$$PD = 16.4\,[C^2\,(1/2\sqrt{\Delta}) + S^2\,(1/2\sqrt{\Delta})]^2$$

Fig. 3 shows power density for both the line source and the square source.

Of more interest is the near-field behavior of circular apertures, either arrays or reflectors. The Hansen one-parameter circular space factor† is a good fit to the

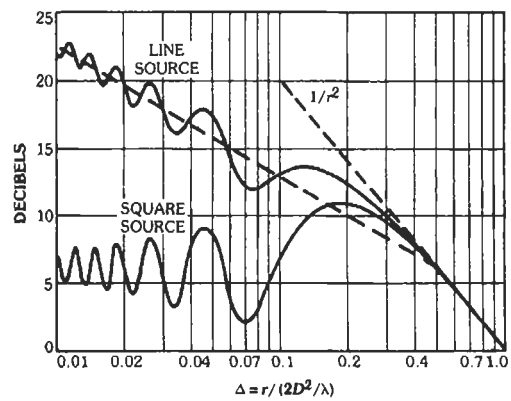

Fig. 3. On-axis power density.

* Ricardi, L. J., and Hansen, R. C. "Comparison of Line and Square Source Near Fields." *Trans. IEEE*, Vol AP-11, November 1963, pp. 711–712.

† Hansen, R. C. "A One-Parameter Circular Aperture Distribution with Narrow Beamwidth and Low Sidelobes." *Trans. IEEE*, Vol. AP-24, July 1976, pp. 477–480.

main beam and near sidelobes of most reflector antennas if the parameter is properly chosen. Similarly, it is an excellent representation for near-field power density near the axis. These robust low-Q distributions are also used for arrays. The axial power density is obtained from numerical integration with only the results given here.* Figs. 4 and 5 give axial power density for circular apertures with sidelobe ratios from 20 to 35 dB. Power density on-axis for a uniformly excited circular aperture is shown in Fig. 6.† Thus, it can be observed that the near-field phase errors do decollimate the beam in both planes, thereby producing a constant power density value around which the near field oscillates. All of these data are normalized to a value of unity at a distance of $2D^2/\lambda$, and the nominal power density at that distance is found simply from

$$PD = PG/[4\pi(2D^2/\lambda)^2]$$

Calculation of near fields off-axis is difficult because the small-angle approximate techniques quickly become useless. At large angles, Geometric Theory of Diffraction techniques are useful.

Antenna Noise Temperature

Antenna noise contributes to system noise and thus will affect system performance. Antenna noise consists of external noise and internal noise, with the latter caused by loss in the antenna, feed, cable, etc. It is customary and convenient to refer noise measurements to the input terminals of the preamplifier or receiver. If there is loss within the antenna or in components between the antenna and the preamplifier input, this loss will change the antenna contribution to system noise. If L is the loss ratio (P_{in}/P_{out}) and T_a is the external noise temperature, the total antenna temperature at the preamplifier input is given by

$$T_{ant}=[290(L-1)+T_a]/L$$

Fig. 7 shows this in graphical form. It is assumed that the lossy components are at an ambient temperature of 290 K. For other ambient temperatures, the coefficient in the formula is, of course, changed. The loss applies only to actual dissipative loss and not to virtual losses such as aperture excitation efficiency. The systems temperature is

$$T_{sys}=[T_0(L-1)+T_a]/L+T_0(F_N-1)+T_0(F_{rec}-1)/G_{pre}$$

where the preamplifier noise figure is F_N and the receiver noise figure is F_{rec}. Note that the preamplifier noise temperature contribution involves (F_N-1); this is because the measurement of amplifier noise figure includes an input standard temperature of $T_0 = 290$ K. An alternate form of the system temperature is:

$$T_{sys}=T_a/L-T_0(F_N-1/L)+T_0(F_{rec}-1)/G_{pre}$$

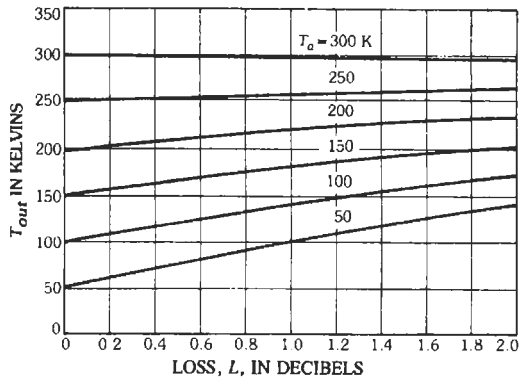

Fig. 7. External plus internal antenna noise temperature.

In these equations, the receiver noise contributions are decreased by the gain of the preamplifier. The external antenna noise temperature is a summation of all of the noises seen by the antenna, weighted by the antenna power pattern. Thus

$$T_a = \frac{\int\int T(\theta,\phi)P(\theta,\phi)d\Omega}{\int\int P(\theta,\phi)d\Omega}$$

In this equation, $T(\theta, \phi)$ is the spatial temperature pattern in kelvins, $P(\theta, \phi)$is the antenna power pattern, and the integration is over all space. Next, specific external noise sources will be reviewed.

Below 10 MHz, the noise is primarily atmospheric and very large. This noise is mostly Gaussian, but there are impulsive tails at low probabilities of occurrence. Extensive data are given by the CCIR.* The highest noise generally occurs in spring in the 2000–2400 time block. The CCIR data have been computerized by Lucas and Harper.† Broadly, atmospheric noise is omnidirectional and independent of distance. A minor exception occurs in the VLF absorption notch around 4 kHz in that noise may be higher in some directions due to rapid attenuation with distance. The atmospheric noise contribution becomes negligible between 35 and 40 MHz. Galactic noise generally consists of noise from a few hot stars plus a varying background that results from many, many stars. The background results, of course, depend on how many discrete star sources have been separated out. Typical charts show measurements made by Taylor‡ at 136 and 400 MHz; see Figs. 8 and 9. A composite fit to these and other measurements is:

$$T \simeq (3.068 \times 10^8)/f_{\mathrm{MHz}}{}^{2.3}$$

This line is shown on the composite noise plot, Fig. 10. The sun is a special case because it subtends a finite angle and is much closer. Sun noise temperature measurements by Hogg and Mumford§ show a slight oscillation about a linear frequency dependence. The latter is

$$T_s = 1.958 \times 10^8/f_{\mathrm{MHz}}$$

For antenna beamwidths larger than 0.5°, the sun noise temperature contribution is

$$T_{\mathrm{sun}} = T_s\theta_s{}^2 G/4\pi$$

where

θ_s is the subtended angle of the sun,
G is the antenna gain in that direction.

For those portions of the antenna pattern that see the earth, the earth will contribute noise at a blackbody temperature of roughly 310 K. In the range from 20 to 600 MHz, all of these noise sources are usually dwarfed by man-made noise. This consists of power-line noise caused by arcs and corona and by user-generated pulses; noise from various transmitters including TV, FM, cellular, and push-to-talk; and noise generated by vehicles. Extensive studies and measurements of urban noise have been made, and the reader is referred to books by Skomal" and Herman. # The most appropriate division into cultural areas now seems to be "business," "residential," and "rural." These divisions and the data of Spaulding and Disney** are used here as seen in Fig. 10. However, it must be recognized that these urban noise envelopes apply away from vehicular traffic streams. That is to say, vehicle noise is included, but the vehicles are not closer than several hundred feet. A vehicle stream at 50 feet can generate noise 20 to 40 dB higher than these envelopes. A single "super-noisy" vehicle can generate as much noise as a stream of vehicles, and at close distances the noise levels can be extremely large. Although few data are available, vehicular noise can be significant at frequencies as high as 5–10 GHz, again for short distances. Atmospheric noise is produced by gaseous absorption, with the low-

est molecular resonance being that for water at 22.235 GHz. Fig. 11 from Smith* gives a composite of absorption data, and the transmission windows around 33, 95, 140, and 230 GHz may be observed.

From the two-dimensional antenna pattern and these noise data, the antenna noise temperature may be readily calculated. The total receiver noise power is then $N = KT_{sys}$ where K = 198.60 dBm. System sensitivity is shown in Fig. 12 in dBm/Hz for various receiver and antenna noise temperatures.

Elliptical and Circular Polarization

An electromagnetic wave is linearly polarized when the electric field lies wholly in one plane containing the direction of propagation. A plane electromagnetic wave, at a given frequency, is elliptically polarized when the extremity of the electric vector describes an

* Smith, E. K. Private communication, 1982.

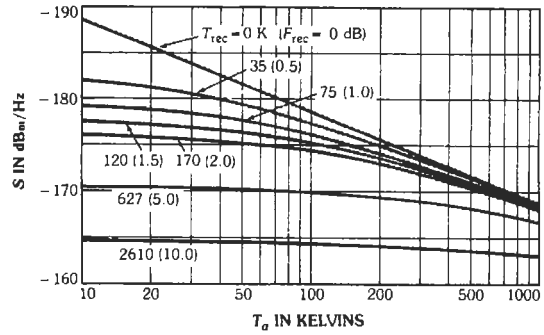

Fig. 12. Absolute sensitivity $S = K(T_a + T_{rec})$.

ellipse in a plane perpendicular to the direction of propagation, making one complete revolution during one period of the wave. If the rotation is clockwise looking in the direction of propagation, the sense is right-hand. More generally, any field vector, electric, magnetic, or other, is elliptically polarized if its extremity describes an ellipse. Two perpendicular axes, *OX* and *OY*, are chosen for reference in the plane of the polarization ellipse (Fig. 13). This plane is usually perpendicular to the direction of propagation. At a given frequency, the field components along these axes are represented by two complex numbers.

$$X = |X| \exp j\theta_1$$
$$Y = |Y| \exp j\theta_2$$

The axial ratio, r, is the ratio of the minor axis, *OB*, to the major axis, *OA*, of the polarization ellipse. The relative power coupling, η, between two elliptically polarized receiving antennas is given by

$$\eta = \frac{1}{2}\left[1 + \frac{(1-r_1^2)(1-r_2^2)\cos 2\theta \pm 4r_1 r_2}{(1+r_1^2)(1+r_2^2)}\right]$$

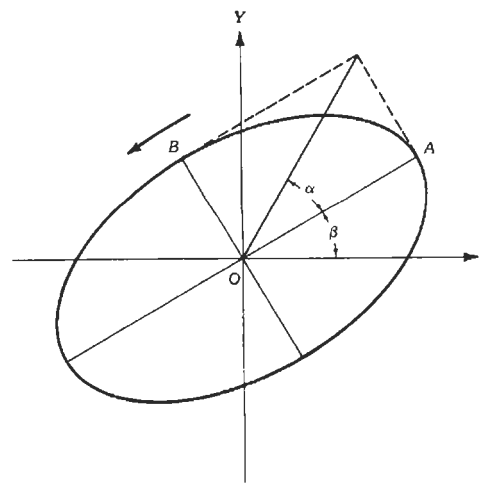

Fig. 13. Polarization ellipse.

In this equation, r_1 and r_2 are the axial ratios of the antennas, and θ is the angle between the major axes of the polarization ellipses. The plus sign is used if both antennas produce the same sense of polarization, and the minus sign is used for opposite senses.* When a typical circularly polarized antenna is measured by a perfect rotating linear antenna, the circularly polarized gain is calculated from

$$G_{cir} = \frac{1}{2}\left[\sqrt{G_{lin\,max}} + \sqrt{G_{lin\,min}}\right]^2$$

Figs. 14 and 15 show transmission efficiency from a nearly linear antenna to a nearly circular antenna for both senses of polarization and for both zero and 90-degree orientation. When antenna gain is measured with a nominally linear standard-gain antenna where the orthogonal powers for two linear polarizations are summed, there is an error if the standard-gain antennas are imperfect. If the antenna under test has axial ratio r_1 and the standard-gain antenna has axial ratio r_2, the error in gain measurement is as follows:

$$\text{Error} = 1 \pm 4\, r_1 r_2 / (1 + r_1^2)\,(1 + r_2^2)$$

LOW-GAIN ANTENNAS

Half-Wave Dipole

The resonant dipole, with length near a half wavelength, is a principal canonical antenna. The half-wave dipole has a rotationally symmetric pattern of cos [(π/2) cos θ]/sin θ, where θ=0° gives the dipole axis. Half-power beamwidth is 78.1°, directivity is 1.641 = 2.15 dB, effective area is $A_e = 0.131\lambda^2$, and effective length is 0.318λ. When the dipole is not oriented along a spherical-coordinate-system z axis, but instead along x (Fig. 18), the pattern becomes

$$E(\theta,\phi) = \frac{\cos\left[(\pi/2)\sin\theta\cos\phi\right]}{\sqrt{1-\sin^2\theta\cos^2\phi}}$$

The far-field half-wave dipole field expressions, with I_0 the feed current, are

$$E_\theta = j\frac{60I_0e^{-jkr}\cos\left[(\pi/2)\cos\theta\right]}{r\sin\theta}$$

$$H_\phi = j\frac{I_0e^{-jkr}\cos\left[(\pi/2)\cos\theta\right]}{2\pi r\sin\theta}$$

These formulas can be used to calculate power densities from $PD = E^2/120\pi$ as close as several wavelengths from the antenna. At closer distances, use the near-field results given below. When the dipole length is not λ/2, the pattern becomes

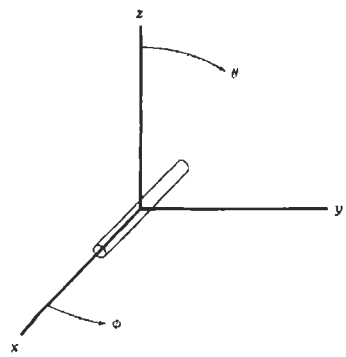

Fig. 18. Dipole along x-axis.

$$E(\theta) = \frac{\cos(kh\cos\theta)-\cos kh}{\sin\theta}$$

Exact near-fields for thin dipoles are:

$$E_\rho = j(30I_0/\rho)\left[(z-h)e^{-jkr_1}/r_1 + (z+h)e^{-jkr_2}/r_2 - (2z\cos kh)e^{-jkr_0}/r_0\right]$$

$$E_z = -j(30I_0)\left[e^{-jkr_1}/r_1 + e^{-jkr_2}/r_2 - (2\cos kh)e^{-jkr_0}/r_0\right]$$

$$H\phi = -j(I_0/4\pi\rho)\left[e^{-jkr_1} + e^{-jkr_2} - (2\cos kh)e^{-jkr_0}\right]$$

Note that this exact near-field is given in a cylindrical coordinate system (ρ, ϕ, z) with the dipole along z. Distances r_1, r_2, r_0 are from the farthest tip, the nearest tip, and the center of the dipole, respectively, to the observation point. These equations describe the discovery many years ago by Schelkunoff that a thin wire radiates a spherical wave from each tip, and from the center if the length is not a half wavelength.

Self-impedance of thin dipoles can be calculated approximately by the Carter zero-order theory, which assumes a sinusoidal current distribution. See Hansen* for an efficient computer algorithm. Fat dipoles require complex integral-equation theory, which is impractical to calculate, or moment method calculations. Because the feed-region geometry greatly affects the input impedance, a common and satisfactory procedure is to use zero-order theory for quick values, and then to measure the input impedance of the actual structure. Fig. 19 shows Z_{in} for several values of h/a and a/λ, where a is the radius. Dipoles are usually made of a

* Hansen, R. C. "Formulation of Echelon Dipole Mutual Impedance for Computer." *Trans. IEEE*, AP-20, Nov. 1972, pp. 780–781.

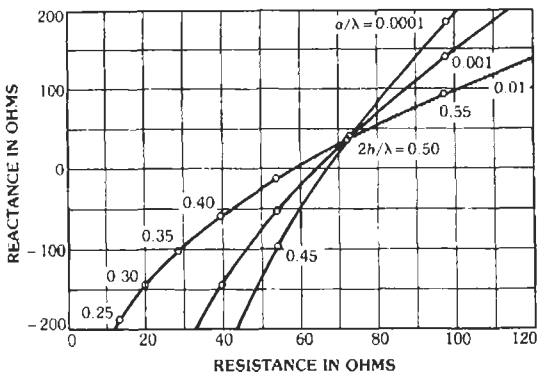

Fig. 19. Dipole self-impedance, zero order.

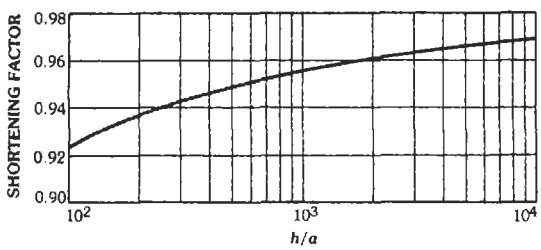

Fig. 20. Dipole shortening due to diameter.

solid or tubular cylinder; when a flat (strip) dipole is used, it is closely equivalent to a cylindrical dipole with $a = w/4$, where w is the strip width. Again, when zero-order theory is used, Fig. 20 gives shortening of resonant length versus h/a. Only a vanishingly thin dipole is resonant at halfwave. The resonant input resistance changes only slowly with a/λ, as seen in Table 3. In the limit of $a = 0$, the resonant resistance is 73.13 ohms.

Dipoles are frequently used parallel to a back screen, especially in arrays. If the dipole-screen spacing is s, the overall pattern, assuming the screen extends past the dipole by several wavelengths in each direction, is the dipole pattern multiplied by the screen array factor:

$$P(\theta) = P_{\text{dipole}}(\theta) \times \sin(ks \cos \theta)$$

TABLE 3. RESONANT RESISTANCE VS a/λ

a/λ	R_{res}(ohms)
0	73.13
0.00001	68.26
0.0001	66.79
0.001	64.11
0.01	58.16

where θ is zero normal to the screen. From this, the beamwidths in the E- and H-planes are 72.67° and 120°. Directivity is determined from the self- and mutual impedance:

$$D = 480/(R_{11} - R_{12})$$

Using zero-order mutual impedance, R_{11} = 73.13 ohms, and a spacing $s = \lambda/4$ gives D = 5.603 = 7.48 dB. Actual directivities will be different because the R_{11} for actual dipoles is not 73 ohms. In principle, use of smaller spacing should increase gain; in practice, when the dipole and its image in the screen are close together the impedance drops so that loss resistance limits the gain.* See Fig. 21.

Sometimes when space is limited, the dipole ends are bent, forming a U dipole. This affects both resonant length and resistance; these have been calculated using moment methods† for $a/\lambda = 0.01$. Fig. 22 shows the change in resonant length and the reduction in radiation resistance as more of the length is in the arms.

Monopoles (whips) are widely used for communications, e.g., on vehicles. When a quarter wavelength cannot be accommodated, a shorter whip can be loaded with a series inductance. The loading coil keeps the current distribution roughly constant from the feed to (and slightly past) the coil, thus increasing radiation resistance by the square of the current moment over the triangular current distribution of a short whip. Moment method studies‡ have shown that efficiency varies slowly with position of the coil, with a peak in the $0.3h$ to $0.5h$ range. Input resistance increases as the

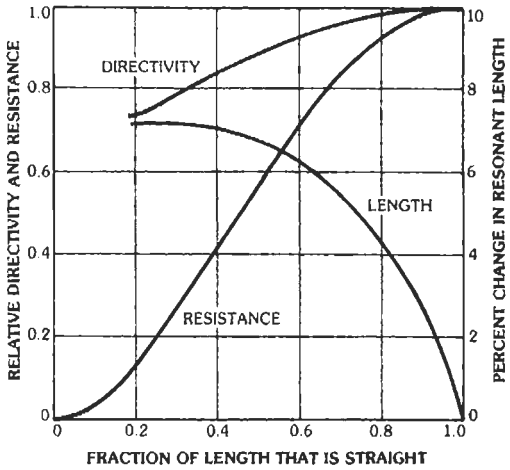

Fig. 22. Characteristics of resonant U dipoles.

coil moves toward the end, and the coil reactance also increases. For whips less than 0.1λ long, it is difficult to produce efficiencies of even 50 percent with high-Q coils. Extensive design curves are given in the reference. Short whips with high impedance are covered in the general section.

The broadest-bandwidth dipole is the open sleeve dipole, which consists of a dipole with two tubes parallel to the dipole, one on each side (Fig. 23). King and Wong* give performance data for various dimensions. The sleeves need not be tubular, but can be flat strips. When crossed dipoles are used for circular polarization, the sleeves can be metal plates or disks. Bandwidth of an octave for VSWR roughly 2 is achievable.

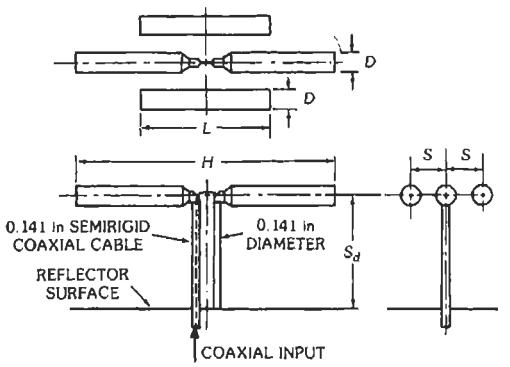

Fig. 23. Open-sleeve dipole.

The behavior of the earth as a reflecting surface is considerably different for horizontal than for vertical polarization. For horizontal polarization, the earth may be considered a perfect conductor; that is, the reflected wave at all vertical angles β is substantially equal to the incident wave and 180° out of phase with it. The approximation is good for practically all types of ground.

For vertical polarization, however, the problem is much more complex, as both the relative amplitude, K, and relative phase, ϕ, change with vertical angle β and vary considerably with different types of ground. Fig. 24 is a set of curves that illustrate the problem. The subscripts to the amplitude and phase coefficients, K and ϕ, refer to the type of polarization, H for horizontal, and V for vertical.

Radial-Wire Ground Systems

A vertical tower antenna for MF and below usually requires a ground system to act as a low-loss "spreader" of current along the surface of the earth and to increase efficiency. Typically, the antenna base is surrounded by a metallic disk or closely spaced wire mesh, with radial wires emanating from this. It is not always possible or economical to make the radials sufficiently long and dense that the monopole perfor-

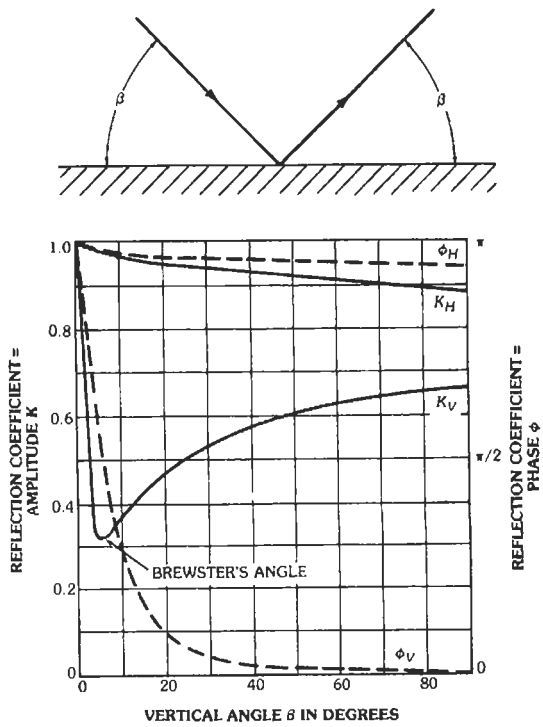

Fig. 24. Typical ground-reflection coefficients for horizontal and vertical polarizations.

mance is independent of the earth parameters. There is some evidence that surface wire radials, if sufficiently long, give higher efficiency than buried radials. Extensive calculations have been made by Maley and King,* but comparisons with measurements are sparse.

Fig. 25 shows experimental measurements at 3 MHz made by Brown et al.† and Christman.‡ Efficiency is given versus monopole height, and number and length of radials. For different earth, the absolute efficiencies will change, but the relative results are useful.

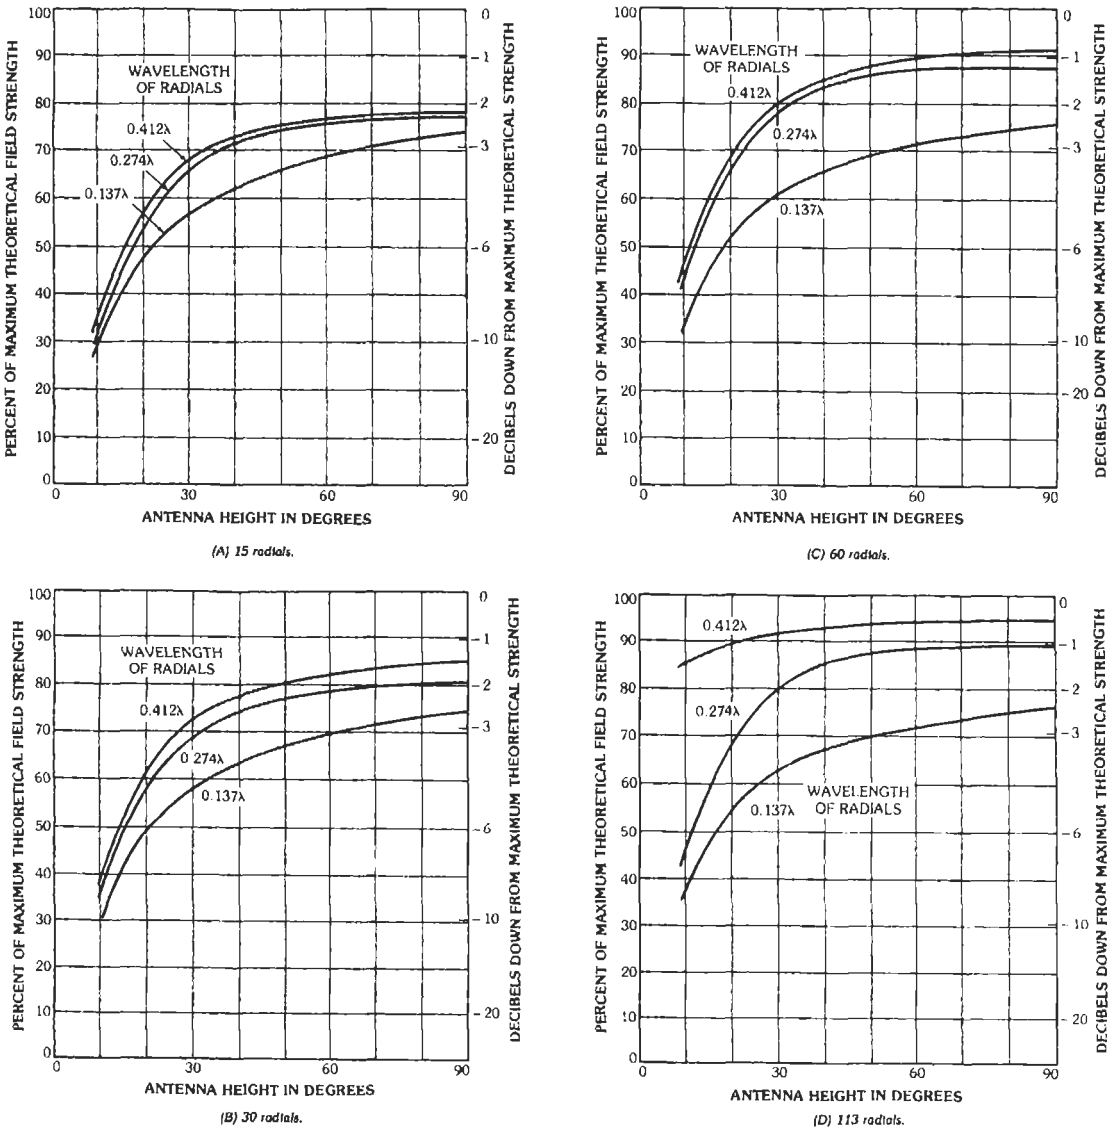

Fig. 25. Efficiency vs monopole height.

Printed-Circuit Antennas

Printed-circuit antennas include stripline slots, printed-circuit-board dipoles, and microstrip patches. A stripline slot consists of a narrow rectangular slot cut in the top stripline ground plane, with the slot excited by proper positioning of the center conductor below the slot. A linear resonant array of collinear slots may be fed by a single center conductor, with this conductor centered under each slot at the proper angle.* Boxed stripline is used to reduce higher modes.

Dipoles may be printed for low-cost fabrication, either as an array of dipoles on a single dielectric substrate, with each dipole fed by a balun which is normal to the dipole array face, or with each dipole and balun on a separate dielectric substrate. The array comprises a stack of these sheets.

The most widely used printed-circuit antenna is the microstrip patch, which in its simplest form is a rectangular or circular patch of metal fed by the microstrip upper conductor; see Fig. 26. Thus the element and feed line, and usually other elements, power dividers, etc., can all be prepared as a single etched PC board. A patch can also be fed from below by a coaxial probe, but this in large part removes the cost advantage. Early work on microstrip antennas was done by Deschamps and Sichak.† A review is given by Pozar.‡

Since microstrip is thin, the patch and ground plane acts as a TM resonator, with the sidewalls (the gaps) acting approximately as magnetic walls. Treating the patch as a lowest mode resonator gives useful results.

More recent methods of analysis make use of a series of cavity modes to match a side wall admittance that includes radiation conductance and discontinuity susceptance.§ More rigorous analyses take into account the effect of microstrip or probe feed." The major disadvantage of patches is their narrow bandwidth, due to the close spacing between patch and ground plane. Fig. 27 shows bandwidth versus substrate height in free space wavelengths, for VSWR < 2. #

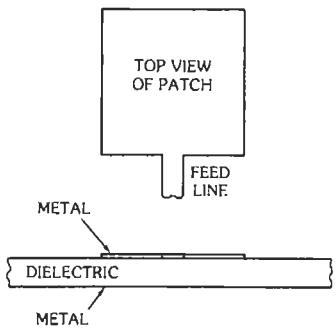

Fig. 26. Microstrip patch.

These are zero order results based on transmission line analysis. Loss and surface wave effects are not included. The bandwidth is approximately:

$$BW \simeq \frac{96t/\lambda_0}{\sqrt{2\epsilon}\left[4+17\sqrt{\epsilon}\right]}$$

Increasing the substrate height does increase the bandwidth, but the coupling to surface wave modes

and the cross-polarized radiation also increase, with undesirable pattern effects. Surface waves may be a problem for larger arrays or large substrates. An easy technique to obviate these is to make the dielectric anisotropic, by drilling holes perpendicular to the slab. Such a slab is sometimes called a Photonic Band Gap material in analogy to quantum mechanics, but this nomenclature is at best misleading. Most techniques for extending the bandwidth of patches have done so at the expense of efficiency, i.e., through use of matching networks with high standing waves. However, the parasitic patch* avoids these problems by keeping the substrate thickness low, with a parasitic patch above the driven patch increasing the effective radiation height. Bandwidth can be doubled, with the parasitic patch dimensions and height above the driven patch adjusted to give a symmetrical impedance curve. Fig. 28 sketches the parasitic patch configuration. These may be arrayed as are ordinary patches. In practice, the parasitic patches are printed on a thin dielectric substrate, with a foam layer used to support this substrate above the microstrip.

Slot coupling can also increase bandwidth. Here coupling is through a slot in the patch groundplane; the latter is usually a stripline plane.† Bandwidth can be roughly doubled as the electromagnetic coupler serves as a matching circuit.

Rectangular or circular patches, as described, are mostly linearly polarized radiators, with patch widths roughly a third of a wavelength. Accordingly, the patterns are between those of a short dipole and a half-wave dipole. Although a square patch could be fed on two adjacent sides with the proper phases to obtain circularly polarized radiation, simpler circularly polarized patches have been developed.‡ The key is to modify dimensions to allow the two cross-polarized modes to be of equal amplitude and 90 degrees out of phase. Fig. 29 sketches four ways of accomplishing this. A simple analysis has been given by Lo and Richards.§ Separate feeds provide wider bandwidth.

More sophisticated patch cutouts, such as ell, cross, etc., have been used to produce CP, or even dual frequency operation. All of these, however, tend to reduce the bandwidth.

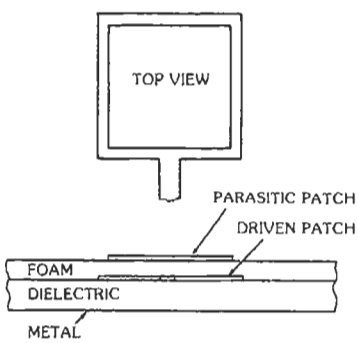

Fig. 28. Parasitic microwave patch.

Loops

Loops small in wavelengths are equivalent to short magnetic dipoles (see the general section at the beginning of this chapter). When the circumference of a loop is small in wavelengths and the area is A, the patterns are given by

$$E_\phi = (120\pi^2 I_0 A\ \mu_e \sin\theta)/r\lambda^2$$

$$H_\theta = (\pi I_0 A\ \mu_e \sin\theta)/r\lambda^2$$

where

I_0 is the loop current,
θ is measured from the loop axis.

Radiation resistance is

$$R_{rad} = 20N^2k^4A^2\mu_e^2$$

where μ_e is the effective permeability of a magnetic core. Effective length is $l_e = Nk\Lambda\mu_e$.

The effective area and directivity are those of a short dipole: $3\lambda^2/8\pi$ and 1.5. Magnetically cored loops almost universally use ferrite cores with the highest permeability available for the frequencies of interest.

Typically, the coil diameter is small in wavelengths, and the core is long compared with the diameter. Whether the coil is distributed over the core or concentrated near the center is important mostly for practical factors such as distributed capacitance. Tape cores can be made of Permalloy type alloys or of rapidly cooled amorphous alloys such as Metglas; these can be used up to a few megahertz with permeabilities of many tens of thousands (see Chapter 4); ferrite cores extend into several hundred megahertz, with permeabilities of thousands at lower frequencies and on the order of 20 at upper frequencies. Effective permeability can be calculated by assuming the core is a prolate spheroid. With the formulas of Wait,* calculations of μ_e, in terms of L/d, the core length/diameter ratio, have been made. Fig. 30 shows these data, which come from:

$$\mu_e/\mu = 1/[(1 + \mu - 1)(\zeta^2 - 1)Q_1]$$

where

$$\zeta = (L/d)/\sqrt{L^2/d^2 - 1}$$

and

$$Q_1 = (\zeta/2)\ln[(\zeta + 1)/(\zeta - 1)] - 1$$

Lower permeabilities require larger L/d to realize μ_e as a significant fraction of μ. The core need not be solid, as much of the magnetic field is concentrated near the surface. Again, a hollow cylindrical core can be approximated by two prolate spheroids, and a formula for μ_e was developed by Wait.† Figs. 31, 32, and 33 show hollow-core effective permeability for $\mu = 20$, 100, and 500, respectively.‡ It is apparent that a significant part of the solid core may be eliminated. Such a hollow core can be assembled from parallel rods or strips around a foam block.

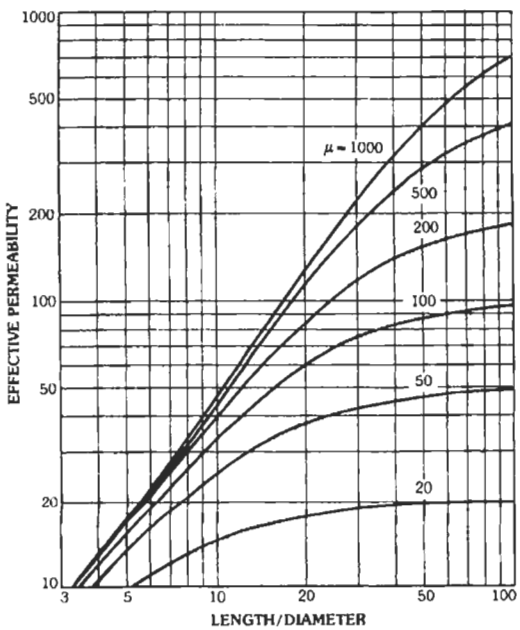

Fig. 30. Effective permeability of spheroidal core.

Slot Antennas

The properties of many slot antennas can be deduced from the properties of the complementary metallic antenna as enunciated by Booker in his exten-

sion of the optical work of Babinet. The admittance, Y_s of the slot antenna is related to the impedance, Z_m, of the metallic antenna by

$$Z_m/Y_s = (120\pi)^2 / 4$$

The magnitude of the electric field, E_s, produced by the slot is proportional to the magnitude of the magnetic field, H_m, of the metallic antenna, and H_s is proportional to E_m. The electric- and magnetic-plane patterns of the slot are similar to the magnetic- and electric-plane patterns, respectively, of the metallic antenna. In Fig. 34, a rectangular slot antenna in an infinite metallic plane is shown with the complementary strip dipole. If the slot radiates on only one side, the relationship is

$$Z_m/Y_s = (120\pi)^2/2$$

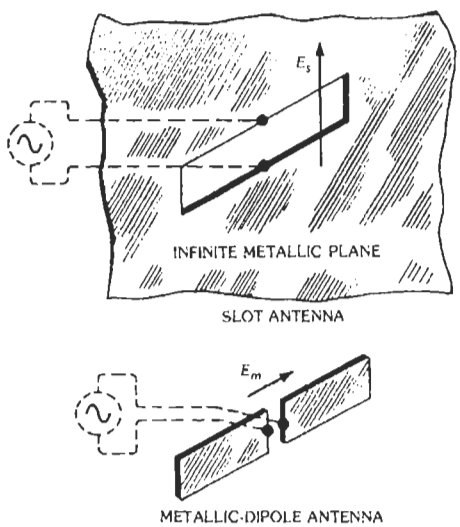

Fig. 34. Slot antenna and strip dipole.

The E-plane pattern of the slot and H-plane pattern of the dipole are omnidirectional, while the slot H-plane pattern is the same as the dipole E-plane pattern.

Due to the ease of feeding, most slots are located in waveguide. Fig. 35 shows displaced longitudinal, inclined, and edge slots; the first and last are widely used for linear and planar arrays. The pattern and mutual admittance of slots in an array are close to those of the Booker complementary strip dipole array, and dipole mutual impedances are used in the design of such arrays. The slot self-admittance, however, contains a term involving reactive energy in the waveguide in the vicinity of the slot. Longitudinal slots are covered here because they are simpler and easier to use. Radiation conductance obtained from the Stevenson formula and for a sinusoidal slot field distribution is*

$$\frac{G_{rad}}{Y_0} = \frac{480(a/b)\left[\sin^2(\pi x/a)\right](\cos\beta l - \cos kl)^2}{\pi(\beta/k)R_0}$$

where

a and b are waveguide width and height,
x and l are the slot displacement and length,
R_0 is the Booker equivalent strip dipole resistance,
β is the guide wavenumber.

Susceptance is difficult to calculate, with both moment methods† and variational methods‡ used. In any high performance array, it is necessary to make careful measurements of single-slot admittance for a family of slot offsets and lengths. Fig. 36 shows the Stevenson resonant conductance, which is a function only of offset. Slot resonant length involves three variables: x/a, a/b, and β/k. Fig. 37 gives resonant length for several frequency-guide combinations. These two

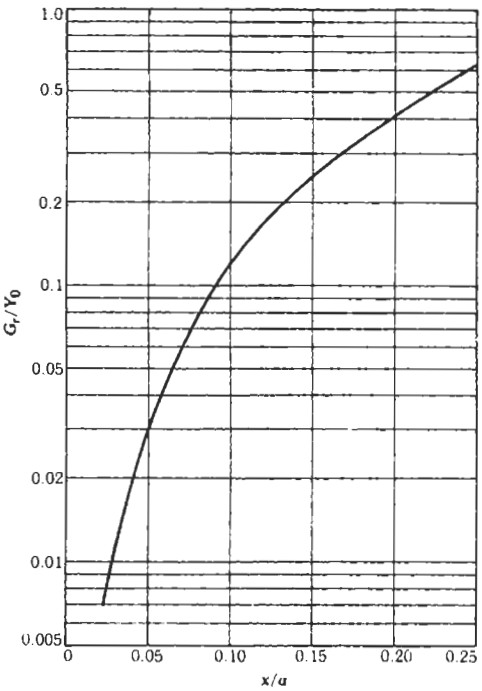

Fig. 36. Resonant conductance of longitudinal slot.

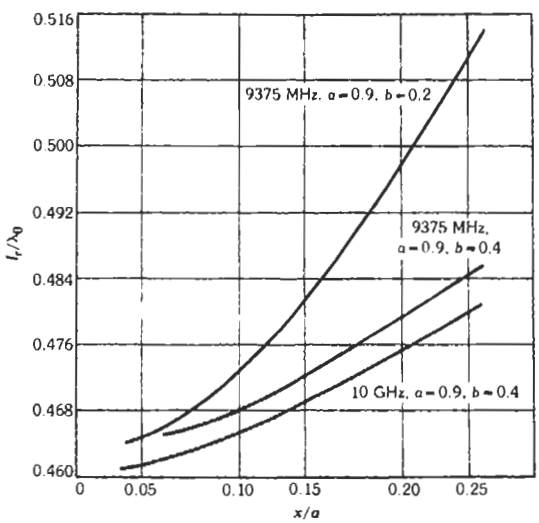

Fig. 37. Resonant length of longitudinal slot.

parameters, resonant length and conductance, are important because they allow slot admittances versus frequency to be plotted in the Kaminow and Stegen "universal" form.* Slot length is given in terms of resonant length, and both conductance and susceptance are given in terms of resonant conductance. The result was originally thought to be a single symmetric curve for G/Y_0 and a single asymmetric curve for B/Y_0. As Fig. 38 shows, it now appears that although all longitudinal slots fit these curves approximately, there are differences that vary with x/a, a/b, and β/k. The precise control of aperture distribution allowed by waveguide slots and the use of computer design have allowed high-performance low-sidelobe or tailored-sidelobe arrays to be constructed.†

Slots are sometimes used on cylinders, in either an axial or circumferential configuration. A circumferential half-wave slot has a smooth pattern, with the cylinder reducing the back lobes. Axial half-wave slots also exhibit shadowing, with pattern ripples around $\phi = \pi$. As ka increases, the number of ripples increases, but their depth and angular extent decrease. For both types of slots, larger cylinders give more shadowing and lower field at $\phi = \pi$. Fig. 39 shows typical axial and circumferential slot patterns in the azimuth plane for $ka = 8$. These were calculated with the formulas of Wait:‡

Axial

$$E_\phi = \frac{1}{\pi ka}\sum_{n=0}^{\infty}\frac{\varepsilon_n j^n \cos n\phi}{H_n^{(2)'}(ka)}$$

Circumferential

$$E_\theta = \frac{ka}{\pi}\sum_{n=0}^{\infty}\frac{\epsilon_n j^n\left[\cos(n\pi/2ka)\right]\cos n\phi}{\left(k^2a^2-n^2\right)H_n^{(2)}(ka)}$$

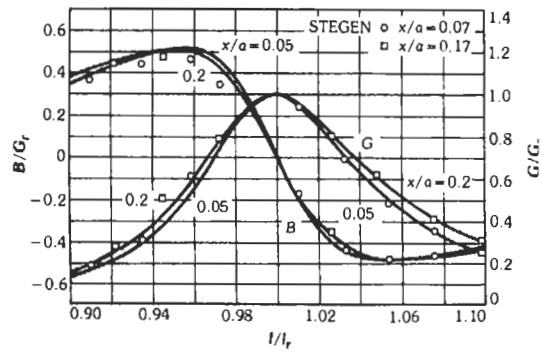

Fig. 38. Longitudinal slot admittance, $a = 0.9$, $b = 0.4$, frequency = 9375 MHz.

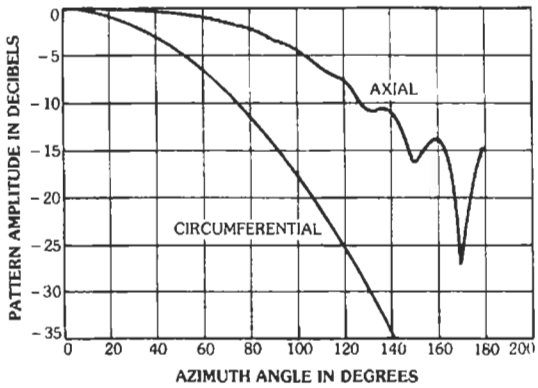

Fig. 39. Half-wave slot on cylinder, $ka = 8$.

Here $\epsilon_n = 1$ for $n = 0$, $\epsilon_n = 2$ for $n > 0$, and $H_n^{(2)}$ is the Hankel function of the second kind. Three-dimensional patterns can be calculated by replacing ka by $ka \sin \theta$, except that finite length cylinders will have end effects that require other calculation methods such as geometric theory of diffraction.*

MEDIUM-GAIN ANTENNAS

Horns

Horns are often used as gain standards, as feeds for dish antennas, and as microwave antennas directly. The simplest type of horn is a flared waveguide. For a flare only in the E-plane or only in the H-plane, directivity can be accurately and simply calculated:†

$$G_E = (64\, a\, R_e/\pi\lambda b)\,[C^2(w) + S^2(w)] = 32\, ab\, F_E/\pi\lambda^2$$

where

$$w = b/\sqrt{2\lambda R_e}$$

and

$$G_H = (4\pi b R_m/\lambda a)\,\{[C(u) - C(v)]^2 + [S(u) - S(v)]^2\}$$
$$= 32\, ab\, F_H/\pi\lambda^2$$

where

$$\sqrt{2}\,u = \sqrt{\lambda R_m}/a + a/\sqrt{\lambda R_m}$$
$$\sqrt{2}\,v = \sqrt{\lambda R_m}/a - a/\sqrt{\lambda R_m}$$

In the formulas above, R_e and R_m are the slant lengths, and C and S are conventional Fresnel integrals.‡ The formulas are also written in terms of directivity reduction factors F_E and F_H, which are shown in Fig. 40. Figs. 41 and 42 show normalized directivity for each of these, and it may be seen that for each slant length there is an optimum width or height. More commonly, a pyramidal horn is used with dimensions selected to be optimum in both planes. However, this may not have coincident phase centers; see below. The

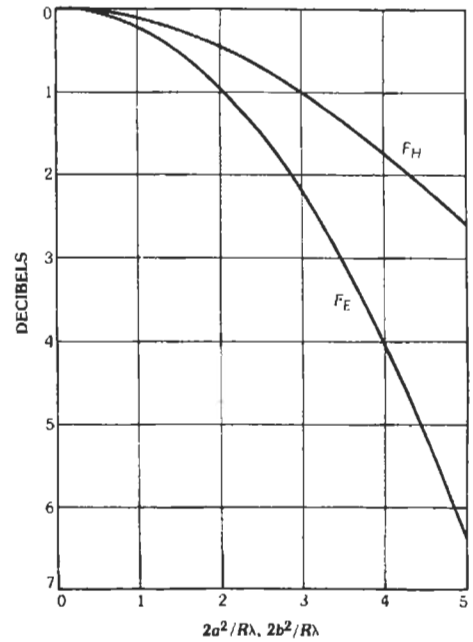

Fig. 40. Sectoral-horn directivity factors.

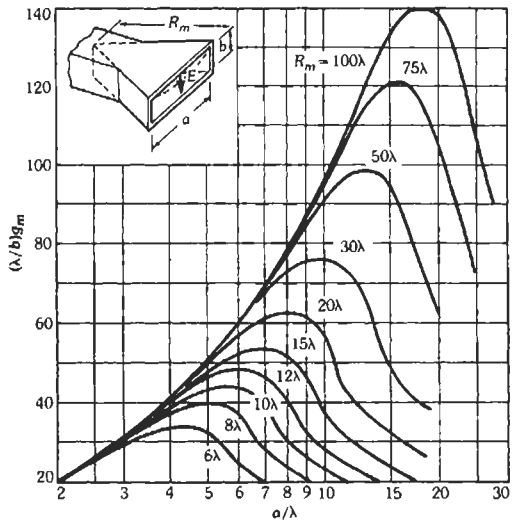

Fig. 42. Directivity of a large horn flared in the magnetic plane (After Schelkunoff.)

pyramidal horn directivity can be calculated from the constituent sectoral horn directivities by

$$G_{\text{pyramidal}} = \pi\lambda^2 G_E G_H/32\,ab = 32\,ab\,F_E F_H/\pi\lambda^2$$

This can also be written in terms of E- and H-plane gain reduction factors as shown in the formula above. Half-power beamwidths are given approximately by $\theta_3 = 51\ \lambda/b$ for the E-plane and $70\lambda/a$ for the H-plane. The beamwidths in each plane are essentially independent of dimensions in the other plane. Fig. 43 shows experimental patterns in both planes for a variety of radial lengths and flare angles.* Wide-angle patterns may be computed by using geometric theory of diffraction; see reprint book by Hansen.† Phase centers of pyramidal horns may also be calculated by using Fresnel integrals.‡ The phase center is generally different for each plane, and it is located toward, but not at, the horn apex. The optimum rectangular pyramidal horn has slightly different dimensions from one designed with coincident phase centers. For some applications this is important.

Pyramidal horns are usually rectangular, whereas corrugated horns are usually circular. The corrugated horn offers a pattern that is nearly symmetric; i.e., the E- and H-plane beamwidths are nearly equal. In addition, the sidelobes can be better controlled. Further discussion of corrugated horns is outside the scope here; refer to papers in the reprint book by Love§ and Olver et al."

In the TEM horn, developed by Kerr,# elimination of the sidewalls allows much greater bandwidth. Best performance obtains when both the conductor spacing and width increase roughly exponentially from throat to mouth. These horns have found wide use for short-pulse and transient applications. Printed circuit versions are also available.** These horns have been integrated with solid-state devices for use in the millimeter and submillimeter bands.††

Helices

A cylindrical helix can radiate a broadside pattern (normal mode) or an end-fire beam (axial mode). Only the latter is discussed here. The circumference must be on the order of a wavelength, and to utilize the end-fire properties effectively, a length on the order of several wavelengths is usually used. Fig. 44 shows beamwidth versus length for several circumferences. The axial-mode helix is broadband but is limited to roughly a 2.5:1 frequency ratio.‡‡ A wider bandwidth can be covered by use of a long multifilar helix such as a quadhelix.§§ In this configuration, the helix consists of four windings spaced 90 degrees with the wires fed with a 90-degree phase progression at the base. Although the feed is complicated, this type of helix does not require a ground plane, although a ground plane may improve performance. A short resonant version of the quadhelix that radiates an omnidirectional circularly polarized pattern is also available."" This quadhelix utilizes a fractional turn but operates with-

out ground plane and can be small in size. A principal application is for GPS.*

Yagi–Uda Antennas

The Yagi–Uda antenna is an end-fire array constructed usually of a single driven dipole with a reflector dipole behind and one or more parasitic director dipoles in front. Fig. 45 sketches a three-element Yagi–Uda antenna. Extensive design curves for three- and four-element Yagi–Uda antennas are given by Uda and Mushiake.† Fig. 46 is extracted from that work. One of the difficulties of designing Yagi–Uda antennas of many elements is the large number of variables. Typically, the spacing between directors is kept constant, and the lengths are adjusted. Table 4 from Stutzman and Thiele‡ shows performance of equally spaced Yagi–Uda antennas with up to seven elements. When the number of elements becomes large, the directors act

as a slow-wave transmission line,* and the directivity can be approximately calculated from this.† Unfortunately, as the number of elements increases, the bandwidth decreases significantly so that arrays of more than three or four elements are quite narrow-band.

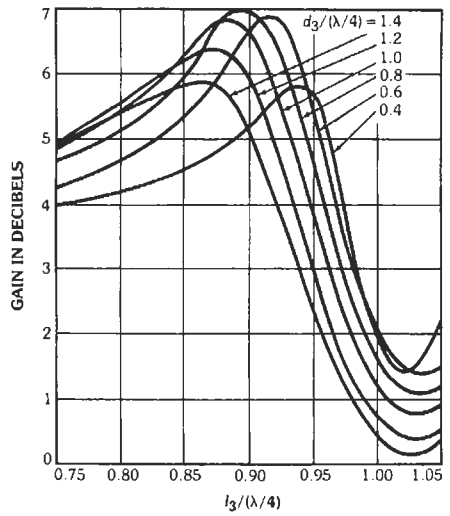

Fig. 46. Calculated gain of three-element Yagi–Uda antenna for indicated values of $d_3/(\lambda/4)$: $l_1 = l_2 = d_2 = \lambda/4$ and $\rho = \lambda/200$. (From Uda, S. and Mushiake, Y. *Yagi–Uda Antenna*, Fig. 9-3, 1954, Sasaki Printing and Publishing Co.)

Even for three- and four-element arrays, if the parameters are adjusted for maximum directivity at one frequency, the bandwidth will be narrow; however, one can adjust the parameters to have slightly less gain over a reasonable bandwidth. A Yagi–Uda antenna can be completely designed by use of array impedance matrix techniques. Here, the set of antenna currents is found from the inverse of the array impedance matrix, with the individual mutual impedance terms calculated by using the zero-order theory of Carter. Extensive calculations have been made by Lawson in a series of articles,‡ using this technique. Fig. 47 shows gain and front-to-back ratio for various three-element Yagi–Uda antennas. Table 5 gives the parasitic lengths and relative resonances for the six curves in each graph. It should be noted that although a single Yagi–Uda can give excellent performance, arraying of Yagi–Udas where the booms are parallel is only partially satisfactory. Surface-wave antennas do not array well because their near fields interact in an undesirable way, and thus the gain realized from an array of Yagi–Uda arrays is always significantly less than the product of the gain of a single Yagi–Uda array times the number of arrays.

A related antenna is the short backfire antenna of Ehrenspeck.§ As shown in Fig. 48, it consists of a flat

plate with a dipole in front of the plate, and with a cylindrical rim around the plate. The dipole feed typically has a dipole and small plate reflector. Performance of the antenna is affected by both the plate diameter and the depth of the rim. A single feed can produce gains in the region of 10 dB. Several of these may be arrayed, all over a flat reflector with a common rim. However, when more than four feed elements are used, a parabolic reflector may be competitive. Because the antenna has dimensions that are in the resonance region, analyses have only been partially successful. Precise analysis will probably require patch moment methods. Information on bandwidth is sketchy, but the aperture efficiencies tend to be well

above those for conventional parabolic-reflector antennas. Higher gain may be realized by feeding the reflecting plate by a feed dipole and dipole reflector, with a number of director dipoles between the feed dipole and the plate. In this scheme, the Yagi–Uda performance is combined with that of the backfire.

Frequency-Independent Antennas

The principle of frequency-independent antennas was established circa 1957 through the recognition that conventional antenna bandwidth limitations occur because critical dimensions change in wavelengths. An antenna specified only in angles should then be frequency independent. Of course, all antennas are of finite size, so an absolute low-frequency cutoff must exist, but within the maximum size the angular prescription can be followed.* A commonly used frequency-independent antenna is the spiral, which exists in two forms. The equiangular spiral is shown in Fig. 49. The conductor edges are formed in polar coordinates by

$$r_1 = r_0 e^{a\Phi}, \; r_2 = c r_1$$

Another version of the spiral is the Archimedean shown in Fig. 50. Although this spiral is not prescribed

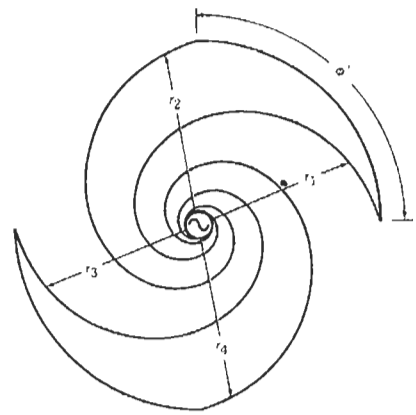

Fig. 49. Two-arm equiangular spiral. (Courtesy E. A. Wolff. *Antenna Analysis*. John Wiley & Sons, 1967)

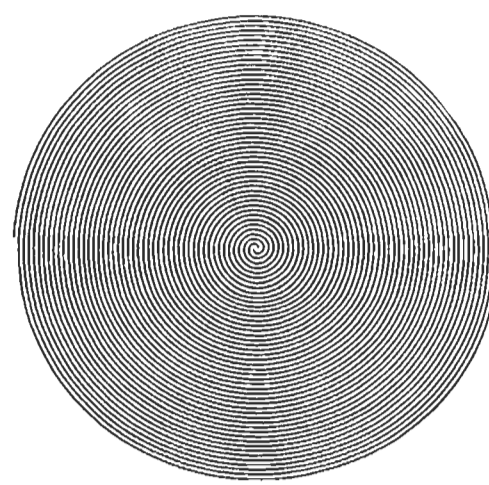

Fig. 50. Archimedean spiral. (Courtesy E. A. Wolff.)

only by angles, it gives excellent performance and is widely used. Both spirals operate through an "active region" from which the radiation takes place. At the

* Rumsey, V. H. *Frequency Independent Antennas*. New York: Academic Press, Inc., 1966. Mayes, P. E. "Frequency-Independent Antennas and Broad-Band Derivatives Thereof." *Proc. IEEE*, Vol. 80, Jan. 1992, pp. 103–112.

highest frequency, the active region is contiguous with the feed, and as the frequency decreases, the active region moves out to the edge. Corresponding with the active-region movement is a rotation of the pattern. The pattern is circularly polarized corresponding to the direction of the spiral arms, and the pattern exhibits a peak on the axis. Typically, the pattern is broad and the gain slightly more than that of a dipole. Since the circumference of the active region is a wavelength, the spiral must have a diameter of more than λ/π at the lowest frequency. The spiral may be used for azimuth direction finding by utilizing four, six, or eight arms. A four-arm spiral, for example, would have four interleaved arms fed with 90-degree phase rotation by a simple network of hybrids. The higher mode utilized in the four-arm spiral requires a diameter twice as large as that of the two-arm spiral so that the diameter now approaches a wavelength. Spirals with more arms require even larger diameters. The spiral by itself radiates on both sides, and a cavity is often used to allow surface mounting. Unfortunately, the cavity usually significantly reduces the bandwidth, and in order to achieve several octaves, it is necessary to accept some gain degradation via the use of absorbing materials and other techniques. Further information may be found in several references.*

The conical spiral consists of a two-arm spiral deployed on a cone with the feed point at the truncated apex as sketched in Fig. 51. This type of antenna gives a unidirectional pattern with the beamwidth controlled by the cone angle and the size. Further information may be found in a number of references.†

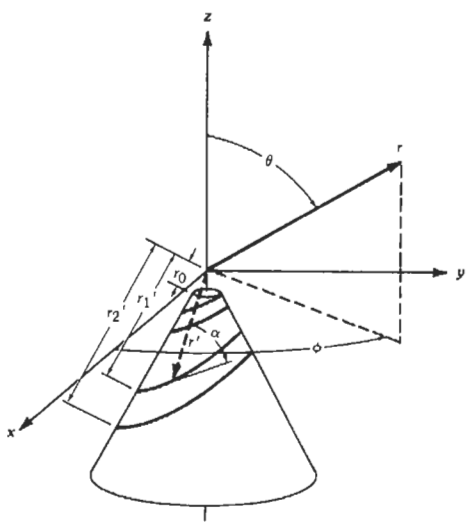

Fig. 51. Conical spiral. (Courtesy E. A. Wolff.)

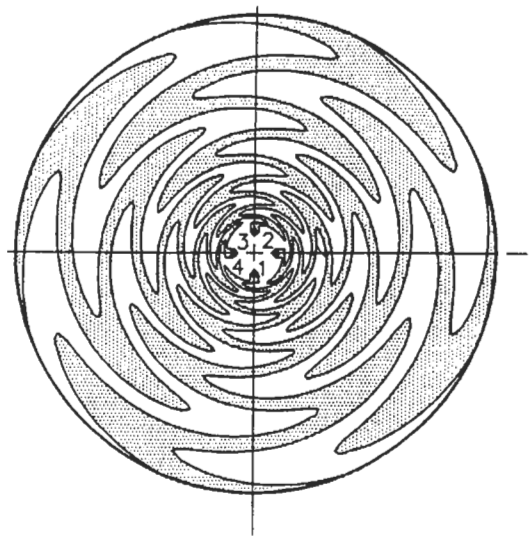

Fig. 51a. Sinuous antenna. (Courtesy R. H. DuHamel.)

DuHamel‡ achieved dual circular polarization by configuring a spiral in a zig-zag manner: this is the sinuous antenna‡ shown in Fig. 51a. Four arms are required for dual CP; six or eight arms allow angle-of-arrival modes to be used.

Another way of achieving a frequency-independent antenna is to design an active region that moves not continuously as in the case of the spiral, but in a discrete fashion. The antenna must now have a performance that is repetitive over a number of suitably related frequency subbands, and this, of course, is the log-periodic antenna discussed next.

Log-Periodic Antennas

Although the term "log-periodic" can be applied to any antenna designed with a structure that is periodic in the logarithm of some normalized dimensions, almost all log-periodic antennas in use are of the dipole-array type or of the trapezoidal-tooth type. Common usage now calls these simply "log-periodic antennas." The log-periodic array is shown in Fig. 52, where the critical parameters σ and τ are described. It can be seen that the dipoles fit within an envelope of fixed angle and that the ratio of spacing is constant. The log-periodic antenna operates through an "active region" from which the radiation takes place. This active region consists of those elements that are around $\lambda/2$ in length. Obviously, the closer τ is to unity, the larger the active region and the higher the gain. The low-frequency cutoff occurs when the active region has reached the large end of the antenna. Conversely, the high-frequency cutoff occurs with the active region at the small end. In principle, the log-periodic antenna may be designed to cover many octaves, but, in practice, the upper frequency is limited by the precision required in constructing the small elements, feed lines, and support structure, and by the feeder loss, since the antenna is fed from the small end. Fig. 53 from Carrel* shows directivity versus σ and τ. Fig. 54 shows typical construction using a two-wire feed line. The dipole diameter is not critical, although it is generally desirable to use smaller diameter dipoles at the small end than at the large end when the bandwidth is large. Log-periodic antennas may be printed on a dielectric substrate, but care must be exercised in the design because substrate thickness will limit performance at the upper frequencies. In principle, one can taper the substrate thickness to maintain scaling along the log periodic, but this, of course, is not practical. The length of the

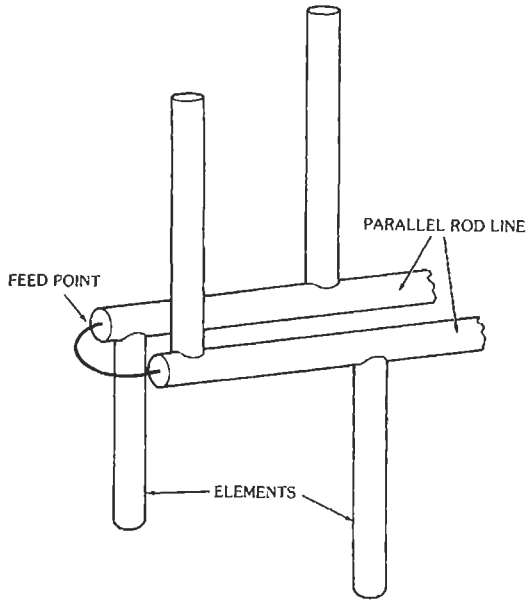

Fig. 54. Log-periodic construction. (Courtesy W. L. Weeks.)

dipoles can be reduced somewhat by loading techniques such as bending with a modest reduction in performance. Reduction of the spacing between elements does not appear practical. Care must be exercised to ensure that resonances are not set up in the feed line; swept impedance and gain measurements are essential for any new log-periodic design. There are several useful log-periodic references.*

The trapezoidal-toothed log-periodic can be in planar form as shown in Fig. 55, but it is more commonly in pyramidal form where the feed is at the apex of a rectangular pyramid and the toothed arms form the sides of the pyramid. Fig. 56 shows a wire version, which, again, is usually used in pyramidal form. In the pyramidal form, the beam is unidirectional. Cross polarized levels are sometimes high.†

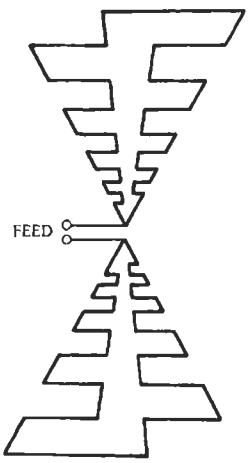

Fig. 55. Planar trapezoidal toothed log-periodic antenna.

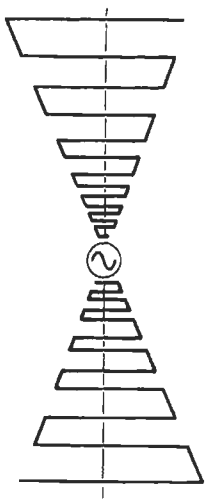

Fig. 56. Log-periodic trapezoid wire antenna (wires are connected to booms).

The log-periodic antenna can be analyzed and designed with the impedance matrix techniques described in the section on arrays, except that the transmission feed line plays an inseparable role in antenna performance. Thus, the transmission line is modeled as series of cascaded short sections with each section loaded by the impedance of the dipole at that

point on the feeder. Of course, the dipole impedance includes all mutual impedances. This results in a transmission-line transformation matrix that is solved in conjunction with the dipole-array impedance matrix. It has been found that although the current distribution on the active-region elements is nearly sinusoidal, elements on either side may have significantly different current distributions. Thus, for accurate results, it is necessary to use either moment method segmentation on the dipoles or to use the three-term current theory of Chang.* The latter is simpler and gives quite satisfactory results.

Fractal Antennas

Fractal theory has been applied to antennas but the results have not been promising. Many parts of nature are well modeled by fractals, e.g. certain ferns; unfortunately Maxwell's equations are not fractal. To see this, consider frequency independent antennas such as the planar spiral and the log-periodic dipole array. High frequency active regions are small and located at (near) the feed; low frequency active regions are large and are located farthest from the feed. Thus, feed currents can activate large active regions with only minor effects in passing through the intervening smaller regions. In contrast, the classic Mandelbrot fractal diagram† has one (largest) blob where the feed would be, with more smaller blobs on the large blob periphery; each smaller blob has its own cluster of still smaller blobs, etc. This topology is just the inverse of the frequency independent antenna topology. Generally, a conventional antenna in the same area (volume) performs better.

ARRAYS

General Characteristics

Arrays of antenna elements are almost always regularly spaced on a rectangular or triangular lattice for planar arrays, equally spaced for linear arrays. Nonuniformly spaced (thinned) arrays will be discussed later. Since fields add, the pattern of an array is the product of the element pattern and the array factor, the latter being that of an array of isotropic elements. Thus, the element and array behavior can be separated for pattern purposes. The array factor for N elements can be written:

$$E(\theta,\phi)=\sum_{n=1}^{N}A_n e^{-j2\pi(u-u_0)}$$

where

$$u=\pi(d/\lambda)\sin\theta\cos\phi$$
$$u_0=\pi(d/\lambda)\sin\theta_0\cos\phi_0$$

The interelement phase shift, u_0, positions the beam at θ_0, ϕ_0. Element spacing is d, and the excitation coefficients are A_n. Symmetric arrays can be written as a real series with terms $A_n\cos n(u-u_0)$. Factoring the array expression displays the zeros in u; these are of critical importance in controlling array-factor behavior. Uniform excitation gives a $\sin\pi u/\pi u$ or $\operatorname{sinc}\pi u$ pattern, and this is both a constituent of a shaped beam pattern (using Woodward–Lawson synthesis‡) and a prototype for low-sidelobe designs. Zeros of $\operatorname{sinc}\pi u$ occur at $u=\pm n$: shifting these zeros controls the sidelobe envelope. Although in the early years of antennas, array and aperture excitation functions were chosen for simplicity and integrability, they are now designed through zero placement to yield optimum performance given the requirements. Computer codes are then employed to furnish needed details. Large arrays, roughly N of 20 or more, are usually designed by sampling a continuous distribution. See the section on aperture distributions. For small arrays, the zeros of a polynomial, such as the Chebyshev, are adjusted; the order of the polynomial matches the number of elements in the array.§ For all types of arrays, design using physical principles of zero placement should be used to obtain optimum performance." This also obviates comparing various well established but meretricious array/aperture distributions.

Examples of two-element arrays for various spacings and phasings have been given by Southworth as shown in Fig. 57.

The 3-dB beamwidth is given by

$$\theta_3=\arcsin(\sin\theta_0+0.443\lambda/Nd)-\arcsin(\sin\theta_0-0.443\lambda/Nd)$$

For $N\geq 6$ this is

$$\theta_3\simeq 0.886\lambda/(Nd\cos\theta_0)$$

These formulas show the beamwidth broadening with scan angle θ_0. With a linear array factor, the pattern is rotationally symmetric about the array axis, with a disk-shaped pattern at broadside. As the beam is moved toward end-fire, the disk becomes a cone, and the inner –3 dB points coalesce along the axis for an angle of:

$$\theta_0=\arcsin(1-0.443\lambda/Nd)$$

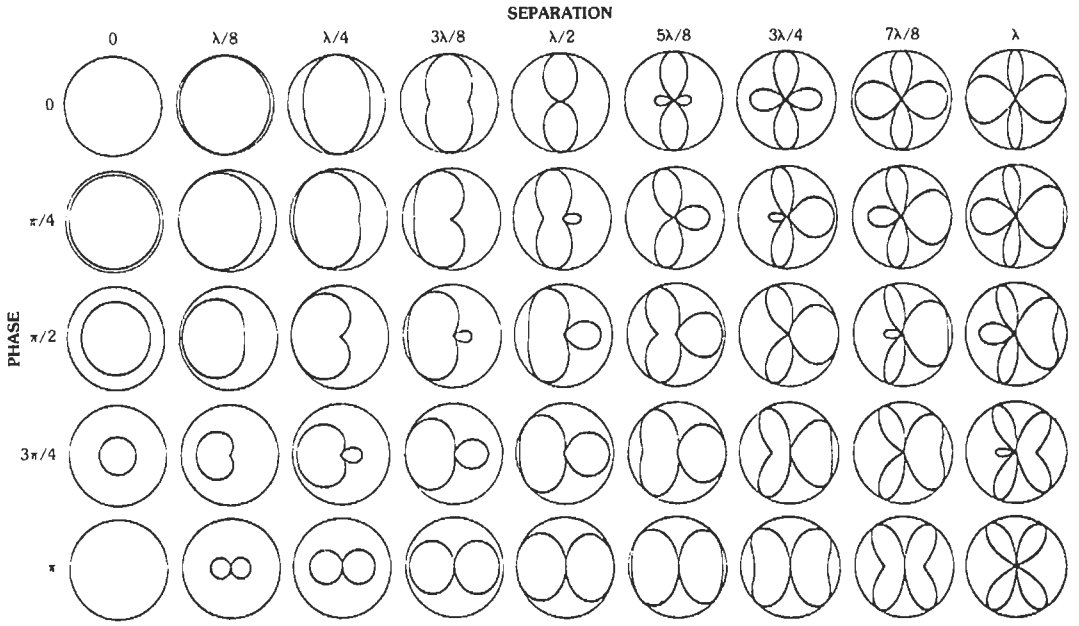

Fig. 57. Patterns of two-element arrays. (From Southworth, G. C. "Certain Factors Affecting the Gain of Directive Antenna Arrays." *Proc. IRE*, Vol. 18, Sept. 1930, pp. 1502–1536.)

For beam angles beyond this angle, a single end-fire beam exists. At end-fire, the beamwidth is larger than broadside beamwidth by the factor:

$$\theta_{3\ \text{endfire}} / \theta_{3\ \text{broadside}} \simeq 2\sqrt{0.886\lambda/(Nd)}$$

When analog phasers are used to produce the inter-element phase shift, u_0, required to scan the beam, any beam position may be reached if the phasers can be set precisely. Digital phasers, however, have a least count of phase shift, and the array positioning will similarly have a least position change. An m-bit phaser has a least count phase shift of

$$\phi_{lc} = 2\pi/2^m$$

and this produces a least beam shift of $kd \sin\theta_{lc}$, $k = 2\pi/\lambda$. These are related by

$$kd \sin \theta_{lc} = \pi/2^{m-1}$$

For the common λ/2-spaced array, the relationship is $\sin \theta_{lc} = 2^{m-1}$. Table 6 shows the fineness of beam steering available versus the number of bits per phaser. Pseudo-randomization can reduce the pointing error.*

TABLE 6. FINENESS OF BEAM STEERING

m	θ_{lc} (degrees)
2	30
3	14.48
4	7.18
5	3.58
6	1.79

Positioning the beam of an array at one frequency requires only a phaser per element. Positioning the beam over a large bandwidth requires the proper time delay, i.e., line length, at each element. The bandwidth allowed with the use of phasers depends on array size; bandwidth is taken as beam movement to the –3-dB point:

$$BW = (f_2 - f_1)/f_0 \simeq (f_2 - f_1)/f_2$$
$$= (\sin \theta_2 - \sin \theta_1)/\sin \theta_1 \simeq \lambda/2L \sin \theta_1$$

Assumed here is a not small array length. For a beam angle of 30 degrees, for example, the fractional bandwidth is

$$BW \simeq \lambda/L$$

Thus, long arrays have less bandwidth in terms of beam shift at the band edges.

Directivity of arrays, unlike fields, cannot be found by combining element and array-factor directivity. The latter for a linear array is given by:

$$G = N \Big/ \left[1 + (2/N) \sum_{n=1}^{N-1} (N-n) \operatorname{sinc} nkd \right]$$

Fig. 58 shows this versus spacing. Linear arrays of half-wave dipoles are often used; directivity is obtained from mutual resistances (for an efficient computer algorithm, see Hansen*) with the proper values used for parallel or collinear dipoles:

$$G = 120N \Big/ \left[R_0 + (2/N) \sum_{n=1}^{N-1} (N-n) R_n \right]$$

Here R_o is the self-resistance and R_n is the mutual resistance between the first and nth dipoles. See Figs. 59 and 60. These directivity curves are for a uniform array with a broadside beam.

The directivity drops at a spacing somewhat less than a wavelength due to the emergence of a grating lobe. (See subsection on grating lobes.) Each time the

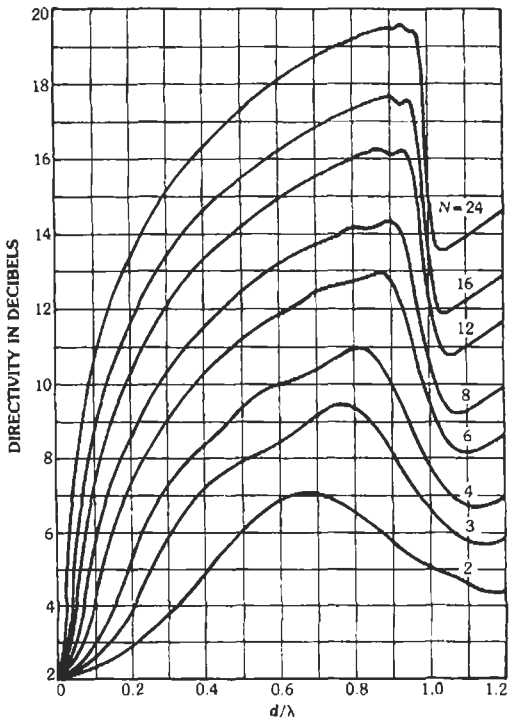

Fig. 59. Directivity of parallel dipole array.

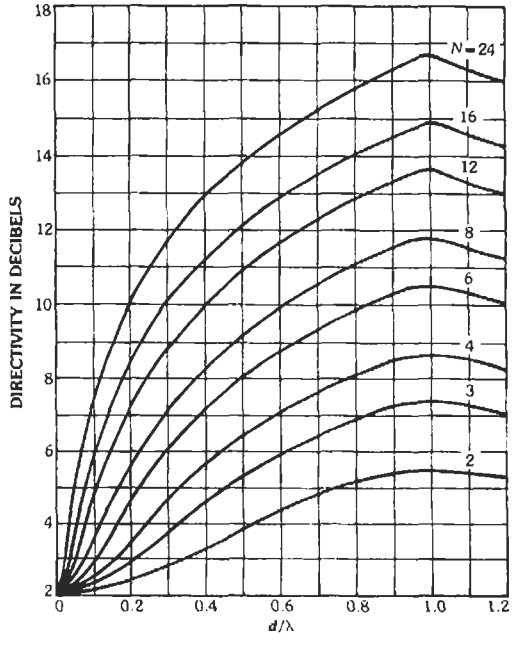

Fig. 60. Directivity of collinear dipole array.

spacing is increased enough to admit another grating lobe, the gain drops proportionately. Directivity of planar arrays can be approximated in lieu of exact calculations, by computing the gain of constituent x- and y-direction linear arrays of the exact elements, multiplying these directivities together, and then adding a correction factor.* Since dipole directivity of 1.604 is included twice, it must be divided out.

Grating and Quantization Lobes

The uniform array equation indicates that a maximum of unity occurs whenever $u = n$. Grating lobes for a small array are shown in Fig. 61. For another array, the pattern is as shown in Fig. 62, which is for a spacing of 0.707λ. For a broadside main beam, a spacing of one wavelength produces a grating lobe at –90° with a symmetric lobe at +90°. Similarly, a main beam scanned to 90° will produce a grating lobe at –90° for half-wave spacing. Fig. 63 shows the grating-lobe angles for various spacings and main beam angles. Here $\theta_0 = 0$ represents broadside. These curves allow the designer to select a spacing to minimize grating-lobe effects. However, they are for appearance of the grating lobe at ±90° so that half of the grating lobe is visible. In some cases, it is desirable to reduce the spacing such that the entire grating lobe is precluded, with the grating-lobe null at ±90°. This spacing reduction has been calculated for the general Taylor one-parameter line source, which includes the uniform as a special case.† The spacing reduction factor is

$$d/d_{gl} = \left(N - \sqrt{1+B^2}\right)/N$$

B is the Taylor parameter; see the section on aperture distributions. Grating lobes for arrays whose elements are on a rectangular lattice can be analyzed by using two linear-array cases. Arrays using hexagonal or triangular lattices are more complex.‡

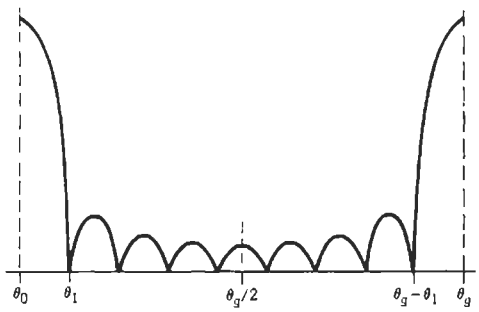

Fig. 61. Array pattern with grating lobe.

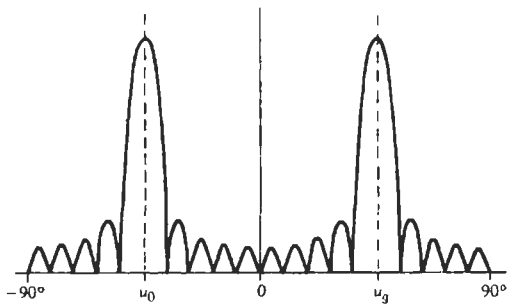

Fig. 62. Array pattern scanned to 45°.

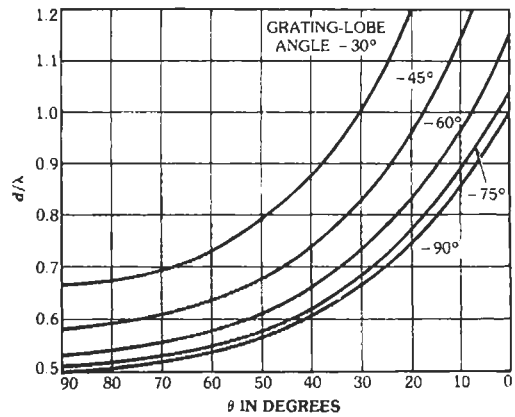

Fig. 63. Element spacing vs grating-lobe angle.

Phaser quantization, as mentioned, affects the beam position least count, and it also distorts the pattern. The desired phase versus position along the array is a straight line whose slope is related to the beam angle, but digital phasers produce a stair-step approximation to this. The effects of the sawtooth error depend on the number of elements that fit within a stair step. If there are two or more elements per step (two element subarray), one or more discrete lobes called quantization lobes will be produced. These have a fixed height that is less than the main beam height, with the height and position both calculable from the element spacing and scan angle. Because of these factors, quantization lobes should not be called grating lobes. Table 7 gives the height of the quantization lobe in terms of number of phaser bits. Where there are fewer than two elements per sawtooth, the errors approach randomness, and the sidelobe level is raised. Fig. 64 shows rms sidelobe level due to phaser quantization for a broad-

side main beam. When a quantization lobe exists, it can be suppressed by introducing a pseudorandomization into the phaser control bits.* However, the energy in the quantization lobe is dispersed, thereby raising the sidelobe level, and the random curves of Fig. 64 apply.

Linear Array Feeds

Resonant arrays have elements spaced along a transmission line feed at half-guide wavelength intervals. The transmission line ends are shorted so that a standing wave is set up in the feed. At center frequency, each element is resonant, and the input conductance is the sum of the element conductances. The bandwidth of resonant arrays is narrow, because at frequencies off resonance the conductances are out of phase. The feed admittance can be calculated by using a cascade of A-B-C-D matrices with the results shown in Fig. 65. The abscissa is the number of elements times percent bandwidth. Within the range shown, the VSWR is monotonic, but for larger frequency excursions, VSWR oscillates about a value of two for the uniformly illuminated array. In these results, mutual coupling has not been included; thus the bandwidth indicated is optimistic. A design procedure for resonant arrays including the effects of mutual impedance has been developed by Elliott.† To avoid splitting of the main beam, arrays should be designed with a VSWR well below 2.0.‡

A traveling-wave array consists of a transmission line with equally spaced elements coupled to it, with spacings that are not any multiple of half-guide wavelength. Power is fed into the feed at one end, and a load is placed at the other end. A portion of the feed energy is coupled to each element, with the power remaining after the last element dissipated in the load. This array is thus nonresonant, and the beam angle will be either forward or backward and will change with frequency. The broadside resonant condition must be avoided. For traveling-wave arrays of many elements, the coupling of each element is small. The element admittances then add nearly randomly, which makes the array reasonably well matched at all points. From transmission line formulations, the conductance of each element may be calculated, including loss in the transmission line. If the loss factor $s = \exp(-2\alpha)$, the conductance for the nth element is given by

$$G_n = F_n s^{-n} \Big/ \left[\left(1 - Ls^{1-N}\right)^{-1} \sum_{m=1}^{N} F_m s^{-m} - \sum_{m=1}^{n} F_m s^{-m} \right]$$

* Hansen, R.C., and Charlton, G. C. "Subarray Quantization Lobe Decollimation." *Trans. IEEE,* Vol. AP-47,.August 1999, pp. 1237–1239.

The F_n excitation coefficients are usually those of the Taylor one-parameter or Taylor $\bar{n}$ distributions described elsewhere in this chapter. A continuous version of the conductance formula is sometimes used, but unless the number of elements is very large, the discrete form above is preferable. Fig. 66 gives slot conductance values for a 29-element array with uniform excitation for several fractions of power dissipated in the load. As expected, the element conductances increase along the feed as there is less power to which to couple. Fig. 67 gives similar curves for a Taylor one-parameter distribution, and Fig. 68 is for a Taylor $\bar{n}$ distribution.

The beam position of a traveling-wave array is easily determined from the phase equation:

$$kd \sin \theta_0 + 2n\pi = \beta d - \pi$$

where

θ is the beam angle measured from broadside,
d is the element spacing,
$k = 2\pi/\lambda$,
β is the waveguide wave number.

For a given waveguide velocity ratio, a curve such as that in Fig. 69 can be plotted; this curve is important in showing the number of beams versus beam angles.

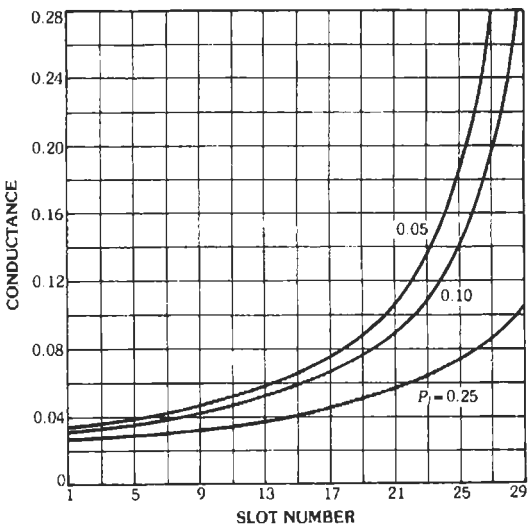

Fig. 66. Slot conductance values, uniform excitation, $N = 29$.

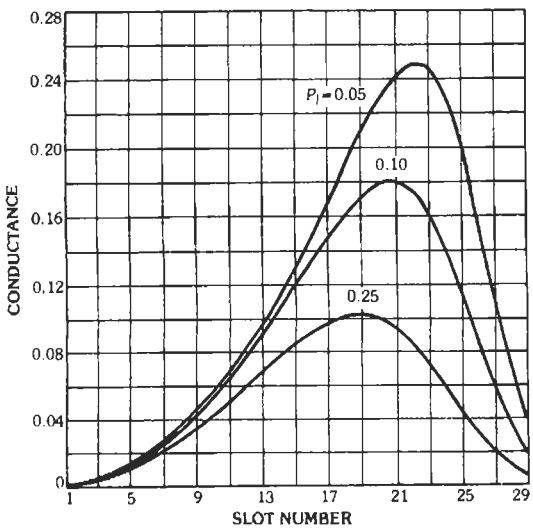

Fig. 67. Slot conductance values, Taylor one-parameter, SLR 25 dB, $N = 29$.

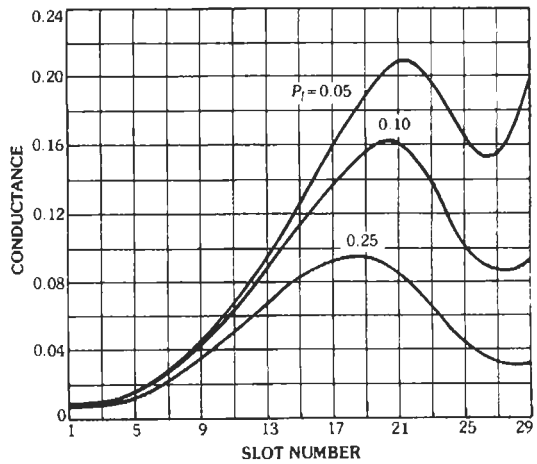

Fig. 68. Slot conductance values, Taylor $\bar{n} = 5$, SLR 25 dB, $N = 29$.

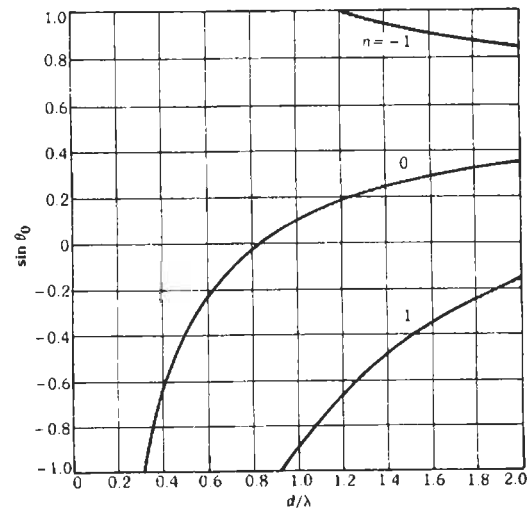

Fig. 69. TW array beam angle vs spacing, $\beta/k = 0.6$.

For example, for spacings smaller than 0.9375λ, only one beam exists, and for most spacings it is a backward-directed beam. Multiple beams are, of course, undesirable; this type of plot enables the single-beam range to be quickly discovered. It is necessary to inspect beam behavior over the entire frequency band of interest, which can be done with other types of plots.* Change of beam angle with frequency is important and can readily be written in a normalized form:

$$f[(d/df)(\sin\theta_0)] = 1/(\beta/k) - \sin\theta_0$$

It can be seen that the normalized slope depends simply on β/k and the beam angle.

Corporate feeds can be used with a linear array; power dividers or hybrid junctions can usually provide significantly greater bandwidth than the array elements. Thus, for wideband arrays corporate feeds are recommended. However, corporate feeds are generally bulky and expensive except for implementation in stripline or microstrip. Thus, printed-circuit arrays are often built with corporate feed networks.

Mutual Impedance

Mutual impedance between elements in any array affects both fixed beam and scanning arrays. In the former, the mutual impedance effects can be accommodated in the design of the array.† Arrays of medium gain elements such as horns, spirals, or dishes may exhibit only minor mutual coupling effects. However, scanning with such large virtual subarrays is severely limited due to quantization lobes (see the subsection on electronic scanning in this chapter). Mutual impedance between low-gain elements is typified by that of halfwave dipoles. Figs. 70, 71, and 72 show complex-plane spiral plots of mutual impedance between parallel, collinear, and 45° echelon dipoles. The circles on the graph represent different values of dipole center-to-center spacing. It is important to note that the *H*-plane coupling is strong while the *E*-plane coupling is weak. Accurate and efficient computer codes in Fortran for the calculation of mutual impedance have been given by Hansen‡ for equal lengths and Hansen and Brunner§[3] for unequal dipoles. These results and codes can be used for slots by replacing the dipole with a Booker equivalent Babinet dipole. The slot admittance and dipole impedance are related by $2Z_{12} = \eta^2 Y_{12}$ where $\eta = 120\pi$. If the slot radiates on both sides, the factor 2 is replaced by 4.

mating this is to use a round or square open-end waveguide radiator with dielectric plugs, etc., to produce equal TE and TM modes.* A simpler way is to use a slot straddled by a pair of monopoles, sometimes called a Clavin slot. The monopole length and spacing can be adjusted to produce a slot E-plane pattern similar to the narrow H-plane pattern. Fig. 73 shows a Clavin slot. These slots were empirically designed by Clavin;† an analytical design was given by Papierz et al.‡ Mutual coupling calculations have also been developed by Elliott.§ Figs. 74 and 75 show complex-plane plots of mutual coupling between Clavin slots for parallel and collinear geometries. It can be noted that these couplings are both small and are more alike. Thus, this type of element should give improved scanning performance in electronically scanned arrays.

Mutual coupling effects in electronic scanning are difficult to calculate and outside the scope here. Only a few general remarks will be made. An array with a feed network that provides fixed drive voltages (using dipoles as an example) can be simply analyzed from an impedance matrix equation. That is, the dipole currents are found by multiplying the array voltage vector by the inverse of the mutual impedance matrix. Since the scan angles are contained in the drive vector, it is

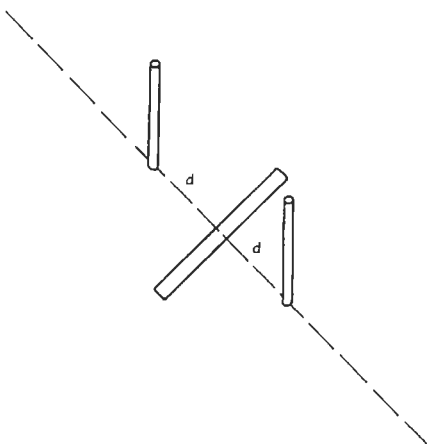

Fig. 73. Slot with parasitic monopoles (Clavin slot).

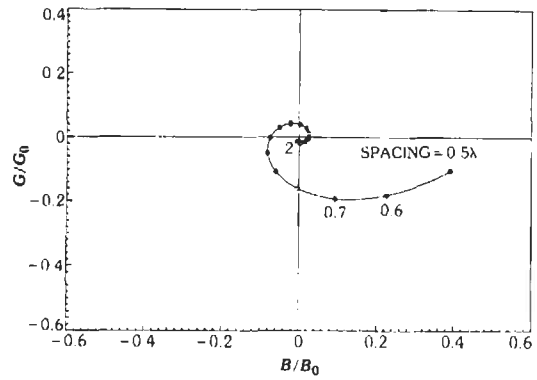

Fig. 74. Parallel Clavin-slot mutual admittance/G_0.

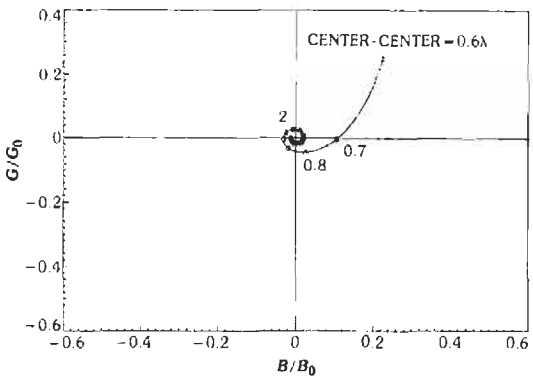

Fig. 75. Collinear Clavin-slot mutual admittance/G_0.

simple to find the Scan Impedance of each element and the resulting array pattern for a given scan angle. Many arrays do not have a constant voltage feed network but are of the constant-available-power type. Here an element impedance mismatch reduces the applied voltage. This approach is more suited to a scattering equation. For details, see Hansen." Lengthy formulas have been developed for Scan Impedance of dipole arrays,# and these can be translated to slot arrays. The Scan Impedance is the element input impedance as modified by mutual coupling from neighboring elements, and this Scan Impedance, of course, varies with scan angle. The array gain versus scan can be calculated by using the isolated element pattern times the nominal array pattern factor times one minus the scan power reflection coefficient. The scan reflection coefficient is, of course, determined

Ibid.

from the Scan Impedance. The array gain can also be calculated from a Scan Element Pattern times the nominal array pattern factor. Here the Scan Element Pattern is the element pattern as affected by mutual coupling. All of these comments are useful only for large arrays, i.e., arrays with many elements in the coordinate under consideration. Small arrays must, in essence, be analyzed by adding the contribution of each element, including mutual coupling or mutual scattering. See the subsection on electronic scanning.

Edge effects in finite arrays have been elucidated by an exact analysis of finite-by-infinite dipole arrays. Oscillations in Scan Impedance occur over the finite dimension of the array, even for larger arrays. These are modeled by a Gibbs type phenomenon, where the oscillation amplitudes increase toward the edges.* The period of the oscillation is scan related and is proportional to $1/(1 - \sin\theta_0)$ where θ_0 is the polar scan angle.

Thinned Arrays

Thinned arrays were originally conceived to offer the resolution of a large array without the large number of elements required for a filled array. However, the sidelobe levels have proved to be unattractively high except when the number of elements used is large. A probabilistic analysis was given by Agrawal and Lo† with results that compare closely with Monte Carlo simulations for both short and long arrays and for low and high probabilities. The results are in terms of array length L/λ and a parameter, α, which is number of elements times power sidelobe level: $\alpha = N \times \text{SLL}$. The probability is given by

$$P = (1 - e^{-\alpha})\, e^{-(2L/\lambda)\sqrt{\pi\alpha/3}\exp(-\alpha)}$$

Fig. 76 shows the probability of achieving a sidelobe level versus parameter α for different length arrays. For example, a 300-wavelength aperture with 150 elements, giving an average element spacing of 2 wavelengths, has only a 40% probability of achieving a −13 dB sidelobe level. Table 8 shows the α values for several different lengths of arrays for a 90% probability. Also shown is the limit of sidelobe ratio that can be achieved when the number of elements is sufficient to fill the array. Of course, if this number of elements were rearranged with constant half-wave spacing, the sidelobe level would be −13.26 dB. The filling ratio necessary to achieve a 90% probability of sidelobes below −10 dB is also shown. From this, it can be seen that either high filling ratios or large arrays are needed to achieve even modest sidelobe levels. A thinned array designed for one frequency and no scan, frequently provides unacceptably high sidelobes at other frequencies, or at other scan angles. A special type of thinned array is the space-tapered array. Here, the spacing of uniformly excited elements is tapered to match a low sidelobe distribution of the type covered in the section on aperture distribution. This scheme is attractive for arrays that have distributed transmitter/receiver modules because it allows all modules and elements to be alike. Experience has shown that the fall-off of sidelobes is not quite as optimistic as the theory predicts. With any space-tapered array, thorough calculations are needed to ensure that no high sidelobes exist, and it may be necessary to adjust the filling ratio and spacing to ensure sidelobe control over the bandwidth and range of scan angles. For

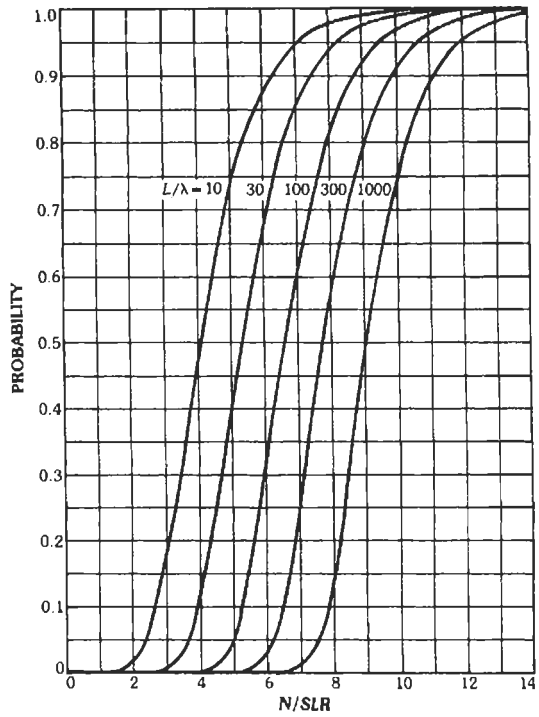

Fig. 76. Probability of random array sidelobe ratio greater than SLR.

information on degree of thinning versus sidelobe level, see Hansen.*

A new thinned array design† has roughly constant sidelobe envelopes over a wideband and over scan; typically the peak sidelobe envelope is –15dB and the RMS envelope is –19dB, both with respect to the main beam peak. Gain is approximately equal to the number of elements.

Tolerances

Random errors in element position, element orientation, and element excitation will affect array performance. Since mechanical tolerances can be controlled much more tightly than excitation, only phase and amplitude excitation errors are of concern. They are assumed to have normal (Gaussian) distribution with zero mean and variance σ^2. These errors reduce the gain a small amount, and on the average add a small constant amount to the sidelobes.‡ The effect on sidelobes is less for large arrays and more for low sidelobes. The gain, with respect to error-free gain, is given by

$$G/G_0 \simeq \exp\left(-{\sigma_{amp}}^2 - {\sigma_{ph}}^2\right)$$
$$\simeq 1/\left(1 + {\sigma_{amp}}^2 + {\sigma_{ph}}^2\right)$$

Thus, errors reduce gain or directivity only to second order, and gain reduction can generally be neglected. For sidelobes, the effect, however, is first order. The mean sidelobe level is related to the error-free sidelobe level by

$$SL = SL_0\sqrt{1+\sigma^2 / G \cdot {SL_0}^2}$$

where

G is the antenna gain,
σ^2 is the total error variance,
SL_0 is the voltage sidelobe level.

Fig. 77 shows mean sidelobe level versus the universal factor $\sigma/\sqrt{G}$. From this, it is apparent that sidelobe designs from 13 to 30 dB are quite robust, whereas low sidelobe designs have sensitive tolerances. Similarly, these curves clearly show that for a given sidelobe level and sidelobe degradation, larger arrays allow larger errors. The probability density function of the pattern with random errors is a modified Rayleigh, and the probability can be written in terms of the Marcum Q function. Curves of probability of certain sidelobes exceeding specified values are beyond the scope here, and are given in Hansen.§

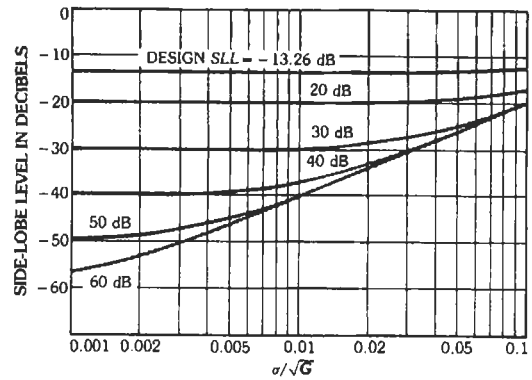

Fig. 77. Mean sidelobe level vs universal factor.

Multiple-Beam Arrays

Multiple-beam arrays usually utilize a beam-forming network (BFN) such as the Butler matrix or Rotman–Gent lens. The BFN, in essence, takes the discrete Fourier transform of the array distribution and produces the transform (space factor) at each beam port. The Butler matrix is, as has been pointed out innumerable times, the microwave equivalent of the FFT. An eight-element, eight-beam Butler BFN is shown in Fig. 78. The beams produced by this network are sketched in Fig. 79. The beam position for any spacing is

$$\sin\theta_i = \pm(2i-1)\lambda/(2Nd), \quad i = 1, 2, \ldots N/2$$

The crossover level is independent of spacing; when the element spacing is increased, the beamwidths become narrower and the beams move closer together. Beam coverage from the center of the leftmost beam to the center of the rightmost beam is

$$\theta_{cov} = 2 \arcsin (N-1)\lambda/(2Nd)$$

When $d = \lambda/2$, the space –90° to +90° is just filled with beams, as indicated in Fig. 79. Larger spacing moves the beams closer together so that the coverage angle of the N beams is less. However, the space will be filled with beams, and thus there is aliasing and directivity loss due to the extra beams, which are essentially grating lobes. The foregoing assumes isotropic or low-gain elements. When moderate-gain elements such as horns are used with larger spacing, the grating lobes are replaced by subarray quantization lobes; i.e., the grating-lobe amplitude is reduced by the element pattern. The sidelobe ratio and crossover level of a Butler BFN approach those of a uniform line source for large N. Table 9 shows these parameters for

32	13.23 dB	−3.92 dB

popular-size Butlers. The performance of a Butler BFN over a frequency band corresponds to that which is the result of change in spacing. At frequencies above the design frequency, the beams become narrow, and additional beams are added at each side. Conversely, at lower frequency, the beams spread out, and one or more beams on each side may disappear.

The Rotman–Gent BFN or lens was originally designed with circular arcs for mechanical scanning. However, they are now usually implemented in microstrip with fixed feeds, and the input-output faces are now allowed to follow the optimum curves. See Fig. 80. When the lens is symmetric, i.e., the input and output curves are the same, the lens can be specified with a single parameter.* Nonsymmetric lenses offer more flexibility and are almost always used.† This type of lens admits a three-point correction, where the center feed and two other symmetrically located feeds can produce a perfectly collimated beam. Note that the bootlace lines connecting the output face to the radiating arrays are an integral part of the lens and are specified by the lens design. The Rotman–Gent lens, being an optical device, has a fixed set of beam positions controlled by the design of the lens. Accordingly, the crossover level at center frequency is adjustable and is a tradeoff with feed mutual coupling and other design factors. At frequencies above or below the design frequency, the beams become narrower or broader, and the crossover level changes accordingly. Rotman–Gent lenses tend to be lossy, and information has not been published on the minimum loss of which this design is capable.

It is known that a multiple-beam antenna designed such that the beams are orthogonal‡ has minimal cross talk between beams. When beams are not orthogonal, the cross talk, which affects both the radiated pattern and the feed reflected power, is produced by the mutual coupling between feed ports and between array ports. When the spacing, d, and excitation are such as to provide orthogonal beams, mutual coupling still exists, of course, but its effects cancel out in the proper directions. Unfortunately, although many configurations have approximately orthogonal beams, only a uniform line source and line sources with a cosine to an integral power distribution are exactly orthogonal. Contrary to older literature, a cosine-on-a-pedestal does not produce orthogonal beams. A discrete array of N isotropic elements can approach orthogonality if N is large, but for small N the condition is not satisfied. The addition of practical elements such as dipoles or slots destroys the orthogonality condition. In spite of all this, arrays with as few as eight elements show excellent sidelobes for collinear dipoles and modest degradation for parallel dipoles, both at half-wave spacing. Table 10 shows the drawbacks of using purely orthogonal distributions in that only the uniform line source has acceptable efficiency and crossover level.

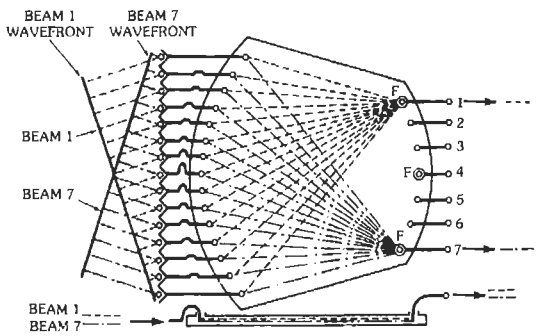

Fig. 80. Rotman BFN

The effects of nonorthogonality can be reduced by those techniques used to reduce mutual coupling between elements in an array. For example, the use of monopole pins astride a slot reduces E-plane coupling.

Low sidelobes in multiple beams can be produced in several ways. However, the only way that is efficient and simple involves the superposition of beams. For example, the Taylor $\bar{n}$ distribution (see the section on aperture distributions) has been written as a sum over $\bar{n}$ sinc beams. Since a Butler matrix or Rotman–Gent lens produces sinc beams if uniformly excited, several beam ports can be combined with suitable weighting to produce a single beam with low sidelobes. Using this technique, Thomas§ achieved –28-dB sidelobes over a 10% bandwidth with a Rotman–Gent lens. All of the above techniques and devices have a one-dimensional radiating array. A two-dimensional array may be handled by cascading rows of Butler BFNs or of Rotman–Gent BFNs, but this requires much hardware. There is no rotationally symmetrical three-dimensional equivalent of the Rotman–Gent lens; the three-dimensional lens has four perfect points but is not symmetric."

There is, however, a Butler matrix for two-dimensional arrays. This applies to an array disposed on a

regular hexagonal lattice. The resulting BFN is a three-dimensional microwave network with multiple-arm hybrid junctions but is simpler than cascading two-dimensional Butler BFNs.*

Electronic Scanning

Some of the design tradeoffs for electronic scanning, such as grating lobes, have been addressed above. A large electronic scanning array, or phased array, can be characterized in terms of Scan Impedance and Scan Element Pattern; the modifier "scan" implies a quantity that varies with scan angles. In the Scan Impedance approach, the pattern is written as the product of three factors. First is the array factor (of isotropic elements), which is h_N; the second is the isolated element pattern, g_i; the last term involves the Scan Impedance. These combine to give a gain pattern of:

$$G(\theta)/(h_N g_i R_i/R_a)\,[1-\Gamma_a|^2]$$

where

R_i is the isolated element resistance,

R_a is the scan element resistance,

Γ_a is the scan reflection coefficient.

Scan Impedance can be measured only when all elements are radiating with the proper amplitude and phase. The Scan Element Pattern can be measured with a distant transmitter and all elements terminated in a matched load. It shows relative behavior versus scan angles. If one element is excited, relative angle behavior is useful but the absolute value is not. Although these formulas show only θ, they apply in general to two-dimensional scanning over θ, ϕ. For such large arrays, a powerful analysis was developed by Oliner and colleagues using the unit cell concept. Here, one element in a large array is seen to be closely equivalent to an element in an infinite array; in the latter, the periodic nature of the array allows a single cell to contain the entire characteristics of the array. This cell, called the unit cell, consists of a virtual waveguide with suitably chosen impedance walls with the waveguide symmetrically located about the element (typically a slot) in the element lattice. The wall boundary conditions are derived from the scan angles. These unit cells are normal to the array face and are contiguous. Interior modes are LSE and/or LSM. If no grating lobes exist, the conductance is given by the single propagating mode in the unit cell waveguide, and thus a closed form result occurs. All modes contribute susceptance, and thus many series terms must be computed. This Floquet method has proved to be powerful and perceptive in the understanding of scanning behavior of arrays. For more detailed information, refer to Oliner and Malech† and Hansen.‡ Applications to arrays of microstrip patches have also been made.§

A blind spot can be produced in an array at a particular angle; the array radiation is zero at this angle. This occurs when the dominant mode is canceled by a higher mode, and can occur because of external or internal structure. External structure often used for matching or for protective purposes includes dielectric sheets over or near the array face and dielectric plugs protruding from waveguide-type elements. Internal structure includes dielectric loaded waveguide elements, monopole loaded slots, etc. Blind spots can be severe for large arrays but usually are negligible for small arrays. In case a blind spot is experienced, the array design can usually be changed to remove it. Typical measures are reducing lattice dimensions, changing design to improve VSWR, and altering the periodicity of the external structure. Simulators have also proved useful. For more detailed information, see Oliner and Malech† and Hansen.‡

Small arrays are usually analyzed with the element-by-element approach. Here, a matrix equation is set up relating the drive voltage to the element currents times the impedance matrix, using dipoles as an example. These simultaneous equations are solved for the currents, from which the impedance of each element is immediately available. Note that solution of complex simultaneous equations is several times faster than matrix inversion. Since the scan direction appears in the drive vector, Scan Impedance is easily obtained. This approach allows the variation of impedance from center to edge elements to be determined. When the elements are slots or dipoles, a convenient and efficient computer algorithm for mutual impedance is useful.¶ The effects of Scan Impedance change over a range of scan angles can be reduced by designing the element to have a pattern close to the "ideal" element pattern.

This is a power pattern of cos θ (for half-wavelength spacing); it is a rotationally symmetric cosine pattern.* Compensation always involves establishing both TE and TM modes (to make the pattern equal in both planes), and perhaps additional modes for pattern shape control. This can be done with open-ended waveguides with appropriately chosen dielectric plugs and slabs.† A simpler but less effective technique uses monopoles astride a slot, the "Clavin pins."‡

Use of sub-arrays, where two or more elements are connected to one phaser, produces quantization lobes (QL) similar to those mentioned under Grating Lobes. These QL occur at the grating lobe angles (for the sub-array spacing) but are reduced by the sub-array patterns. It has recently been discovered that these sub-array QL can be partially decollimated by using a pseudo-random phase.§ Fig. 80a shows the suppressed QL for an array of 2-element sub-arrays and 30-degree scan. This technique is most useful for 2-element (or 2x2) sub-arrays, due to the pattern effects of larger sub-arrays.

Adaptive Arrays

Adaptive arrays are sometimes used to suppress interfering sources; the array is automatically adjusted to provide a pattern null in the direction of the interferer. The simplest type is the sidelobe canceller in which an auxiliary element is used with the main antenna to provide a single null. A feedback loop is used to adjust the phase and amplitude of the single element to produce a subtraction of the interfering signal. A more powerful configuration is the adaptive array in which each element is controlled. There are three general types of adaptive arrays, which differ in the reference signal used for driving the control loops that provide the weights (amplitude and phase) for each element. The first type uses an externally provided steering vector that indicates the desired signal direction. This type of array is called Applebaum–Howells (Fig. 81); it is sensitive to errors." The second type uses a signal replica that correlates with the desired signal. This replica may be from a subcarrier oscillator, a binary sequence of the proper bit rate, etc. This type of adaptive array is associated with Widrow and is frequently called an LMS array. Fig. 82 shows a simplified configuration. The control loops produce a least-mean-square error between the desired signal and the replica, hence the LMS name. The third type of adaptive array does not have an externally supplied reference signal. This array is called a power inversion array and has been associated with Compton. It will form a null on the strongest signal with additional nulls formed on weaker signals.

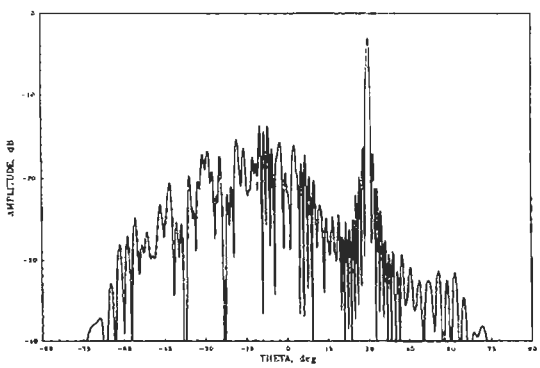

Fig. 80a. Linear array, 100 elements, 50 sub-arrays, $\theta = 30°$.

All of these adaptive arrays have $N - 1$ degrees of freedom, where N is the number of elements in one plane, and $N - 1$ nulls can, in general, be placed in this plane. If there are more degrees of freedom than interferers, the power inversion array tends to null out the desired signal as well, since it cannot tell the desired signal from interfering signals. The improvement available, essentially independent of the type of adaption, is related to the interference-to-noise ratio. To illustrate, a single interferer is assumed. The ratio of signal to interference plus noise before and after adaption indicates the improvement (Fig. 83). For large I/N, the improvement in $S/(I + N)$ is essentially just I/N, but for small values the improvement rapidly decreases. Convergence depends on the ratio of the strongest signal to the desired signal; strong interferers require reduced loop gain to avoid instability, and this slows convergence. Methods of accelerating convergence can utilize orthogonalization of Eigenvalues, or a modified control law. The control loops and weighting can be performed either with analog or digital hardware. Thus, there are several configurations possible. Analog control loops are simple, but some control laws such as accelerated convergence are difficult to implement other than digitally. Adaption in beam space, after a beamformer, allows preservation of desired signals and better rejection control.# Adaptation of wideband

signals may require a tapped (and adjustable) delay line at each element. Further information is in several sources.*

APERTURE DISTRIBUTIONS

Design of Distributions

Aperture distributions of concern here are used to produce patterns with one or two narrow main beams with the rest of space occupied by sidelobes. These distributions are often sampled to yield excitation coefficients for arrays of many elements. For arrays of a few elements, adjustment of zeros of a polynomial is used.† In earlier years, aperture distributions were chosen for easy integratibility. With the advent of computers, it is possible to design aperture distributions based on physical principles without concern about the form of the result. These physical principles were enunciated primarily by Taylor:‡ symmetric amplitude distributions are more efficient; array polynomial zeros should be real; far-out zeros should be separated by unity; and a distribution with a pedestal gives a $1/\lambda$ far-out sidelobe envelope and is more efficient than a distribution that is zero at the ends. In all that follows, the variable $u = (L/\lambda)\sin\theta$ is used. In general, then, a narrow beam distribution is designed by making the spacing of zeros for large u approximately unity, and then by adjusting the close-in zeros to give the desired first sidelobe level. The achievement of a $1/u$ envelope assures a robust, low-Q distribution. It is convenient to use sidelobe ratio (SLR) as the ratio of beam peak to first sidelobe; SLR, of course, is the inverse of sidelobe level.

The distributions that will be discussed here differ in the shape of the close-in sidelobe envelope, and whether they are for line (or rectangular) or circular sources. These distributions are now widely used and have superseded such distributions as cosine^n-on-a-pedestal, Gaussian, etc. The latter distributions not only have inefficient zero placement, but they involve two or more parameters. For example, a practical Gaussian must be truncated, and two parameters must be specified to determine performance indices. Incidentally, when the Gaussian is truncated, its advantages of a simple transform disappear. For these distributions, it is difficult to perform optimization: for example, determination of parameters to give maximum efficiency for a given sidelobe level is difficult. In contrast, the Taylor one-parameter distribution yields all performance indices as a function of that single parameter, while the Taylor $\bar{n}$ distribution is easily optimized because of the physical meaning of the parameters. See Hansen.§

Taylor One-Parameter Line Source Distribution

In this distribution, the far-out zeros are placed at integer values of u, while close-in zeros are shifted to reduce close-in sidelobes to suitable values. Taylor accomplished this by using zeros

$$u = \sqrt{n^2 + B^2}$$

where B is the single parameter. The pattern is written in two forms, depending on whether u is less or greater than B. These are

$$F(u) = (\sinh \pi\sqrt{B^2 - u^2})/\ \pi\sqrt{B^2 - u^2}\,,\ u \le B$$

$$F(u) = (\sin \pi\sqrt{u^2 - B^2})/\ \pi\sqrt{u^2 - B^2}\,,\ u \ge B$$

§ Hansen, R. C. "Array Pattern Control and Synthesis." *Proc. IEEE*, Vol. 80, January 1992, pp. 141–151.

The sidelobe ratio is given by

$$\text{SLR} = 20 \log (\sinh \pi B / \pi B) + 13.26 \text{ dB}$$

Taking the inverse transform of the pattern gives the Taylor one-parameter line source distribution:

$$g(p) = I_0 (\pi B \sqrt{1 - p^2})$$

where

p is 0 at the aperture center and 1 at each end,
I_0 is the modified Bessel function.

A special case occurs for $B = 0$. This is the uniformly excited line source (constant amplitude), which has a pattern of simply $\sin \pi u / \pi u$. The Taylor pattern is a modified $\sin \pi u / \pi u$ pattern, with a transition from that to the hyperbolic form at $u = B$, on the side of the main beam. The hyperbolic form provides the central part of the main beam as indicated in the formula above for SLR. Fig. 84 shows a typical one-parameter pattern or space factor. Typical aperture distributions are shown in Fig. 85. Only half of a symmetric distribution is shown. Not unexpectedly, the pattern with lower sidelobes has a smaller pedestal at the end of the aperture. The integral for aperture efficiency can be reduced to a tabulated function, $\bar{I}_0$.*

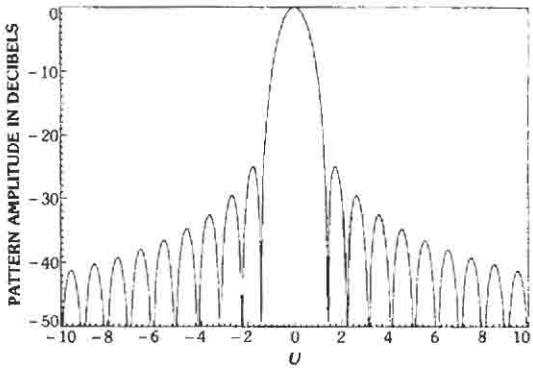

Fig. 84. Taylor one-parameter line source pattern for SLR 25 dB.

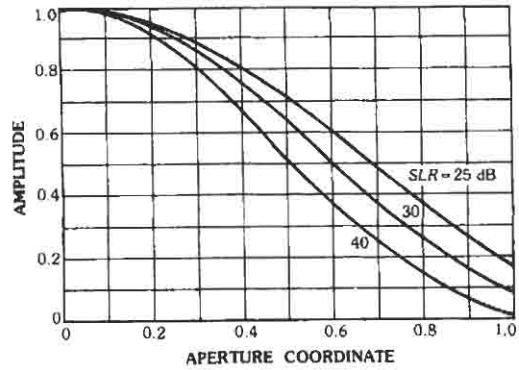

Fig. 85. Taylor one-parameter aperture distributions.

$$\eta = (2 \sinh^2 \pi B) / [\pi B \bar{I}_0 (2 \pi B)]$$

Although all of the performance indices can be given in terms of a table of equally spaced values of B, it is more convenient to specify sidelobe ratio. Table 11 gives beamwidth, efficiency, and beam efficiency. The beamwidth is normalized and is converted to an actual angle by

$$\theta_3 / (\lambda / L) = (2L/\lambda) \arcsin [u_3 / (L/\lambda)] \simeq 2u_3$$

The efficiency relates the directivity to that of a uniformly excited source. Beam efficiency is the fraction of radiated energy contained in the main beam, null to null.† Given a desired performance index, the formulas allow B to be found, and from B all other indices can be determined. Taylor described this work in a Hughes Aircraft report; a review and tables are contained in Hansen.‡

Taylor $\bar{n}$ Line Source Distribution

A modest improvement in efficiency can be obtained by making the first few sidelobes at equal level, with a transition from the equal-level envelope to the $1/u$ envelope. This offers a compromise between the one-parameter distribution and the Chebyshev distribution. In the latter, the sidelobes are all of equal height, the aperture distribution is singular at the ends, the energy storage is high, and the distribution is sensitive to errors. For $\bar{n}$ small, the distribution gives improved efficiency and narrower beamwidth without significantly degrading its robust nature. The distribution is a modification of the continuous equivalent of a Chebyshev distribution, with a dilation factor used to modify the first $\bar{n}$ zeros. The pattern is given by a canonical product on zeros.*

$$F(u) = \left[(\sin \pi u)/\pi u\right] \prod_{n=1}^{\bar{n}-1} \left(1 - u^2/z_n^{\,2}\right) \Big/ \left(1 - u^2/n^2\right)$$

$$= \sum_{n=-(\bar{n}-1)}^{n=\bar{n}-1} F(n, A, \bar{n}) \operatorname{sinc} \pi(u+n)$$

In the second form, the pattern is a superposition of $\bar{n}$ sinc beams. The pattern coefficients are

$$F(n, A, \bar{n}) = \frac{\left[(\bar{n}-1)!\right]^2}{(\bar{n}-1+n)!(\bar{n}-1-n)!} \prod_{m=1}^{n-1} \left(1 - n^2/z_m^{\,2}\right)$$

with $F(0, A, \bar{n}) = 1$. Here the zeros are:

$$Z_n = \pm \sigma \sqrt{A^2 + (n - 1/2)^2} \qquad 1 \le n \le \bar{n}$$

$$Z_n = \pm n \qquad \bar{n} \le n$$

where

A is the sidelobe parameter,
σ is the dilation index.

The dilation index is

$$\sigma = \bar{n} \Big/ \sqrt{A^2 + (\bar{n} - 1/2)^2}$$

The corresponding aperture distribution is

$$g(p) = 1 + 2 \sum_{n=1}^{\bar{n}-1} F(n, A, \bar{n}) \cos n\pi p$$

Tables of aperture distribution are not given because of the ease of calculating these with a computer. Values for check purposes can be obtained from Hansen.† Table 12 gives parameter A and beamwidth factor u_3 for several values of SLR. Also shown are σ values for $\bar{n}$. The beamwidth in u is approximately $2\pi u_3$; this may be converted to angle by using the formula in the previous subsection. Fig. 86 shows a typical Taylor $\bar{n}$ pattern; Fig. 87 shows typical aperture distributions. The value of $\bar{n}$ must be carefully chosen. If $\bar{n}$ is too small, the zero spacing in the transition region will oscillate, thereby producing oscillations in the sidelobe envelope. If $\bar{n}$ is large, the aperture distribution will not be monotonic; for suitably large $\bar{n}$ the end value

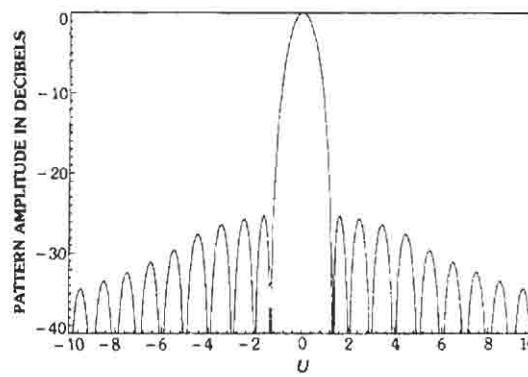

Fig. 86. Taylor line source pattern for SLR = 25 dB, $\bar{n} = 5$.

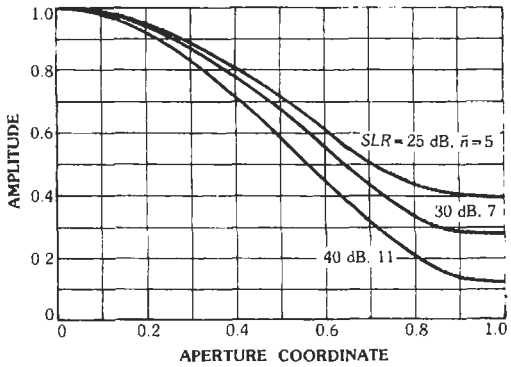

Fig. 87. Taylor $\bar{n}$ aperture distributions.

may be larger than the center value, which is clearly disastrous. There is a value of $\bar{n}$ that gives maximum efficiency. Table 13 gives these values and the largest $\bar{n}$ that maintains a monotonic distribution. Note that the maximum efficiency values require an aperture distribution with peaks at the ends and so are generally not desirable.

Aperture efficiency is easily calculated from

$$\eta = 1 \Big/ \left[1 + 2 \sum_{n=1}^{\bar{n}-1} F^2(n, A, \bar{n}) \right]$$

The difference in efficiency between the maximum $\bar{n}$ case and the monotonic $\bar{n}$ case is roughly 1%, so the monotonic $\bar{n}$ should be used as an upper limit. The best $\bar{n}$ can be selected by comparing computer runs of patterns for various values of $\bar{n}$. For additional information, see Hansen.*

Bayliss $\bar{n}$ One-Parameter Difference Line Source

The Bayliss space factor is a difference pattern (for tracking purposes) constructed to have the same features as the Taylor $\bar{n}$ space factor. That is, it has $\bar{n}$ roughly equal-level sidelobes adjacent to each difference beam, with a $1/u$ envelope beyond. Taylor started with an "ideal" pattern, $\cos \pi\sqrt{(u^2 - A^2)}$, which has equal-level sidelobes. Then a space factor was constructed with $\bar{n}$ close-in zeros matching those of the "ideal" and with remaining zeros to give a $1/u$ envelope. Finally, a dilation factor was used to make a smooth transition around $u = \bar{n}$. A good starting point to get a difference pattern is to differentiate the "ideal" sum pattern. This gives u sinc $\pi\sqrt{(u^2 - A^2)}$. Unfortunately, not all sidelobes are of equal level; the first several are tapered. Bayliss used an iterative procedure to adjust these zeros to yield equal-level sidelobes. It was necessary to adjust only four. Since these four zeros (and A) depend on the sidelobe ratio, results for each were given in terms of fourth-order polynomials in SLR. Table 14 gives the results, for various values of SLR, for z_1, z_2, z_3, z_4, A, and u_0. The latter is the value of u at the difference peak. These zeros are used for both Bayliss line sources and circular sources.† For $n > \bar{n}$, $z_n = \sqrt{A^2 + n^2}$. Next, the Taylor procedure is followed, where the envelope is made to approach $1/u$

TABLE 14. BAYLISS LINE SOURCE PARAMETERS

	SLR, Decibels					
	15	20	25	30	35	40
A	1.00790	1.22474	1.43546	1.64126	1.84308	2.04154
z_1	1.51240	1.69626	1.88266	2.07086	2.26025	2.45039
z_2	2.25610	2.36980	2.49432	2.62754	2.76748	2.91231
z_3	3.16932	3.24729	3.33506	3.43144	3.53521	3.64518
z_4	4.12639	4.18544	4.25273	4.32758	4.40934	4.49734
z_0	0.66291	0.71194	0.75693	0.79884	0.83847	0.87649

for large u, and with a smooth transition. The difference pattern is

$$F(u) = u\cos\pi u = \frac{\prod_{n=1}^{\bar{n}-1}\left(1-u^2/\sigma^2 z_n^2\right)}{\prod_{n=0}^{\bar{n}-1}\left(1-u^2/(n+1/2)^2\right)}$$

As before,

$$\sigma = (\bar{n}+1/2)/\sqrt{A^2+\bar{n}^2}$$

Fig. 88 shows a Bayliss line source pattern for SLR 25 dB, $\bar{n} = 5$. The aperture distribution for $-1 \le p \le 1$ is

$$g(p) = \sum_{n=0}^{\bar{n}-1} B_n \sin\pi p(n+1/2)$$

where

$$B_m = -(-1)^m (m-1/2)^2 \frac{\prod_{n=1}^{\bar{n}-1}\left[1-(m+1/2)^2/\sigma^2 z_n^2\right]}{\prod_{\substack{n=0 \\ n\neq m}}^{\bar{n}-1}\left[1-(m+1/2)^2/(n+1/2)^2\right]}$$

These formulas allow rapid calculation of Bayliss space factors and aperture distributions. Fig. 89 gives the aperture distribution corresponding to the space factor of Fig. 88. Fig. 89 shows only amplitude; each half of the aperture has constant phase, with the two halves out of phase. Excitation efficiency, which is the ratio of directivity (at one difference peak) to that of a uniformly excited line source, is given by

$$\eta = \frac{2u_0^2\cos^2\pi u_0 \sum_{n=0}^{\bar{n}-1}(-1)^n B_n/\left[u_0^2-(n+1/2)^2\right]}{\sum_{n=0}^{\bar{n}-1} B_n^2}$$

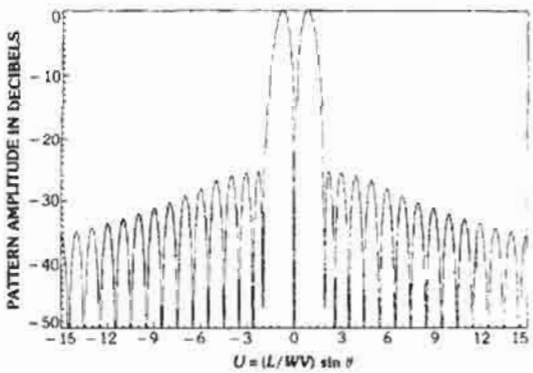

Fig. 88. Bayliss space factor for SLR = 25 dB, $\bar{n} = 5$.

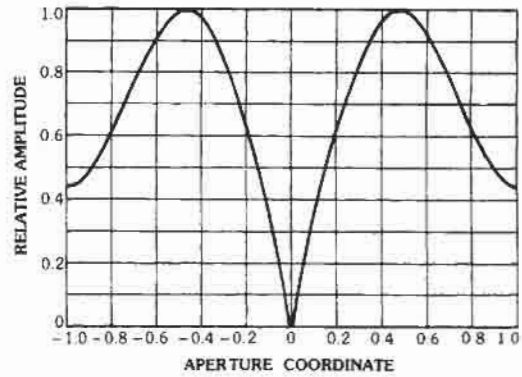

Fig. 89. Bayliss distribution for SLR = 25 dB, $\bar{n} = 5$.

The slope at $u = 0$ is given by

$$S = (2/\pi)\sum_{n=0}^{\bar{n}-1}(-1)^n B_n/(n+1/2)^2$$

This value is 0.6366 over the range of SLR in Table 15. Table 15 gives efficiency and normalized slope values (normalized for maximum linear phase slope of unity) for Bayliss space factors.

Low Sidelobe Distributions

High sidelobe ratios, in the range from 30 to 60 dB, have recently attracted more interest. The one-parameter space factors have very low pedestals for this range of SLR, and thus the Taylor $\bar{n}$ space factors are more appropriate. Again, efficient design requires properly spaced space-factor zeros. In contrast, most of the popular distributions were coined before the computer allowed performance evaluations to be easily performed. The Taylor $\bar{n}$ distribution is, in essence, perfect for low sidelobes because it is low-Q, which eases the tolerance problem, and because the zeros are monotonically and smoothly spaced. This can be made

TABLE 15. BAYLISS EFFICIENCY AND PATTERN SLOPE

SLR (dB)	$\bar{n}$	Efficiency η	Normalized Slope S
15	4	0.5959	0.9567
20	4	0.5846	0.8974
25	5	0.5633	0.8427
30	6	0.5393	0.7912
35	7	0.5162	0.7448
40	8	0.4951	0.7037

evident by comparing the Taylor with the popular Hamming distribution. The latter* is

$$g(p) = 0.54 + 0.46 \cos \pi p = a + b \cos \pi p$$

The excitation efficiency of the Hamming is

$$\eta = 2a^2/(2a^2 + b^2) = 0.7338$$

The space factor has zeros at $u = 2, 3, 4....$ and, in addition, a zero at $u = \sqrt{a/(a-b)} = 2.5981$. This close spacing of the first three zeros produces an uneven sidelobe envelope with the fourth sidelobe the highest at –42.7 dB. Thus, the Hamming is compared with a Taylor $\bar{n}$ distribution with SLR = 42.7 dB. Table 16 shows the zeros, and it can be observed that both of the Taylor space factors have a smoothly increasing zero spacing from the first zero out to the transition point, beyond which the spacing is unity. The Hamming, on the other hand, has a first spacing of 0.598, a second spacing of 0.402, and the remaining spacings all unity. This is obviously not as good a design, as the following will show.

Table 17 gives efficiency and normalized beamwidth for the three Taylor cases and for the Hamming. It may be seen that the Hamming beamwidth is roughly 3% broader, while the efficiency is roughly 3% lower. Thus, by use of appropriate space factors such as the Taylor $\bar{n}$, improved performance can be obtained at no additional cost in complexity, hardware, or tolerances. For rectangular arrays with separable aperture distributions, Taylor distributions may, of course, be used along each coordinate. For circular disk apertures, the circular Taylor $\bar{n}$ distribution is similarly excellent.

TABLE 16. ZEROS OF DISTRIBUTIONS FOR SLR = 42.7 DB

Measurement of Low-Sidelobe Patterns

In addition to the obvious problem of providing a pattern range with a low background level, the measurement of low sidelobe patterns imposes restrictions on the measurement distance. A distance of $2D^2/\lambda$ is adequate for patterns with modest sidelobe ratios (25 dB or less), but larger distances are needed to measure lower sidelobes accurately, due to the quadratic phase error produced by a finite distance. As the measurement distance is reduced, the first sidelobe and first null fills in, and then the sidelobe becomes a shoulder on the main beam. (The second sidelobe is only slightly raised at this point.) At closer distances, the main beam broadens, and the second sidelobe and second null rise, and again the main beam eventually absorbs the sidelobe. Calculations have been made of the change in sidelobe level versus measurement distance for the universal Taylor $\bar{n}$ linear space factor.† Fig. 90 gives these results for a uniform line source.

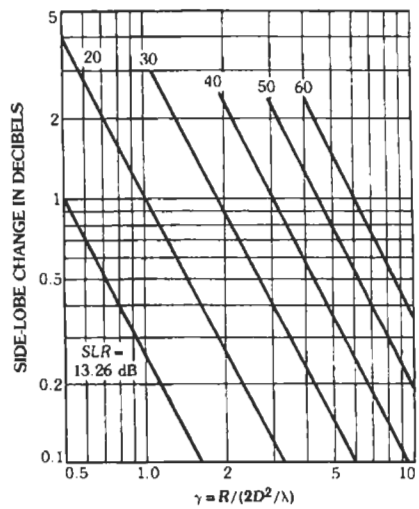

Fig. 90. Sidelobe increase due to measurement distance.

and for 20 (10) 60-dB Taylor $\bar{n}$ line sources. Distance is normalized to $2D^2/\lambda$, where

$$\gamma = R/(2D^2/\lambda)$$

Each curve terminates when the sidelobe becomes a shoulder on the main beam, without any dip.

Optimum low sidelobe difference patterns are also of interest. Calculations have been made for Bayliss space factors for a uniform line source and for sidelobe ratios of 20 (10) 50 dB.* See Fig. 91.

Hansen One-Parameter Circular Source Distribution

A symmetric distribution for circular disk apertures analogous to the Taylor one-parameter line source distribution has been developed by Hansen.† This is a modified $2J_1(\pi u)/\pi u$ pattern just as the Taylor one-parameter was a modified sinc πu. The close-in zeros are shifted to produce the desired SLR. The single parameter is H, and the space factor is again written in two forms depending on whether u is less or greater than H. These are

$$F(u) = 2J_1(\pi\sqrt{u^2 - H^2})/\pi\sqrt{u^2 - H^2} \qquad u \geq H$$

$$F(u) = 2I_1(\pi\sqrt{H^2 - u^2})/\pi\sqrt{H^2 - u^2} \qquad u \leq H$$

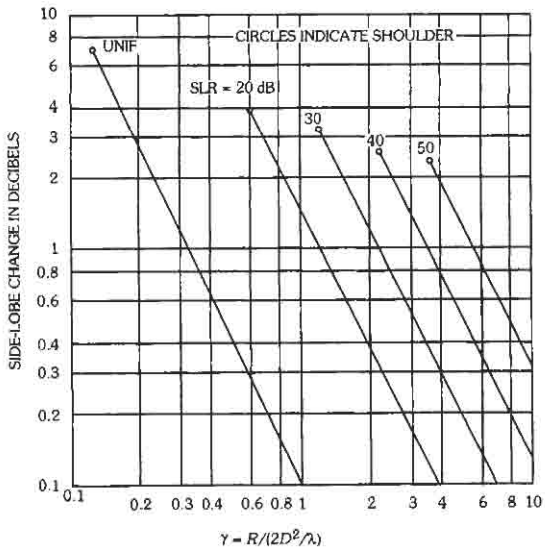

Fig. 91. Sidelobe change versus normalized measurement distance for Bayliss line source.

The sidelobe ratio is given by

$$\text{SLR} = 20 \log [2I_1(\pi H)/\pi H] + 17.57 \text{ dB}$$

In these formulas, J_1 and I_1 are the usual Bessel and modified Bessel functions of first kind and order one. Again, the top portion of the main beam is provided by the modified Bessel form, while the remainder of the main beam and the sidelobe structure are provided by the Bessel form. The aperture distribution is

$$g(p) = I_0(H\sqrt{\pi^2 - p^2})$$

where p is zero at the center of the aperture and the aperture radius is π. The patterns and aperture distributions are much like those of the Taylor $\bar{n}$ line source and so have not been included. Table 18 gives parameter H, beamwidth u_3, the aperture excitation efficiency, and the beam efficiency. The latter is the fraction of energy that is contained in the main beam, null to null. The actual beamwidth is approximately $2u_3$. A more exact result for apertures small in wavelengths is found in a previous section for the Taylor one-parameter line source. The excitation efficiency is given by the expression

$$\eta = 4I_1^2(\pi H)/\pi^2 H^2[I_0^2(\pi H) - I_1^2(\pi H)]$$

The I_0 used above is the modified Bessel function of order zero. This distribution, like the Taylor distribution, is low-Q and robust, and has been found to fit well to many reflector antenna patterns, for the main beam and close-in sidelobes.

Taylor $\bar{n}$ Circular Source Distribution

The Taylor $\bar{n}$ circular source distribution offers an improvement in efficiency and beamwidth over the Hansen one-parameter circular source distribution, just as the Taylor $\bar{n}$ line source distribution shows an improvement over the Taylor one-parameter source distribution. The circular aperture is a disk with rotationally symmetric excitation, and, again, the starting point is the uniform $2J_1(\pi u)/\pi u$ space factor. On each side of the main beam, $\bar{n}$ zeros are modified by mov-

TABLE 18. CHARACTERISTICS OF HANSEN ONE-PARAMETER DISTRIBUTION

SLR (dB)	H	u_3 (rad)	η	η_b

ing them to produce the desired sidelobe ratio.* Again, a dilation factor, σ, is used to provide a smooth transition between the roughly equal-level sidelobes and the tapered-envelope sidelobes. The pattern is given by a canonical product on zeros:

$$F(u) = \left[2J_1(\pi u)/\pi u\right]\prod_{n=1}^{\bar{n}-1}\left(1-u^2/u_n^2\right)\left(1-u^2/\mu_n^2\right)$$

where μ_n are the zeros of $J_1(\pi u)$. The close-in pattern zeros are given by

$$u_n = \pm\sigma\sqrt{A^2+(n-1/2)^2} \qquad 1 \le n \le \bar{n}$$

while

$$\sigma = \mu_{\bar{n}}\Big/\sqrt{A^2+(\bar{n}-1/2)^2}$$

Table 19 gives the sidelobe parameter, A, the beamwidth, u_3, and values of σ for various values of $\bar{n}$. The actual beamwidth for large apertures is $2\sigma u_3$. The patterns and aperture distributions are much like those of the Taylor $\bar{n}$ line source and so have not been included. The aperture distribution is

$$g(p) = \left(2/\pi^2\right)\sum_{n=0}^{\bar{n}-1} F_n J_0(p\mu_n)\Big/\left[J_0(\pi\mu_n)\right]^2$$

where

$$p = 2\pi\rho/D$$

and

$$F_m = -J_0(\pi\mu_m)\frac{\prod_{n=1}^{\bar{n}-1}\left(1-\mu^2{}_m/u^2{}_n\right)}{\prod_{\substack{n=1\\ n\neq m}}^{\bar{n}-1}\left(1-\mu^2{}_m/\mu^2{}_n\right)}$$

All of these formulas are easily computed, so no tables have been included. For checking purposes, reference may be made to tables of Hansen.† The aperture excitation efficiency is given by

$$\eta = 1\Big/\left[1+\sum_{n=1}^{\bar{n}-1} F_n^2/J_0{}^2(\pi\mu_n)\right]$$

Table 20 gives the aperture excitation efficiency for several combinations of SLR and $\bar{n}$.

REFLECTORS

Parabolic Reflectors

The parabolic reflector commonly exists in both focal feed and Cassegrain form (Figs. 92 and 93). Offset reflectors are covered later. For a front-fed reflector, the reflector f/D must be matched to the feed pattern. Reflectors with pattern sidelobes roughly –25 dB and

good efficiency typically have illumination edge tapers of – 10 to – 11dB. For lower sidelobes, the edge taper must be lower. The tradeoff between edge taper and sidelobe level can be accurately determined from the circular one-parameter distributions in the section on aperture distributions. Fig. 94 shows the total reflector subtended angle versus f/D, where

$$\theta = 2 \text{ arc tan } [(8f/D)/(16f^2/D^2 - 1)]$$

Fig. 95 gives the differential path loss between the edge ray and the apex ray, also as a function of f/D:

$$R_{edge}/f = 1 + 1/(16f^2/D^2)$$

The edge illumination is, of course, the feed pattern value at the edge angle plus the differential path loss. Fig. 96 allows horn beamwidth at any level to be converted to the –10 dB beamwidth; this curve is an excellent empirical fit to a large amount of experimental data:

$$E_{dB} = 10\,(\theta/\theta_{10})^2$$

Aperture blockage is a major limitation of front-fed reflectors, especially for low design sidelobes. Fig. 97 shows deterioration of sidelobe level versus blockage

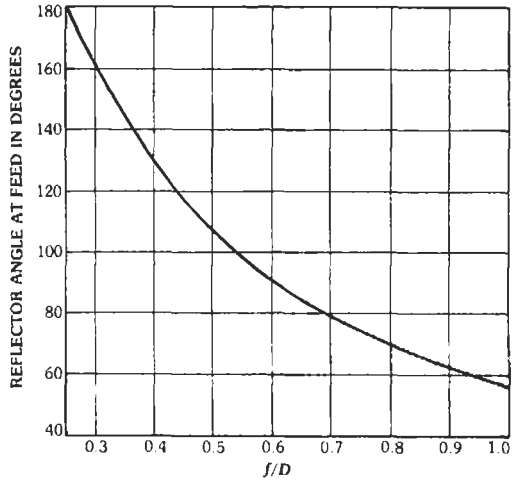

Fig. 94. Angle of reflector at feed.

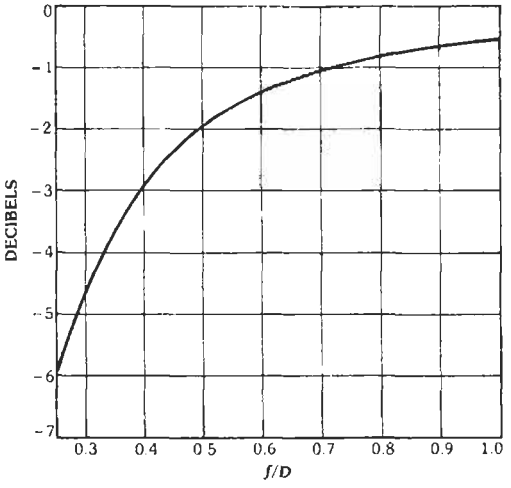

Fig. 95. Edge-center space loss.

diameter ratio for the Hansen universal one-parameter circular distribution. The reflector curvature produces cross polarization off the axis with a resulting gain loss. Determination of aperture efficiency or gain is complex and involves calculation of aperture taper efficiency, feed spillover, feed cross polarization loss, blockage loss, and reflector cross polarization loss. For more information, refer to Rusch et al.* Random

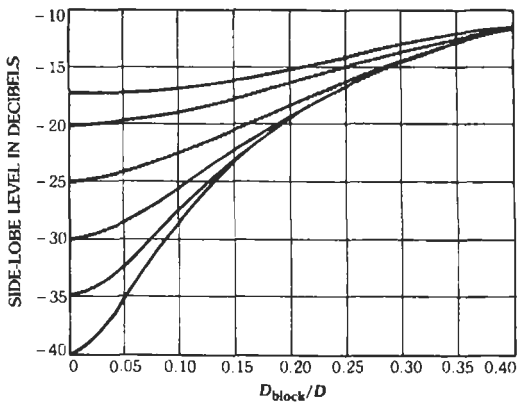

Fig. 97. Sidelobe level vs the blockage diameter ratio for Hansen one-parameter circular distribution.

errors in the reflector surface raise the sidelobes and reduce the gain. The effect on sidelobes can be estimated by using the universal curve in Fig. 97, where sidelobe degradation is plotted against $\sigma / \sqrt{G}$. Note, however, that the σ measured for a reflector surface must be doubled before being used in that figure, due to the reflective operation of the surface. Directivity loss has been calculated by Ruze* with a modification added by Wested† to take into account *f/D*. His result, which is

$$G/G_0 = (A + 1)/[A + \exp(4\pi\epsilon/\lambda)^2]$$

where

$$A = 1/[16f^2/D^2 \ln(1 + 1/16f^2/D^2)] - 1$$

is shown in Fig. 98, which gives gain decrease against one sigma tolerance in wavelengths (ϵ/λ) for several values of *f/D*. It can be seen that for loss of more than a few tenths of a decibel, *f/D* needs to be included. Most narrow-band reflector antennas have aperture efficiency (gain compared to that of a uniformly excited area) in the 55–65% range. Wideband antennas using log periodic or conical spiral feeds may have efficiencies anywhere from 20 to 50%.

The Cassegrain antenna, through use of a hyperboloidal subreflector, allows the feed to protrude through a hole in the dish. Thus, low-noise and/or high-power components can be conveniently located behind the dish. The minimum blockage condition exists when the feed blockage equals the subreflector blockage. Fig. 99 shows gain decrease for equal-blockage Cassegrain reflectors versus beamwidth. From this and previous material, it is apparent that front-fed reflectors are attractive for moderate beamwidths, whereas Cassegrains are attractive for beamwidths of several degrees or less. Cross-polarization effects of a Cassegrain reflector are shown in Fig. 100. A high-efficiency Cassegrain may be designed by shaping the two reflector surfaces; only small changes on the order of a wavelength at the edge are needed.‡ This accomplishes an aperture distribution closer to uniform;

overall efficiencies as high as 80% have been reported. However, the (corrugated) horn required to provide the requisite feed pattern tends to provide only limited bandwidth.

Scanning and Multiple-Beam Reflectors

When the feed is moved laterally, the beam moves in the opposite direction, but through a slightly smaller angle. The ratio of beam movement to feed movement is called "beam deviation factor." It is shown in Fig. 101 versus *f/D* for the universal one-parameter circular distribution.

There is a concomitant loss of directivity due to coma, and this was calculated by Ruze* for several distributions. A recalculation using the circular one-parameter distribution is shown in Fig. 102. These cal-

culations are only approximate as they are based on the pattern peak value, instead of integrating over the entire pattern.

When the coma loss is unacceptably large, an array feed can be used in the transverse focal region. One coma correction scheme sums the array element outputs with weighting that is the conjugate of the focal field. As the scan angle becomes larger the array feed must be larger, to cover the larger coma distribution. Since the coma is all on one side of boresight, the feed array need only cover this area, but as the azimuth scan angle changes, the feed array must be rotated to match.

Another method requires only phase correction and utilizes a beam-forming network connected to the feed array. The phases at the BFN output are then corrected with line lengths (in transform space) and summed.* When a single horn is moved off axis, the surface giving the smallest diameter circle of confusion is not plane and is called the Petzval surface. The maximum-gain surface also is not plane and deviates slightly from the Petzval surface. Generally the precise focal surface used is not important. Multiple-beam antennas typically employ a cluster of horns with each horn producing a separate beam. These configurations are usually offset to reduce the large blockage that would occur with a front-fed reflector. For further information, see Rusch et al.†

33 Electromagnetic-Wave Propagation

Revised by
Douglass D. Crombie

Radio waves may be propagated* from the transmitting antenna to the receiving antenna through or along the surface of the earth, through the atmosphere, or by reflection or scattering from natural or artificial reflectors. The conductivity and dielectric constant of the ground vary considerably from those of the atmosphere. At very-low frequencies, ground waves may be satisfactorily propagated for distances of several thousand kilometers. At high frequencies, however, the losses are so great that signals can be propagated for only a few hundred kilometers by ground wave. Propagation in the medium- and high-frequency bands is chiefly by ground wave and by reflection from the ionosphere, and severe fading is caused in these frequency bands by the interference between ground and ionospheric waves.

The refractive index of the atmosphere is an important factor in radio propagation. At frequencies between about 100 and 8000 megahertz, scattering of radio waves by inhomogeneities in the electromagnetic characteristics of the atmosphere can be used to provide satisfactory wideband communication up to several times the line-of-sight distance. New techniques are being developed for generating coherent high-power waves in the optical spectrum. Atmospheric absorption at these frequencies is high, but the large bandwidths and small antenna beam widths may make such frequencies practical for certain applications.

VERY-LOW FREQUENCIES—UP TO 30 KILOHERTZ

The propagation of long radio waves is of considerable importance in reliable communication, long-range navigation, and the detection of nuclear explosions. Considerable progress has been made in recent years in understanding the propagation of such waves in the earth-ionosphere waveguide.†

At short distances from a transmitter, the received signal is chiefly by a ground or surface wave, and at very-low frequencies its intensity is essentially inversely proportional to distance. At greater distances, the field intensity falls at a higher rate because of losses in the ground and because of the curvature of the earth. These losses increase with frequency. At sufficiently great distances, the received level is chiefly due to sky waves reflected from the ionosphere. At intermediate distances, the field is a combination of sky waves and ground waves that result in an interference pattern. The total field at the receiver may be obtained in two distinct ways. The first method, which leads to the geometric-optics theory, directly sums the contributions at the receiver from the primary source and each of its images. The second method treats the source and its images as self-illuminating diffraction gratings, one above the earth and one below, and leads to the waveguide mode theory. The advantages of mode theory are restricted to very-low frequencies, where relatively few modes can be supported in the earth-ionosphere waveguide. For example, when the height of the ionosphere is 80 kilometers and the wavelength is 20 kilometers, only the first eight modes can be supported. When the wavelength is 2 kilometers, however, all modes up to the 80th can be supported.

Thus at very-low frequencies, and for distances greater than say 3000 kilometers, it is simpler to use the mode of lowest order to obtain the received field. At distances less than about 1000 kilometers, it is simpler to use ray theory. The above is based on an idealized condition, since it has been assumed that the earth is flat, that the ionosphere is sharply bounded, and that the effect of the magnetic field of the earth can be ignored. Even with these simplifying assumptions, the results are useful. A full treatment of the general case can be obtained by reference to several sources.*

The results of calculations made by Wait and Spies, taking into account the curvature of the earth and the conductivities of the earth and the ionosphere, are shown in Figs. 1 and 2, where σ_g = ground conductivity, ω_r = ionospheric conductivity parameter, and n = mode order. It is seen that the lowest attenuation of mode 1 in the daytime (h = 70 km) is at about 18 kilohertz and at night (h = 90 km) it is at about 15 kilohertz.

The phase velocity ratio of mode 1 in the daytime is greater than 1 for frequencies less than about 13 kilohertz and less than 1 for higher frequencies. At night the crossover frequency is about 9 kilohertz.

In daylight, the attenuation of mode 1 is always less than that of mode 2. At night, the attenuation for the two modes may be of the same order.

LOW AND MEDIUM FREQUENCIES—30 TO 3000 KILOHERTZ†

For low and medium frequencies of approximately 30 to 3000 kilohertz with a short vertical antenna over perfectly reflecting ground

$$E = 186.4(P_r)^{1/2} \text{ millivolts rms/meter at 1 mile}$$

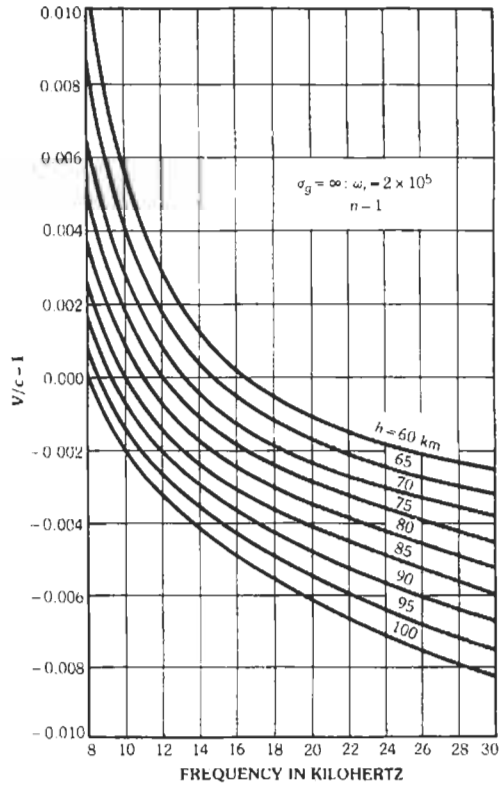

Fig. 2. Phase velocity V as a function of ionospheric height h and frequency, relative to the velocity in free space, c. (*From* Radio Spectrum Utilization, *Joint Technical Advisory Committee (IEEE and EIA), IEEE, New York, 1964; p. 105.*)

$$E = 300(P_r)^{1/2} \text{ millivolts rms/meter at 1 kilometer}$$

where P_r = radiated power in kilowatts.

Actual inverse-distance fields at 1 kilometer for a given transmitter output power depend on the height and power radiation efficiency of the antenna and associated circuit losses.

Typical values found in practice for well-designed stations are:

Small L or T antennas as on ships:

$40(P_t)^{1/2}$ millivolts/meter at 1 kilometer

Vertical radiators 0.15 to 0.25λ high:

$290(P_t)^{1/2}$ millivolts/meter at 1 kilometer

Vertical radiators 0.25 to 0.40λ high:

$322(P_t)^{1/2}$ millivolts/meter at 1 kilometer

Vertical radiators 0.40 to 0.60λ high or top-loaded vertical radiators:

$386(P_t)^{1/2}$ millivolts/meter at 1 kilometer

where P_t = transmitter output power in kilowatts. These values can be increased by directive antenna systems.

It has been found that the concept of basic transmission loss, also called path loss, is convenient for the analysis of radio communication systems. Basic transmission loss is the dimensionless ratio P_R/P_A, where P_R is the power radiated from a lossless, isotropic transmitting antenna and P_A is the power available from a lossless, isotropic receiving antenna in a matched load. The isotropic antennas are at the same physical locations and operate in the same band of frequencies as the actual antennas.

Surface-wave (commonly called ground-wave) basic transmission loss is plotted in Fig. 3 for vertically polarized propagation over land having a representative conductivity and dielectric constant and in Fig. 4 for vertically polarized propagation over sea water. Both antennas are 30 feet above the surface in both figures.

In the low-frequency and medium-frequency ranges, propagation losses for horizontally polarized transmission between antennas on the surface of the earth are impractically high. Ground constants typical of various terrain types are listed in Table 1.

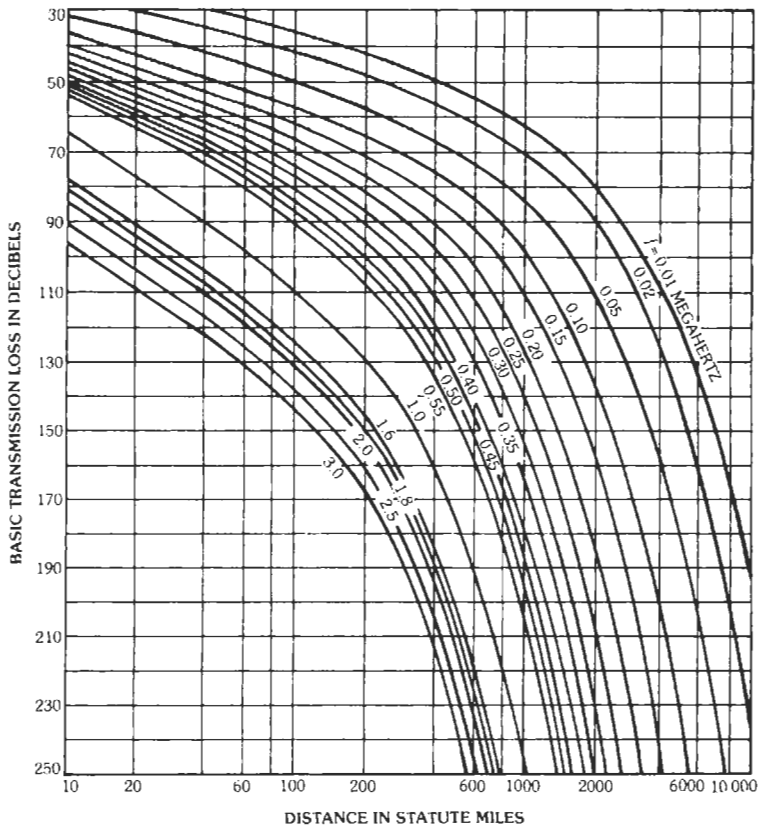

Fig. 3. Basic transmission loss expected for surface waves propagated over a smooth spherical earth. Over land: $\sigma = 0.005$ mho/meter, $\epsilon = 15$. Lossless isotropic antennas 30 feet above the surface. Vertical polarization. (*Adapted from K. A. Norton,* Transmission Loss in Radio Propagation: II, *National Bureau of Standards Technical Note 12, June 1959; Fig. 7.*)

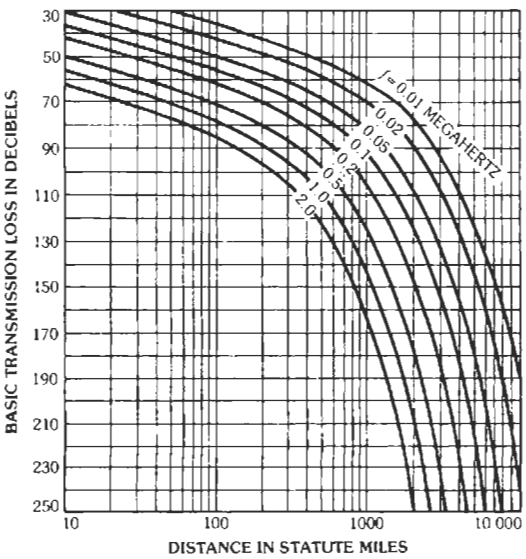

Fig. 4. Basic transmission loss expected for surface waves propagated over a smooth spherical earth. Over sea water: $\sigma = 5$ mhos/meter, $\epsilon = 80$. Lossless isotropic antennas 30 feet above the surface. Vertical polarization. (*Adapted from K. A. Norton,* Transmission Loss in Radio Propagation: II, *National Bureau of Standards Technical Note 12, June 1959; Fig. 8.*)

Under the conditions used in Figs. 3 and 4, the surface of the earth behaves like a nearly perfect reflector for the isotropic antennas that are only a small fraction of a wavelength from it and that are used to calculate the basic transmission loss. As a result, each isotropic antenna together with the surface of the earth has a gain of nearly 3.01 dB in the general direction of the horizon. By contrast, a lossless quarter-wave monopole erected over a good ground screen would have a gain of 5.16 dB, and a short lossless monopole would have a gain of 4.77 dB. It follows that the transmission loss between quarter-wave monopoles on the surface of the earth is very nearly $2 \times (5.16 - 3.01) = 4.30$ dB less than the basic transmission loss given in Figs. 3 and 4, and the transmission loss between short monopoles is $2 \times (4.77 - 3.01) = 3.52$ dB less.

Figs. 3 and 4 do not include the effect of sky waves reflected from the ionosphere. Sky waves cause fading at medium distances and produce higher field strengths than the surface wave at longer distances, particularly at night. Sky-wave field strength is subject to diurnal, seasonal, and irregular variations due to changing properties of the ionosphere.

Fig. 5 shows a family of propagation curves for F_0 computed from

$$F_0 = 80.2 - 10 \log D - 0.00176 f^{0.26} D$$

TABLE 1. GROUND CONDUCTIVITY AND DIELECTRIC CONSTANT FOR MEDIUM-AND LONG-WAVE PROPAGATION TO BE USED WITH NORTON, BURROWS, BREMMER, OR OTHER DEVELOPMENTS OF SOMMERFELD PROPAGATION EQUATION

Terrain	Conductivity σ (mhos/meter)	Dielectric Constant ϵ (esu)
Sea water	5	80
Fresh water	8×10^{-3}	80
Dry, sandy, flat coastal land	2×10^{-3}	10
Marshy, forested flat land	8×10^{-3}	12
Rich agricultural land, low hills	1×10^{-2}	15
Pastoral land, medium hills and forestation	5×10^{-3}	13
Rocky land, steep hills	2×10^{-3}	10
Mountainous (hills up to 3000 feet)	1×10^{-3}	5
Cities, residential areas	2×10^{-3}	5
Cities, industrial areas	1×10^{-4}	3

In this equation, D = distance in kilometers, f = frequency in kilohertz, and F_0 is the annual median received field strength in decibels above 1 microvolt per meter that would be produced by a short, vertical transmitting dipole at or near the surface of the earth and *radiating* 1 kilowatt. The empirical equation is based on measured data. Fig. 5 therefore includes the effects of both sky-wave and surface-wave propagation. More recent work has been described by the CCIR.*

The extent to which the lower strata influence the effective ground constants depends on the depth of penetration of the radio energy. This in turn depends on the value of the constants and the frequency. If the depth of penetration is defined as that depth in which

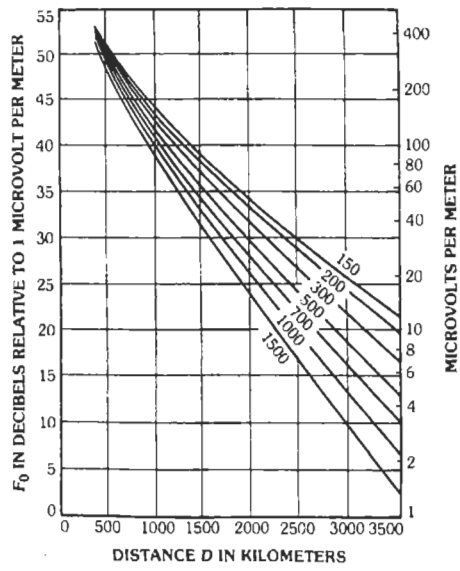

Fig. 5. Family of basic curves of F_0 to be used to determine the annual median value of the field strength for the frequencies (in kilohertz) on the curves. (*From CCIR XIIIth Plenary Assembly, Geneva, 1974, Vol. VI, Report 264-3; p. 108.*)

the wave has been attenuated to $1/e$ (37%) of its value at the surface, then over the frequency range from 10 kHz to 10 MHz, δ has the values shown in Table 2. It will be seen that, at frequencies of 10 MHz and above, only the surface of the ground need be considered, but at lower frequencies, strata down to a depth of 100 meters or more must be taken into account. It is particularly important to take account of the lower strata when the upper strata are of lower conductivity, since more energy penetrates to the lower levels than happens with an upper layer of higher conductivity.

HIGH FREQUENCIES—3 TO 30 MEGAHERTZ*

At frequencies between about 3 and 25 megahertz and distances greater than about 100 miles, transmis-

100 kHz	0.80	15	50
3 MHz	0.14	5	17
10 MHz	0.08	2	9

sion depends chiefly on sky waves reflected from the ionosphere. This is a region high above the surface of the earth where the rarefied air is sufficiently ionized (primarily by ultraviolet sunlight) to reflect or absorb radio waves, such effects being controlled almost exclusively by the free-electron density. The ionosphere is usually considered as consisting of the following layers.

D Layer: At heights from about 50 to 90 kilometers, it exists only during daylight hours, and ionization density corresponds with the elevation of the sun.

This layer reflects very-low- and low-frequency waves, absorbs medium-frequency waves, and weakens high-frequency waves through partial absorption.

E Layer: At a height of about 110 kilometers, this layer is important for high-frequency daytime propagation at distances less than 1000 miles, and for medium-frequency nighttime propagation at distances in excess of about 100 miles. Ionization density corresponds closely with the elevation of the sun. Irregular cloud-like areas of unusually high ionization, called sporadic *E*, may occur up to more than 50 percent of the time on certain days or nights. Sporadic *E* occasionally prevents frequencies that normally penetrate the *E* layer from reaching higher layers and also causes occasional long-distance transmission at very-high frequencies. Some portion (perhaps the major part) of the sporadic-*E* ionization is ascribable to visible- and subvisible-wavelength bombardment of the atmosphere.

F_1 *Layer*: At heights of about 175 to 250 kilometers, it exists only during daylight. This layer occasionally is the reflecting region for high-frequency transmission, but usually oblique-incidence waves that penetrate the *E* layer also penetrate the F_1 layer and are reflected by the F_2 layer. The F_1 layer introduces additional absorption of such waves.

F_2 *Layer*: At heights of about 250 to 400 kilometers, F_2 is the principal reflecting region for long-distance high-frequency communication. Height and ionization density vary diurnally, seasonally, and over the sunspot cycle. Ionization does not follow the elevation of the sun in any fashion, since (at such extremely low air densities and molecular-collision rates) the medium can store received solar energy for many hours, and, by energy transformation, can even detach electrons during the night. At night, the F_1 layer merges with the F_2 layer at a height of about 300 kilometers. The absence of the F_1 layer, and reduction in absorption of the *E* layer, causes nighttime field intensities and noise to be generally higher than during daylight.

As indicated to the right on Fig. 6, these layers are contained in a thick region throughout which ionization generally increases with height. The layers are said to exist where the ionization gradient is capable of refracting waves back to earth. Obliquely incident waves follow a curved path through the ionosphere due to gradual refraction or bending of the wave front. When attention need be given only to the end result, the process can be assimilated to a reflection.

Depending on the ionization density at each layer, there is a critical or highest frequency, f_c, at which the layer reflects a vertically incident wave. Frequencies higher than f_c pass through the layer at vertical incidence. At oblique incidence, and distances such that the curvature of the earth and ionosphere can be neglected, the maximum usable frequency is given by

$$\text{muf} = f_c \sec \phi$$

where,

muf is the maximum usable frequency for the particular layer and distance,
ϕ is the angle of incidence at the reflecting layer.

At greater distances, curvature is taken into account by the modification

$$\text{muf} = kf_c \sec \phi$$

where k is a correction factor that is a function of distance and vertical distribution of ionization.

Both f_c and height, and hence ϕ for a given distance, vary for each layer with local time of day, season, latitude, and throughout the 11-year sunspot cycle. The various layers change in different ways with these parameters. In addition, ionization is subject to frequent abnormal variations.

Ionospheric losses are a minimum near the maximum usable frequency and increase rapidly for lower frequencies during daylight.

High frequencies travel from the transmitter to the receiver by reflection from the ionosphere and earth in one or more hops as indicated in Figs. 6 and 7. Additional reflections may occur along the path between the bottom edge of a higher layer and the top edge of a lower layer, the wave finally returning to earth near the receiver.

Fig. 6 indicates transmission on a common frequency, (1) single-hop via *E* layer, Denver to Chicago, and (2) single-hop via F_2, Denver to Washington, with (3)

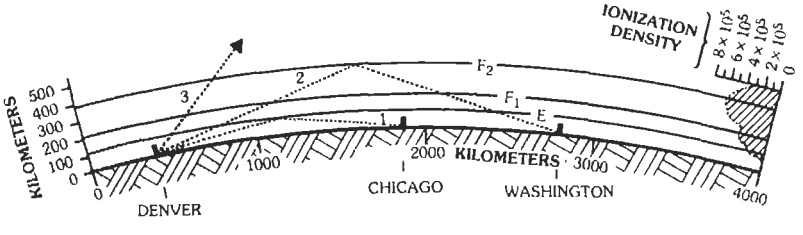

Fig. 6. Schematic explanation of skip-signal zones.

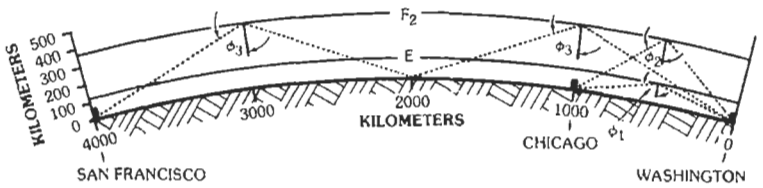

Fig. 7. Single-hop and two-hop transmission paths due to E and F_2 layers.

the wave failing to reflect at higher angles, thus producing a skip region of no signal between Denver and Chicago. Fig. 7 illustrates single-hop transmission, Washington to Chicago, via the E layer (ϕ_1). At higher frequencies over the same distance, single-hop transmission would be obtained via the F_2 layer (ϕ_2). Fig. 7 also shows two-hop transmission, Washington to San Francisco, via the F_2 layer (ϕ_3).

Actual transmission over long distances is more complex than indicated by Figs. 6 and 7, because the layer heights and critical frequencies differ with time (and hence longitude) and with latitude. Further, scattered reflections occur at the various surfaces.

Typical values of critical frequency for Washington, D.C., are shown in Fig. 8.

Preferably, operating frequencies should be selected from a specific frequency band that is bounded above and below by limits that are systematically determinable for the transmission path under consideration. The recommended upper limit is called the *optimum working frequency* (fot) and is selected below the muf to provide some margin for ionospheric irregularities and turbulence, as well as for the statistical deviation of day-to-day ionospheric characteristics from the predicted monthly median value. So far as may be consistent with available frequency assignments, operation in reasonable proximity to the upper frequency limit is preferable, in order to reduce absorption loss.

The lower limit of the normally available band of frequencies is called the *lowest useful high frequency* (luf). Below this limit, ionospheric absorption and radio noise levels are likely to be such that radiated-power requirements become uneconomical. For a given path, season, and time, the luf may be predicted by a systematic graphic procedure. Unlike the muf, the predicted luf must be corrected by a series of factors dependent on radiated power, directivity of transmitting and receiving antennas in azimuth and elevation, class of service, and presence of local noise sources. Available data include atmospheric-noise maps, transmission-loss charts, antenna diagrams, and nomograms facilitating the computation. The procedure is formidable but worthwhile.

The upper and lower frequency limits change continuously throughout the day, whereas it is ordinarily impracticable to change operating frequencies correspondingly. Each operating frequency, therefore, should be selected to fall within the above limits for a substantial portion of the daily operating period.

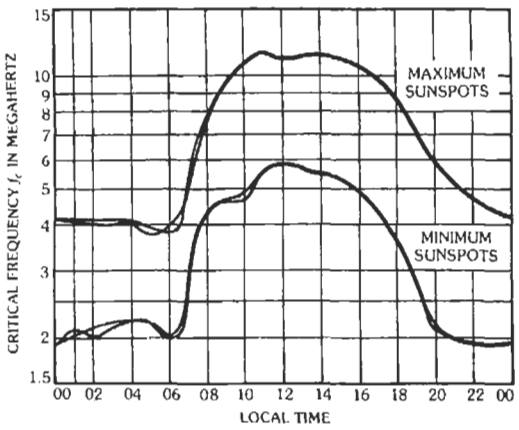

Fig. 8. Critical frequency for Washington, D.C. (*From National Bureau of Standards Circular 462.*)

Angles of Departure and Arrival

Angles of departure and arrival are of importance in the design of high-frequency antenna systems. These angles, for single-hop transmission, are obtained from the geometry of a triangular path over a curved earth with the apex of the triangle placed at the virtual height assumed for the altitude of the reflection. Fig. 9 is a family of curves showing radiation angle for different distances.

D = great-circle distance in statute miles
H = virtual height of ionosphere layer in kilometers
Δ = radiation angle in degrees
ϕ = semiangle of reflection at ionosphere

Forecasts of High-Frequency Propagation

The CCIR publishes "Basic Indices for Ionospheric Propagation" predictions several months in advance in the *Telecommunications Journal* (ITU, Geneva). A list of organizations concerned with issuing forecasts of propagation conditions is published by the CCIR.*

In designing a high-frequency communication cir-

* CCIR XVth Plenary Assembly, Geneva, 1982, Vol. VI, Report 313-4.

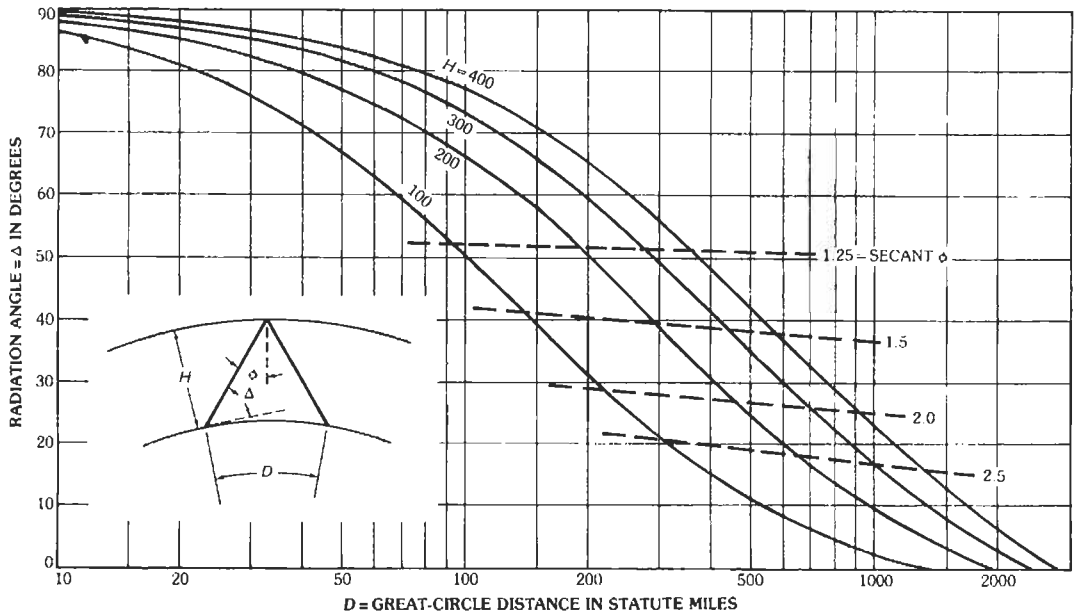

Fig. 9. Single-reflection radiation angle and great-circle distance.

cuit, it is necessary to determine the optimum traffic frequencies, system loss, signal-to-noise ratio, angle of arrival, and circuit reliability. Manual methods for calculating the values of these factors have been described,* as has the use of electronic computers for predicting the performance of high-frequency sky-wave communication circuits.†

Table 3 is a typical performance prediction prepared by computer. A general description of the circuit parameters used in the calculations is shown in the heading of the computer printout. Starting at the top of the page and reading from left to right, the heading may be described as follows.

The first line contains the month, the solar activity level in 12-month moving average Zurich sunspot number, and a circuit identification number. The second and third lines contain the transmitter and receiver locations, the bearings, and the distance. The fourth and fifth lines contain the antenna system for each terminal and their orientation relative to the great-circle path. The minimum angle indicates the lowest vertical angle considered in the mode selection.

The sixth line is the power delivered to the transmitting antenna, the man-made noise level assumed for the area in dBW in a 1-hertz bandwidth at 3 megahertz, and the hourly median signal-to-noise ratio required to provide the service requested. The signal is in the same units as the transmitter power, and the noise is in a 1-hertz bandwidth. The seventh line contains the heading for the operating frequencies, which are given in megahertz in the eighth line. In addition to the operating frequencies, the eighth line also contains the time heading (GMT) and the classically defined maximum-usable-frequency heading (muf), i.e., frequency which has a 50% probability of having a sky-wave path.

For each time and operating frequency the body of the tabulation contains: (*A*) the mode having the greatest probability (MODE), (*B*) the median vertical angle associated with this mode (ANGLE), (*C*) the propagation time in tenths of milliseconds (DELAY), (*D*) the percentage of days that any sky-wave mode is expected to exist, circuit probability (C.PROB.), (*E*) the median of the hourly median signal-to-noise ratios for the days sky-wave modes exist (S/N..DB), and (*F*) the percentage of days within the month that the median required signal-to-noise ratio is expected to be equalled or exceeded (REL.).

Bandwidth Limitations*

In high-frequency transmission, the communication bandwidth is limited by multipath propagation. The greatest limitation occurs when two or more paths exist with a different number of hops. The bandwidth may

then be as small as 100 hertz, but such multipath may be minimized by operating near the muf. Operation at a frequency within approximately 10% of the muf is necessary for paths less than about 600 kilometers to obtain bandwidths greater than, say, 1 kilohertz. The multipath reduction factor (mrf) is defined as the smallest ratio of muf to operating frequency for which the range of multipath propagation time difference is less than a specified value. The mrf thus defines the frequency above which a specified minimum protection

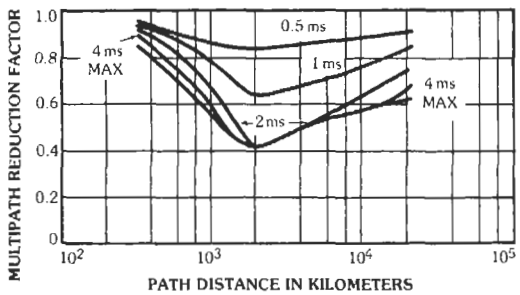

Fig. 10. Multipath reduction factor as a function of path distance. (*From Salaman, R. K. "A New Ionospheric Multipath Reduction Factor (MRF)." © 1962, Institute of Radio Engineers.*)

against multipath is provided. Fig. 10 shows the mrf for various lengths of path.*

Diversity†

It has been shown that if two or more high-frequency radio channels are sufficiently separated in space, frequency, angle of arrival, time, or polarization, the fading on the various channels is more or less independent. Diversity systems make use of this fact to improve the overall performance, combining or selecting separate radio channels on a single high-frequency circuit.

Satisfactory diversity improvement can be obtained if the correlation coefficient of the fading on the various channels does not exceed about 0.6, and experiments have indicated that a frequency separation of the order of 400 hertz gives satisfactory diversity performance on long high-frequency paths. Spacing between antennas at right angles to the direction of propagation should be about 10 wavelengths. Polarization diversity has been found to be about equivalent to space diversity in the high-frequency band. Measurements have indicated that times varying from 0.05 to 95 seconds may be necessary to obtain fading correlation coefficients as low as 0.6 in high-frequency time-diversity systems. Angle-of-arrival diversity requires the use of large antennas so as to obtain the required vertical directive characteristics. Differences in the angle of arrival of 2° have been shown to give satisfactory diversity improvement on high-frequency circuits.

Great-Circle Calculations

With reference to Fig. 11, A and B are two places on the surface of the earth the latitudes and longitudes of which are known. In the figure, B = place of greater latitude (nearer the pole), L_A = latitude of A, L_B = latitude of B, and C = difference of longitude between A and B. Angles X and Y at A and B of the great circle passing through the two places and the distance, Z, between A and B along the great circle can be calculated as follows:

$$\tan \tfrac{1}{2}(Y - X) = \cot \tfrac{1}{2} C \frac{\sin \tfrac{1}{2}(L_B - L_A)}{\cos \tfrac{1}{2}(L_B + L_A)}$$

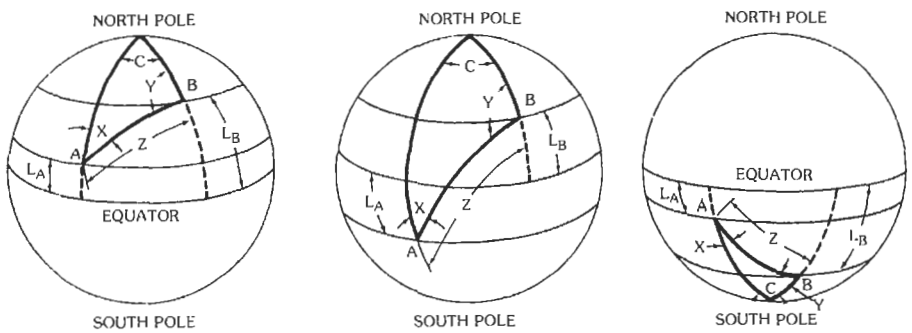
and

$$\tan \tfrac{1}{2}(Y + X) = \cot \tfrac{1}{2} C \frac{\cos \tfrac{1}{2}(L_B - L_A)}{\sin \tfrac{1}{2}(L_B + L_A)}$$

give the values of $\frac{1}{2}(Y - X)$ and $\frac{1}{2}(Y + X)$ from which

$$\tfrac{1}{2}(Y + X) + \tfrac{1}{2}(Y - X) = Y$$

and



(A) Both points located in northern hemisphere. *(B) In opposite hemispheres.* *(C) Both points located in southern hemisphere.*

Fig. 11. Three globes representing points A and B.

* Salaman, R. K. "A New Ionospheric Multipath Reduction Factor (MRF)." *IRE Transactions on Communication Systems*, Vol. CS-10, June 1962; pp. 220–222.

† "Bandwidth and Signal-to-Noise Ratios in Complete Systems," CCIR, Geneva, 1982, Vol. III, Report 195. Grisdale, G. L., Morriss, J. H., and Palmer, D. S. "Fading of Long-Distance Radio Signals and a Comparison of Space and Polarization Diversity Reception in the 6–18 Mc Range," *Proceedings of the IEE*, Part B, No. 13, Jan. 1957, pp. 39–51.

$$\tfrac{1}{2}(Y + X) - \tfrac{1}{2}(Y - X) = X$$

In the above equations, north latitudes are taken as positive and south latitudes as negative. For example, if B is latitude 60° N and A is latitude 20° S,

$$\frac{L_B + L_A}{2} = \frac{60 + (-20)}{2} = \frac{60 - 20}{2} = \frac{40}{2} = 20°$$

$$\frac{L_B - L_A}{2} = \frac{60 - (-20)}{2} = \frac{60 + 20}{2} = \frac{80}{2} = 40°$$

If both places are in the southern hemisphere and $L_B + L_A$ is negative, it is simpler to call the place of greater south latitude B and to use the above method for calculating bearings from true south and to convert the results afterward to bearings east of north.

The distance Z (in degrees) along the great circle between A and B is given by the following:

$$\tan \tfrac{1}{2} Z = \tan \tfrac{1}{2}(L_B - L_A) \times [\sin \tfrac{1}{2}(Y + X)]/[\sin \tfrac{1}{2}(Y - X)]$$

The angular distance Z (in degrees) between A and B may be converted to linear distance as follows.

Z (in degrees) × 111.12 = kilometers
Z (in degrees) × 69.05 = statute miles
Z (in degrees) × 60.00 = nautical miles

In multiplying, the minutes and seconds of arc must be expressed in decimals of a degree. For example, Z = 37°45′36″ becomes 37.755°.

Example: Find the great-circle bearings at Brentwood, Long Island, longitude 73°15′10″W, latitude 40°48′40″N, and at Rio de Janeiro, Brazil, longitude 43°22′07″W, latitude 22°57′09″S; and the great-circle distance in statute miles between the two points. Refer to Chart 1.

Great-circle initial courses and distances are conveniently determined by means of navigation tables such as:

The above tables and charts may be obtained at a nominal charge from the United States Navy Department Hydrographic Office, Washington, D.C.

EFFECT OF NUCLEAR EXPLOSIONS ON RADIO PROPAGATION*

Nuclear explosions below an altitude of about 15 kilometers have little effect on radio transmission. However, a detonation occurring at an altitude between 15 and 60 kilometers can produce blackout in the low-frequency, medium-frequency, and high-frequency bands over a radius of several hundred kilometers. This effect lasts only for a few minutes except in an area close to the site of the explosion. In general, it can be said that the effect of nuclear explosions is greatest near the site of the detonation, but the effects of ionization and shock waves do not last longer than a few minutes at distances greater than a few hundred kilometers from the site of the explosion.

High-altitude nuclear explosions (at altitudes greater than about 150 km) increase the electron density in the upper atmosphere by orders of magnitude. As a result, the propagation of signals at frequencies as high as 100 GHz between satellites and from satellites to earth is impaired. The impairments take the form of large attenuation and time delays together with rapid variation of signal strength and frequency-selective fading which can limit the available bandwidth and data rates.

IONOSPHERIC SCATTER PROPAGATION†

This type of transmission permits communication in the frequency range from approximately 30 to 60 megahertz and over distances from about 1000 to 2000 kilometers. It is believed that this type of propagation is due to scattering from the lower D region of the ionosphere and that the useful bandwidth is restricted to less than 10 kilohertz. The greatest use for this type of transmission has been for printing-telegraph channels, particularly in the auroral regions where conventional high-frequency ionospheric transmission is often unreliable.

The median attenuation over paths between 800 and 1000 miles in length is about 80 decibels greater than the free-space path attenuation at 30 megahertz and about 90 decibels greater than the free-space value at 50 megahertz.

METEOR-BURST PROPAGATION*

Frequencies in the very-high- and ultrahigh-frequency bands may be propagated by reflection from columns of ionization produced by meteors entering the lower E region. Experimental single-channel two-way telegraph circuits have been operated in the frequency range from 30 to 40 megahertz over distances of 600 to 1300 kilometers with transmitter powers of 1 to 3 kilowatts. One-way transmission of voice and facsimile have also been made with transmitter powers of 1 kilowatt and 20 kilowatts, respectively.

The frequency range from about 50 to 80 megahertz has been found best suited for meteor-burst transmission.

PROPAGATION ABOVE 30 MEGAHERTZ, LINE-OF-SIGHT CONDITIONS*

Radio Refraction†

Under normal propagation conditions, the refractive index of the atmosphere decreases with height so that radio rays travel more slowly near the ground than at higher altitudes. This variation in velocity with height

* Bullington, K., "Radio Propagation at Frequencies Above 30 Megacycles," *Proceedings of the IRE*, Vol. 35, October 1947, pp. 1122–1136. Kerr, D. E., *Propagation of Short Radio Waves*. New York: McGraw-Hill Book Co., 1951. CCIR XVth Plenary Assembly, Geneva, 1982, Vol. V.

† Bean, B. R., and Dutton, E. J. *Radio Meteorology*. Monograph 92, Institute for Telecommunication Sciences and Aeronomy, Environmental Science Services Administration (ESSA). Washington: Superintendent of Documents, 1966.

results in bending of the radio rays. Uniform bending may be represented by straight-line propagation, but with the radius of the earth modified so that the relative curvature between the ray and the earth remains unchanged. The new radius of the earth is known as the effective earth radius, and the ratio of the effective earth radius to true earth radius is usually denoted by K. The average value of K in temperate climates is about 1.33; however, values from about 0.6 to 5.0 are to be expected.

The decrease in the refractive index with height may at times be so great that the ray is bent down with a radius equal to that of the earth so that the earth may then be considered to be flat. A further increase in the refractive-index gradient results in the radio ray being bent down sufficiently to be reflected from the earth. The ray then appears to be trapped in a duct between the earth and the maximum height of the radio path.

Under certain atmospheric conditions, the refractive index may increase with height, causing the radio rays to bend upward. Such inverse bending results in a decrease in path clearance on line-of-sight paths.

The distance to the radio horizon over smooth earth, when the height, h, is very small compared with the radius of the earth, is given with a good approximation by the expression

$$d = (3Kh/2)^{1/2}$$

where,

h = height in feet above the earth,
d = distance to radio horizon in miles,
K = ratio of the effective to the true radius of the earth.

Over a smooth earth, a transmitter antenna at height h_t (feet) and a receiving antenna at height h_r (feet) are in radio line-of-sight provided the spacing in miles is less than $(2h_t)^{1/2} + (2h_r)^{1/2}$ (assuming $K = 1.33$).

The nomogram in Fig. 12 gives the radio-horizon distance between a transmitter at height h_t and a receiver at height h_r. Fig. 13 extends the first nomogram to give the maximum radio-path length between

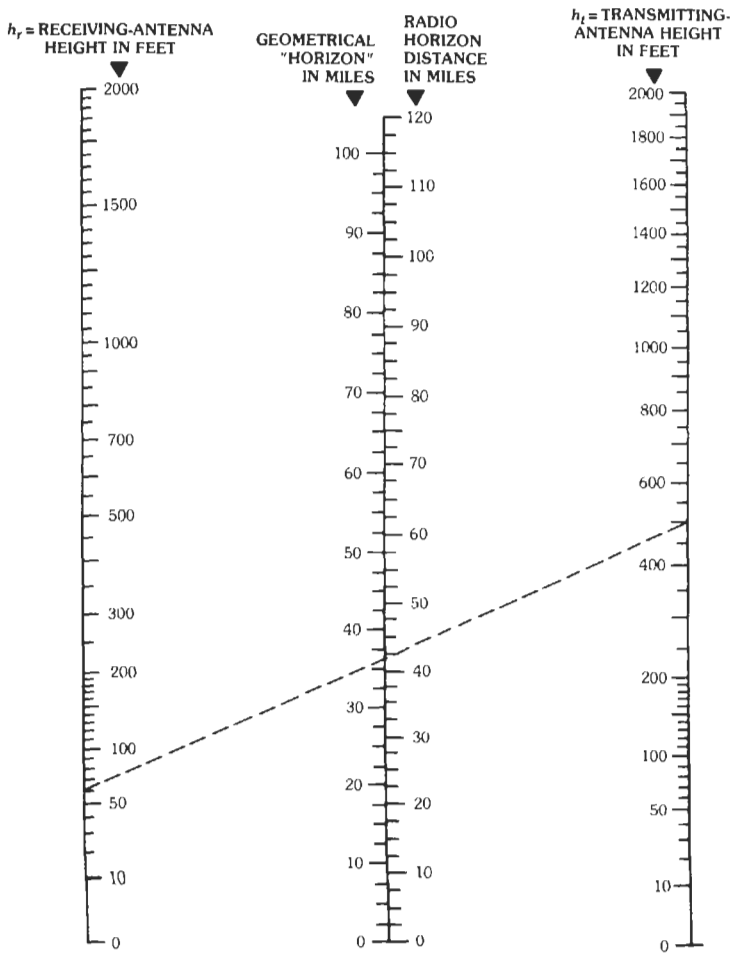

Fig. 12. Nomogram giving radio-horizon distance in miles when h_r and h_t are known. Example shown: Height of receiving antenna 60 feet; height of transmitting antenna 500 feet; maximum radio-path length = 41.5 miles. ($K = 1.33$)

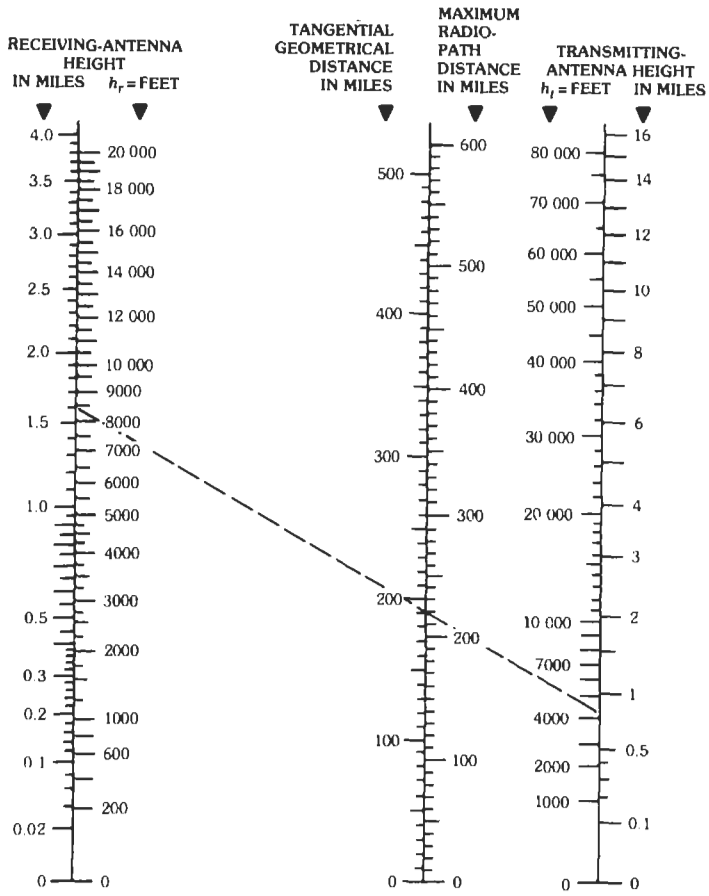

Fig. 13. Nomogram giving radio-path length and tangential distance for transmission between two airplanes at heights h_r and h_t. Example shown: Height of receiving-antenna airplane 8500 feet (1.6 miles); height of transmitting-antenna airplane 4250 feet (0.8 mile); maximum radio-path distance = 220 miles. (K = 1.33)

two airplanes whose altitudes are known. Both figures assume a value of K = 1.33.

Path Plotting and Profile-Chart Construction

Path Plotting—When laying out a microwave system, it is usually convenient to plot the path on a profile chart. Such charts are scaled to indicate the departure of the curvature of the earth from a straight line. With reference to Fig. 14,

$$D^2 + R^2 = (h + R)^2 = h^2 + 2Rh + R^2$$

$$D^2 = h^2 + 2Rh$$

where,

D = distance,
R = radius of earth (3960 miles),
h = altitude.

Since $h \ll R$, $D = (2Rh)^{1/2}$, and inserting the true earth radius with R and D in statute miles and h in feet

$$D = \left(\frac{2 \times 3960}{5280} h\right)^{1/2}$$

$$D = [(3/2)h]^{1/2}$$

$$h = (2/3)D^2$$

for true earth, where D is in miles and h in feet. For a value of K = 1.33

$$D = [(3/2)h]^{1/2}(4/3)^{1/2} = (2h)^{1/2}$$

$$h = D^2/2$$

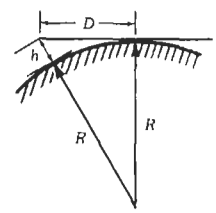

Fig. 14. Straight line tangent to surface of earth.

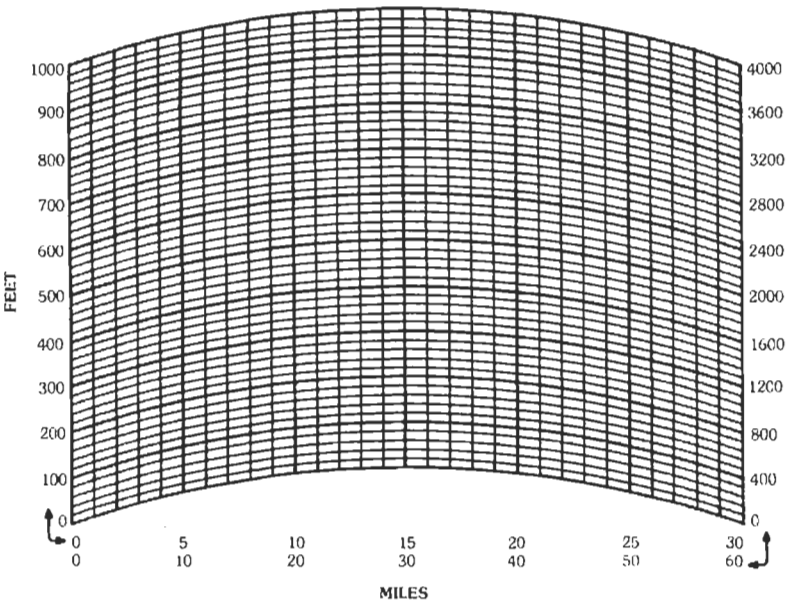

Fig. 15. Typical 4/3-earth profile paper, 1000-foot scale.

Or more generally

$$h = 2D^2/3K$$

Profile Paper—If a 4/3 effective-radius factor is used, the departure from a horizontal tangent line is

$$h = D^2/2$$

where symbols are as above. By using this equation, a template can be made for convenient drawing of profile paper (Fig. 15). For instance, if the horizontal scale is 10 miles/inch, the vertical scale 100 feet/inch, and a width corresponding to 40 miles is desired, the points in Table 4 may be plotted.

A typical example of a template constructed according to these figures is given in Fig. 16. If a different scale is desired than is provided on available profile-chart paper (for example, if a 50-mile hop is to be plotted on 30-mile paper), then the scale of miles may be doubled to extend the range of the paper to 60 miles. The vertical scale in feet must then be quadrupled; i.e., 100-foot divisions become 400-foot divisions, as on the right in Fig. 15.

TABLE 4. POINTS FOR CONSTRUCTING TEMPLATE

Distance From Center (Horizontal)	Distance From Horizontal (Vertical)
0 miles = 0 inches	0 feet = 0 inches
5 miles = ½ inch	12½ feet = ⅛ inch
10 miles = 1 inch	50 feet = ½ inch
15 miles = 1½ inches	112½ feet = 1⅛ inches
20 miles = 2 inches	200 feet = 2 inches

Fresnel Zones

The Fresnel-Kirchhoff theory was originally developed to account for the diffraction of light when obstructed by diaphragms, and when transmitting through apertures of various shapes and sizes. This theory may be applied to radio and sound waves and is based on the concept that any small element of space in the path of a wave may be considered as the source of a secondary wavelet, and that the radiated field can be built up by the superposition of all these wavelets (Huygens principle).

Consider a transparent screen between a distant transmitter, T, and a receiver, R, with the distance from screen to transmitter being at least 10 times the distance from screen to receiver, and with the plane of the screen perpendicular to direction T-R. Concentric circles may be drawn on this screen, with the centers at the point where line T-R intersects the screen at O, the radius of the first circle being such that the difference in length between path O-R and the path from the circumference of this circle to R is $\frac{1}{2}$ wavelength (λ). The radii of the other circles are such that the corresponding path-length differences are integral multiples of $\frac{1}{2}\lambda$. The radius of the first circle is $(d\lambda)^{1/2}$, where d is the distance from O to R, and the radius of the second circle is $(2d\lambda)^{1/2}$, of the third $(3d\lambda)^{1/2}$, etc. The area within the first circle is called the first Fresnel zone, and the other ring-shaped areas are the second, third, etc., Fresnel zones. The fields from the odd-number zones are in phase at R, and the fields from the even-number zones are also in phase at R but are opposite in phase to the fields from the

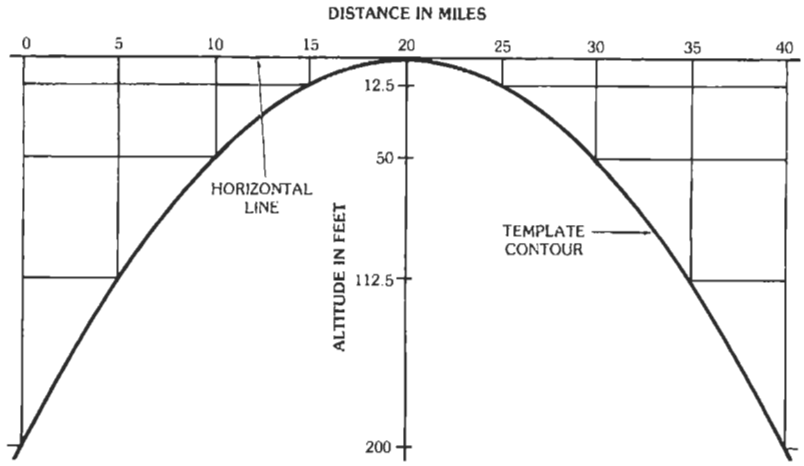

Fig. 16. Construction of a template for profile charts.

odd-number zones. It can be shown that the effect at R of each zone is nearly equal. If an infinitely absorbing screen is provided with an aperture of the same diameter as the first Fresnel zone, it will be found that the field at R is twice as great as the unobstructed or free-space field. If the aperture is increased to include the second zone, the field at R will then be nearly zero, since the fields from zones 1 and 2 are nearly equal in amplitude and opposite in phase. With a continued increase in the diameter of the aperture, further maxima and minima appear; the amplitude of these oscillations decreases very gradually until eventually the field at R approaches the free-space value, which is half that due to the first Fresnel zone. If the distance from the screen to the transmitter is d_1, and from the screen to the receiver is d_2, then the general expression for the radius of the nth Fresnel zone is

$$\{n\lambda[(d_1 \times d_2)/(d_1 + d_2)]\}^{1/2}$$

Required Path Clearance

A criterion to determine whether the earth is sufficiently removed from the radio line-of-sight ray to allow mean free-space propagation conditions to apply is to have the first Fresnel zone clear all obstacles in the path of the rays. This first zone is bounded by points for which the transmission path from transmitter to receiver is greater by one-half wavelength than the direct path. Let d be the length of the direct path and d_1 and d_2 be the distances to the transmitter and receiver from a point, P. The radius of the first Fresnel zone at P is approximately given by

$$R_1^2 = \lambda(d_1 d_2/d)$$

where all quantities are expressed in the same units.

If d is in miles and frequency F in megahertz, the first Fresnel-zone radius in feet at P is given by

$$R_{1m} = 2280(d_1 d_2/Fd)^{1/2}$$

The maximum occurs when $d_1 = d_2$ and is equal to

$$R_{1m} = 1140(d/F)^{1/2}$$

While a fictitious earth of 4/3 of true earth radius is generally accepted for determining first Fresnel-zone clearance under normal refraction conditions, unusual conditions that occur in the atmosphere may make it desirable to allow first Fresnel clearance of an effective earth radius of 0.7 to 0.5 of the true radius.

Fig. 17 shows the effect of path clearance on radio transmission.*

Interference Between Direct and Reflected Rays

Where there is one reflected ray combining with the direct ray at the receiving point (Fig. 18), the resulting field strength (neglecting the difference in angles of arrival, and assuming perfect reflection at T) is related to the free-space intensity, irrespective of the polarization, by

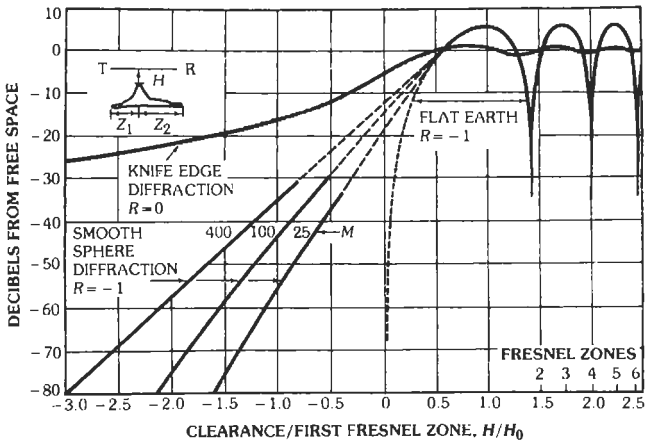
$$E = 2E_d \sin 2\pi(\delta/2\lambda)$$

where,

E = resulting field strength, } same
E_d = direct-ray field strength, } units
δ = geometrical length difference between direct and reflected paths, which is given to a close approximation by $\delta = 2h_{at}h_{ar}/d$,

where h_{at} and h_{ar} are the heights of the antennas above a

* Bullington, K. "Radio Propagation Fundamentals," *Bell System Tech. J.*, Vol. 36, No. 3, 1957, pp. 593–626.



R = reflection coefficient of surface
H = clearance
H_0 = first Fresnel zone radius = $[(\lambda Z_1 \cdot Z_2)/(Z_1 + Z_2)]^{1/2}$
$M = [H_1/K^{1/3}]\{[1 + (H_2/H_1)^{1/2}]/2\}^2(F/4000)^{2/3}$
H_1, H_2 = antenna height in feet above a smooth sphere
F = frequency in megahertz
K = (effective earth radius)/(true earth radius)

Fig. 17. Effect of path clearance on radio transmission. (*From Bullington, K. "Radio Propagation Fundamentals."* Bell System Tech. J., *Vol. 36, No. 3, Fig. 8, ©1957 American Telephone and Telegraph Co.*)

reflecting plane tangent to the effective earth. (See Fig. 18.)

The following cases are of interest:

$$E = 0 \qquad \text{for } h_{at}h_{ar} = d\lambda/2$$

$$E = 2E_d \qquad \text{for } h_{at}h_{ar} = d\lambda/4$$

$$E = E_d \qquad \text{for } h_{at}h_{ar} = d\lambda/12$$

In case $h_{at} = h_{ar} = h$,

$$E = 0 \qquad \text{for } h = (d\lambda/2)^{1/2}$$

$$E = 2E_d \qquad \text{for } h = (d\lambda/4)^{1/2}$$

$$E = E_d \qquad \text{for } h = (d\lambda/12)^{1/2}$$

All these equations are written with the same units for all quantities.

Space-Diversity Reception

When h_{ar} is varied, the field strength at the receiver varies approximately according to the preceding equation. The use of two antennas at different heights provides a means of compensating to a certain extent for changes in electrical-path differences between direct and reflected rays (space-diversity reception).

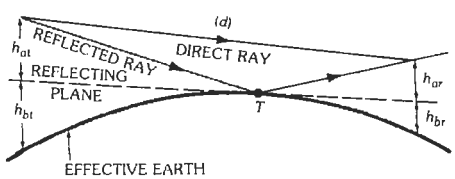


Fig. 18. Interference between direct and reflected rays.

The antenna spacing at the receiver should be approximately such as to give a $\lambda/2$ variation between geometrical-path differences in the two cases. An approximate value of the spacing is given by $\lambda d/4h_{at}$ when all quantities are in the same units.

The spacing in feet for d in miles, h_{at} in feet, λ in centimeters, and f in megahertz is given by

$$\text{spacing} = 43.4\lambda d/h_{at}$$

$$= 1.3 \times 10^6\, d/fh_{at}$$

Example: $\lambda = 3$ centimeters, $d = 20$ miles, and $h_{at} = 50$ feet; therefore spacing = 52 feet.

Variation of Field Strength With Distance

Fig. 19 shows the variation of resultant field strength with distance and frequency; this effect is due to interference between the free-space wave and the ground-reflected wave as these two components arrive in or out of phase.

To compute the field accurately under these conditions, it is necessary to calculate the two components separately and to add them in the correct phase relationship. The phase and amplitude of the reflected ray are determined by the geometry of the path and the change in magnitude and phase at ground reflection. For horizontally polarized waves, the reflection coefficient can be taken as approximately 1, and the phase shift at

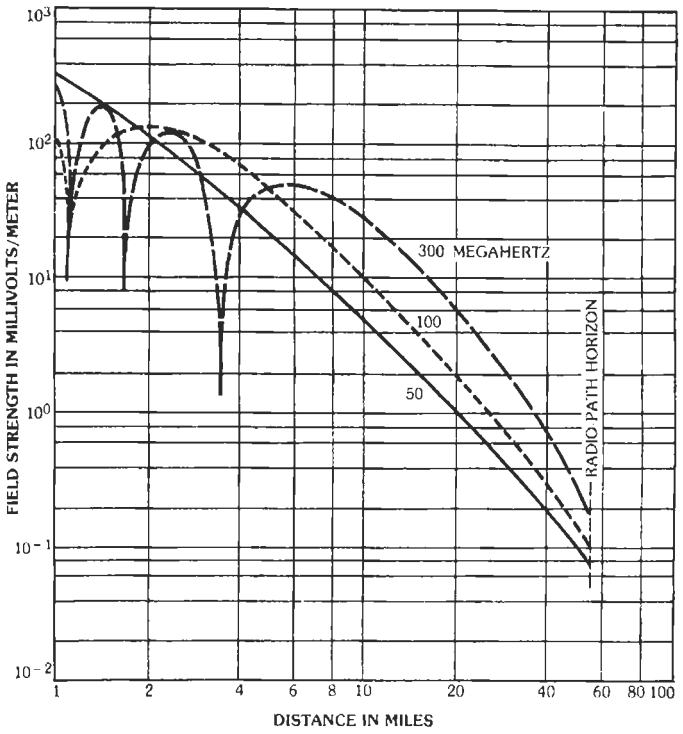

Fig. 19. Variation of resultant field strength with distance and frequency. Antenna heights: 1000 feet, 30 feet; power: 1 kilowatt; ground constants: $\sigma = 5 \times 10^{-14}$ emu, $\epsilon = 15$ esu; polarization: horizontal.

reflection as 180 degrees, for nearly all types of ground and angles of incidence. For vertically polarized waves, the reflection coefficient and phase shift vary appreciably with the ground constants and angle of incidence. (See Fig. 24 of Chapter 32.)

Measured field strengths usually show large deviations from point to point because of reflections from ground irregularities, buildings, trees, etc.

For transmission paths of the order of 30 miles and for frequencies up to about 6000 megahertz, good engineering practice should allow for possible increases of signal strength of +10 decibels with respect to free-space propagation and should allow a fading margin depending on the degree of reliability desired in accordance with the following:

10 decibels—90 percent

20 decibels—99 percent

30 decibels—99.9 percent

40 decibels—99.99 percent

Fading and Diversity*

Line-of-sight propagation at ultrahigh frequencies is affected both by signal-strength variation due to multipath transmission and by bending of the beam due to abnormal variation of refractive index with height in the lower atmosphere.

At frequencies below about 8000 megahertz, and on paths having adequate clearance, the fading on line-of-sight paths is due to multipath transmission. Multipath fading may be divided into two main types; the first is relatively rapid and is caused by interference between two or more rays arriving by slightly different paths; this is known as *atmospheric-multipath*. The second type of fading is less rapid and is due to interference between direct and reflected rays; this is referred to as *reflection-multipath*. In general, the number of fades per unit time due to atmospheric-multipath increases with path length; however, the duration of a fade of a given depth tends to decrease with increasing path length. Fig. 20 shows the typical fading characteristics of a terrestrial line-of-sight path. See Chapter 27 for earth-to-space paths.

Either frequency or space diversity may be used to reduce the amplitude of multipath fading. In the case of atmospheric-multipath fading on line-of-sight paths, it

W., "Method for the Prediction of the Fading Performance of a Multisection Microwave Link." *Proceedings of the IEE*, Vol. 112, No. 7, July 1965; pp. 1291–1300. CCIR XVth Plenary Assembly, Geneva, 1982, Vol. V, Report 338-4; pp. 279–314.

Transmission Loss Predictions for Tropospheric Communication Circuits. National Bureau of Standards Technical Note No. 101.

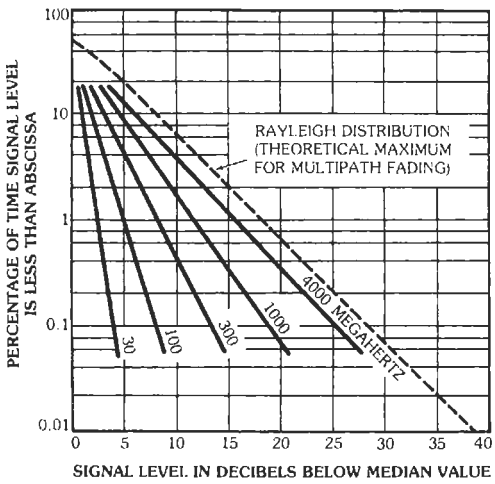

Fig. 20. Typical fading characteristics in the worst month on line-of-sight paths of 30 to 40 miles with clearance of 50 to 100 feet. (*From Bullington, K. "Radio Propagation Fundamentals."* Bell System Technical Journal, *Vol. 36, No. 3, Fig. 4; ©1957 American Telephone and Telegraph Co.*).

has been found that considerable diversity improvement can usually be obtained with a frequency difference of 100 to 200 megahertz or with a vertical antenna spacing of between 100 and 200 wavelengths.

Atmospheric Absorption

Gaseous Attenuation*—Oxygen and water vapor may absorb energy from a radio wave by virtue of the permanent electric dipole moment of the water molecule and the permanent magnetic dipole moment of the oxygen molecule. Fig. 21 shows water-vapor absorption γ_w and oxygen absorption γ_o as functions of frequency.

For a path through the atmosphere, the total attenuation depends on the scale heights of the oxygen and water-vapor components, which are approximately 8 km and 2 km, respectively, and on the elevation angle, θ. Then the total attenuation, A, in decibels is given by

$$A = (8\gamma_o + 2\gamma_w)/\sin\theta \qquad \theta > 10°$$

or by

$$A = 16\gamma_o(\sin^2\theta + 16/R + \sin\theta)^{-1/2} + 4\gamma_o(\sin^2\theta + 4/R + \sin\theta)^{-1/2} \qquad \theta \leq 10°$$

where R is the effective earth radius, including refraction, which is approximately 8500 km.

Rain Attenuation†—In addition to gaseous absorption, which is relatively small except in the narrow

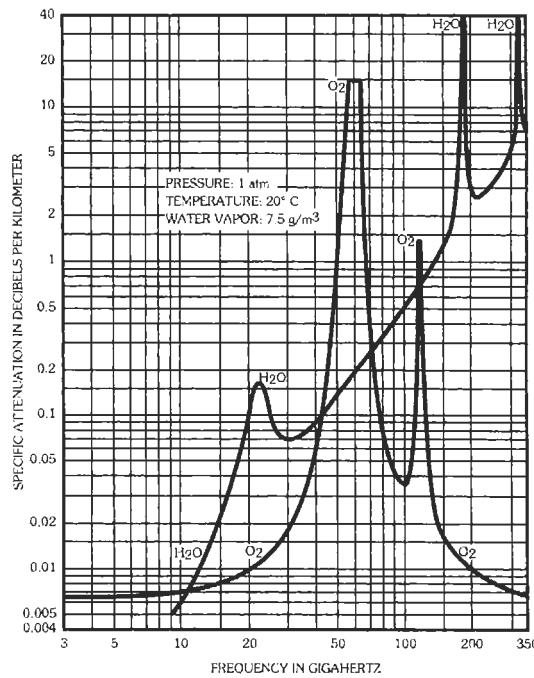

Fig. 21. Specific attenuation due to atmospheric gases (reference 4).

spectral regions shown in Fig. 21, rain attenuation must also be considered. Specific attenuation, γ_R (decibels per kilometer of path length), depends on the frequency f (GHz) and rain rate R_p (mm/hr), and is given by

$$\gamma_R = a(f) \cdot R_p^{b(f)}$$

where $a(f)$ and $b(f)$ are given in Table 5.* Fig. 22 shows this dependence for terrestrial paths.

Rain rate depends on the location of the path and on the season. For computational purposes, the world is divided into the various rain-rate regions shown in Fig. 23 and, in more detail for part of North America, in Fig. 24. The fraction of an average year during which a given rain rate is exceeded in each of these regions is shown in Table 6. In practice, annual statistics of rain rates can be misleading because of seasonal dependency and because the occurrence of rain is not random. Examples of the frequency of rain events and their duration as a function of rain rate for the United Kingdom are shown in Fig. 25. Similar data for selected locations in the USA are shown in Tables 6, 7, 8, and 9.† In temperate climates, rain rates exceeding 2.54 mm/h are not likely to occur over an area larger than about 6 km in diameter.

* Reference 2.

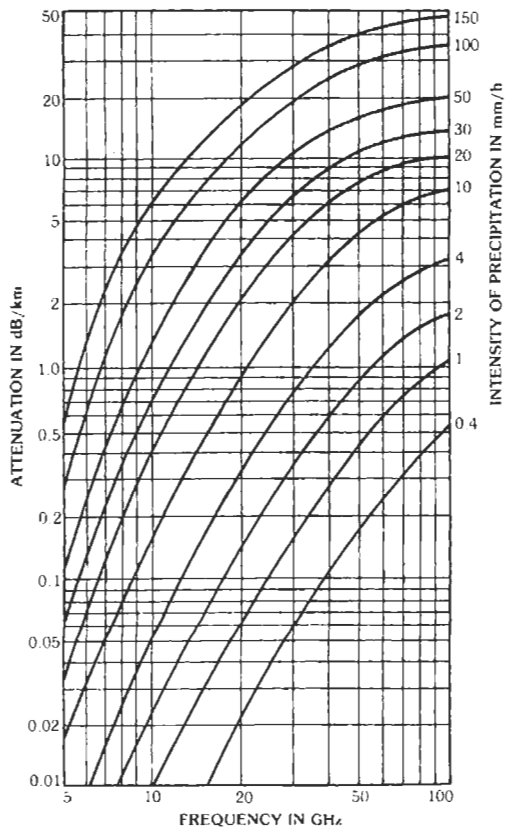

Fig. 22. Attenuation due to precipitation. (*From CCIR XIIIth Plenary Assembly, Geneva, 1974, Vol. V, Report 233-3.*)

Given the specific attenuation γ_R, the path attenuation, A, in decibels is provided by

$$A = \gamma_R L r$$

where,

L is the path length (km),
r is a path length modification factor which takes into account that the rain rate may not be uniform along the path.

The factor r is*

$$r = \gamma(L) \cdot R_p^{-\delta(L)}$$

where R is the point rain rate in millimeters per hour and the coefficients $\gamma(L)$ and $\delta(L)$ are shown in Figs. 26 and 27. The resulting dependence of r on the point rainfall rate and path lengths is shown in Fig. 28.

Free-Space Transmission Equations

If the incoming wave is a plane wave having a power flow per unit area equal to P_0, the available power at the output terminals of a receiving antenna may be expressed as

$$P_r = A_r P_0$$

where A_r is the effective area of the receiving antenna.

* Reference 3.

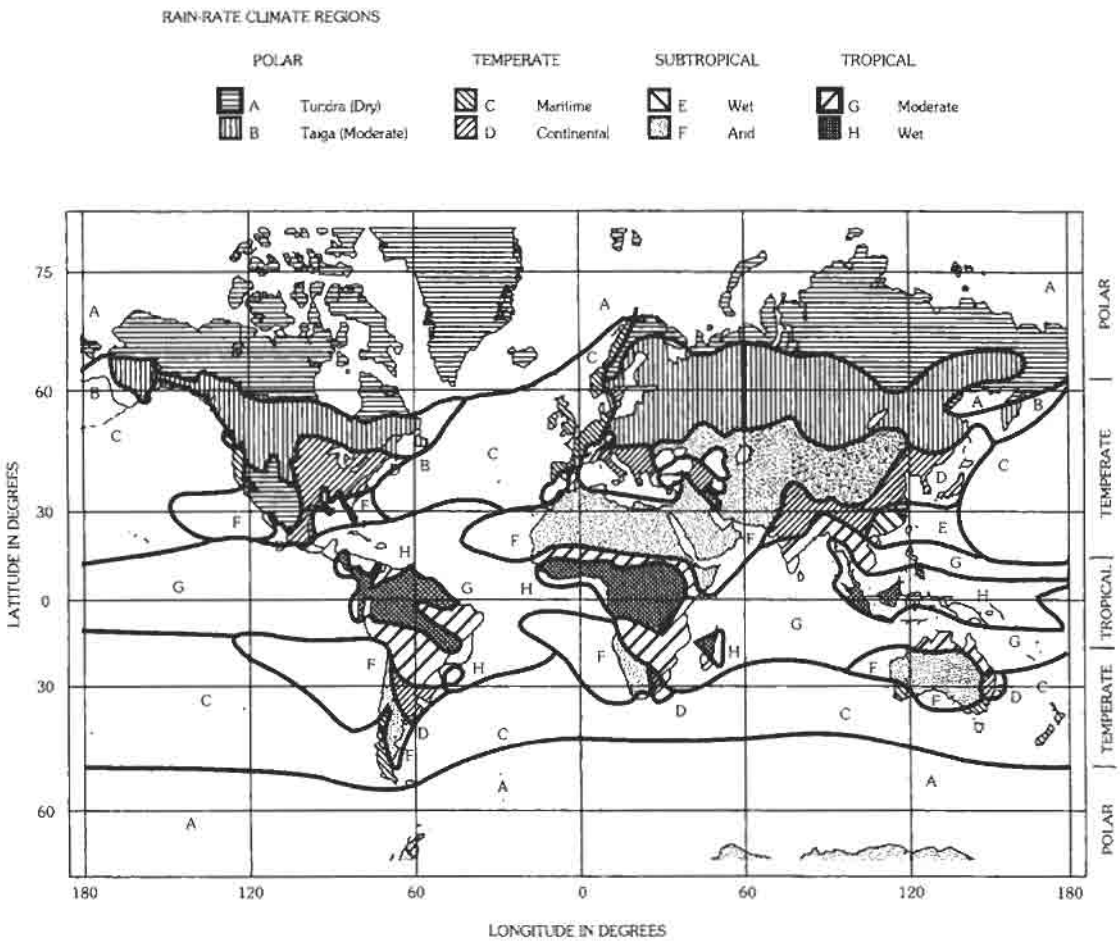

Fig. 23. Global rain-rate climate regions including the ocean areas.

The free-space path attenuation is given by

$$\text{attenuation} = 10 \log (P_t/P_r)$$

where P_t is the power radiated from the transmitting antenna (same units as for P_r). Then

$$P_r/P_t = A_r A_t/d^2\lambda^2$$

where,

A_r = effective area of receiving antenna,
A_t = effective area of transmitting antenna,
λ = wavelength,
d = distance between antennas.

The length and surface units in the equation should be consistent. This is valid provided $d >> 2a^2/\lambda$, where a is the largest linear dimension of either of the antennas.

Path attenuation between isotropic antennas is

$$P_t/P_r = 4.56 \times 10^3 f^2 d^2$$

where f is in megahertz and d is in miles.

Path attenuation α (in decibels) is

$$\alpha = 36.6 + 20 \log f + 20 \log d$$

A nomogram for determining the solution of α is given in Fig. 29.

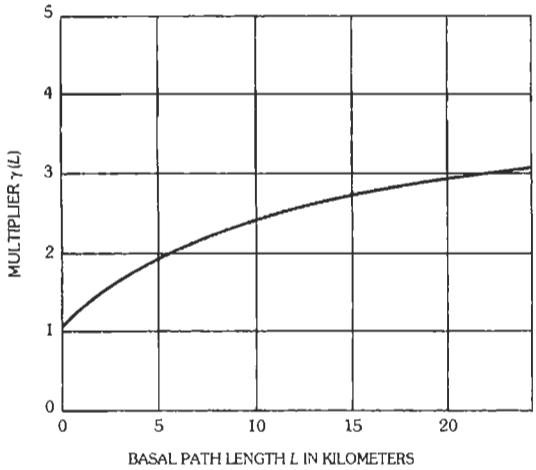

Fig. 26. Multiplier in the path averaging model.

Horn producing maximum field for given horn length

$$A = 0.45S$$

The aperture sides of the horn are assumed to be large compared with the wavelength.

Antenna Gain Relative to Hypothetical Isotropic Antennas

If directive antennas are used in place of isotropic antennas, the transmission equation becomes

$$P_r/P_t = G_t G_r [P_r/P_t]_{\text{isotropic}}$$

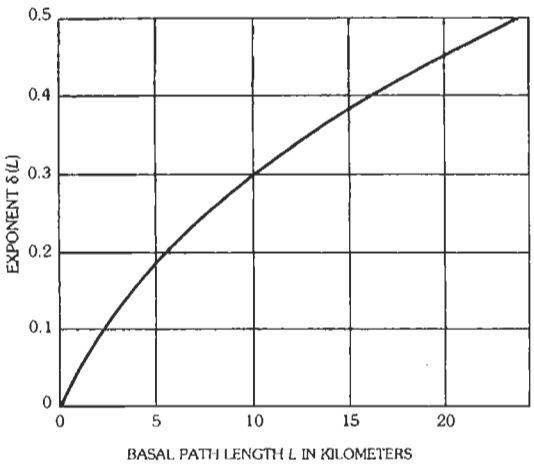

Fig. 27. Exponent in the path averaging model.

where G_t and G_r are the power gains due to the directivity of the transmitting and receiving antennas, respectively.

The apparent power gain is equal to the ratio of the effective area of the antenna to the effective area of the isotropic antenna (which is equal to $\lambda^2/4\pi \approx 0.08\lambda^2$).

The apparent power gain due to a paraboloidal reflector is thus

$$G = 0.54(\pi D/\lambda)^2$$

where D is the aperture diameter, and an illumination factor of 0.54 is assumed. In decibels, this becomes

$$G_{\text{dB}} = 20 \log f + 20 \log D - 52.6$$

where,

f = frequency in megahertz,
D = aperture diameter in feet.

The solution for G_{dB} may be found in Fig. 30.

Antenna Beam Width

The beam angle, θ, in degrees is related to the apparent power gain, G, of a paraboloidal reflector with respect to isotropic antennas approximately by

$$\theta^2 \approx 27\,000/G$$

Since $G = 5.5 \times 10^{-6} D^2 f^2$, the beam angle becomes

$$\theta \approx (7 \times 10^4)/fD$$

where,

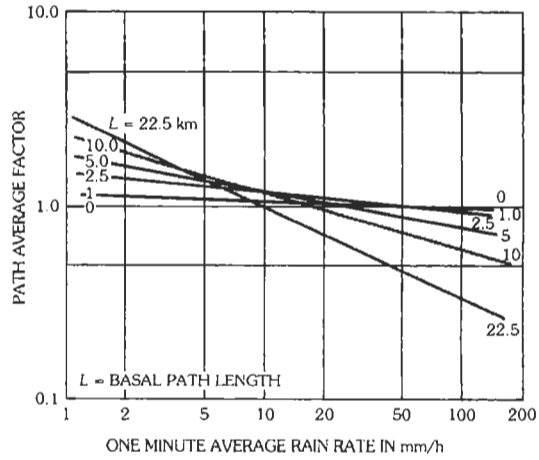

Fig. 28. Effective path average factor model for different basal path lengths.

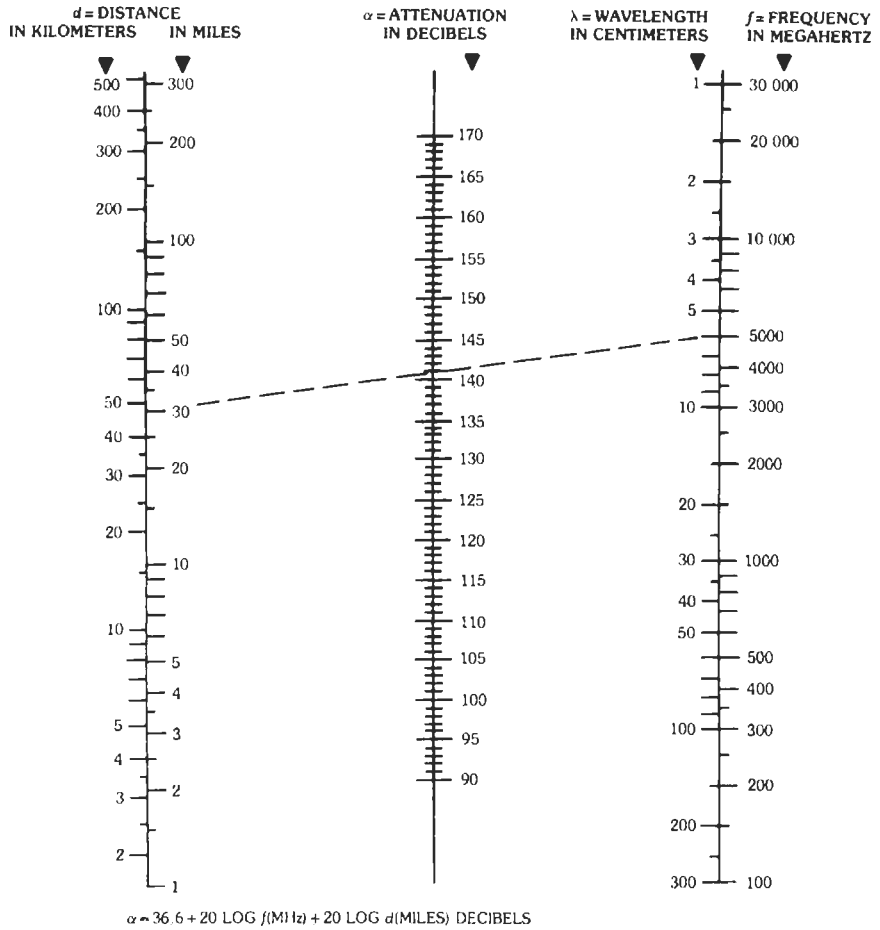

Fig. 29. Nomogram for solution of free-space path attenuation α between isotropic antennas. Example shown: distance 30 miles; frequency 5000 megahertz; attenuation = 141 decibels.

θ = beam width between 3-decibel points in degrees,
f = frequency in megahertz,
D = diameter of paraboloid in feet.

Transmitter Power for a Required Output Signal/Noise Ratio

Based on the above expressions for path attenuation and reflector gain, the ratio of transmitted power to theoretical receiver noise, in decibels, is given by

$$10 \log (P_t/P_n) = A_p + (S/N) + (nf) - G_t - G_r - (\overline{nif})$$

where,

S/N = required signal/noise ratio at receiver in decibels,
(nf) = noise figure of receiver in decibels,
$(\overline{nif})$ = noise improvement factor in decibels due to modulation methods where extra bandwidth is used to gain noise reduction,
P_n = theoretical noise power in receiver,
P_t = radiated transmitter power,
G_t = gain of transmitting antenna in decibels,
G_r = gain of receiving antenna in decibels,
A_p = path attenuation in decibels.

An equivalent way to compute the transmitter power for a required output signal/noise ratio is given below directly in terms of reflector dimensions and system parameters.

(A) Normal free-space propagation

$$P_t = \frac{\beta_1 \beta_2}{40} \frac{BL^2}{f^2 r^4} \frac{F}{K} \frac{S}{N}$$

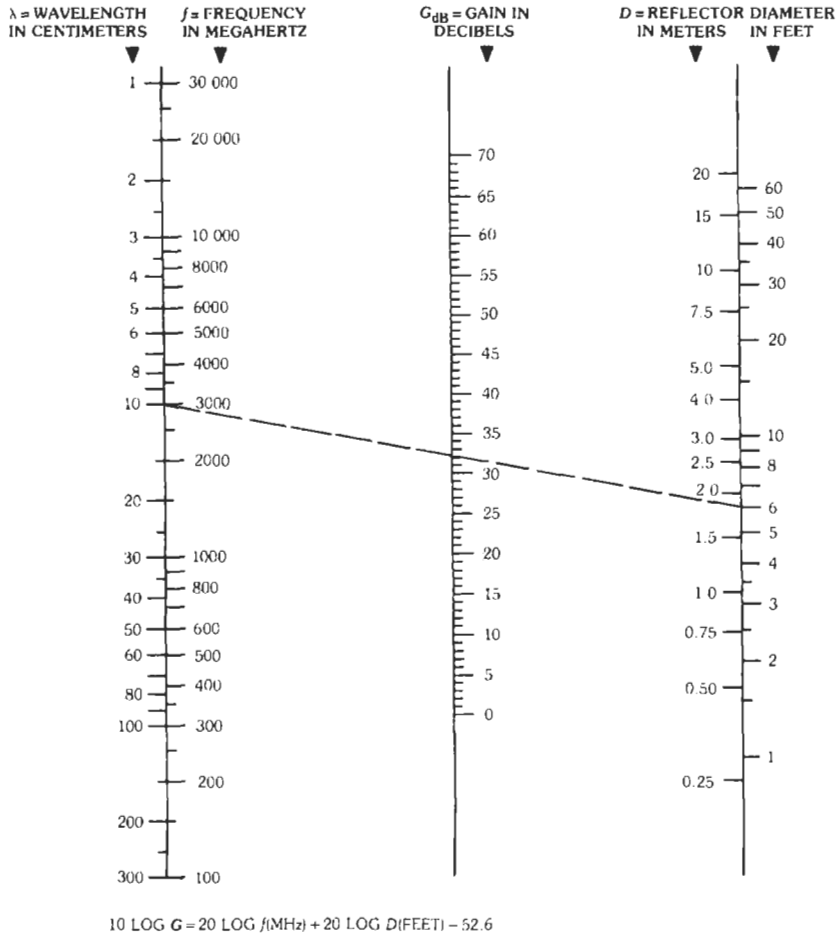

Fig. 30. Nomogram for determination of apparent power gain G_{dB} (in decibels) of a paraboloidal reflector. Example shown: frequency 3000 megahertz; diameter 6 feet; gain = 32 decibels.

(B) With allowance for fading

$$P_t = \frac{\beta_1\beta_2}{40}\frac{BL^2}{f^2r^4}\frac{F}{K}\sigma\left(\frac{S}{N}\right)_m$$

(C) For multirelay transmission in n equal hops

$$P_t = \frac{\beta_1\beta_2}{40}\frac{BL^2}{f^2r^4}\frac{F}{K}\sigma\left(\frac{S}{N}\right)_{nm}$$

(D) Signal/noise ratio for nonsimultaneous fading is

$$10 \log (S/N)_n = 10 \log \sigma (S/N)_{1m} - 10 \log \bar{n}$$

where,

P_t = power in watts available at transmitter output terminals (kept constant at each repeater point),

β_1 = loss power ratio (numerical) due to transmission line at transmitter,

β_2 = same as β_1 at receiver,

B = root-mean-square bandwidth (generally approximated to bandwidth between 3-decibel attenuation points) in megahertz,

L = total length of transmission in miles,

f = carrier frequency in megahertz,

r = radius of paraboloidal reflectors in feet,

F = power-ratio noise figure of receiver (a numerical factor),

K = improvement in signal/noise ratio due to the modulation used. (For instance, $K = 3m^2$ for frequency modulation, where m is the ratio of maximum frequency deviation to maximum modulating frequency. Note that this is the numerical power ratio.)

σ = numerical ratio between available signal power in case of normal propagation to available signal power in case of maximum expected fading,
S/N = required signal/noise power ratio at receiver,
$(S/N)_m$ = minimum required signal/noise power ratio in case of maximum expected fading,
$(S/N)_{nm}$ = same as above in case of n hops, at repeater number n,
$(S/N)_{1m}$ = same as above at first repeater,
$(S/N)_n$ = same as above at end of n hops,
n = number of equal hops,
m = number of hops where fading occurs,

$$\bar{n} = n - m + \sum_{1}^{m} \sigma_h$$

σ_h = ratio of available signal power for normal conditions to available signal power in case of actual fading in hop number h (equation holds in case signal power is increased instead of decreased by abnormal propagation or reduced hop distance).

KNIFE-EDGE DIFFRACTION PROPAGATION*

Diffraction loss at an ideal knife-edge can be estimated from Fig. 31. However, the transmission loss over a practical knife-edge diffraction path depends critically on the shape of the diffracting edge. Since a natural obstacle, such as a mountain ridge, may depart considerably from an ideal knife-edge, the diffraction loss in practice is usually 10 to 20 decibels greater than that estimated for the ideal case.

A nonuniform transverse profile of the diffracting edge, or reflections on the transmission paths each side of the diffracting edge, may result in multipath transmission causing variations in the received level as a function of frequency, space, and time. The amplitude of such variations may be reduced by either space or frequency diversity and by the use of narrow-beamwidth antennas.

TROPOSPHERIC SCATTER PROPAGATION†

Weak but reliable fields are propagated several hundred miles beyond the horizon in the very-high-, ultrahigh-, and superhigh-frequency bands. An important parameter in scatter propagation is the scatter angle or angle of intersection of the transmitting and receiving antenna beams. This angle, θ, in radians is given by

$$\theta = \frac{2d - d_t - d_v}{2R} + \frac{h_t - H_t}{d_t} + \frac{h_v - H_v}{d_v}$$

where,

d = great-circle distance between transmitting and receiving antennas,
d_t = distance to the horizon from the transmitting antenna,
d_v = distance to the horizon from the receiving antenna,
h_t = height above sea level of the transmitting horizon,
h_v = height above sea level of the receiving horizon,
H_t = height above sea level of the transmitting antenna,
H_v = height above sea level of the receiving antenna,
R = effective radius of the earth.

The same units are used for distances and heights.

The effective radius of the earth is a function of the refractive index gradient and may be estimated from Fig. 32. This curve is based on the correlation found between the decrease in the refractive index in the first kilometer of altitude above the surface of the earth and the surface value of the refractive index. Fig. 33 shows typical mean values of the refractive index at sea level.

The long-term median transmission loss (in decibels) due to forward scatter is approximately

$$L(50) = 30 \log f - 20 \log d + F(\theta d) - G_p - V(d_e)$$

where $F(\theta d)$ is shown in Fig. 34 as a function of the product θd. Angular distance θ is the angle between radio horizon rays in the great-circle plane containing the antennas, and d is the distance between antennas.

A semiempirical estimate of the path antenna gain, G_p (in decibels), is provided by

$$G_p = G_t + G_r - 0.07 \exp [0.055(G_t + G_r)]$$

for values of G_t and G_r each less than 50 dB.

Fig. 35 shows $V(d_e)$, an adjustment for the indicated types of climate.

This division is, of course, rather crude, and local geographical conditions may require serious modifications. A brief description of these climates is given in Annex 1 of CCIR Report 238-2, Geneva, 1974.

Fast and slow fading is experienced on tropospheric scatter paths. Fast fading is due to multipath transmission, is in general Rayleigh distributed, and can be considerably reduced by diversity, an antenna spacing

of 60 wavelengths usually being adequate. Slow fading, with periods of hours or days, is caused by changes in the gradient of the refractive index of the atmosphere along the transmission path and is little affected by diversity.

The plane-wave gains of large antennas are not fully realized on tropospheric scatter paths. The power on such a path is received, not from a single point source, but from a volume in the atmosphere that subtends a solid angle at the receiving antenna. If the antenna beam angles are such as to limit the available scattering volume, then the received power will be correspondingly limited, and the antennas are said to suffer an antenna-to-medium coupling loss. The resulting median loss of received power is likely to be about 5 decibels for two 40-decibel-gain plane-wave antennas, and 17 decibels for two 50-decibel-gain antennas. The extent to which the path antenna gain is a function of the scatter angle, θ, or the height of the scatter volume has not yet been established.

Multipath transmission limits the communication bandwidth that can be used on a single carrier; however, useful bandwidths of several megahertz have been shown to be available on some 200-mile scatter paths. Narrow-beam antennas and diversity reduce the effects of multipath transmission.

EARTH-SPACE COMMUNICATION

Communication between earth and outer space (see Chapter 27, Satellite and Space Communications) must pass through the atmosphere of the earth, so that the optimum frequencies for this service are those that pass through the atmosphere with minimum attenuation. A range of frequency little attenuated by the atmosphere is known as a window; one such window occurs between the critical frequency of the ionosphere and the frequency absorbed by rainfall and oxygen. This frequency range extends from about 10 to 10 000 megahertz. Another window exists in the optical and infrared region of 10^6 to 10^9 megahertz. Fig. 36 shows the general frequency limits for earth-space communication.

34 Radio Noise and Interference

Revised by
George W. Swenson, Jr. and A. Richard Thompson

Radio noise and interference limit the performance of all communications systems by restricting the operating range, generating errors in messages, and in extreme cases preventing the successful operation of receivers. At locations where man-made noise is low, natural noise sources determine receiver performance. When man-made noise encroaches upon receiving sites, the performance of receiving equipment is degraded below design levels.

When noise from sources external to a receiver is involved, the gain and orientation of the antenna must be considered. For narrow-band receivers, noise is usually flat in amplitude across the bandwidth of a receiver. For such cases, noise power affecting receiver performance is proportional to the bandwidth. For wideband receivers, the noise may not be flat across the receiver bandwidth, and the determination of effective noise power requires further consideration.

Noise level can be expressed in terms of voltage or power at the terminals of a receiver, the strength of an electromagnetic field at an antenna location, or thermal noise power at a temperature referenced to 290 kelvins. Noise that is flat in amplitude across the bandwidth of a receiver is often expressed in terms of an effective antenna noise factor, f_a, which is defined as

$$f_a = P_n/kT_0B = T_a/T_0 \qquad \text{(Eq. 1)}$$

where,

P_n = noise power in watts from an equivalent lossless antenna,
k = Boltzmann's constant,
T_0 = reference temperature (290 kelvins),
B = receiver noise bandwidth in hertz,
T_a = antenna noise temperature in the presence of external noise.

NATURAL NOISE

Natural noise consists of thermal noise, atmospheric noise, and cosmic noise. These noise sources usually

determine the minimum detectable signal level of a receiver operated in an environment free of man-made noise sources.

Thermal Noise

For many years, thermal noise in the first stage of a receiver was usually the main factor limiting the sensitivity of radar and microwave receivers. Recent advances in low-noise amplifier performance have reduced thermal noise of microwave amplifiers to very low levels, and thermal radiation from nearby objects, ground, and the sky are now major factors that must be considered in choosing sites for satellite receivers and radars. Fig. 1 shows noise temperatures for various devices (as of 1984) and natural limits at microwave frequencies. Receivers operated at frequencies below about 20 MHz usually encounter noise from other sources that is considerably above the thermal noise of conventional amplifiers; hence, low-noise amplifier performance is not usually a factor in the design of low-frequency receivers. An exception occurs for VLF receivers operating in the Arctic and Antarctic, where atmospheric noise is extremely low and cosmic noise is screened by the ionosphere.

Atmospheric Noise

Lightning from thunderstorms produces bursts of impulsive noise. At low frequencies, these bursts are propagated to distant receivers by normal ionospheric modes. The noise is dependent on the weather, time of day, season, location of the receiver with respect to storm areas, and ionospheric propagation conditions. Atmospheric noise generally decreases with increasing latitude and increases in high-latitude equatorial areas. Atmospheric noise sources are particularly active during the rainy season in the Caribbean, the East Indies, equatorial Africa, northern India, and the Far East. An excellent summary of worldwide atmospheric noise levels is contained in CCIR Report 322.* An example of a CCIR developed map of atmospheric noise levels in the summer during daytime hours is shown in Fig. 2.

* CCIR Report 322, Vol. VI, 10th Plenary Assembly, Geneva; 1963.

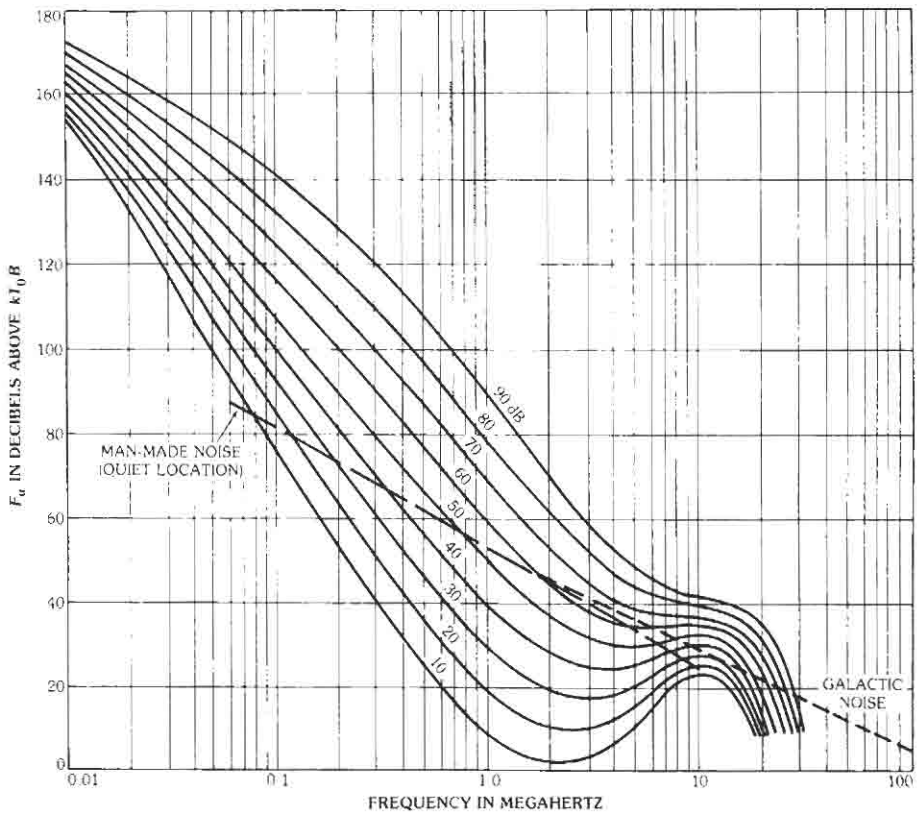

Fig. 3. Variation of radio noise with frequency, for data given in Fig. 2 legend. (*From CCIR Report 322, 10th Plenary Assembly, Geneva; 1963.*)

The map shows the median noise level in decibels above kTB at a frequency of 1 MHz as received on a short vertical rod antenna installed over ground (k is Boltzmann's constant, T is 290 kelvins, and B is the receiver bandwidth in hertz). This parameter is related to noise field strength by

$$E_n = F_a + 20 \log_{10} f_{\text{MHz}} - 65.5 \quad \text{(Eq. 2)}$$

where,

E_n = rms noise field strength in a 1-kHz bandwidth in decibels above 1 microvolt/meter,
F_a = noise level in decibels above kTB,
f_{MHz} = frequency in megahertz.

The level of atmospheric noise at a receiver site decreases with increasing frequency. Fig. 3 shows the frequency dependence of atmospheric noise for the data shown in Fig. 2. These levels represent the median amplitude of the noise bursts. Individual bursts can vary in amplitude from insignificant to very strong. An example of an individual atmospheric burst propagated at HF frequencies over a one-hop ionospheric mode is shown in Fig. 4. The data were obtained with a rapidly scanning receiver and a time memory display. The noise burst originated from a lightning event that was accompanied by numerous discharges lasting about one second. The wide-bandwidth impulsive energy produced by the lightning discharge was modified by the ionospheric propagation path so that only a portion of the discharge was seen at the distant receiver (2000 km from the storm to the receiver). The maximum propagating frequency and the minimum propagating frequency of the ionosphere are shown.

Cosmic Noise

The sources of cosmic noise are external to the atmosphere of the earth; primary sources are the sun, the Milky Way galaxy, and other discrete cosmic sources. Radio astronomy activities have identified a very large number of sources of cosmic noise. Radio noise from cosmic sources must penetrate the atmosphere of the earth to reach antennas located on the surface of the earth. Ionospheric absorption limits the reception of cosmic noise at frequencies below about 20 MHz, while molecular absorption processes limit the

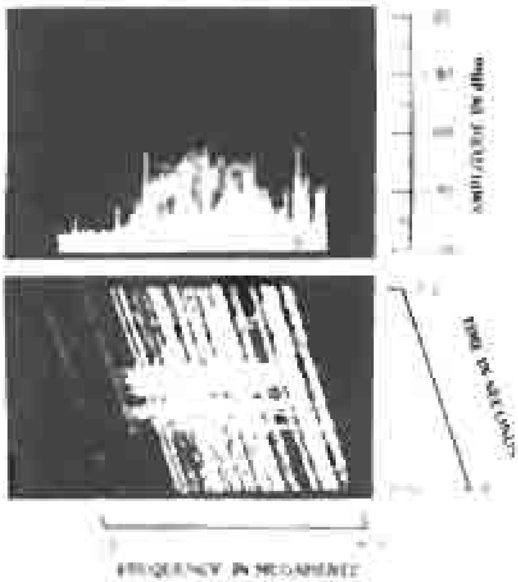

Fig. 4. Atmospheric noise burst.

reception of extraterrestrial noise at frequencies above about 10 GHz. Satellite-borne receivers above about 1000 km do not encounter these limitations.

Recent advances in low-noise receiver design (see Fig. 1) and the widespread deployment of satellites and space probes have increased the importance of cosmic noise. Satellite communications systems, the broadcasting of television from satellites, and the need for data links between the space vehicles and the earth have increased the number of skyward-pointed antennas equipped with sensitive receivers that are capable of receiving cosmic noise. Cosmic noise often limits the performance of such systems.

Figs. 8 and 9 of Chapter 32 show detailed radio-sky maps of the celestial sphere for the 136-megahertz and 400-megahertz space research satellite frequency bands.

Fig. 5 shows the level of galactic noise in decibels relative to a noise temperature of 290 K when receiving on a half-wave dipole. The noise levels shown in this figure assume no atmospheric absorption and refer to the following sources of cosmic noise.

Galactic Plane: Galactic noise from the galactic plane in the direction of the center of the galaxy. The noise levels from other parts of the galactic plane can be as much as 12 to 15 decibels below the levels given in Fig. 5.

Quiet Sun: Noise from the "quiet" sun, that is, solar noise at times when there is little or no sunspot activity.

Disturbed Sun: Noise from the "disturbed" sun. The term "disturbed" refers to times of sunspot and solar flare activity.

Cassiopeia A: Noise from a high-intensity discrete source of cosmic noise known as Cassiopeia A. This is one of thousands of known discrete sources. Cassiopeia A subtends a solid angle at the surface of the earth of only about 5 arc minutes.

The levels of cosmic noise received by a highly directive antenna with main lobe pointed along the galactic plane can be obtained from equations given by Kraus[7] for the antenna-noise temperature (T_A) at the output terminals of an ideal, loss-free, antenna as

$$T_A = \frac{\int_0^{\theta = 90^\circ + \theta_0} \int_0^{\phi = 2\pi} T(\theta,\phi) G(\theta,\phi) \sin\theta \, d\theta \, d\phi}{\int_0^{\theta = 90^\circ + \theta_0} \int_0^{\phi = 2\pi} G(\theta,\phi) \sin\theta \, d\theta \, d\phi} \text{ K}$$

where,

θ = 0° at zenith,
ϕ = 360° azimuth angle,
$T(\theta,\phi)$ = brightness-noise temperature distribution from radio-sky map, kelvins,
$G(\theta,\phi)$ = antenna radiation pattern gain distribution, assumed symmetrical,
θ_0 = minimum elevation angle between antenna main-lobe axis and the horizon, degrees.

However, for a practical antenna, Taylor and Stocklin[8] give a simplified approximation for T_A including contributions from the main lobe, side lobes, and back lobe as

$$T_A = (0.82\,\bar{T}_{ML} + 0.15\,\bar{T}_{SL} + T_E) \text{ K, for a solid-angle beam, } \theta_{HPBW} = \phi_{HPBW} \approx 25^\circ$$

where,

$\bar{T}_{ML}$ = mean value of sky-brightness temperature within main-lobe HPBW in kelvins,
$\bar{T}_{SL}$ = mean value of sky-brightness temperature within antenna side lobes, in kelvins,
$T_E = T_e$ = 290 K, effective noise temperature of earth.

For example, a 136-megahertz, phased-array, directive antenna with main-lobe HPBW equal to 12° pointed near Cassiopeia A, has a value of T_A equal to approximately 870 K for $\bar{T}_{ML}$ equal to 950 K and $\bar{T}_{SL}$ equal to 400 K obtained from Fig. 8 of Chapter 32.

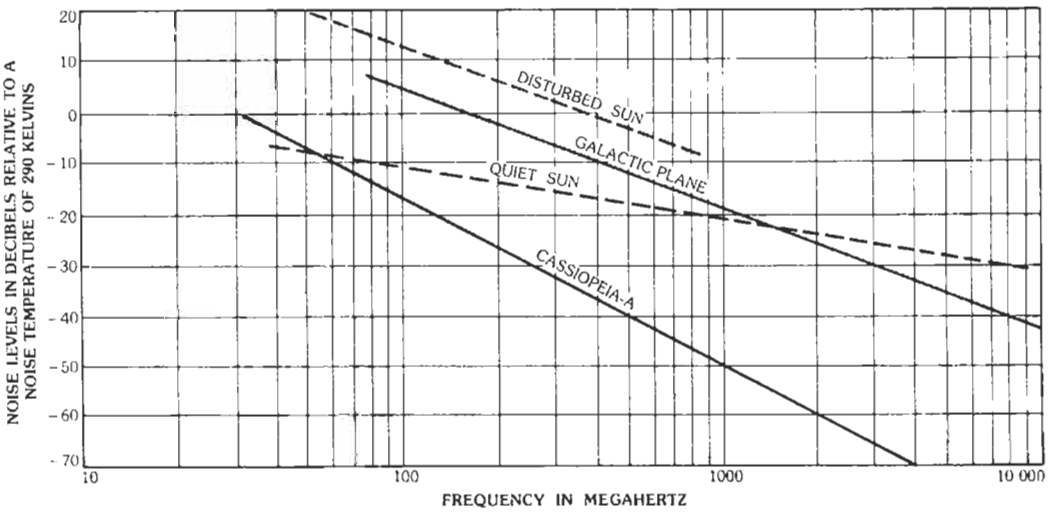

Fig. 5. Cosmic noise levels for a half-wave-dipole receiving antenna.

MAN-MADE RADIO NOISE

Man-made radio noise frequently limits the performance of receivers. This is particularly true for land-mobile communications, television reception, high-frequency radio, and other radio services below UHF. Man-made radio noise originates from a wide variety of sources; some examples are noise from ignition systems of gasoline engines, corona noise from high-voltage power lines, gap noise from utility distribution lines, noise from radio-frequency stabilized welders, and noise produced by many other electrical devices found in homes and businesses. Fig. 6 shows the frequency range that is affected by several common types of man-made noise. Sources that affect the performance of low-frequency receivers generally do not produce harmful noise at higher frequencies. The reverse is also true in that sources that produce harmful noise at VHF and UHF generally do not produce harmful noise at low frequencies. Since noise amplitude decreases with distance from the source, the magnitude of noise at a receiver site is dependent on spacial parameters, temporal variations of the noise source, directional properties of the noise-radiating elements, and the directional properties of the receiving antenna. Sometimes harmful noise is inductively coupled or conducted from its source into a receiver.

The average levels of man-made noise are higher in urban and suburban areas than in rural areas because of the larger number of sources in areas of higher population. Fig. 7 shows median values of average noise power in urban and suburban areas. In remote quiet locations, man-made noise can be extremely low, and background noise in most parts of the radio spectrum may be determined by natural noise (atmospheric noise below about 20 MHz and galactic noise above about 20 MHz). In general, man-made noise levels decrease with increasing frequency, although a specific source may not comply with this general rule.

Near-Zone and Far-Zone Noise Sources

Most cases of harmful man-made noise affecting a receiver involve only one or two sources. A general background level of man-made noise from numerous sources is seldom encountered. Frequently, the sources of harmful noise are relatively close to a receiver. The propagation from the noise source to the receiver sometimes involves the near-zone field rather than the far-zone field of the source. For such cases, both the electric- and magnetic-field components of the noise source must be measured in order to define fully the ability of noise to affect receivers. Table 1 provides a general set of rules for the measurement of noise. When the path from the noise source to the receiver is greater than one wavelength, the far-field approximation ap-

TABLE 1. GENERAL RULES FOR MEASUREMENT OF NOISE

Distance Source to Sensor	Zone	Measure
Greater than λ	Distant	Either E or B
Less than $\lambda/6$	Inductive	Must measure both E and B
Between $\lambda/6$ and λ	Mixed	Recommend E and B

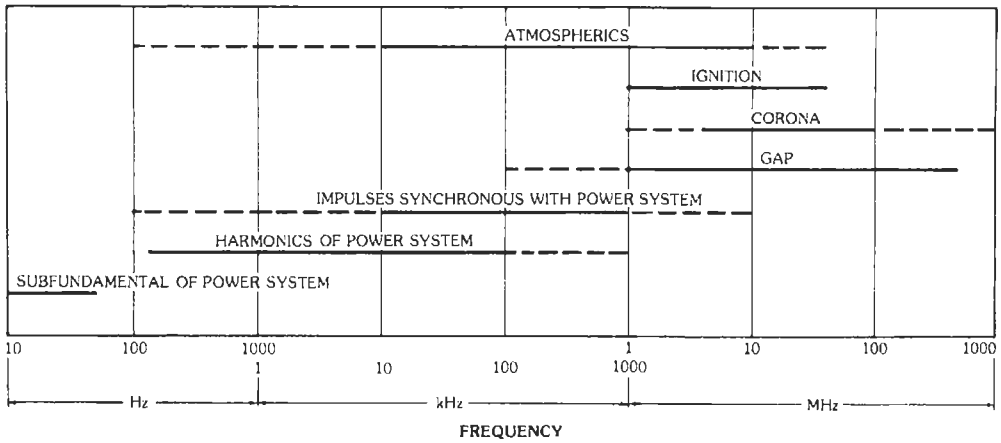

Fig. 6. Frequency range affected by man-made noise.

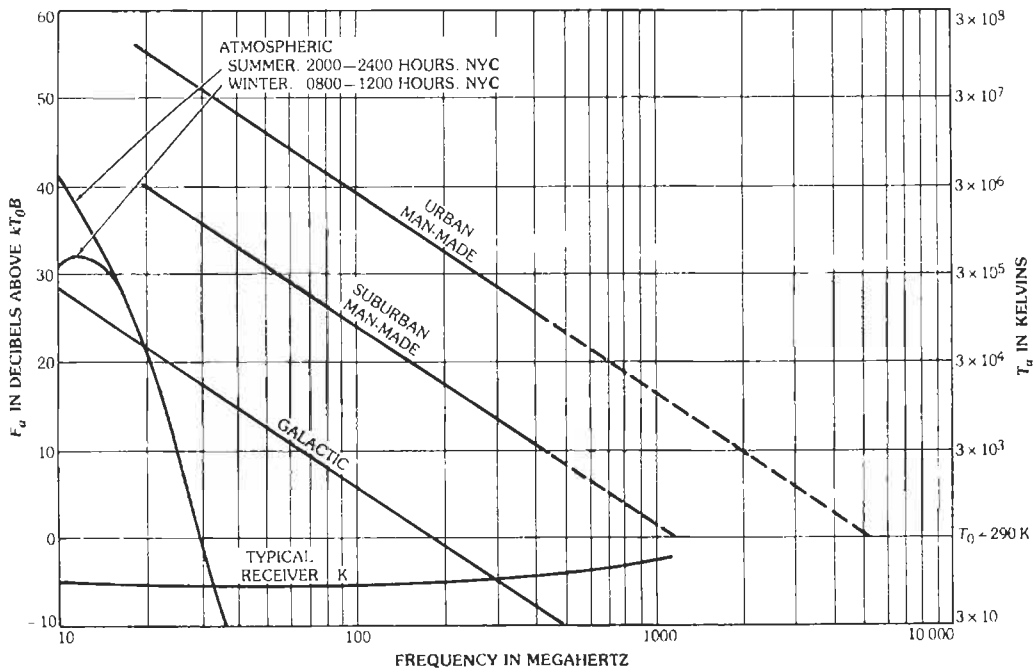

Fig. 7. Median values of average noise power expected from various sources (omnidirectional antenna near surface).

plies, and the noise can be measured with either an electric-field or a magnetic-field antenna. The electric- and magnetic-field strengths can be related by the free-space impedance of $120\pi = 377$ ohms. This applies to measurements of man-made noise at frequencies above about 30 MHz. At lower frequencies, the noise source may be electrically close to the receiving antenna. At distances from the source to the affected receiver of one sixth of a wavelength or less, i.e., $< \lambda/2\pi$, the receiver is in the near field of the source. At these short distances, the ratio of E to H is no longer equal to 377 ohms, and both the electric and magnetic fields must be measured in order to define the impact of a noise source on a receiver.

Power Line Noise

The temporal and spectral properties of man-made noise vary considerably from one type of source to another. Noise associated with a power line usually

contains bursts of noise at intervals determined by the fundamental frequency of the power line. The temporal properties of gap noise (formed by the minute electrical breakdown between two pieces of metallic hardware exposed to a strong electric field) are shown in Fig. 8. Multiple bursts of noise occur each time the power-line voltage reaches a maximum. Individual impulses within a burst are spaced very close together (less than 1 ms apart), while the bursts are spaced 8.33 ms apart for a power line operating at 60 Hz. Individual bursts have the same amplitude. A careful inspection of the waveform in Fig. 8 shows that two gap-noise sources are present in the view.

PRECIPITATION STATIC

Precipitation static is produced by rain, hail, snow, or dust storms in the vicinity of the receiving antenna and is important chiefly at frequencies below 10 MHz. This form of interference can be reduced by eliminating sharp points from the antenna and its surroundings, and also by providing means for dissipating the charges that build up on an antenna and on its surroundings during electrical storms.

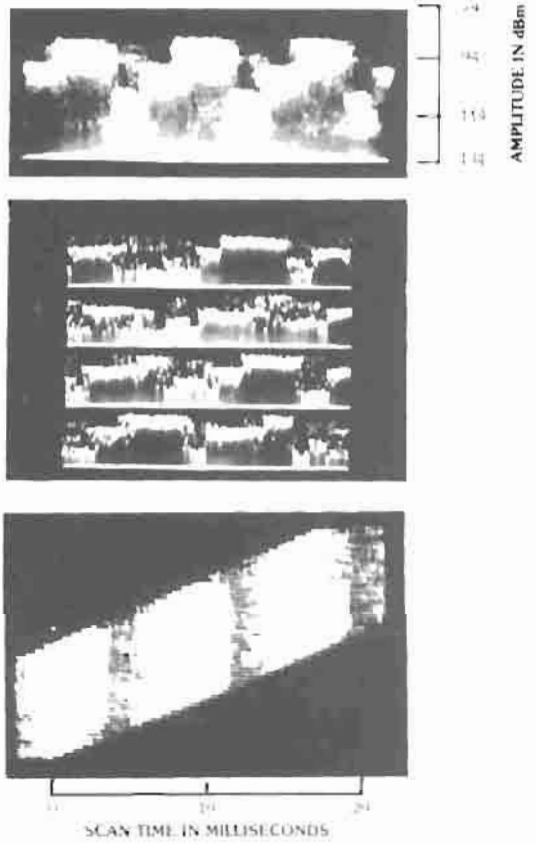

Fig. 8. Temporal structure of gap noise from 138-kV transmission line.

THERMAL NOISE CALCULATIONS

Thermal noise is caused by the thermal agitation of electrons in resistances. Let R be the resistive component in ohms of an impedance Z. The mean-square value of thermal-noise voltage is given by

$$E^2 = 4RkT \cdot \Delta f$$

where,

k is Boltzmann's constant (1.38×10^{-23} joules/kelvin),
T is the absolute temperature in kelvins,
Δf is the bandwidth in hertz,
E is the root-mean-square noise voltage.

The equation given above assumes that thermal noise has a uniform distribution of power through the bandwidth Δf.

In case two impedances Z_1 and Z_2 with resistive components R_1 and R_2 are in series at the same temperature, the square of the resulting root-mean-square voltage is the sum of the squares of the root-mean-square noise voltages generated in Z_1 and Z_2:

$$E^2 = E_1^2 + E_2^2 = 4(R_1 + R_2)kT \cdot \Delta f$$

In case the same impedances are in parallel at the same temperature, the resulting impedance Z is calculated as is usually done for alternating-current circuits, and the resistive component R of Z is then determined. The root-mean-square noise voltage is the same as it would be for a pure resistance R.

It is customary in temperate climates to assign to T a value such that $1.38T = 400$, corresponding to about 17 degrees Celsius or 63 degrees Fahrenheit. Then $E^2 = 1.6 \times 10^{-20} R \cdot \Delta f$.

NOISE MEASUREMENTS

Measurement for Broadcast Receivers

For standard broadcast receivers the noise properties are determined by means of the equivalent noise sideband input (ensi). The receiver is connected as shown in Fig. 9. Components of the standard dummy antenna are $C_1 = 200$ picofarads, $C_2 = 400$ picofarads, $L = 20$ microhenrys, and $R = 400$ ohms.

The equivalent noise sideband input is

$$(\text{ensi}) = mE_s(P'_n/P'_s)^{1/2}$$

where,

E_s = root-mean-square unmodulated carrier-input voltage,
m = degree of modulation of signal carrier at 400 hertz,

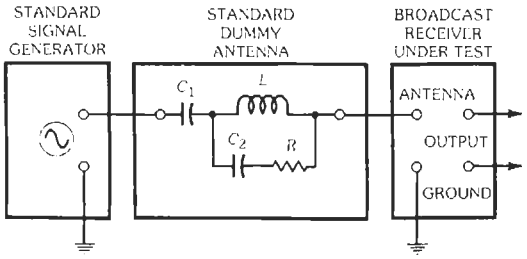

Fig. 9. Measurement of equivalent noise sideband input of a broadcast receiver.

P'_s = root-mean-square signal-power output when signal is applied.
P'_n = root-mean-square noise-power output when signal input is reduced to zero.

It is assumed that no appreciable noise is transferred from the signal generator to the receiver, and that m is small enough for the receiver to operate without distortion.

Noise Factor of a Receiver

A more precise evaluation of the quality of a receiver as far as noise is concerned is obtained by means of its noise factor.

It should be clearly realized that the noise factor evaluates only the linear part of the receiver, i.e., up to the demodulator.

The equipment used for measuring noise factor is shown in Fig. 10. The incoming signal (applied to the receiver) is replaced by an unmodulated signal generator with R_0 = internal resistive component, E_i = root-mean-square open-circuit carrier voltage, and E_n = root-mean-square open-circuit noise voltage produced in signal generator. Then

$$E_n^2 = 4kT_0R_0\Delta f'$$

where,

k is Boltzmann's constant (1.38×10^{-23} J/K),
T_0 is the temperature in kelvins,

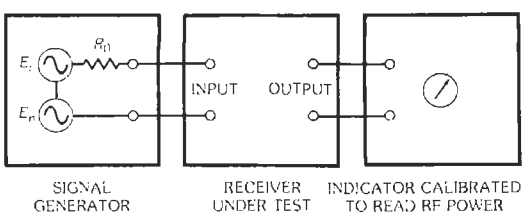

Fig. 10. Measurement of the noise factor of a receiver. The receiver is considered as a 4-terminal network. Output refers to last intermediate-frequency stage.

$\Delta f'$ is the effective bandwidth of the receiver (determined as below).

If the receiver does not include any other source of noise, the ratio E_i^2/E_n^2 is equal to the power carrier/noise ratio measured by the indicator:

$$E_i^2/E_n^2 = (E_i^2/4R_0)/kT_0\Delta f' = P_i/N_i$$

The quantities $E_i^2/4R_0$ and $kT_0\Delta f'$ are called the *available* carrier and noise powers, respectively.

The output carrier/noise power ratio measured in a resistance R may be considered as the ratio of an available carrier-output power P_0 to an available noise-output power N_0.

The noise factor, F, of the receiver is defined by

$$P_0/N_0 = F^{-1}(P_i/N_i)$$

$$F = (N_0/N_i)(P_0/P_i)^{-1}$$

$$= E_{i:1}^2/4kT_0R_0\Delta f' = P_{i:1}/kT_0\Delta f'$$

where,

P_0/P_i = available gain G of the receiver,
$P_{i:1}$ = available power from the generator required to produce a carrier-to-noise ratio of one at the receiver output.

Noise figure is the noise factor expressed in decibels:

$$F_{dB} = 10 \log_{10} F$$

Effective bandwidth $\Delta f''$ of the receiver is

$$\Delta f' = G^{-1} \int G_f df$$

where G_f is the differential available gain. Generally, $\Delta f'$ is approximated to the bandwidth of the receiver between those points of the response showing a 3-dB attenuation with respect to the center frequency.

Measurement of Noise Figure With a Thermal Noise Source

For the case where the spurious responses of the receiver are negligible, receiver noise figure can be conveniently measured by using the noise output of a thermal noise source having an equivalent generator resistance equal to that specified for use with the receiver.

With the noise source off, but still possessing the correct output resistance, receiver gain is adjusted for a convenient amount of noise power output; then with the noise source on, and still possessing the correct output resistance, the noise power output is increased by a

convenient power ratio (N_2/N_1). The measured noise figure is then given by

$$NF = (excess)_{dB} - 10 \log[(N_2/N_1) - 1]$$

For a thermal diode operating in the temperature limited emission mode

$$(excess)_{dB} = 10 \log(20R_dI_d)$$

where,

R_d is the noise source output resistance,
I_d is the diode current in amperes.

When the receiver has appreciable spurious responses, the correction factor that must be used with the above simple equation is a complex function of the spurious response ratios, and of the percentage of total internal receiver noise produced by the circuits preceding the mixer causing the spurious responses. For the simple case of no preselection and a diode mixer having negligible excess noise, 3 dB must be added to the measured noise figure to obtain the true noise figure.

A thermal noise source designed for a given generator impedance R_1 can be used to measure the noise figure of a receiver designed for a higher generator R_2 by adding a resistor ($R_2 - R_1$) between noise source and receiver input and using

$$NF = NF_{read} - 10 \log (R_2/R_1)$$

Conversion of receiver noise temperature to noise factor:

$$F = 1 + (T_R/T_0)$$

where,

T_R = receiver noise temperature in kelvins,
T_0 = 290 K,
F = noise factor of receiver (power ratio).

Conversely,

$$T_R = (F - 1)T_0$$

Determination of effective noise temperature of receiving system (i.e., antenna, transmission line, and receiver):

$$T_E = T_A + (LF - 1)T_0$$

where,

T_E = effective noise temperature of receiving system,
T_A = antenna noise temperature,
L = transmission line loss (power ratio),
F = noise factor of receiver (power ratio),
T_0 = 290 K.

Determination of the effective input noise power of the receiving system:

$$N_i = kBT_E$$

where,

N_i = effective input noise power of the receiving system,
k = Boltzmann's constant (1.38×10^{-23} joules/kelvin),
B = bandwidth in hertz,
T_E = effective noise temperature in Kelvins.

$$dBm_i = -198.6 + 10 \log B + 10 \log T_E$$

Calculation of Noise Figure

The active device can be defined for noise-figure calculations as in Fig. 11.

The value of R_{eq} can be obtained experimentally by measuring, with a "zero impedance" generator, the equivalent microvolts of noise V_{sc}, in a bandwidth B, in series with the input terminals, with an almost-short-circuit on the output terminals. Then R_{eq} is given by

$$R_{eq} = |V_{sc}|^2/1.64 \times 10^{-20}\langle BW\rangle \quad \text{(Eq. 3)}$$

The value of R_e is obtained straightforwardly by input impedance measurements with a short-circuit on the output terminals.

The value of ρ can be obtained experimentally by approximately open-circuiting the input terminals at the frequency of interest with a tuned circuit of parallel resonant resistance R_0, and measuring the total equivalent microvolts of noise produced across the input terminals, with an almost-short-circuit on the output terminals. Then, assuming negligible correlation

$$\rho = [1 + (R_e/R_0)]^2\{[|V_\infty|^2/(1.64 \times 10^{-20}\langle BW\rangle R_e)| - (R_{eq}/R_e)\} - (R_e/R_0) \quad \text{(Eq. 4)}$$

When the above characterized device is used with an input transforming circuit of parallel resonant resistance R_r, the resulting noise factor can be calculated as follows: First calculate R_1 and β from

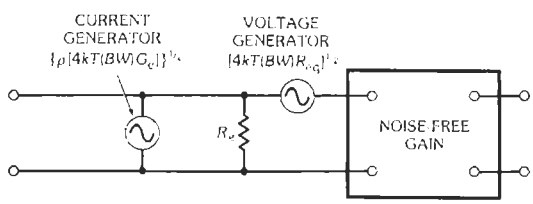

Fig. 11. Calculation of the noise figure of a receiver.

$$R_1^{-1} = R_r^{-1} + R_e^{-1} \quad \text{(Eq. 5)}$$

$$\beta = [1 + \rho(R_r/R_e)]/[1 + (R_r/R_e)] \quad \text{(Eq. 6)}$$

In terms of the above quantities and the transformed generator resistance R_s seen by the input terminals of the active device, the resulting noise factor is given by

$$F = 1 + 2(R_{eq}/R_1) + (R_{eq}/R_s) + (R_s/R_1) \times [\beta + (R_{eq}/R_1)] \quad \text{(Eq. 7)}$$

It should be noted that to minimize noise figure the input circuit should always be tuned so as to null any part of the noise due to βR_1, which is correlated with the noise due to R_{eq}. Equation 7 can be applied to this best noise figure tuning case if ρ is obtained, by some method, from only the uncorrelated part of the βR_1 noise.

This resulting noise figure is minimized when the transformed generator resistance has the value

$$R_{s\,opt} = \{(R_1 R_{eq}/\beta)/[1 + (R_{eq}/\beta R_1)]\}^{1/2} \quad \text{(Eq. 8)}$$

and with this optimum source resistance

$$F_{opt} = 1 + 2\beta(R_{eq}/R_1)^{1/2} \times \{[1 + (R_{eq}/R_1)]^{1/2} + (R_{eq}/R_1)^{1/2}\} \quad \text{(Eq. 9)}$$

Noise Factor of Cascaded Networks

The overall noise factor of two networks, a and b, in cascade (Fig. 12) is

$$F_{ab} = F_a + [(F_b - 1)/G_a]$$

provided $\Delta f_b' \leq \Delta f_a'$.

The additional noise due to external sources influencing real antennas (such as galactic noise) may be accounted for by an apparent antenna temperature, bringing the available noise-power input to $kT_a\Delta f'$ instead of $N_i = kT_0\Delta f'$ (the physical antenna resistance at temperature T_0 is generally negligible in high-frequency systems). The internal noise sources contribute $(F - 1)N_i$ as before, so that the new noise factor is given by

$$F'N_i = (F - 1)N_i + kT_0\Delta f'$$

$$F' = (F - 1) + (T_a/T_0)$$

The average temperature of the antenna for a 6-MHz equipment is found to be 3000 kelvins, approximately. The contribution of external sources is thus of the order of 10, compared with a value of $(F - 1)$ equal to 1 or 2, and becomes the limiting factor of reception. At 3000 MHz, however, values of T_a may fall below T_0.

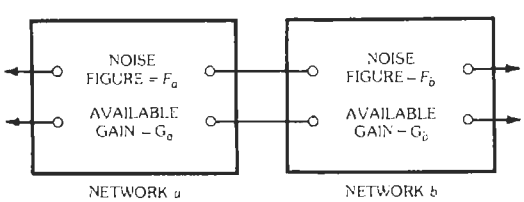

Fig. 12. Overall noise figure F_{ab} of two networks, a and b, in cascade.

INTERFERENCE FROM SIGNALS OF OTHER SERVICES

Although the usage of the radio spectrum is subject to the detailed system of regulations described in Chapter 1, there are many circumstances in which a service operating in compliance with the radio regulations can cause interference to another service. This most often results from sharing of an allocated band by more than one service. For example, the Fixed service (communications between fixed stations on the Earth) often shares a band with the Mobile service (communications between vehicles, sometimes including a fixed station). These two services also share some bands with a satellite service. Even if the systems have been designed to avoid interference most of the time, it is difficult to prevent interference when, for example, a nongeostationary satellite moving close to the horizon passes through the horizontally pointing beam of an antenna of the Fixed service, or when a mobile station is close to such an antenna. Interference can also be caused by transmitters operating in other bands, if out-of-band transmissions such as harmonics are radiated. The extensive out-of-band radiation that results from unfiltered transmitters using the direct sequence form of spread-spectrum modulation can cause harmful interference to very sensitive systems such as those used in radio astronomy, even though such side lobes are low enough to go undetected by most other services.

For any particular situation, it is possible to determine by calculation whether harmful interference will occur. First it is necessary to know the EIRP (effective isotropically radiated power) of the particular transmitter in the direction of the victim receiver. If the direction does not fall within the main beam of the transmitter, one may need to know the radiation pattern of the antenna. In the case of large parabolic antennas, the reference radiation pattern recommended by the CCIR* may be useful. This model applies to large paraboloids of diameter greater than 100 wavelengths in the frequency range 2 to 30 GHz. The envelope of the side-lobe pattern corresponds to a gain, in dB relative to an isotropic radiator, of $32 - 25 \log \phi$, where ϕ is the direction in degrees measured from the axis of the main beam. This relationship applies for values of ϕ from 1°

* Reference 1.

to 47.9°. For greater values of ϕ, the gain is -10 dBi. For other types of antennas, if specific details of the power pattern are not available, it may be necessary to use a "worst-case" estimate based on general information about the type of antenna. After the transmitted EIRP has been estimated, the next step is to find the power flux density (PFD) at the receiver location. This requires determination of the propagation loss, for which methods are described in Chapter 33. For free-space propagation the situation is simple, but propagation between two widely separated points on the surface of the Earth may involve diffraction around a spherical model earth, diffraction over one or more knife-edge ridges, or tropospheric scatter. Curves and formulae for such cases are given in Chapter 33. From the estimated PFD, the power received in the antenna of the victim receiver can be calculated if the gain of the antenna in the direction of the transmitter is known. As in the case of the transmitting antenna, this may involve an estimation of the side-lobe gain. Finally, it is necessary to compare the received power with the power level that corresponds to the threshold of harmful interference at the input of the particular receiving system involved. This harmful threshold can be calculated from the theory of operation of the receiver, or determined from laboratory measurements on the receiver. The harmful threshold is a measure of the vulnerability of a system to interference. The most vulnerable service is radio astronomy (see for example reference 2) followed by activities such as Earth exploration by passive sensing and reception of information from spacecraft at deep-space ranges. At the other end of the vulnerability scale, systems using spread spectrum techniques or digital modulation with error-correcting codes can function in the presence of interfering signals as much as 100 dB greater than those harmful to radio astronomy.

The extensive literature of the CCIR,* in the form of Reports and Recommendations of the various CCIR study groups, contains many studies of interservice interference, sharing of frequency bands, and related topics. This material provides technical input to the conferences at which the international radio regulations are revised, and is a highly authoritative source of reference.

To illustrate the consequences of overlaying an actively transmitting service on a sensitive passive service, assume a typical spread-spectrum personal communication system, radiating 0.1 watt isotropically over a 10-megahertz band centered at about 2.0 gigahertz. It would produce an interfering power density of the order of 3×10^{-19} watt/hertz in the far-out side-lobes of a receiving antenna one kilometer away. This would represent an increase in the system temperature of the service receiving interference of 20 000 kelvins. As a result, the typical performance of a modern communication system would be degraded by a factor of 200. Such a penalty would reduce the maximum distance for communication with a spacecraft by a factor of 14. It would reduce the volume of the Universe from which an astronomical radio telescope could receive useful data by a factor of 200. Terrestrial services would suffer the same type of degradation from overlaid spread-spectrum services. Further, in addition to this interference to the overlaid services, the "direct-sequence" type of spread-spectrum system typically emits interference well outside the band it utilizes for communication unless well designed bandpass filters are employed at the output of the transmitter.

35 Broadcasting, Cable Television, and Recording System Standards

F. M. Remley, J. F. X. Browne, and S. N. Baron

In this age of rapid technical change, it is no longer accurate to assume that communications services directed to the public at large are "broadcasting" in the traditional sense. More and more of the general public is served by cable television and by transmissions from satellites. In addition, the video cassette recorder is an integral part of millions of home entertainment systems, and in this case the signals reaching the viewer are distributed by lengths of magnetic tape. In consideration of these facts, this chapter will not only describe conventional over-the-air broadcasting of radio and television programs, and cable and satellite television, but also will focus on the elements that enter into program recording for other media that serve the public.

The various transmission systems, and the signals that they convey to the public, must meet certain technical specifications. Much of this chapter will consist of summaries and lists of such specifications. Sources for current versions of relevant specifications are also identified.

In the United States, broadcasting is regulated by the Federal Communications Commission (FCC), which assigns frequencies and establishes technical standards. Three general classes of broadcast stations have traditionally been identified. These are standard broadcast stations (amplitude modulation in the band 535–1605 kHz), FM broadcast stations (frequency modulation in the band 88–108 MHz), and television broadcast stations (operating in the bands 54–72, 76–88, 174–216 and 470–806 MHz with vestigial-sideband amplitude modulation of the visual carrier and frequency modulation of the aural carrier). Technical specifications for these broadcast services are summarized in this chapter. Cable television systems also have channel assignment and other specifications; they are also summarized in this chapter.

Certain technical aspects of international broadcasting are described. International broadcasting ("short wave") uses frequencies between 5950 and 26 100 kHz in accordance with international agreements.

Other technical information related to broadcasting is covered under auxiliary services, intercity relay transmission, and terminal facilities.

This chapter provides a comprehensive reference for standards applicable to audio recording and video recording. North American standards are listed, and reference is made to comparable international standards. Lists of standards are provided.

The rapidly evolving field of advanced television systems using digital technologies is described in separate sections. Both national and international specifications are listed. A listing of relevant standards promulgated by CCIR, ISO, and IEC concludes the chapter.

TABLE 1. CLASSIFICATION OF STANDARD-BROADCAST STATIONS

Class of Channel	Class of Station	Permissible Power (kW)	Signal-Intensity Contour of Area Protected from Objectionable Interference (microvolts/meter)		Permissible Interfering Signal on Same Channel (microvolts/meter)	
			Day[1]	Night	Day[1]	Night[3]
Clear	I-A	50	SC = 100 AC = 500	SC = 500[2] AC = 500[1]	5	25
	I-B	10–50	SC = 100 AC = 500	SC = 500[2] AC = 500[1]	5	25
	II-A	0.25–50 day 10–50 night	500	500[1]	25	25
	(II-B / II-D)	0.25–50	500	2500[1]	25	125
	(II-B / II-D)[4]	0.25–1	500	10 000	25	500
Regional	III-A	1–5	500	2500[1]	25	125
	III-B	0.5–5 day 0.5–1 night	500	4000[1]	25	200
Local	IV	0.25–1 day 0.25 night	500	not prescribed	25	not prescribed

Notes:
SC—same channel, AC—adjacent channel.
[1]Ground wave.
[2]50% sky wave.
[3]10% sky wave.
[4]Applies to those Class II-B and II-D stations described in Part 73 of FCC Rules and Regulations.

BROADCAST AND CABLE TRANSMISSION SYSTEMS

Standard Broadcasting*

Standard-broadcast stations are licensed for operation on channels spaced by 10 kHz† and occupy the band from 535 to 1700 kHz. The major station classifications prior to 1992 are shown in Table 1.

Field-Strength Requirements—Field strength requirements have been established by the FCC to provide specified minimum signal levels in various types of locations. These vary somewhat with the class of station but more specifically with the anticipated man-made noise levels in a particular area. As of 1991 these levels generally are as follows. (As noted above, the FCC Rules were undergoing major changes in service and interference criteria in 1992, and a current version of the FCC Rules and Regulations should be consulted.)

Primary Service:

City business, factory areas—10 to 50 millivolts/meter, ground wave.

City residential areas—2 to 10 millivolts/meter, ground wave.

Rural, all areas during winter or northern areas during summer—0.1 to 0.5 millivolt/meter, ground wave.

Rural, southern areas during summer—0.25 to 1.0 millivolt/meter, ground wave.

Secondary Service: All areas having sky-wave field strength equal to or greater than 500 microvolts/meter for 50% or more of the time.

For a station employing a directional antenna, all determinations of service and interference are based on the inverse field of a "standard pattern" for that station. When applied to nighttime operation, this includes the radiation pattern in the horizontal plane as well as

* FCC Rules and Regulations, Part 73, Subpart A. These rules were undergoing substantial changes in early 1992, and a current version of the Rules should be consulted for latest classifications and requirements.

† 10-kHz spacing is used only in ITU Region 2. Regions 1 and 3 employ 9-kHz spacing.

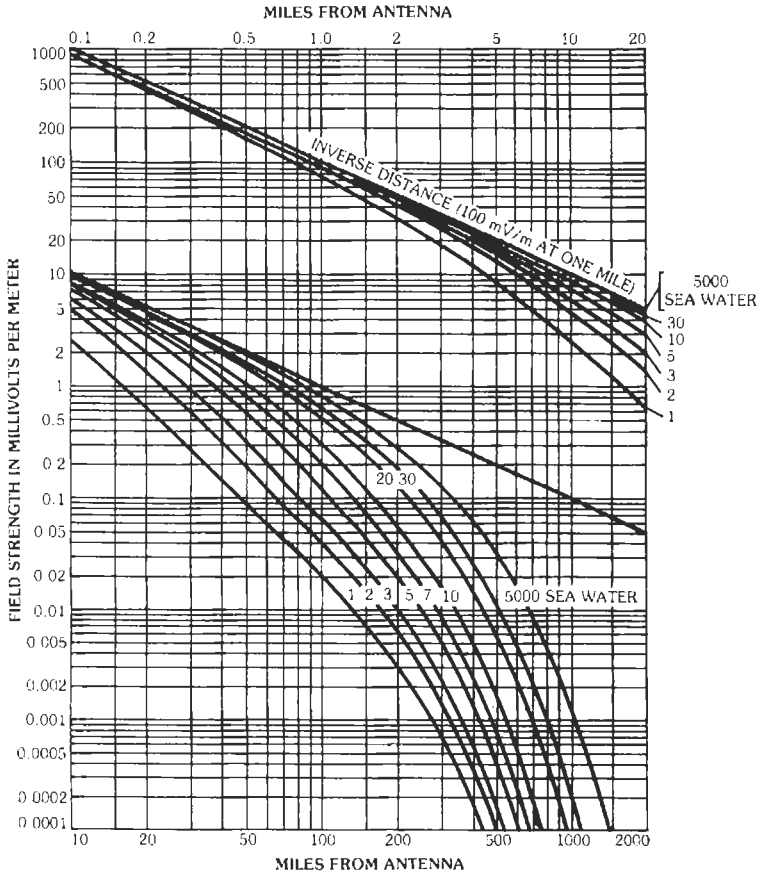

Fig. 1. Ground-wave field strength plotted against distance. Computed for 550 kilohertz. Dielectric constant = 15. Ground-conductivity values are in millimhos/meter.

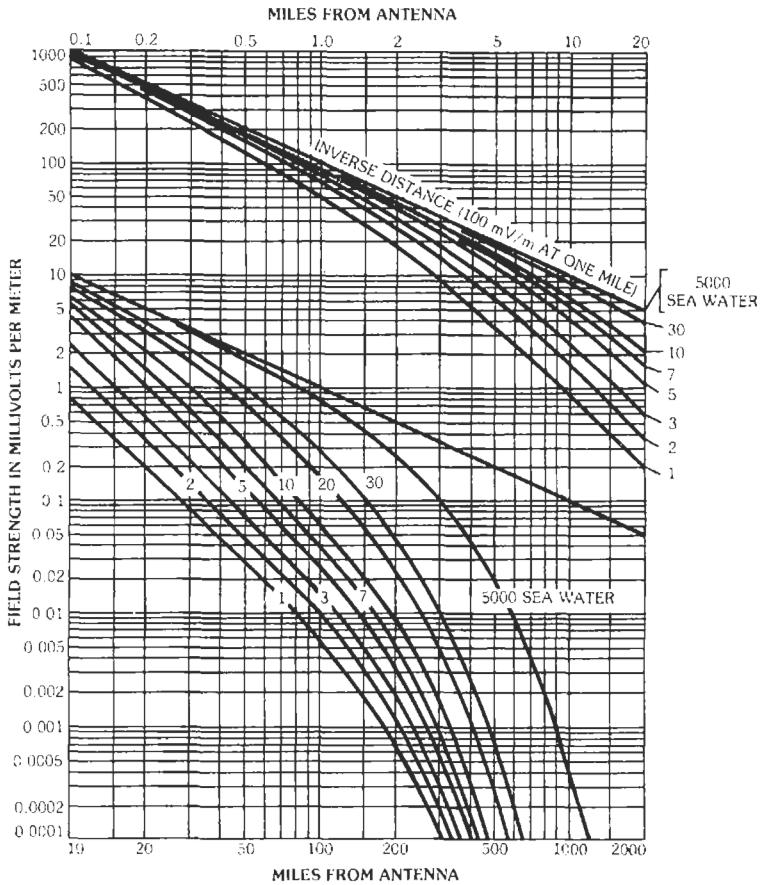

Fig. 2. Ground-wave field strength plotted against distance. Computed for 1000 kilohertz. Dielectric constant = 15. Ground-conductivity values are in millimhos/meter.

radiation at angles above the horizontal plane (vertical radiation pattern).

Table 1 outlines generally the protected contours and permissible interference for the various classes of stations. There are additional details and some exceptions in Sections 73.21–73.29 and 73.181–73.190 of Part 73 of the FCC Rules and Regulations. (See previous footnote regarding changes to these rules. The new rules will require stations to employ new interference criteria and to reduce existing interference for a site change.)

Coverage Data—Figs. 1, 2, and 3 show computed values of ground-wave field strength as a function of the distance from the transmitting antenna. These are used to determine coverage and interference. They were computed for the frequencies indicated, for a dielectric constant equal to 15 for land and 80 for sea water (referred to air as unity), and for the surface conductivities noted. The curves are for radiation from a short vertical antenna at the surface of a uniformly conductive spherical earth with an antenna efficiency and input power such that the inverse-distance field is 100 millivolts/meter at one mile. Fig. 4 shows the estimated effective field for vertical omnidirectional antennas of various heights. Figs. 5 and 6 show the effective ground conductivity for various parts of the US and Canada, and Fig. 7 shows the sky-wave fields for 10% and 50% of the time.

Transmission System Requirements

Modulation: 85% on peaks of frequent recurrence at authorized operating power. Not greater than 100% on negative peaks or 125% on positive peaks.
