CONTENTS

Part C: Piping Systems

Part D: Nonmetallic Piping

Part E: Appendices

PREFACE

It is with great sense of gratitude and humility I take this blessed moment to offer this Seventh Edition of *Piping Handbook.* The challenge presented by the success of the Sixth Edition, coupled with our objective to enhance its reference value and widen its scope, motivated us to reach out and draw upon the recognized expertise on piping related topics not covered in the Sixth Edition. In addition, we directed our synergetic efforts to upgrade the existing contents to include the latest advances and developments in the field of piping and related technologies.

Fifteen (15) new chapters and nine (9) new appendixes have been added. These additions accord a unique status to this resource book as it covers piping related topics not covered in any one book. Inclusion of metric and/or SI units along with US customary units is intended to accommodate the growing needs of the shrinking world and the realities of the international market. We have maintained the familiar and easy to use format of the Sixth Edition.

I consider myself fortunate to have the opportunity to associate and work with renowned and recognized specialists and leaders whose contributions are not limited to this *Piping Handbook,* but go far beyond. For me it has been a rewarding and enlightening experience. I find myself humbled by depth of their knowledge, practical experience, and professional achievements. These distinguished contributors have offered the sum total of their know how in the form of guidance, cautions, prohibitions, recommendations, practical illustrations, and examples, which should be used prudently with due consideration for application requirements. The strength, authenticity, and utility of this reference book lie in the wide spread diversity of their expertise and unity of their professionalism.

Based upon the feedback received over the past seven years from the users of the Sixth Edition of this handbook, I feel honored to express my and users gratitude to all the contributors for their commitment to their profession and their higher goal of helping others. They have made the difference. Their spirit of giving back has not only continued, but has brought in new contributors to expand the scope and enhance the utility of this handbook. I feel confident that all the contributors shall enjoy the professional satisfaction and the gratitude of users of this handbook.

The selfless efforts of all the reviewers listed in the Honors List are of great significance in making improvements in presentation of the subject matter. The extent of their experience, knowledge, and an insight of topics has been instrumental in extracting the best out of contributors and upgrading the contents of this handbook.

The contributors and reviewers have earned a distinguished status. I salute their commitment; admire their efforts; respect their professionalism; and applaud their achievements. I want to recognize their perseverance, dedication, hard work and sincerity of their commitment in spite of increasing demands on their time.

I am indebted to the members of the editorial team who spent countless hours and made personal sacrifices to make this team project a reality. Jill Hershey, Troy Skillen, and Soami Suri did not spare any effort to not only fulfill their commitment, but went beyond to accomplish the objectives. They offered constructive comments,

new ideas and energy to support them. In addition to contributing, they assisted me in reviewing, editing, checking and correcting the manuscript. Furthermore, they provided an objective assessment of needs of progressive professionals involved in piping related fields. Their efforts reinforced my faith in bright future of our profession. The support and assistance provided by Ervin L. Geiger and Sabin Crocker, Jr., as Associate Editors, is key to the successful completion of this effort.

Each and every individual providing administrative, technical and automation services, listed in Honors List, kept the entire process moving smoothly by their sincere efforts. Linda Ludewig, Peggy Lamb, and the others at McGraw-Hill could not be better or more cooperative in accommodating our reasonable and unreasonable requests in producing this handbook to the best of their abilities.

Whenever you, the readers and users of this handbook, find it to be of help in your mission, please thank the contributors, reviewers, technical, administrative and automation personnel listed in the Honors List, and the editorial and production staff of McGraw-Hill. If, at any time, this handbook falls short of your expectations, please do not hesitate to pass it on to me. It will help us improve the contents and their utility. I shall owe you my gratitude.

I take pride in recognizing the active support of my daughters, Mukta and Mahak; and my son, Manav; who helped me in researching and collecting data; preparing manuscript; reviewing proof pages; and performing other tasks, as needed. This time they not only allowed me to devote their share of my life to this handbook, but also dedicated a part of their life to it. My wife, Prabha, provided the proverbial support a spouse can hope for, in doing and accomplishing what I aimed for. No words can convey my feelings and thoughts for her contributions.

Mohinder L. Nayyar

HOW TO USE THIS HANDBOOK

As with any handbook, the user of this handbook can seek the topic covered either with the help of the table of contents or the index. However, an understanding of the organization and the format of this handbook will enhance its utility.

The handbook is organized in five parts:

Part A, Piping Fundamentals: There are ten chapters in Part A, numbered Al through A10, dealing with commonly used terminology associated with piping units—U.S. Customary units and metric/SI units, piping components, materials, piping codes and standards, manufacturing of piping, fabrication and installation of piping, bolted joints, prestressed concrete piping, and grooved and Pressfit piping systems, Each chapter is a self-contained unit. The chapter numbers, figures and tables sequentially preceded. For example, in the case of Chapter Al, the figures are numbered as Fig. A1.1, Fig. A1.2, and so on, and tables are numbered as Table A1.1, Table A1.2, and so on. Pages are numbered sequentially throughout each part, starting with A.1.

Part B, Generic Design Considerations: The Part B consists of fourteen chapters. The topics covered deal with generic design considerations, which may be applicable to any piping system irrespective of the fluid or the mixture carried by the piping. The generic topics are design documents, design bases, piping layout, stress analysis, piping supports, heat tracing, thermal insulation, and flow of fluids. In addition, the lined piping systems: cement, rubber, epoxy and plastic lined piping systems are included to provide guidance when corrosion is a concern. A chapter on double containment piping systems provides needed guidance to handle hazardous fluids. The last chapter in Part B deals with pressure testing of piping systems. The chapter, page, figure, and table numbering scheme is similar to that described for Part A.

Part C, Piping Systems: There are 17 chapters in Part C, each dealing with a specific type of piping system or systems involving application of specific considerations. The piping systems covered include water, fire protection, steam, building services, oil, gas, chemical and refinery (process piping), cryogenic, refrigeration, toxic and hazardous wastes, slurry and sludge, stormwater and wastewater, plumbing, ash handling, compressed air and vacuum, fuel gas and laboratory piping systems. The numbering approach for Part C is similar to Part A.

Part D, Nonmetallic Piping: Part D has two chapters, Dl and D2. Chapter Dl addresses thermoplastics piping, and Chapter D2 covers fiberglass piping systems. The numbering scheme for pages, figures, and tables is similar to the one followed for Part A.

Part E, Appendixes: Part E of the handbook contains reference technical data and information that could be very handy and useful to the users. It consists of 10 appendixes, El through E10. They include conversion tables, pipe and tube properties, pressure drop tables, ASTM and international piping materials, fluid properties, piping related computer programs, and an exhaustive list of international standards.

Depending upon the need, level of piping knowledge, and requirements, the

user of this handbook may find it very convenient to locate the desired information by focusing on a specific part of the handbook.

Last but not least, the Seventh Edition of *Piping Handbook* includes metric/SI units in parentheses. The values stated in each system are not exact equivalents; therefore, each system must be used independently of the other. At times, unit equivalents are rounded off while at places they are approximated to provide a measure of equivalency. Different approaches have been followed depending upon the practices prevalent in a segment of the piping industry. We regret the variations and expect the users to understand the state of the art in regard to use of units. The users are cautioned to check and verify units prior to making calculations with the help of equations included in the handbook or elsewhere.

PIPING FUNDAMENTALS

CHAPTER A1
INTRODUCTION TO PIPING

Mohinder L Nayyar, P. E.
ASME Fellow
Bechtel Power Corporation

INTRODUCTION

Piping systems are like arteries and veins. They carry the lifeblood of modern civilization. In a modern city they transport water from the sources of water supply to the points of distribution; convey waste from residential and commercial buildings and other civic facilities to the treatment facility or the point of discharge. Similarly, pipelines carry crude oil from oil wells to tank farms for storage or to refineries for processing. The natural gas transportation and distribution lines convey natural gas from the source and storage tank forms to points of utilization, such as power plants, industrial facilities, and commercial and residential communities. In chemical plants, paper mills, food processing plants, and other similar industrial establishments, the piping systems are utilized to carry liquids, chemicals, mixtures, gases, vapors, and solids from one location to another.

The fire protection piping networks in residential, commercial, industrial, and other buildings carry fire suppression fluids, such as water, gases, and chemicals to provide protection of life and property. The piping systems in thermal power plants convey high-pressure and high-temperature steam to generate electricity. Other piping systems in a power plant transport high- and low-pressure water, chemicals, low-pressure steam, and condensate. Sophisticated piping systems are used to process and carry hazardous and toxic substances. The storm and wastewater piping systems transport large quantities of water away from towns, cities, and industrial and similar establishments to safeguard life, property, and essential facilities.

In health facilities, piping systems are used to transport gases and fluids for medical purposes. The piping systems in laboratories carry gases, chemicals, vapors, and other fluids that are critical for conducting research and development. In short, the piping systems are an essential and integral part of our modern civilization just as arteries and veins are essential to the human body.

The design, construction, operation, and maintenance of various piping systems involve understanding of piping fundamentals, materials, generic and specific design considerations, fabrication and installation, examinations, and testing and inspection requirements, in addition to the local, state and federal regulations.

PIPING

Piping includes pipe, flanges, fittings, bolting, gaskets, valves, and the pressure-containing portions of other piping components. It also includes pipe hangers and supports and other items necessary to prevent overpressurization and overstressing of the pressure-containing components. It is evident that pipe is one element or a part of piping. Therefore, pipe sections when joined with fittings, valves, and other mechanical equipment and properly supported by hangers and supports, are called *piping*.

Pipe

Pipe is a tube with round cross section conforming to the dimensional requirements of

- ASME B36.10M   Welded and Seamless Wrought Steel Pipe
- ASME B36.19M   Stainless Steel Pipe

Pipe Size

Initially a system known as *iron pipe size* (IPS) was established to designate the pipe size. The size represented the approximate inside diameter of the pipe in inches. An IPS 6 pipe is one whose inside diameter is approximately 6 inches (in). Users started to call the pipe as 2-in, 4-in, 6-in pipe and so on. To begin, each pipe size was produced to have one thickness, which later was termed as *standard* (STD) or *standard weight* (STD. WT.). The outside diameter of the pipe was standardized.

As the industrial requirements demanded the handling of higher-pressure fluids, pipes were produced having thicker walls, which came to be known as *extra strong* (XS) or *extra heavy* (XH). The higher pressure requirements increased further, requiring thicker wall pipes. Accordingly, pipes were manufactured with *double extra strong* (XXS) or *double extra heavy* (XXH) walls while the standardized outside diameters are unchanged.

With the development of stronger and corrosion-resistant piping materials, the need for thinner wall pipe resulted in a new method of specifying pipe size and wall thickness. The designation known as *nominal pipe size* (NPS) replaced IPS, and the term *schedule* (SCH) was invented to specify the nominal wall thickness of pipe.

Nominal pipe size (NPS) is a dimensionless designator of pipe size. It indicates standard pipe size when followed by the specific size designation number without an inch symbol. For example, NPS 2 indicates a pipe whose outside diameter is 2.375 in. The NPS 12 and smaller pipe has outside diameter greater than the size designator (say, 2, 4, 6, . . .). However, the outside diameter of NPS 14 and larger pipe is the same as the size designator in inches. For example, NPS 14 pipe has an outside diameter equal to 14 in. The inside diameter will depend upon the pipe wall thickness specified by the schedule number. Refer to ASME B36.10M or ASME B36.19M. Refer to App. E2 or E2M.

Diameter nominal (DN) is also a dimensionless designator of pipe size in the metric unit system, developed by the International Standards Organization (ISO). It indicates standard pipe size when followed by the specific size designation number

TABLE A1.1 Pipe Size Designators: NPS and DN

NPS	DN	NPS	DN	NPS	DN	NPS	DN
⅛	6	3½	90	22	550	44	1100
¼	8	4	100	24	600	48	1200
¾	10	5	125	26	650	52	1300
½	15	6	150	28	700	56	1400
¾	20	8	200	30	750	60	1500
1	25	10	250	32	800	64	1600
1¼	32	12	300	34	850	68	1700
1½	40	14	350	36	900	72	1800
2	50	16	400	38	950	76	1900
2½	65	18	450	40	1000	80	2000
3	80	20	500	42	1050	—	—

Notes:

1. For sizes larger than NPS 80, determine the DN equivalent by multiplying NPS size designation number by 25.

without a millimeter symbol. For example, DN 50 is the equivalent designation of NPS 2. Refer to Table A1.1 for NPS and DN pipe size equivalents.

Pipe Wall Thickness

Schedule is expressed in numbers (5, 5S, 10, 10S, 20, 20S, 30, 40, 40S, 60, 80, 80S, 100, 120, 140, 160). A schedule number indicates the approximate value of the expression 1000 *P/S,* where *P* is the service pressure and *S* is the allowable stress, both expressed in pounds per square inch (psi). The higher the schedule number, the thicker the pipe is. The outside diameter of each pipe size is standardized. Therefore, a particular nominal pipe size will have a different inside diameter depending upon the schedule number specified.

Note that the original pipe wall thickness designations of STD, XS, and XXS have been retained; however, they correspond to a certain schedule number depending upon the nominal pipe size. The nominal wall thickness of NPS 10 and smaller schedule 40 pipe is same as that of STD. WT. pipe. Also, NPS 8 and smaller schedule 80 pipe has the same wall thickness as XS pipe.

The schedule numbers followed by the letter S are per ASME B36.19M, and they are primarily intended for use with stainless steel pipe. The pipe wall thickness specified by a schedule number followed by the letter S may or may not be the same as that specified by a schedule number without the letter S. Refer to ASME B36.19M and ASME B36.10M.[10,11]

ASME B36.19M does not cover all pipe sizes. Therefore, the dimensional requirements of ASME B36.10M apply to stainless steel pipe of the sizes and schedules not covered by ASME B36.19M.

PIPING CLASSIFICATION

It is usual industry practice to classify the pipe in accordance with the pressure-temperature rating system used for classifying flanges. However, it is not essential

TABLE A1.2   Piping Class Ratings Based on ASME B16.5 and Corresponding PN
Designators

Class	150	300	400	600	900	1500	2500
PN	20	50	68	110	150	260	420

Notes:

1. Pressure-temperature ratings of different classes vary with the temperature and the material of construction.
2 For pressure-temperature ratings, refer to tables in ASME B16.5, or ASME B16.34.

that piping be classified as Class 150, 300, 400, 600, 900, 1500, and 2500. *The piping rating must be governed by the pressure-temperature rating of the weakest pressure-containing item in the piping.* The weakest item in a piping system may be a fitting made of weaker material or rated lower due to design and other considerations. Table A1.2 lists the standard pipe class ratings based on ASME B16.5 along with corresponding *pression nominal* (PN) rating designators. *Pression nominal* is the French equivalent of pressure nominal.

In addition, the piping may be classified by class ratings covered by other ASME standards, such as ASME B16.1, B16.3, B16.24, and B16.42. A piping system may be rated for a unique set of pressures and temperatures not covered by any standard.

Pression nominal (PN) is the rating designator followed by a designation number, which indicates the approximate pressure rating in *bars.* The bar is the unit of pressure, and 1 bar is equal to 14.5 psi or 100 kilopascals (kPa). Table A1.2 provides a cross-reference of the ASME class ratings to PN rating designators. It is evident that the PN ratings do not provide a proportional relationship between different PN numbers, whereas the class numbers do. Therefore, it is recommended that class numbers be used to designate the ratings. Refer to Chap. B2 for a more detailed discussion of class rating of piping systems.

OTHER PIPE RATINGS

Manufacturer's Rating

Based upon a unique or proprietary design of a pipe, fitting, or joint, the manufacturer may assign a pressure-temperature rating that may form the design basis for the piping system. Examples include Victaulic couplings and the Pressfit system discussed in Chap. A9.

In no case shall the manufacturer's rating be exceeded. In addition, the manufacturer may impose limitations which must be adhered to.

NFPA Ratings

The piping systems within the jurisdiction of the National Fire Protection Association (NFPA) requirements are required to be designed and tested to certain required pressures. These systems are usually rated for 175 psi (1207.5 kPa), 200 psi (1380 kPa), or as specified.

AWWA Ratings

The American Water Works Association (AWWA) publishes standards and specifications, which are used to design and install water pipelines and distribution system piping. The ratings used may be in accordance with the flange ratings of AWWA C207, Steel Pipe Flanges; or the rating could be based upon the rating of the joints used in the piping.

Specific or Unique Rating

When the design pressure and temperature conditions of a piping system do not fall within the pressure-temperature ratings of above-described rating systems, the designer may assign a specific rating to the piping system. Examples of such applications include main steam or hot reheat piping of a power plant, whose design pressure and design temperature may exceed the pressure-temperature rating of ASME B16.5 Class 2500 flanges. It is normal to assign a specific rating to the piping. This rating must be equal to or higher than the design conditions. The rating of all pressure-containing components in the piping system must meet or exceed the specific rating assigned by the designer.

Dual Ratings

Sometimes a piping system may be subjected to full-vacuum conditions or submerged in water and thus experience external pressure, in addition to withstanding the internal pressure of the flow medium. Such piping systems must be rated for both internal and external pressures at the given temperatures. In addition, a piping system may handle more than one flow medium during its different modes of operation. Therefore, such a piping system may be assigned a dual rating for two different flow media. For example, a piping system may have condensate flowing through it at some lower temperature during one mode of operation while steam may flow through it at some higher temperature during another mode of operation. It may be assigned two pressure ratings at two different temperatures.

GENERAL DEFINITIONS

Absolute Viscosity.   Absolute viscosity or the coefficient of absolute viscosity is a measure of the internal resistance. In the centimeter, gram, second (cgs) or metric system, the unit of absolute viscosity is the poise (abbreviated P), which is equal to 100 centipoise (cP). The English units used to measure or express viscosity are slugs per foot-second or pound force seconds per square foot. Sometimes, the English units are also expressed as pound mass per foot-second or poundal seconds per square foot. Refer to Chap. B8 of this handbook.

Adhesive Joint.   A joint made in plastic piping by the use of an adhesive substance which forms a continuous bond between the mating surfaces without dissolving either one of them. Refer to Part D of this handbook.

Air-Hardened Steel.   A steel that hardens during cooling in air from a temperature above its transformation range.[1]

Alloy Steel.   A steel which owes its distinctive properties to elements other than carbon. Steel is considered to be alloy steel when the maximum of the range given for the content of alloying elements exceeds one or more of the following limits[2]:

Manganese	1.65 percent
Silicon	0.60 percent
Copper	0.60 percent

or a definite range or a definite minimum quantity of any of the following elements is specified or required within the limits of the recognized field of constructional alloy steels:

Aluminum	Nickel
Boron	Titanium
Chromium (up to 3.99 percent)	Tungsten
Cobalt	Vanadium
Columbium	Zirconium
Molybdenum	

or any other alloying element added to obtain a desired alloying effect.

Small quantities of certain elements are unavoidably present in alloy steels. In many applications, these are not considered to be important and are not specified or required. When not specified or required, they should not exceed the following amounts:

Copper	0.35 percent
Chromium	0.20 percent
Nickel	0.25 percent
Molybdenum	0.06 percent

Ambient Temperature.   The temperature of the surrounding medium, usually used to refer to the temperature of the air in which a structure is situated or a device operates.

Anchor.   A rigid restraint providing substantially full fixation, permitting neither translatory nor rotational displacement of the pipe.

Annealing.   Heating a metal to a temperature above a critical temperature and holding above that range for a proper period of time, followed by cooling at a suitable rate to below that range for such purposes as reducing hardness, improving machinability, facilitating cold working, producing a desired microstructure, or obtaining desired mechanical, physical, or other properties.[3] (A softening treatment is often carried out just below the critical range which is referred to as a subcritical annealing.)

Arc Cutting.   A group of cutting processes in which the severing or removing of metals is effected by melting with the heat of an arc between an electrode and the base metal (includes carbon, metal, gas metal, gas tungsten, plasma, and air carbon arc cutting). *See also* Oxygen Cutting.

Arc Welding.   A group of welding processes in which coalescence is produced by heating with an electric arc or arcs, with or without the application of pressure and with or without the use of filler metal.[3,4]

Assembly. The joining together of two or more piping components by bolting, welding, caulking, brazing, soldering, cementing, or threading into their installed location as specified by the engineering design.

Automatic Welding. Welding with equipment which performs the entire welding operation without constant observation and adjustment of the controls by an operator. The equipment may or may not perform the loading and unloading of the work.[3,5]

Backing Ring. Backing in the form of a ring that can be used in the welding of piping to prevent weld spatter from entering a pipe and to ensure full penetration of the weld to the inside of the pipe wall.

Ball Joint. A component which permits universal rotational movement in a piping system.[5]

Base Metal. The metal to be welded, brazed, soldered, or cut. It is also referred to as *parent* metal.

Bell-Welded Pipe. Furnace-welded pipe produced in individual lengths from cut-length skelp, having its longitudinal butt joint forge-welded by the mechanical pressure developed in drawing the furnace-heating skelp through a cone-shaped die (commonly known as a *welding bell*), which serves as a combined forming and welding die.

Bevel. A type of edge or end preparation.

Bevel Angle. The angle formed between the prepared edge of a member and a plane perpendicular to the surface of the member. See Fig. A1.1.

Blank Flange. A flange that is not drilled but is otherwise complete.

Blind Flange. A flange used to close the end of a pipe. It produces a blind end which is also known as a *dead end.*

Bond. The junction of the weld metal and the base metal, or the junction of the base metal parts when weld metal is not present. See Fig. A1.2.

Branch Connection. The attachment of a branch pipe to the run of a main pipe with or without the use of fittings.

Braze Welding. A method of welding whereby a groove, fillet, plug, or slot weld is made using a nonferrous filler metal having a melting point below that of the
FIGURE A1.1 Bevel angle.
FIGURE A1.2 Bond between base metal and weld metal.

base metals, but above 800°F. The filler metal is not distributed in the joint by capillary action.[5] (*Bronze* welding, the term formerly used, is a misnomer.)

Brazing. A metal joining process in which coalescence is produced by use of a nonferrous filler metal having a melting point above 800°F but lower than that of the base metals joined. The filler metal is distributed between the closely fitted surfaces of the joint by capillary action.[5]

Butt Joint. A joint between two members lying approximately in the same plane.[5]

Butt Weld. Weld along a seam that is butted edge to edge. See Fig. A1.3.

Bypass. A small passage around a large valve for warming up a line. An emergency connection around a reducing valve, trap, etc., to use in case it is out of commission.
FIGURE A1.3 A circumferential butt-welded joint.

Carbon Steel. A steel which owes its distinctive properties chiefly to the carbon (as distinguished from the other elements) which it contains. Steel is considered to be carbon steel when no minimum content is specified or required for aluminum, boron, chromium, cobalt, columbium, molybdenum, nickel, titanium, tungsten, vanadium, or zirconium or for any other element added to obtain a desired alloying effect; when the specified minimum for copper does not exceed 0.40 percent; or when the maximum content specified for any of the following elements does not exceed the percentages noted: manganese, 1.65 percent; silicon, 0.60 percent; copper, 0.60 percent.[2]

Cast Iron. A generic term for the family of high carbon-silicon-iron casting alloys including gray, white, malleable, and ductile iron.

Centrifugally Cast Pipe. Pipe formed from the solidification of molten metal in a rotating mold. Both metal and sand molds are used. After casting, if required the pipe is machined, to sound metal, on the internal and external diameters to the surface roughness and dimensional requirements of the applicable material specification.

Certificate of Compliance. A written statement that the materials, equipment, or services are in accordance with the specified requirements. It may have to be supported by documented evidence.[6]

Certified Material Test Report (CMTR). A document attesting that the material is in accordance with specified requirements, including the actual results of all required chemical analyses, tests, and examinations.[6]

Chamfering. The preparation of a contour, other than for a square groove weld, on the edge of a member for welding.

Cold Bending. The bending of pipe to a predetermined radius at any temperature below some specified phase change or transformation temperature but especially at or near room temperature. Frequently, pipe is bent to a radius of 5 times the nominal pipe diameter.

Cold Working. Deformation of a metal plastically. Although ordinarily done at room temperature, cold working may be done at the temperature and rate at which strain hardening occurs. Bending of steel piping at 1300°F (704°C) would be considered a cold-working operation.

Companion Flange. A pipe flange suited to connect with another flange or with a flanged valve or fitting. A loose flange which is attached to a pipe by threading, van stoning, welding, or similar method as distinguished from a flange which is cast integrally with a fitting or pipe.

Consumable Insert. Preplaced filler metal which is completely fused into the root of the joint and becomes part of the weld.[1] See Fig. A1.4.

Continuous-Welded Pipe. Furnace-welded pipe produced in continuous lengths from coiled skelp and subsequently cut into individual lengths, having its longitudinal butt joint forge-welded by the mechanical pressure developed in rolling the hot-formed skelp through a set of round pass welding rolls.[3]

Contractor. The entity responsible for furnishing materials and services for fabrication and installation of piping and associated equipment.

FIGURE A1.4 Consumable insert ring inserted in pipe joint eccentrically for welding in horizontal position.

Control Piping. All piping, valves, and fittings used to interconnect air, gas, or hydraulically operated control apparatus or instrument transmitters and receivers.[2]

Controlled Cooling. A process of cooling from an elevated temperature in a predetermined manner to avoid hardening, cracking, or internal damage or to produce a desired metallurgical microstructure. This cooling usually follows the final hot-forming or postheating operation.

Corner Joint. A joint between two members located approximately at right angles to each other in the form of an L. See Fig. A1.5.

Coupling. A threaded sleeve used to connect two pipes. Commercial couplings have internal threads to fit external threads on pipe.

FIGURE A1.5 Corner joint.

Covered Electrode. A filler metal electrode, used in arc welding, consisting of a metal core wire with a relatively thick covering which provides protection for the molten metal from the atmosphere, improves the properties of the weld metal, and

stabilizes the arc. Covered electrodes are extensively used in shop fabrication and field erection of piping of carbon, alloy, and stainless steels.

Crack. A fracture-type imperfection characterized by a sharp tip and high ratio of length and depth to opening displacement.

Creep or Plastic Flow of Metals. At sufficiently high temperatures, all metals flow under stress. The higher the temperature and stress, the greater the tendency to plastic flow for any given metal.

Cutting Torch. A device used in oxygen, air, or powder cutting for controlling and directing the gases used for preheating and the oxygen or powder used for cutting the metal.

Defect. A flaw or an imperfection of such size, shape, orientation, location, or properties as to be rejectable per the applicable minimum acceptance standards.[7]

Density. The density of a substance is the mass of the substance per unit volume. It may be expressed in a variety of units.

Deposited Metal. Filler metal that has been added during a welding operation.[8]

Depth of Fusion. The distance that fusion extends into the base metal from the surface melted during welding. See Fig. A1.6.
FIGURE A1.6   Depth of fusion.

Designer. Responsible for ensuring that the engineering design of piping complies with the requirements of the applicable code and standard and any additional requirements established by the owner.

Dew Point. The temperature at which the vapor condenses when it is cooled at constant pressure.

Dilatant Liquid. If the viscosity of a liquid increases as agitation is increased at constant temperature, the liquid is termed *dilatant.* Examples are clay slurries and candy compounds.

Discontinuity. A lack of continuity or cohesion; an interruption in the normal physical structure of material or a product.[7]

Double Submerged Arc-Welded Pipe. Pipe having a longitudinal butt joint produced by at least two passes, one of which is on the inside of the pipe. Coalescence is produced by heating with an electric arc or arcs between the bare metal electrode or electrodes and the work. The welding is shielded by a blanket of granular, fusible material on the work. Pressure is not used, and filler metal for the inside and outside welds is obtained from the electrode or electrodes.

Ductile Iron. A cast ferrous material in which the free graphite is in a spheroidal form rather than a fluke form. The desirable properties of ductile iron are achieved by means of chemistry and a ferritizing heat treatment of the castings.

Eddy Current Testing. This is a nondestructive testing method in which eddy current flow is induced in the test object. Changes in the flow caused by variations in the object are reflected into a nearby coil or coils for subsequent analysis by suitable instrumentation and techniques.

Edge Joint. A joint between the edges of two or more parallel or nearly parallel members.

Edge Preparation. The contour prepared on the edge of a member for welding. See Fig. A1.7.
FIGURE A1.7 Edge preparation.

Electric Flash-Welded Pipe. Pipe having a longitudinal butt joint in which coalescence is produced simultaneously over the entire area of abutting surfaces by the heat obtained from resistance to the flow of electric current between the two surfaces and by the application of pressure after heating is substantially completed. Flashing and upsetting are accompanied by expulsion of metal from the joint.[4]

Electric Fusion-Welded Pipe. Pipe having a longitudinal or spiral butt joint in which coalescence is produced in the preformed tube by manual or automatic electric arc welding. The weld may be single or double and may be made with or without the use of filler metal.[4]

Electric Resistance-Welded Pipe. Pipe produced in individual lengths or in continuous lengths from coiled skelp and subsequently cut into individual lengths having a longitudinal butt joint in which coalescence is produced by the heat obtained from resistance of the pipe to the flow of electric current in a circuit of which the pipe is a part and by the application of pressure.[3]

Electrode. *See* Covered Electrode.

End Preparation. The contour prepared on the end of a pipe, fitting, or nozzle for welding. The particular preparation is prescribed by the governing code. Refer to Chap. A6 of this handbook.

Engineering Design. The detailed design developed from process requirements and conforming to established design criteria, including all necessary drawings and specifications, governing a piping installation.[5]

Equipment Connection. An integral part of such equipment as pressure vessels, heat exchangers, pumps, etc., designed for attachment of pipe or piping components.[8]

Erection. The complete installation of a piping system, including any field assembly, fabrication, testing, and inspection of the system.[5]

Erosion. Destruction of materials by the abrasive action of moving fluids, usually accelerated by the presence of solid particles.[9]

Examination. The procedures for all visual observation and nondestructive testing.[5]

Expansion Joint.   A flexible piping component which absorbs thermal and/or terminal movement.[5]

Extruded Nozzles.   The forming of nozzle (tee) outlets in pipe by pulling hemispherically or conically shaped dies through a circular hole from the inside of the pipe. Although some cold extruding is done, it is generally performed on steel after the area to be shaped has been heated to temperatures between 2000 and 1600°F (1093 and 871°C).

Extruded Pipe.   Pipe produced from hollow or solid round forgings, usually in a hydraulic extrusion press. In this process the forging is contained in a cylindrical die. Initially a punch at the end of the extrusion plunger pierces the forging. The extrusion plunger then forces the contained billet between the cylindrical die and the punch to form the pipe, the latter acting as a mandrel.

One variation of this process utilizes autofrettage (hydraulic expansion) and heat treatment, above the recrystallization temperature of the material, to produce a wrought structure.

Fabrication.   Primarily, the joining of piping components into integral pieces ready for assembly. It includes bending, forming, threading, welding, or other operations upon these components, if not part of assembly. It may be done in a shop or in the field.[5]

Face of Weld.   The exposed surface of a weld on the side from which the welding was done.[5,8]

Filler Metal.   Metal to be added in welding, soldering, brazing, or braze welding.[8]

Fillet Weld.   A weld of an approximately triangular cross section joining two surfaces approximately at right angles to each other in a lap joint, tee joint, corner joint, or socket weld.[5] See Fig. A1.8.

Fire Hazard.   Situation in which a material of more than average combustibility or explodibility exists in the presence of a potential ignition source.[5]

Flat-Land Bevel.   A square extended root face preparation extensively used in inert-gas, root-pass welding of piping. See Fig. A1.9.
FIGURE A1.8   Fillet weld.
FIGURE A1.9   Flat-land bevel.
FIGURE A1.10   Welding in the flat position.

Flat Position.   The position of welding which is performed from the upper side of the joint, while the face of the weld is approximately horizontal. See Fig. A1.10.

Flaw.   An imperfection of unintentional discontinuity which is detectable by a nondestructive examination.[7]

Flux.   Material used to dissolve, prevent accumulation of, or facilitate removal of oxides and other undesirable substances during welding, brazing, or soldering.

Flux-Cored Arc Welding (FCAW).   An arc welding process that employs a continuous tubular filler metal (consumable) electrode having a core of flux for shielding. Adding shielding may or may not be obtained from an externally supplied gas or gas mixture.

Forge Weld.   A method of manufacture similar to hammer welding. The term *forge welded* is applied more particularly to headers and large drums, while *hammer welded* usually refers to pipe.

Forged and Bored Pipe.   Pipe produced by boring or trepanning of a forged billet.

Full-Fillet Weld.   A fillet weld whose size is equal to the thickness of the thinner member joined.[8]

Fusion.   The melting together of filler and base metal, or of base metal only, which results in coalescence.[8]

Fusion Zone.   The area of base metal melted as determined on the cross section of a weld. See Fig. A1.11.

Galvanizing.   A process by which the surface of iron or steel is covered with a layer of zinc.
FIGURE A1.11   Fusion zone is the section of the parent metal which melts during the welding process.

Gas Metal Arc Welding (GMAW).   An arc welding process that employs a continuous solid filler metal (consumable) electrode. Shielding is obtained entirely from an externally supplied gas or gas mixture.[4,8] (Some methods of this process have been called *MIG* or CO_2 welding.)

Gas Tungsten Arc Welding (GTAW).   An arc welding process that employs a tungsten (nonconsumable) electrode. Shielding is obtained from a gas or gas mix-

ture. Pressure may or may not be used, and filler metal may or may not be used. (This process has sometimes been called *TIG* welding.) When shielding is obtained by the use of an inert gas such as helium or argon, this process is called *inert-gas tungsten arc welding.*[8]

Gas Welding. Welding process in which coalescence is produced by heating with a gas flame or flames, with or without the application of pressure and with or without the use of filler metal.[4]

Groove. The opening provided for a groove weld.

Groove Angle. The total included angle of the groove between parts to be joined by a groove weld. See Fig. A1.12.
FIGURE A1.12 The groove angle is twice the bevel angle.
FIGURE A1.13 A groove face.

Groove Face. That surface of a member included in the groove. See Fig. A1.13.

Groove Radius. The radius of a J or U groove. See Fig. A1.14.

Groove Weld. A weld made in the groove between two members to be joined. The standard type of groove welds are square, single-V, single-bevel, single-U, single-J, double-V, double-U, double-bevel, double-J, and flat-land single, and double-V groove welds. See Fig. A1.15 for a typical groove weld.
FIGURE A1.14 A groove radius.
FIGURE A1.15 Groove weld.

Hammer Weld. Method of manufacturing large pipe (usually NPS 20 or DN 500 and larger) by bending a plate into circular form, heating the overlapped edges to a welding temperature, and welding the longitudinal seam with a power hammer applied to the outside of the weld while the inner side is supported on an overhung anvil.

Hangers and Supports. Hangers and supports include elements which transfer the load from the pipe or structural attachment to the supporting structure or equipment. They include hanging-type fixtures such as hanger rods, spring hangers, sway braces, counterweights, turnbuckles, struts, chains, guides, and anchors and bearing-type fixtures such as saddles, bases, rollers, brackets, and sliding supports.[5] Refer to Chap. B5 of this handbook.

Header. A pipe or fitting to which a number of branch pipes are connected.

Heat-Affected Zone. That portion of the base metal which has not been melted but whose mechanical properties or microstructure has been altered by the heat of welding or cutting.[8] See Fig. A1.16.
FIGURE A1.16 Welding zones.
FIGURE A1.17 Horizontal position fillet weld.

Heat Fusion Joint. A joint made in thermoplastic piping by heating the parts sufficiently to permit fusion of the materials when the parts are pressed together.

Horizontal Fixed Position. In pipe welding, the position of a pipe joint in which the axis of the pipe is approximately horizontal and the pipe is not rotated during the operation.

Horizontal-Position Fillet Weld. Welding is performed on the upper side of an approximately horizontal surface and against an approximately vertical surface. See Fig. A1.17.

Horizontal-Position Groove Weld. The position of welding in which the weld axis lies in an approximately horizontal plane and the face of the weld lies in an approximately vertical plane. See Fig. A1.18.
FIGURE A1.18 Horizontal position groove weld.
FIGURE A1.19 Horizontal rolled position.

Horizontal Rolled Position. The position of a pipe joint in which welding is performed in the flat position by rotating the pipe. See Fig. A1.19.

Hot Bending. Bending of piping to a predetermined radius after heating to a suitably high temperature for hot working. On many pipe sizes, the pipe is firmly packed with sand to avoid wrinkling and excessive out-of-roundness.

Hot Taps. Branch piping connections made to operating pipelines, mains, or other facilities while they are in operation.

Hot Working. The plastic deformation of metal at such a temperature and rate that strain hardening does not occur. Extruding or swaging of chrome-moly piping at temperatures between 2000 and 1600°F (1093 and 871°C) would be considered hot-forming or hot-working operations.

Hydraulic Radius. The ratio of area of flowing fluid to the wetted perimeter.

$$\text{Hydraulic radius} = \frac{\text{area of flowing fluid}}{\text{wetted perimeter}}$$

Impact Test. A test to determine the behavior of materials when subjected to high rates of loading, usually in bending, tension, or torsion. The quantity measured is the energy absorbed in breaking the specimen by a single blow, as in Charpy or Izod tests.

Imperfection. A condition of being imperfect; a departure of a quality characteristic from its intended condition.[5]

Incomplete Fusion. Fusion which is less than complete and which does not result in melting completely through the thickness of the joint.

Indication. The response or evidence from the application of a nondestructive examination.[5]

Induction Heating. Heat treatment of completed welds in piping by means of placing induction coils around the piping. This type of heating is usually performed during field erection in those cases where stress relief of carbon- and alloy-steel field welds is required by the applicable code.

Inspection. Activities performed by an authorized inspector to verify whether an item or activity conforms to specified requirements.

Instrument Piping. All piping, valves, and fittings used to connect instruments to main piping, to other instruments and apparatus, or to measuring equipment.[2]

Interpass Temperature. In a multiple-pass weld, the minimum or maximum temperature of the deposited weld metal before the next pass is started.

Interrupted Welding. Interruption of welding and preheat by allowing the weld area to cool to room temperature as generally permitted on carbon-steel and on chrome-moly alloy-steel piping after sufficient weld passes equal to at least one-third of the pipe wall thickness or two weld layers, whichever is greater, have been deposited.

Joint. A connection between two lengths of pipe or between a length of pipe and a fitting.

Joint Penetration. The minimum depth a groove weld extends from its face into a joint, exclusive of reinforcement.[5] See Fig. A1.20.

FIGURE A1.20   Weld joint penetration.

Kinematic Viscosity. The ratio of the absolute viscosity to the mass density. In the metric system, kinematic viscosity is measured in strokes or square centimeters per second. Refer to Chap. B8 of this handbook.

Laminar Flow.   Fluid flow in a pipe is usually considered laminar if the Reynolds number is less than 2000. Depending upon many possible varying conditions, the flow may be laminar at a Reynolds number as low as 1200 or as high as 40,000; however, such conditions are not experienced in normal practice.

Lap Weld.   Weld along a longitudinal seam in which one part is overlapped by the other. A term used to designate pipe made by this process.

Lapped Joint.   A type of pipe joint made by using loose flanges on lengths of pipe whose ends are lapped over to give a bearing surface for a gasket or metal-to-metal joint.

Liquid Penetrant Examination or Inspection.   This is a nondestructive examination method for finding discontinuities that are open to the surface of solid and essentially nonporous materials. This method is based on capillary action or capillary attraction by which the surface of a liquid in contact with a solid is elevated or depressed. A liquid penetrant, usually a red dye, is applied to the clean surface of the specimen. Time is allowed for the penetrant to seep into the opening. The excess penetrant is removed from the surface. A developer, normally white, is applied to aid in drawing the penetrant up or out to the surface. The red penetrant is drawn out of the discontinuity, which is located by the contrast and distinct appearance of the red penetrant against the white background of the developer.

Local Preheating.   Preheating of a specific portion of a structure.

Local Stress-Relief Heat Treatment.   Stress-relief heat treatment of a specific portion of a weldment. This is done extensively with induction coils, resistance coils, or propane torches in the field erection of steel piping.

Machine Welding.   Welding with equipment which performs the welding operation under the observation and control of an operator. The equipment may or may not perform the loading and unloading of the work.

Magnetic Particle Examination or Inspection.   This is a nondestructive examination method to locate surface and subsurface discontinuities in ferromagnetic materials. The presence of discontinuities is detected by the use of finely divided ferromagnetic particles applied over the surface. Some of these magnetic particles are gathered and held by the magnetic leakage field created by the discontinuity. The particles gathered at the surface form an outline of the discontinuity and generally indicate its location, size, shape, and extent.

Malleable Iron.   Cast iron which has been heat-treated in an oven to relieve its brittleness. The process somewhat improves the tensile strength and enables the material to stretch to a limited extent without breaking.

Manual Welding.   Welding wherein the entire welding operation is performed and controlled by hand.[5]

Mean Velocity of Flow.   Under steady state of flow, the mean velocity of flow at a given cross section of pipe is equal to the rate of flow Q divided by the area of cross section A. It is expressed in feet per second or meters per second.

$$v = \frac{Q}{A} \qquad\qquad (A1.1)$$

where v = mean velocity of flow, in feet per second, ft/s (meters per second, m/s)

   Q = rate of flow, in cubic feet per second, ft³/s (cubic meters per second, m³/s)

   A = area of cross section, in square feet, ft² (square meters, m²)

Mechanical Joint.   A joint for the purpose of mechanical strength or leak resistance or both, where the mechanical strength is developed by threaded, grooved, rolled, flared, or flanged pipe ends or by bolts, pins, and compounds, gaskets, rolled ends, caulking, or machined and mated surfaces. These joints have particular application where ease of disassembly is desired.[5]

Mill Length.   Also known as random length. The usual run-of-mill pipe is 16 to 20 ft (5 to 6 m) in length. Line pipe and pipe for power plant use are sometimes made in double lengths of 30 to 35 ft (10 to 12 m).

Miter.   Two or more straight sections of pipe matched and joined on a line bisecting the angle of junction so as to produce a change in direction.[4]

Newtonian Liquid.   A liquid is called newtonian if its viscosity is unaffected by the kind and magnitude of motion or agitation to which it may be subjected, as long as the temperature remains constant. Water and mineral oil are examples of newtonian liquids.

Nipple.   A piece of pipe less than 12 in (0.3 m) long that may be threaded on both ends or on one end and provided with ends suitable for welding or a mechanical joint. Pipe over 12 in (0.3 m) long is regarded as cut pipe. Common types of nipples are close nipple, about twice the length of a standard pipe thread and without any shoulder; shoulder nipple, of any length and having a shoulder between the pipe threads; short nipple, a shoulder nipple slightly longer than a close nipple and of a definite length for each pipe size which conforms to manufacturer' standard; long nipple, a shoulder nipple longer than a short nipple which is cut to a specific length.

Nominal Diameter (DN).   A dimensionless designator of pipe in metric system. It indicates standard pipe size when followed by the specific size designation number without the millimeter symbol (for example, DN 40, DN 300).

Nominal Pipe Size (NPS).   A dimensionless designator of pipe. It indicates standard pipe size when followed by the specific size designation number without an inch symbol (for example, NPS 1½, NPS 12).[2]

Nominal Thickness.   The thickness given in the product material specification or standard to which manufacturing tolerances are applied.[5]

Nondestructive Examination or Inspection.   Inspection by methods that do not destroy the item, part, or component to determine its suitability for use.

Normalizing.   A process in which a ferrous metal is heated to a suitable temperature above the transformation range and is subsequently cooled in still air at room temperature.[5]

Nozzle. As applied to piping, this term usually refers to a flanged connection on a boiler, tank, or manifold consisting of a pipe flange, a short neck, and a welded attachment to the boiler or other vessel. A short length of pipe, one end of which is welded to the vessel with the other end chamfered for butt welding, is also referred to as a welding nozzle.

Overhead Position. The position of welding performed from the underside of the joint.

Oxidizing Flame. An oxyfuel gas flame having an oxidizing effect caused by excess oxygen.

Oxyacetylene Cutting. An oxygen-cutting process in which metals are severed by the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by means of gas flames obtained from the combustion of acetylene with oxygen.

Oxyacetylene Welding. A gas welding process in which coalescence is produced by heating with a gas flame or flames obtained from the combustion of acetylene with oxygen, with or without the addition of filler metal.

Oxyfuel Gas Welding (OFGW). A group of welding processes in which coalescence is produced by heating with a flame or flames obtained from the combustion of fuel gas with oxygen, with or without the application of pressure and with or without the use of filler metal.

Oxygen Cutting (OC). A group of cutting processes used to sever or remove metals by means of the reaction of oxygen with the base metal at elevated temperatures. In the case of oxidation-resistant metals, the reaction is facilitated by use of a chemical flux or metal powder.[8]

Oxygen Gouging. An application of oxygen cutting in which a chamfer or groove is formed.

Pass. A single progression of a welding or surfacing operation along a joint, weld deposit, or substrate. The result of a pass is a weld bead, layer, or spray deposit.[8]

Peel Test. A destructive method of examination that mechanically separates a lap joint by peeling.[8]

Peening. The mechanical working of metals by means of hammer blows.

Pickle. The chemical or electrochemical removal of surface oxides. Following welding operations, piping is frequently *pickled* in order to remove mill scale, oxides formed during storage, and the weld discolorations.

Pipe. A tube with a round cross section conforming to the dimensional requirements for nominal pipe size as tabulated in ASME B36.10M and ASME B36.19M. For special pipe having diameter not listed in the above-mentioned standards, the nominal diameter corresponds to the outside diameter.[5]

Pipe Alignment Guide. A restraint in the form of a sleeve or frame that permits the pipeline to move freely only along the axis of the pipe.[8]

Pipe Supporting Fixtures. Elements that transfer the load from the pipe or structural attachment to the support structure or equipment.[8]

Pipeline or Transmission Line. A pipe installed for the purpose of transmitting gases, liquids, slurries, etc., from a source or sources of supply to one or more distribution centers or to one or more large-volume customers; a pipe installed to interconnect source or sources of supply to one or more distribution centers or to one or more large-volume customers; or a pipe installed to interconnect sources of supply.[2]

Piping System. Interconnected piping subject to the same set or sets of design conditions.[1]

Plasma Cutting. A group of cutting processes in which the severing or removal of metals is effected by melting with a stream of hot ionized gas.[1]

Plastic. A material which contains as an essential ingredient an organic substance of high to ultrahigh molecular weight, is solid in its finished state, and at some stage of its manufacture or processing can be shaped by flow. The two general types of plastic are thermoplastic and thermosetting.

Polarity. The direction of flow of current with respect to the welding electrode and workpiece.

Porosity. Presence of gas pockets or voids in metal.

Positioning Weld. A weld made in a joint which has been so placed as to facilitate the making of the weld.

Postheating. The application of heat to a fabricated or welded section subsequent to a fabrication, welding, or cutting operation. Postheating may be done locally, as by induction heating; or the entire assembly may be postheated in a furnace.

Postweld Heat Treatment. Any heat treatment subsequent to welding.[5]

Preheating. The application of heat to a base metal immediately prior to a welding or cutting operation.[5]

Pressure. The force per unit that is acting on a real or imaginary surface within a fluid is the pressure or intensity of pressure. It is expressed in pounds per square inch:

$$p = 144 \cdot w \cdot h + p_a \qquad \text{(A1.2)}$$

$$p = 10^4 w \cdot h + p_a \qquad \text{(A1.2M)}$$

where p = absolute pressure at a point, psi (kg/cm²)
  w = specific weight, lb/ft³ (kg/m³)
  h = height of fluid column above the point, ft (m)
  p_a = atmospheric pressure, psi (kg/cm²)

The gauge pressure at a point is obtained by designating atmospheric pressure as zero:

$$p = 144 \cdot w \cdot h \tag{A1.3}$$

$$p = 10^4 (w \cdot h) \quad \text{(metric)} \tag{A1.3M}$$

where p = gauge pressure. To obtain absolute pressure from gauge pressure, add the atmospheric pressure to the gauge pressure.

Pressure Head. From the definition of pressure, the expression p/w is the pressure head. It can be defined as the height of the fluid above a point, and it is normally measured in feet.

Purging. The displacement during welding, by an inert or neutral gas, of the air inside the piping underneath the weld area in order to avoid oxidation or contamination of the underside of the weld. Gases most commonly used are argon, helium, and nitrogen (the last is principally limited to austenitic stainless steel). Purging can be done within a complete pipe section or by means of purging fixtures of a small area underneath the pipe weld.

Quenching. Rapid cooling of a heated metal.

Radiographic Examination or Inspection. Radiography is a nondestructive test method which makes use of short-wavelength radiations, such as X-rays or gamma rays, to penetrate objects for detecting the presence and nature of macroscopic defects or other structural discontinuities. The shadow image of defects or discontinuities is recorded either on a fluorescent screen or on photographic film.

Reinforcement. In branch connections, reinforcement is material around a branch opening that serves to strengthen it. The material is either integral in the branch components or added in the form of weld metal, a pad, a saddle, or a sleeve. In welding, reinforcement is weld metal in excess of the specified weld size.

Reinforcement Weld. Weld metal on the face of a groove weld in excess of the metal necessary for the specified weld size.[5]

Repair. The process of physically restoring a nonconformance to a condition such that an item complies with the applicable requirements, including the code requirements.[6]

Resistance Weld. Method of manufacturing pipe by bending a plate into circular form and passing electric current through the material to obtain a welding temperature.

Restraint. A structural attachment, device, or mechanism that limits movement of the pipe in one or more directions.[8]

Reverse Polarity. The arrangement of direct-current arc welding leads with the work as the negative pole and the electrode as the positive pole of the welding arc; a synonym for direct-current electrode positive.[8]

Reynolds Number. A dimensionless number. It is defined as the ratio of the dynamic forces of mass flow to the shear stress due to viscosity. It is expressed as

$$R = \frac{Dv\rho}{\mu} \tag{A1.4}$$

where R = Reynolds number
v = mean velocity of flow, ft/s (m/s)
ρ = weight density of fluid, lb/ft³ (kg/m³)
D = internal diameter of pipe, ft (m)
μ = absolute viscosity, in pound mass per foot second [lbm/(ft·s)] or poundal seconds per square foot (centipoise)

Rolled Pipe. Pipe produced from a forged billet which is pierced by a conical mandrel between two diametrically opposed rolls. The pierced shell is subsequently rolled and expanded over mandrels of increasingly large diameter. Where closer dimensional tolerances are desired, the rolled pipe is cold- or hot-drawn through dies and then machined. One variation of this process produces the hollow shell by extrusion of the forged billet over a mandrel in a vertical, hydraulic piercing press.

Root Edge. A root face of zero width.

Root Face. That portion of the groove face adjacent to the root of the joint. This portion is also referred to as the *root land*. See Fig. A1.21.
FIGURE A1.21 Nomenclature at joint of groove weld.

Root of Joint. That portion of a joint to be welded where the members to be joined come closest to each other. In cross section, the root of a joint may be a point, a line, or an area. See Fig. A1.21.

Root Opening. The separation, between the members to be joined, at the root of the joint.[5] See Fig. A1.21.

Root Penetration. The depth which a groove weld extends into the root of a joint as measured on the centerline of the root cross section. Sometimes welds are considered unacceptable if they show incomplete penetration. See Fig. A1.21.

Root Reinforcement.   Weld reinforcement at the side other than that from which the welding was done.

Root Surface.   The exposed surface of a weld on the side other than that from which the welding was done.

Run.   The portion of a fitting having its end in line, or nearly so, as distinguished from branch connections, side outlets, etc.

Saddle Flange.   Also known as *tank flange* or *boiler flange.* A curved flange shaped to fit a boiler, tank, or other vessel and to receive a threaded pipe. A saddle flange is usually riveted or welded to the vessel.

Sample Piping.   All piping, valves, and fittings used for the collection of samples of gas, steam, water, oil, etc.[2]

Sargol.   A special type of joint in which a lip is provided for welding to make the joint fluid tight, while mechanical strength is provided by bolted flanges. The Sargol joint is used with both Van Stone pipe and fittings.

Sarlun.   An improved type of Sargol joint.

Schedule Numbers.   Approximate values of the expression $1000P/S,$ where P is the service pressure and S is the allowable stress, both expressed in pounds per square inch.

Seal Weld.   A fillet weld used on a pipe joint primarily to obtain fluid tightness as opposed to mechanical strength; usually used in conjunction with a threaded joint.[8]

Seamless Pipe.   A wrought tubular product made without a welded seam. It is manufactured by hot-working steel or, if necessary, by subsequently cold-finishing the hot-worked tubular product to produce the desired shape, dimensions, and properties.

Semiautomatic Arc Welding.   Arc welding with equipment which controls only the filler metal feed. The advance of the welding is manually controlled.[3]

Semisteel.   A high grade of cast iron made by the addition of steel scrap to pip iron in a cupola or electric furnace. More correctly described as *high-strength gray iron.*

Service Fitting.   A street ell or street tee having a male thread at one end.

Shielded Metal Arc Welding (SMAW).   An arc welding process in which coalescence is produced by heating with an electric arc between a covered metal electrode and the work. Shielding is obtained from decomposition of the electrode covering. Pressure is not used, and filler metal is obtained from the electrode.[8]

Shot Blasting.   Mechanical removal of surface oxides and scale on the pipe inner and outer surfaces by the abrasive impingement of small steel pellets.

Single-Bevel-, Single-J, Single-U, Single-V-Groove Welds.   All are specific types of groove welds and are illustrated in Fig. A1.22.
FIGURE A1.22   Groove welds. (*a*) Single-bevel; (*b*) single-J; (*c*) double-U; (*d*) double-V.

Single-Welded Butt Joint.   A butt joint welded from one side only.[8]

Size of Weld.   For a groove weld, the joint penetration, which is the depth of chamfering plus the root penetration. See Fig. A1.21. For fillet welds, the leg length of the largest isosceles right triangle which can be inscribed within the fillet-weld cross section. See Fig. A1.23.
FIGURE A1.23   Size of weld (*a*) in fillet weld of equal legs and (*b*) in fillet weld of unequal legs.

Skelp.   A piece of plate prepared by forming and bending, ready for welding into pipe. Flat plates when used for butt-welded pipe are called *skelp.*

Slag Inclusion.   Nonmetallic solid material entrapped in weld metal or between weld metal.[8]

Slurry.   A two-phase mixture of solid particles in an aqueous phase.[9]

Socket Weld.   Fillet-type seal weld used to join pipe to valves and fittings or to other sections of pipe. Generally used for piping whose nominal diameter is NPS 2 (DN 50) or smaller.

Soldering.   A metal-joining process in which coalescence is produced by heating to a suitable temperature and by using a nonferrous alloy fusible at temperatures below that of the base metals being joined. The filler metal is distributed between closely fitted surfaces of the joint by capillary action.[5]

Solution Heat Treatment.   Heating an alloy to a suitable temperature, holding at that temperature long enough to allow one or more constituents to enter into solid solution, and then cooling rapidly enough to hold the constituents in solution.

Solvent Cement Joint.   A joint made in thermoplastic piping by the use of a solvent or solvent cement which forms a continuous bond between the mating surfaces.

Source Nipple.   A short length of heavy-walled pipe between high-pressure mains and the first valve of bypass, drain, or instrument connections.

Spatter.   In arc and gas welding, the metal particles expelled during welding that do not form part of the weld.[8]

Spatter Loss.   Difference in weight between the amount of electrode consumed and the amount of electrode deposited.

Specific Gravity.   The ratio of its weight to the weight of an equal volume of water at standard conditions.

Specific Volume.   The volume of a unit mass of a fluid is its specific volume, and it is measured in cubic feet per pound mass (ft^3/lbm).

Specific Weight.   The weight of a unit volume of a fluid is its specific weight. In English units, it is expressed in pounds per cubic foot (lb/ft^3).

Spiral-Riveted.   A method of manufacturing pipe by coiling a plate into a helix and riveting together the overlapped edges.

Spiral-Welded.   A method of manufacturing pipe by coiling a plate into a helix and fusion-welding the overlapped or abutted edges.

Spiral-Welded Pipe.   Pipe made by the electric-fusion-welded process with a butt joint, a lap joint, or a lock-seam joint.

Square-Groove Weld.   A groove weld in which the pipe ends are not chamfered. Square-groove welds are generally used on piping and tubing of wall thickness no greater than ⅛ in (3 mm).

Stainless Steel.   An alloy steel having unusual corrosion-resisting properties, usually imparted by nickel and chromium.

Standard Dimension Ratio (SDR).   The ratio of outside pipe diameter to wall thickness of thermoplastic pipe. It is calculated by dividing the specified outside diameter of the pipe by the specified wall thickness in inches.

Statically Cast Pipe.   Pipe formed by the solidification of molten metal in a sand mold.

Straight Polarity. The arrangement of direct-current arc welding leads in which the work is the positive pole and the electrode is the negative pole of the welding arc; a synonym for *direct-current electrode negative.*

Stress Relieving. Uniform heating of a structure or portion thereof to a sufficient temperature to relieve the major portion of the residual stresses, followed by uniform cooling.[5]

Stringer Bead. A type of weld bead made by moving the electrode in a direction essentially parallel to the axis of the bead. There is no appreciable transverse oscillation of the electrode. The deposition of a number of string beads is known as *string beading* and is used extensively in the welding of austenitic stainless-steel materials. *See also* Weave Bead.

Structural Attachments. Brackets, clips, lugs, or other elements welded, bolted, or clamped to the pipe support structures, such as stanchions, towers, building frames, and foundation. Equipment such as vessels, exchangers, and pumps is not considered to be pipe-supporting elements.

Submerged Arc Welding (SAW). An arc welding process that produces coalescence of metals by heating them with an arc or arcs drawn between a bare metal electrode or electrodes and the base metals. The arc is shielded by a blanket of granular fusible material. Pressure is not used, and filler metal is obtained from the electrode and sometimes from a supplementary welding rod, flux, or metal granules.

Supplemental Steel. Structural members that frame between existing building framing steel members and are significantly smaller than the existing steel.[8]

Swaging. Reducing the ends of pipe and tube sections with rotating dies which are pressed intermittently against the pipe or tube end.

Swivel Joint. A joint which permits single-plane rotational movement in a piping system.

Tack Weld. A small weld made to hold parts of a weldment in proper alignment until the final welds are made.

Tee Joint. A welded joint between two members located approximately at right angles to each other in the form of a T.

Tempering. A process of heating a normalized or quench-hardened steel to a temperature below the transformation range and, from there, cooling at any rate desired. This operation is also frequently called *stress relieving.*

Testing. An element of verification for the determination of the capability of an item to meet specified requirements by subjecting the item to a set of physical, chemical, environmental, or operating conditions.[6]

Thermoplastic. A plastic which is capable of being repeatedly softened by increase of temperature and hardened by decrease of temperature.[2] Refer to Chap. D1 of this handbook.

Thermosetting Plastic. Plastic which is capable of being changed into a substantially infusible or insoluble product when cured under application of heat or chemical means.[2] Refer to Chap. D2 of this handbook.

Thixotropic Liquid. If the viscosity of a liquid decreases as agitation is increased at constant temperature, the liquid is called *thixotropic.* Examples include glues, greases, paints, etc.

Throat of a Weld. A term applied to fillet welds. It is the perpendicular distance from the beginning of the root of a joint to the hypotenuse of the largest right triangle that can be inscribed within the fillet-weld cross section. See Fig. A1.23.

Toe of Weld. The junction between the face of a weld and the base metal.[8] See Fig. A1.23.

Transformation Range. A temperature range in which a phase change is initiated and completed.

Transformation Temperature. A temperature at which a phase change occurs.

Trepanning. The removal by destructive means of a small section of piping (usually containing a weld) for an evaluation of weld and base-metal soundness. The operation is frequently performed with a hole saw.

Tube. A hollow product of round or any other cross section having a continuous periphery. Round tube size may be specified with respect to any two, but not all three, of the following: outside diameter, inside diameter, and wall thickness. Dimensions and permissible variations (tolerances) are specified in the appropriate ASTM or ASME specifications.

Turbinizing. Mechanical removal of scale from the inside of the pipe by means of air-driven centrifugal rotating cleaners. The operation is performed on steel pipe bends after hot bending to remove loose scale and sand.

Turbulent Flow. Fluid flow in a pipe is usually considered turbulent if the Reynolds number is greater than 4000. Fluid flow with a Reynolds number between 2000 and 4000 is considered to be in ''transition.''

Ultrasonic Examination or Inspection. A nondestructive method in which beams of high-frequency sound waves that are introduced into the material being inspected are used to detect surface and subsurface flaws. The sound waves travel through the material with some attendant loss of energy and are reflected at interfaces. The reflected beam is detected and analyzed to define the presence and location of flaws.

Underbead Crack. A crack in the heat-affected zone or in previously deposited weld metal paralleling the underside contour of the deposited weld bead and usually not extending to the surface.

Undercut. A groove melted into the base material adjacent to the toe or root of a weld and left unfilled by weld material.[8]

Van Stoning. Hot upsetting of lapping pipe ends to form integral lap flanges, the lap generally being of the same diameter as that of the raised face of standard flanges.

Vapor Pressure. The pressure exerted by the gaseous form, or vapor, of liquid. When the pressure above a liquid equals its vapor pressure, boiling occurs. If the pressure at any point in the flow of a liquid falls below the vapor pressure or becomes equal to the vapor pressure, the liquid flashes into vapor. This is called *cavitation.* The vapor thus formed travels with the liquid and collapses where the pressure is greater than vapor pressure. This could cause damage to piping and other components.

Vertical Position. With respect to pipe welding, the position in which the axis of the pipe is vertical, with the welding being performed in the horizontal position. The pipe may or may not be rotated.

Viscosity. In flowing liquids, the internal friction or the internal resistance to relative motion of the fluid particles with respect to one another.

Weave Bead. A type of weld bead made with oscillation of the electrode transverse to the axis of the weld. Contrast to string bead.

Weld. A localized coalescence of material produced either by heating to suitable temperatures, with or without the application of pressure, or by application of pressure alone, with or without the use of filler material.

Weld Bead. A weld deposit resulting from a pass.

Weld Metal. That portion of a weld which has been melted during welding. The portion may be the filler metal or base metal or both.

Weld Metal Area. The area of the weld metal as measured on the cross section of a weld.

Weld Penetration. *See* Joint Penetration *and* Root Penetration.

Weld-Prober Sawing. Removal of a boat-shaped sample from a pipe weld for examination of the weld and its adjacent base-metal area. This operation is usually performed in graphitization studies.

Weld Reinforcement. Weld material in excess of the specified weld size.

Weldability. The ability of a metal to be welded under the fabrication conditions imposed into a specific, suitably designed structure and to perform satisfactorily in the intended service.

Welded Joint. A localized union of two or more members produced by the application of a welding process.

Welder. One who is capable of performing a manual or semiautomatic welding operation.[8]

Welder Performance Qualification. Demonstration of a welder's ability to produce welds in a manner described in a welding procedure specification that meets prescribed standards.

Welding Current. The current which flows through the electric welding circuit during the making of a weld.

Welding Fittings. Wrought- or forged-steel elbows, tees, reducers, and similar pieces for connection by welding to one another or to pipe. In small sizes, these fittings are available with counterbored ends for connection to pipe by fillet welding and are known as *socket-weld* fittings. In large sizes, the fittings are supplied with ends chamfered for connection to pipe by means of butt welding and are known as *butt-welding* fittings.

Welding Generator. The electric generator used for supplying welding current.

Welding Machine. Equipment used to perform the welding operation.

Welding Operator. One who operates a welding machine or automatic welding equipment.[8]

Welding Procedure. The detailed methods and practices involved in the production of a weldment.[1]

Welding Procedure Qualification Record. Record of welding data and test results of the welding procedure qualifications, including essential variables of the process and the test results.

***Welding Procedure Specification* (WPS).** The document which lists the parameters to be used in construction of weldments in accordance with the applicable code requirements.[1]

Welding Rod. Filler metal, in wire or rod form, used in gas welding and brazing procedures and those arc welding processes where the electrode does not furnish the filler metal.

Welding Sequence. The order of making the welds in a weldment.

Weldment. An assembly whose component parts are to be joined by welding.[5]

Wrought Iron. Iron refined in a plastic state in a puddling furnace. It is characterized by the presence of about 3 percent of slag irregularly mixed with pure iron and about 0.5 percent carbon and other elements in solution.

Wrought Pipe. The term *wrought pipe* refers to both wrought steel and wrought iron. Wrought in this sense means "worked," as in the process of forming furnace-welded pipe from skelp or seamless pipe from plates or billets. The expression *wrought pipe* is thus used as a distinction from cast pipe. Wrought pipe in this sense should not be confused with *wrought-iron pipe,* which is only one variety of wrought pipe. When wrought-iron pipe is referred to, it should be designated by its complete name.

FORCES, MOMENTS, AND EQUILIBRIUM

Simple Forces. When two or more forces act upon a body at one point, they may be single or combined into a resultant force. Conversely, any force may be resolved
FIGURE A1.24 Vectors and moments.

into component forces. In Fig. A1.24, let the vectors F_1 and F_2 represent two forces acting on a point O. The resultant force F is represented in direction and magnitude by the diagonal of the parallelogram of which F_1 and F_2 are the sides. Conversely, any force F may be resolved into component forces by a reverse of the above operation.

Moments. The moment of a force with respect to a given point is the tendency of that force to produce rotation around it. The magnitude of the moment is represented by the product of the force and the perpendicular distance from its line of action to the point or center of moment. In the English system of weights and measures, moments are expressed as the product of the force in pounds and the length of the moment arm in feet or inches, the unit of the moment being termed the *pound-foot* or the *pound-inch*. Moments acting in a clockwise direction are designated as positive, and those acting in a counterclockwise direction are negative. They may be added and subtracted algebraically, as moments, regardless of the direction of the forces themselves.

With respect to Fig. A1.24, moments about an arbitrary point x are calculated as follows: Extend the line of action of F_1 until its extension intersects the perpendicular ax drawn from point x. Draw bx from x perpendicular to F_2. The sum of moments about point x due to the two forces is then

$$\sum M_x = F_1 \times ax - F_2 \times bx$$

Alternatively, since F_1 and F_2 have been shown to be the vector equivalent of the resultant F, the moments about x can be calculated as

$$\sum M_x = F \times cx \qquad (A1.5)$$

Couples. Two parallel forces of equal magnitude acting in opposite directions constitute a couple. The moment of the couple is the product of one of the forces and the perpendicular distance between the two. A couple has no single resultant and can be balanced only by another couple of equal moment of opposite sign.

Law of Equilibrium. When a body is at rest, the external forces acting upon it must be in equilibrium and there must be a zero net moment on the body. This means that (1) the algebraic sums of the components of all forces with reference to any three axes of reference at right angles with one another must each be zero and (2) the algebraic sum of all moments with reference to any three such axes must be zero. When the forces all lie in the same plane, the algebraic sums of their components with respect to any two axes must be equal to zero and the algebraic sum of all moments with respect to any point in the plane must be zero.

WORK, POWER, AND ENERGY

Work. When a body is moved against a resistance, work must be done upon the body. The amount of work done is the product of the force and the distance through which it acts. The unit of work in the English system is the foot-pound, which is the amount of work done by a force of 1 lb acting through a distance of 1 ft. The following symbols are used in this section in defining the interrelation of work, power, and energy:

A = area, in^2 or ft^2 (mm^2 or m^2) as noted

F = force, lbf (newton, N)

g = local acceleration of gravity, ft/s^2 ($9 \cdot 81$ m/s^2)

g_c = conversion constant, $ft \cdot lbf/(lbm \cdot s^2)$ $[m \cdot kgf/(kgm \cdot s^2)]$

h = vertical distance, ft (m)

H = enthalpy, Btu ($gram \cdot cal$)

hp = horsepower (J/s, kW)

kW = kilowatts

KE = kinetic energy, $ft \cdot lbf$ ($m \cdot kgf$)

PE = potential energy, $ft \cdot lbf$ ($m \cdot kgf$)

p = pressure, psi (kPa, kg/cm^2)

l = distance, ft (m)

T = time, s

v = velocity, ft/s (m/s)

V = volume, ft^3 (m^3)

w = weight, lb (kg)

W = work, $ft \cdot lb$ ($m \cdot kg$)

According to the above definition of work, the following expressions may be written to represent work:

$$W = \int F \, dl = \int \frac{w}{g_c} g \, dh = \int p A \, dl = \int p \, dV$$

If the force is independent of distance, if the process takes place at sea level, if pressure and area are independent of distance, and if pressure is independent of volume, respectively, the above expressions reduce to

$$W = F(l_2 - l_1) = w(h_2 - h_1) = p A(l_2 - l_1) = p(V_2 - V_1) \tag{A1.6}$$

where the subscripts 2 and 1 refer to final and initial states, respectively. The above expressions contain no term involving time, since the measure of work is independent of the time interval during which it is performed.

Power. Power is the time rate of performing work. The English unit of power is the horsepower, which is defined at 33,000 $ft \cdot lb/min$ or 550 $ft \cdot lb/s$. Electric power is commonly expressed in watts or kilowatts, 1 kW being equivalent to 1.34 hp and

1 hp to 0.746 kW. The expressions for horsepower corresponding to those given above for work are

$$\text{hp} = \frac{W}{550T} = \frac{Fl}{550T} \quad \text{etc.}$$

Electric power is the product of volts and amperes, i.e.,

$$\text{kW} = \frac{\text{volts} \times \text{amperes}}{1000}$$

The above expression for the determination of electric power is strictly true for direct current and for alternating current with a zero power factor. For the latter case, if the power factor is different from zero, the expression becomes

$$\text{kW} = \frac{\text{volts} \times \text{amperes}}{1000} \times \text{power factor} \tag{A1.7}$$

Energy. Energy is the capacity for doing work possessed by a system through virtue of work having previously been done upon it. Whenever work has been done upon a system in producing a *change* in its *motion,* its *position,* or its *molecular condition,* the system has acquired the capacity for doing work. Energy may be that due to motion, termed *kinetic energy;* that due to position, termed *potential energy;* or that due to molecular activity or configuration and is manifest as a change in its internal or stored energy. These three forms of energy are mutually convertible. In the English system, the units of energy are the foot-pound and the Btu, which are related by the fact that 1 Btu is equivalent to 778 ft·lb. Some of the more common expressions for energy are as follows:

1. The potential energy of a body of weight w lb mass which has been raised h ft against gravity is $\text{PE} = (wg/g_c)h$.
2. The kinetic energy possessed by a body of weight w lb mass moving at a velocity v ft/s is $\text{KE} = wv^2/(2g_c)$.
3. If the body of 1, initially at rest, were to fall freely through the distance h, its potential energy would be converted to kinetic energy and it would acquire a velocity v determined as follows:

$$\text{PE} = wh = \text{KE} = wv^2/2g_c$$
$$\text{hence} \quad wh = wv^2/2h \quad \text{and} \quad v = \sqrt{2g_c h}$$

4. The energy, resulting from its temperature, of a gas in motion is measured by its specific enthalpy h with units of Btu per pound mass. This energy is available for conversion to kinetic energy, as given by

$$\Delta H = \Delta \text{KE}$$
$$w\Delta h = \frac{w}{778 \times 2g_c}(v_2^2 - v_1^2)$$

If the initial velocity v_1 is negligible, there is obtained

$$v_2 = 223.7\sqrt{\Delta h}$$

5. Energy is measured in the English system in horsepower-hours, kilowatthours, Btu, and foot-pounds. The relations among these units are as follows:

$$1 \text{ hp} \cdot \text{h} = 0.746 \text{ kWh} = 2546 \text{ Btu} = 1,980,788 \text{ft} \cdot \text{lb}$$

$$1 \text{ kWh} = 1.34 \text{ hp} \cdot \text{h} = 3412 \text{ Btu} = 2,654,536 \text{ft} \cdot \text{lb}$$

HEAT AND TEMPERATURE

Units of Heat.   The unit of heat commonly used in the English system is the British thermal unit, or Btu, and is approximately equal to the quantity of heat that must be transferred to one pound of water in order that its temperature be raised one degree Fahrenheit. In laboratory work and throughout much of the world, the calorie is the common unit of heat. A gram calorie is the approximate quantity of heat that must be transferred to 1 gram (g) of water in order to raise its temperature by 1°C. The kilocalorie, sometimes called the kilogram calorie, is equal to 1000 gram calories.

The definitions above are indicated as being approximate because, over the temperature range from freezing to boiling points of water, different quantities of heat are required to produce a unit temperature change. For this reason, the calorie and the Btu have been defined in international units as

$$1 \text{ IT calorie (cal)} = 1/860 \text{ international watthour (Wh)}$$

$$\text{IT} = \text{INTERNATIONAL TABLE}$$

$$1 \text{ Btu} = 251.996 \text{ IT cal}$$

In most engineering work, it is sufficiently accurate to use 1 kg·cal = 3.968 Btu and 1 Btu = 0.252 kg·cal.

Units of Temperature.   The relative "hotness" or "coldness" of a body is denoted by the term *temperature.* The temperature of a substance is measured by noting its effect upon a thermometer or pyrometer whose thermal properties are known. The mercury thermometer is suitable for measuring temperatures from −39 to about 600°F. This limit may be extended to 1000°F if the capillary tube above the mercury is filled with nitrogen or carbon dioxide under pressure. High temperatures must be measured with thermocouples or optical pyrometers. The most commonly used thermometer scales are the Fahrenheit and the Celsius. Thermometer scales have as their bases the melting and boiling points of water, both measured at atmospheric pressure. The relation of the Fahrenheit and Celsius scales is as follows:

	Absolute zero	Freezing point of water	Boiling point of water
Degrees Fahrenheit	−459.6	32	212
Degrees Celsius	−273	0	100

The relation between the two scales is

$$°C = \frac{5}{9}(°F − 32) \qquad \text{and} \qquad °F = \frac{9}{5}°C + 32$$

in which C is the reading on the Celsius scale and F is the reading on the Fahrenheit scale.

In certain calculations, it is necessary to express the temperature in "absolute" units. The absolute temperature associated with the Fahrenheit scale is called the *Rankine temperature,* and that associated with the Celsius scale is termed the *Kelvin temperature.* The relationships among these scales are as follows:

$$R = °F + 459.6$$

$$K = °C + 273$$

$$R = 1.8K$$

$$K = \frac{5}{9}R$$

where R and K designate absolute temperatures on the Rankine and Kelvin scales, respectively.

Specific Heat. The specific heat of a substance is the quantity of heat required to produce a unit temperature change in a unit mass of that substance. Typical units are calories per gram per degree Celsius and Btu per pound per degree Fahrenheit. The numerical value of specific heat is a function of the process by which the unit temperature change is effected. If a gas expands at constant pressure owing to the addition of heat, work is done by the walls of the containing vessel on the surrounding atmosphere, and the heat addition must be greater than would have been required to cause the same temperature change at constant volume. The two most frequently used specific heats are those at constant volume and constant pressure, and they are represented symbolically as c_v and c_p, respectively.

The definition of specific heat given in the preceding paragraph is convenient for engineering applications. By thermodynamic analysis, it can be shown that the two specific heats referred to are given by

$$c_v = \left(\frac{\partial u}{\partial T} \right)_v$$

$$c_p = \left(\frac{\partial h}{\partial T} \right)_p$$

where u and h represent internal energy and enthalpy, respectively, and v and p indicate that volume or pressure remains constant during the measurement of the corresponding specific heat.

The specific heats of most substances vary with temperature. For a general functional relationship, the mean value of specific heat over a temperature range from T_1 to T_2 is given by

$$c_{\text{mean}} = \frac{\int_{T_1}^{T_2} c(T) dT}{T_2 - T_1}$$

If the algebraic relationship between specific heat and temperature is not known but the relation is available in the form of a graph or table, it is usually sufficiently accurate to evaluate the average or mean specific heat at the average of temperature over the temperature range in question.

LENGTHS, AREAS, SURFACES, AND VOLUMES

List of Symbols

A = angle, deg*

C = length of chord

d = diameter of circle or sphere = $2r$

h = height of segment, altitude of cone, etc., as explained in context

π = ratio of circumference to diameter of circle = 3.1416

θ = angle in radian measure*

S = length of arc, slant height, etc., as explained in context

r = radius of circle or sphere = $d/2$

R = mean radius of curvature for pipe bends

Areas are expressed in square units and volumes in cubic units of the same system in which lengths are measured.

Triangle. Area = ½(base) × altitude.

Circle. (See Fig. A1.25.)

Circumference = $\pi d = 2\pi r$.

Area = $\pi r^2 = \pi d^2/4$.

Length of arc $S = \theta r = 0.0175Ar$.

Length of chord $C = 2r \sin(\theta/2) = 2r \sin(A/2)$.
FIGURE A1.25 Length of arc and chord.

Area of Sector. (See Fig. A1.26.)

$$\text{Area} = \frac{1}{2}rS = \frac{1}{2}r^2\theta = \frac{\pi r^2 A}{360} = 0.008727r^2 A$$

Area of Segment. (Method 1, Fig. A1.27) Find the area of the sector having same arc and area of triangle formed by chord and radii of sector. The area of the segment
FIGURE A1.26 Area of sector.
FIGURE A1.27 Area of segment, method 1.

* Degrees can be converted to radian measure by multiplying by 0.0175, since 2π rad = 360°. Hence, $\theta = 0.0175A$.

equals the sum of these two areas if the segment is greater than a semicircle, and it equals their difference if the segment is less than a semicircle.

$$\text{Area} = \frac{1}{2}r^2(\theta \pm \sin\theta)$$

$$= \frac{1}{2}r^2(0.0175A + \sin A)$$

Area of Segment.   [Method 2 (approximate)]*

When $h = 0$ to $\frac{1}{4}d$, area $= h\sqrt{1.766dh - h^2}$.

When $h = \frac{1}{4}d$ to $\frac{1}{2}d$, area $= h\sqrt{0.017d^2 + 1.7dh - h^2}$.

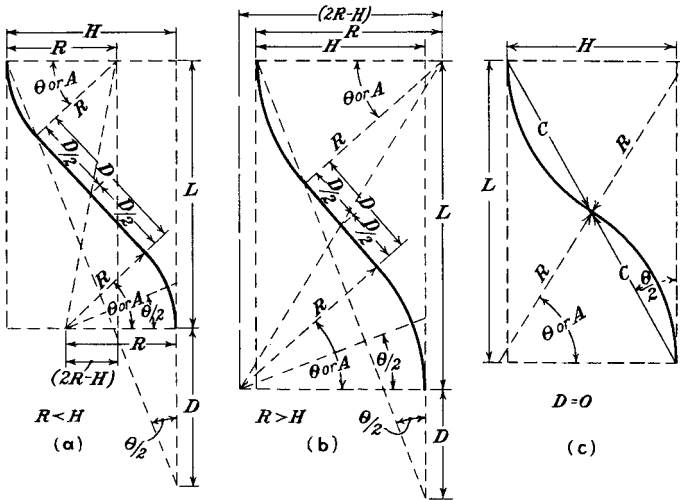
When $h = \frac{1}{2}d$ to d, subtract area of empty sector from area of entire circle.


FIGURE A1.28   Offset bends.

Offset Bends.   (See Fig. A1.28.) The relation of D, R, H, and L is determined by geometry for the general case shown in Fig. A1.28a and b as follows: Consider the diagonal line joining the centers of curvature of the two arcs in either figure as

---

* For a sketch and table of volumes in partly full horizontal tanks, see Table A1.6. The greatest error possible by this method is 0.23 percent.

forming the hypotenuse of three right-angle triangles, and write an equation between the squares of the two other sides. Thus,

$$2\sqrt{\left(\frac{D}{2}\right)^2 + R^2} = \sqrt{(2R - H)^2 + L^2}$$

Squaring both sides and solving for each term in turn, we have

$$D = \sqrt{H^2 - 4HR + L^2}$$

$$L = \sqrt{D^2 + 4HR - H^2}$$

$$H = 2R - \sqrt{4R^2 - L^2 + D^2}$$

$$R = \frac{L^2 + H^2 - D^2}{4H}$$

where $\theta = 2 \tan^{-1}(HL + D)$ (from similarity of triangles, see Fig. A1.28a). When $D = 0$ (Fig. A1.28c),

$$L = \sqrt{(4R - H)H}$$

$$R = \frac{L^2 + H^2}{4H}$$

$$C = \sqrt{RH}$$

Length of pipe in offset:

$$L = 2R\theta + D$$

$$= 0.035RA + D$$

$$= 4R \tan^{-1} \frac{H}{L + D} + D$$

where the angle is expressed in radians.

Cylinder

$$\text{Area} = 2\pi rh + 2\pi r^2 = 2\pi r(h + r)$$

where r = radius of base
h = height

$$\text{Volume} = \pi r^2 h$$

Pyramid. Right pyramid (i.e., vertex directly above center of base):

$$\text{Lateral area} = \tfrac{1}{2}(\text{slant height}) \times \text{perimeter of base}$$

$$\text{Volume} = \tfrac{1}{3}(\text{altitude}) \times \text{area of base}$$

Cone

Volume $= \tfrac{1}{3}(\text{area of base}) \times$ perpendicular distance from vertex to plane of base

Right circular cone:

$$\text{Lateral area} = \pi r s$$

$$\text{Volume} = \frac{1}{3}\pi r^2 h$$

where s = slant height
r = radius of base
h = perpendicular distance from vertex to plane of base

Frustum of right circular cone:

$$\text{Lateral area} = \pi s (r + r') s = \sqrt{(r - r')^2 + h^2}$$

where r = radius of lower base
r' = radius of upper base
h = height of frustum
s = slant height of frustum

$$\text{Volume} = \frac{1}{3}\pi h (r^2 + rr' + r'^2)$$

Sphere

$$\text{Area} = 4\pi r^2 = \pi d^2$$

$$\text{Volume} = \frac{4}{3}\pi r^3 = \frac{1}{6}\pi d^3$$

ACRONYMS AND ABBREVIATIONS

Listed below are some abbreviations and acronyms which are associated with activities related to piping.

AAE	American Association of Engineers

USEFUL TABLES

Following are tables of units and measures associated with piping. For convenience of calculation, Table A1.3 provides decimal equivalents of eighths, sixteenths, thirty-seconds, and sixty-fourths of an inch. Table A1.4 provides diameters and thicknesses of wire and sheet-metal gauges. Table A1.5 provides volume of contents, in cubic

TABLE A1.3 Decimal Equivalents of Eighths, Sixteenths, Thirty-Seconds, and Sixty-Fourths of an Inch

Eighths	$9/32 = 0.28125$	$19/64 = 0.296875$
$1/8 = 0.125$	$11/32 = 0.34375$	$21/64 = 0.328125$
$1/4 = 0.250$	$13/32 = 0.40625$	$23/64 = 0.359375$
$3/8 = 0.375$	$15/32 = 0.46875$	$25/64 = 0.390625$
$1/2 = 0.500$	$17/32 = 0.53125$	$27/64 = 0.421875$
$5/8 = 0.625$	$19/32 = 0.59375$	$29/64 = 0.453125$
$3/4 = 0.750$	$21/32 = 0.65625$	$31/64 = 0.484375$
$7/8 = 0.875$	$23/32 = 0.71875$	$33/64 = 0.515625$
Sixteenths	$25/32 = 0.78125$	$35/64 = 0.546875$
$1/16 = 0.0625$	$27/32 = 0.84375$	$37/64 = 0.578125$
$3/16 = 0.1875$	$29/32 = 0.90625$	$39/64 = 0.609375$
$5/16 = 0.3125$	$31/32 = 0.96875$	$41/64 = 0.640625$
$7/16 = 0.4375$	**Sixty-fourths**	$43/64 = 0.671875$
$9/16 = 0.5625$	$1/64 = 0.015625$	$45/64 = 0.703125$

Formulas for determination of approximate capacity of horizontal cylindrical tanks for any depth. Given: diameter of tank d and height of segment h.

To find area of segment

when $h = 0$ to $\frac{1}{4}d$; area $= h\sqrt{1.766dh - h^2}$

when $h = \frac{1}{4}d$ to $\frac{1}{2}d$; area $= h\sqrt{0.017d^2 + 1.7dh - h^2}$

1 ft³ = 7.4805 U.S. gal = 6.2288 Imperial gal

1 m³ = 264.17 U.S. gal = 219.97 Imperial gal

1 m³ = 35.3147 ft³ = 1000 L

UNITS AND CONVERSION TABLES

The units and conversion factors for the commonly used quantities associated with piping are given in tables contained in App. E1 of this handbook. The following is a list of tables in App. E1.

In addition to App. E1, conversion tables and factors are included in various chapters of this handbook.

CHAPTER A2
PIPING COMPONENTS

Ervin L. Geiger, P.E.
Engineering Supervisor
Bechtel Power Corporation, Frederick, Maryland

The term *piping* refers to the overall network of pipes, fittings, flanges, valves, and other components that comprise a conduit system used to convey fluids. Whether a piping system is used to simply convey fluids from one point to another or to process and condition the fluid, piping components serve an important role in the composition and operation of the system. A system used solely to convey fluids may consist of relatively few components, such as valves and fittings, whereas a complex chemical processing system may consist of a variety of components used to measure, control, condition, and convey the fluids. In the following sections, the characteristics and functions of the various piping components are described.

PIPE AND TUBE PRODUCTS

Pressure pipe and tube products are manufactured to a variety of standard specifications of varying designs, employing different manufacturing practices and using a wide variety of materials. The end user of these products must apply the least-cost product suitable for the specified service conditions. Typically, steel and alloy pressure piping is available in cast, wrought, and seam-welded forms. Welded and seamless wrought steel pipe is supplied in standard sizes and wall thickness conforming to ASME B36.10M. Stainless-steel pipe is supplied in standard sizes and wall thickness conforming to ASME B36.19M. These standard pipe dimensions are tabulated in Apps. E2 and E2M, and the metric size equivalent DN of the NPS is given in Chap. A1. Some commonly specified piping materials are listed in Table A2.1.

Pressure Tubing

Pressure-tube applications commonly involve external heat applications, as in boilers or superheaters. Pressure tubing is produced to the actual outside diameter and minimum or average wall thickness specified by the purchaser. Pressure tubing may be hot- or cold-finished. The wall thickness is normally given in decimal parts of an inch rather than as a fraction or gauge number. When gauge numbers are given

TABLE A2.1 Prevalent Piping Specifications

Specification	Product form	Size range (NPS)	Application
ASTM A53	Seamless/welded	⅛ to 26	Ordinary use in gas, air, oil, water, steam
ASTM A106	Seamless	⅛ to 48	High-temperature service (steam, water, gas, etc.)
ASTM A369	Forged and bored	Custom	High-temperature service
ASTM A335	Seamless	Custom	High-temperature service
ASTM A333	Seamless/welded	⅛ and larger	Service requiring excellent fracture toughness at low temperatures
ASTM A671	Electric fusion-welded	16 and larger	Low-temperature service
ASTM A672	Electric fusion-welded	16 and larger	Moderate-temperature service
ASTM A691	Electric fusion-welded	16 and larger	High-temperature service
ASTM A312	Seamless/welded	⅛ and larger	Low- to high-temperature and corrosive service
API 5L	Seamless/welded		Line pipe, refinery, and transmission service

without reference to a system, Birmingham wire gauge (BWG) is implied. Weights of commercial tubing are given in Apps. E3 and E3M.

Pressure tubing is usually made from steel produced by the open-hearth, basic oxygen, or electric furnace processes. Seamless pressure tubing may be either hot-finished or cold-drawn. Cold-drawn steel tubing is frequently process-annealed at temperatures above 1200°F (650°C). To ensure quality, maximum hardness values are frequently specified. Hot-finished or cold-drawn seamless low-alloy steel tubes generally are process-annealed at temperatures between 1200°F (650°C) and 1350°F (730°C). Austenitic stainless-steel tubes are usually annealed at temperatures between 1800°F (980°C) and 2100°F (1150°C), with specific temperatures varying somewhat with each grade. This is generally followed by pickling, unless bright annealing was done.

Pipe Fittings

The major piping materials are also produced in the form of standard fittings. Among the more widely used materials are ductile or cast iron, malleable iron, brass, copper, cast steel, forged steel, and wrought steel. Other major nonferrous piping materials are also produced in the form of cast and wrought fittings. Ductile and cast-iron fittings are made by conventional foundry methods for a variety of joints including bell-and-spigot, push-on flanged, and mechanical (gland-type) or other proprietary designs.

Ductile and Cast-Iron Fittings

Cast-iron fittings are covered by a number of ASME and ANSI/AWWA standards:

ASME B16.1   Cast Iron Pipe Flanges and Flanged Fittings, Class 25, 125, 250, and 800 (The standard also includes bolt, nut, and gasket data.)

ASME B16.4	Gray Iron Threaded Fittings, Class 125 and 250
ASME B16.12	Cast Iron Threaded Drainage Fittings
ANSI/AWWA C110/A21.10	Ductile Iron and Gray Iron Fittings, 3-in through 48-in (76 mm through 6200 mm), for Water and Other Liquids
ANSI/AWWA C115/A21.15	Ductile Iron and Gray Iron Fittings, 3-in through 48-in (76 mm through 1200 mm), for Water
ANSI/AWWA C153/A21.53	Ductile Iron Compact Fittings, 3-in through 24-in (76 mm through 610 mm) and 54-in through 64-in (1400 mm through 1600 mm), for Water Service

Cast-Iron Threaded Fittings

Cast-iron threaded fittings are covered by ASME Standard B16.4. The standard specifies the below-listed attributes for Class 125 and Class 250 tees, crosses, 45° and 90° elbows, reducing tees, caps, couplings, and reducing couplings in sizes ranging from NPS ¼ (DN 6) through NPS 12 (DN 300), inclusive. However, in Class 250, the standard only covers 45° and 90° elbows, straight tees, and straight crosses.

- Pressure-temperature ratings
- Size and method of designating openings of reducing fittings
- Marking
- Minimum requirements for materials
- Dimensions and tolerances
- Threading
- Coatings

TABLE A2.2 Pressure-Temperature Rating of ANSI/ASME B16.4 Cast-Iron Fittings

Temperature (°F)	Class 125 (psi)	Class 250 (psi)
−20 to 150	175	400
200	165	370
250	150	340
300	150	310
350	125*	300
400	· · ·	250†

* Permissible for service temperature up to 353°F, reflecting the temperature of saturated steam at 125 psig.
† Permissible for service temperature up to 406°F, reflecting the temperature of saturated steam at 250 psig.

The pressure-temperature ratings of Class 125 and Class 250 are listed in Table A2.2. The ratings are independent of the contained fluid and are the maximum nonshock pressure at the listed temperature. As a minimum, the material must conform to class A of ASTM A126. The fittings are threaded with ASME B1.20.1 pipe threads.

TABLE A2.3 Pressure-Temperature Rating of ASME B16.3 Malleable-Iron Threaded Fittings

Temperature (°F)	Class 150 (psig)	Class 300 (psig)		
		Sizes ¼ to 1	Sizes 1¼ to 2	Sizes 2½ to 3
−20 to 150	175	2000	1500	1000
200	265	1785	1350	910
250	225	1575	1200	825
300	185	1360	1050	735
350	150*	1150	900	650
400	. . .	935	750	560
450	. . .	725	600	475
500	. . .	510	450	385
550	. . .	300	300	300

* Permissible for service temperature up to 366°F, reflecting the temperature of saturated steam at 150 psig.

Malleable-Iron Threaded Fittings

Malleable-iron fittings are also extensively produced. They are generally made with threaded joints. Malleable-iron threaded fittings for Classes 150 and 300 are standardized in ASME B16.3. The standard specifies the same attributes for Class 150 and 300 fittings as discussed under ASME B16.4 for gray-iron fittings. The fittings are available in a variety of configurations from NPS ⅛ (DN 3) through NPS 6 (DN 150). The pressure-temperature ratings of these fittings are listed in Table A2.3. As with cast-iron fittings, the ratings are independent of the contained fluid and are maximum nonshock pressures at the listed temperatures. Malleable-iron fittings are furnished black, galvanized, or as otherwise ordered by the buyer. The galvanized threaded fittings commonly used in water piping for homes are Class 150 malleable iron. Minimum properties of malleable iron are required to meet ASTM A197 Cupola Malleable Iron requirements. The fittings are threaded with ASME B1.20.1 pipe threads.

Cast-Brass and Cast-Bronze Threaded Fittings

Cast-brass and -bronze threaded fittings are commonly produced for use with brass pipe. The fittings are manufactured in accordance with ASME B16.15 in pressure Classes 125 and 250. The standard establishes pressure-temperature ratings, size and method of designating openings of reducing fittings, marking, minimum requirements for casting quality, and materials. The nonshock pressure-temperature ratings are listed in Table A2.4. The permitted materials for the fittings are:

ASTM B62, alloy C83600

ASTM B584, alloy C83800 and C84400

ASTM B16, alloy C36000 (bar stock)*

ASTM B140, alloy C32000 or C31400 (bar stock)*

* Used for manufacture of threaded plugs, bushings, and caps.

TABLE A2.4 Pressure-Temperature Rating for Classes 125 and 250 Cast-Bronze Threaded Fittings (ANSI/ ASME B16.15-1985)*

Temperature (°F)	Class 125 (psi)	Class 250 (psi)
−20 to 150	200	400
200	190	385
250	180	365
300	165	335
350	150	300
400	125	250

* Ratings are independent of the contained fluid.

Soldered-Joint Fittings

Soldered-joint wrought metal and cast-brass or -bronze fittings for use with copper water tubes are covered by ASTM B88 and H23.1. The fittings are made in accordance with ASME B16.22 and B16.18, respectively. Joints using these types of fittings and made with 50–50 tin-lead solder, 95-tin 5-antimony solder, or solder melting above 1100°F (593°C) have the pressure-temperature ratings shown in Table A2.5. (*Note:* Lead-bearing solder is not permitted for potable water service.)

Wrought copper fittings normally have a minimum copper content of 83 percent. Cast-brass fittings conform to ASTM B62 and have a nominal composition of 85 percent copper, 5 percent tin, 5 percent lead, and 5 percent zinc. The minimum requirements for 50–50 tin-lead solder generally used with these fittings are covered in ASTM B32 alloy grade 50A. Metal thickness tolerances and general dimensions of fittings are given in ASME B16.18.

TABLE A2.5 Pressure Ratings for Solder Joints (ASME B16.18-1984). Maximum Working Pressure (psi).

Solder used in joints	Working temperatures (°F)	⅛–1 in, incl.*	1¼–2 in, incl.*	2½–4 in, incl.*	5–8 in, incl.*
50–50 tin-lead†	100	200	175	150	135
	150	150	125	100	90
	200	100	90	75	70
	250	85	75	50	45
95–5, tin-antimony	100	500	400	300	270
	150	400	350	275	250
	200	300	250	200	180
	250	200	175	150	135
Solders melting at or above 1100°F	‡	‡	‡	‡	‡

* Standard water tube sizes.
† ASTM B32 alloy grade 50A.
‡ Rating to be consistent with materials and procedures employed.

Cast-Iron Flanged Fittings

Cast-iron flanged fittings are produced in accordance with ASME B16.1. The standard specifies pressure-temperature ratings, sizes, marking, minimum requirements for materials, dimensions and tolerances, bolting, gasketing, and testing requirements. The fittings are manufactured in a variety of configurations (tees, elbows, crosses, laterals, etc.) in pressure Classes 25, 125, 250, and 800. Not all sizes and styles are available in all ratings. The sizes available in each class are listed below:

Pressure class	Size range, NPS (DN)
25	4 (100) through 72 (1800)
125	1 (25) through 96 (2400)
250	1 (25) through 30 (750)
800	2 (50) through 12 (300)

The nonshock pressure-temperature ratings for the four pressure classes are listed in Table A2.6. The materials of construction are ASTM A 126 class A or B, as shown in Table A2.6.

Cast- and Forged-Steel and Nickel-Alloy Flanged Fittings

Flanged fittings of steel and nickel alloys are manufactured in accordance with ASME B16.5. The standard covers ratings, materials, dimensions, tolerances, marking, testing, and methods of designating openings for pipe flanges and flanged fittings in sizes NPS ½ (DN 15) through NPS 24 (DN 600) and in rating Classes 150, 300, 400, 600, 900, 1500, and 2500. However, not all sizes are available in all pressure classes. Dimensions of more commonly used fittings are given in Table A2.7. The standard also contains recommendations and requirements for bolting and gaskets.

Within each pressure class, the dimensions of the fittings are held constant, irrespective of the materials being used. Since the physical properties of different materials vary, the pressure-temperature ratings within each pressure class vary with the material. As an example, a Class 600 forged carbon steel (A105) flange is rated at 1270 psig at 400°F, whereas a Class 600 forged stainless steel (A182, F304) flange is rated at 940 psig at 400°F. The matrix of materials and pressure classes is too numerous to reproduce here; therefore, the reader is referred to ASME B16.5 for the flanged fitting pressure-temperature ratings. Figures A2.1, A2.2, and A2.3 illustrate the reduction in pressure rating with increase in temperature for group 1.1 (ASTM A105), 1.10 (ASTM A182, Gr. F22, Cl. 3), and 2.1 (ASTM A182, Gr. F304) materials.

Forged-Steel Threaded and Socket-Welding Fittings

Forged-steel socket welding and threaded fittings are manufactured in accordance with ASME B16.11. The standard covers pressure-temperature ratings, dimensions, tolerances, marking, and material requirements for forged carbon and alloy steel fittings in the styles and sizes listed in Tables A2.8 and A2.9. Acceptable material forms are forgings, bars, seamless pipe, and seamless tubes which conform to the

TABLE A2.6 Pressure-Temperature Rating of Cast-Iron Pipe Flanges and Flanged Fittings (ASME B16.1-1989).

Pressure is in lb/in² gauge.

NPS is nominal pipe size.

Hydrostatic tests are not required unless specified by user. The test pressure is equal to 1.5 times the 100°F pressure rating.

* Limitations:

(1) Class 25. When Class 25 cast-iron flanges and flanged fittings are used for gaseous service, the maximum pressure shall be limited to 25 psig. Tabulated pressure-temperature ratings above 25 psig for Class 25 cast-iron flanges and flanged fittings are applicable for nonshock hydraulic service only.

(2) Class 250. When used for liquid service, the tabulated pressure-temperature ratings in NPS 14 and larger are applicable to Class 250 flanges only and not to Class 250 fittings.

(3) Class 800. The tabulated rating is not a steam rating and applies to nonshock hydraulic pressure only.

† 353°F (max.) to reflect the temperature of saturated steam at 125 psig.

‡ 406°F (max.) to reflect the temperature of saturated steam at 250 psig.

* L = height of raised face of ring-joint flanges.

† D = approximate distance between flange faces when ring is compressed.

‡ Center-to-face dimensions shown for fittings with ring-joint flanges apply to straight sizes only. For reducing fittings and reducers, use dimensions shown for raised-face flanges of largest opening; Class 400 and higher classes, subtract the ¼-in raised face for each flange (do not subtract the 1/16-in raised face in Class 150 and 300); add height of ring-joint raised face (L) applying to each flange.

    For calculating the "laying length" of fittings with ring joints, add the approximate distance (D) between flange faces when ring is compressed to the center-to-face dimensions in these tables.

FIGURE A2.2 Operating temperature versus allowable working pressure for ASME B16.5 flanges and flanged fittings—Group 1.10 materials. (*From ASME B16.5, 1996*)
FIGURE A2.3 Operating temperature versus allowable working pressure for ASME B16.5 flanges and flanged fittings—Group 2.1 materials. (*From ASME B16.5, 1996*)

chemical compositions, melting practices, and mechanical property requirements of ASTM A105, A182, or A350.

Threaded fittings are available in pressure Classes 2000, 3000, and 6000. Socket-welded fittings are available in pressure Classes 3000, 6000, and 9000. Limitations on fitting size and service conditions are as provided for by the code governing the installation. The maximum allowable pressure of the fitting is equal to that computed for straight seamless pipe of equivalent material, considering manufacturing tolerance, corrosion allowance, and mechanical strength allowance. Also, for socket-welding fittings, the pressure rating must be matched to the pipe wall thickness to ensure that the flat of the band can accommodate the size of the fillet weld required by the applicable code. The recommended fitting pressure class for the various pipe wall thicknesses is as follows:

Pipe schedule and designation	Threaded class	Socket-welded class
80/XS or less	2000	3000
160	3000	6000
XXS	6000	9000

Internal threads of threaded fittings are in accordance with ASME B1.20.1-Pipe Threads, General Purpose (Inch).

Wrought-Steel Butt-Welding Fittings

Wrought-steel welding fittings include elbows, tees, crosses, reducers, laterals, lap-joint stub ends, caps, and saddles.

Wrought-steel fittings are made to the dimensional requirements of ASME B16.9 in sizes NPS ½ (DN 15) through NPS 48 (DN 1200). Also, short-radius elbows and returns are produced in accordance with ASME B16.28 in sizes NPS ½ (DN 15) through NPS 24 (DN 600). The wrought fitting materials conform to ASTM A234, A403, or A420, the grades of which have chemical and physical properties equivalent to that of the mating pipe. ASME B16.9 requires that the pressure-temperature rating of the fitting equal or exceed that of the mating pipe of the same or equivalent material, same size, and same nominal wall thickness. The pressure-temperature rating may be established by analysis or by proof testing. Short-radius elbows and returns (fitting centerline bend radius is equal to the fitting NPS) manufactured under ASME B16.28 are rated at 80 percent of the rating calculated for seamless straight pipe of the same size and nominal thickness and same or equivalent material. Therefore, both standards require that, in lieu of specifying any pressure rating, the pipe wall thickness and pipe material type with which the fittings are intended to be used be identified on the fitting.

Pressure testing of the fittings is not required by either standard. However, the fittings are required to be capable of withstanding, without leakage, a test pressure equal to that prescribed in the specification of the pipe with which the fitting is recommended to be used.

Both ASME B16.9 and B16.28 prescribe dimensions and manufacturing tolerances of wrought butt-welded fittings. The standards establish laying dimensions,

* Pipe schedule numbers in accordance with ASME B36.10M.
† Filling weights are not tabulated in ASME B16.28.
‡ This size and thickness has no corresponding schedule number.
§ Dimensional data for pipe sizes NPS 26 and larger are not included in ASME B16.28.

which remain fixed for each size and type of fitting irrespective of the fitting wall thickness. Tables A2.11, A2.12, A2.13, A2.14, and A2.15 list the laying dimensions and approximate weights for selected fitting sizes, pipe schedules, and configurations.

Laterals are not governed by any national standard. However, dimensions of laterals commonly used are given in Table A2.16. Working pressures are rated at 40 percent of the allowable working pressure established for pipe from which laterals are made. Where full allowable pipe pressures must be met, the laterals are generally made from heavier pipe with ends machined to match standard pipe dimensions. Dimensional tolerances of laterals vary not more than ±1/32 in (1.0 mm) for sizes up to and including NPS 8 (DN 200) and ±1/16 in (2.0 mm) for sizes NPS 10 (DN 250) through NPS 24 (DN 600).

Forged Branch Fittings

Under the various pressure piping codes, branch connections may be made by welding the branch pipe or a welding outlet fitting to the run pipe, provided sufficient reinforcement is available to compensate for the material removed from the run pipe to create the branch opening. The reinforcement may be in the form of excess material already available in the run and branch pipes, or it may be added. At the writing of this book, national standards governing the dimensions, tolerances, and manufacture of welding outlet fittings had not been issued. However, MSS-SP-97, 1995, has been developed to cover forged-carbon-steel 90° branch outlet fittings in butt-welding, socket-welding, and threaded outlet ends. The standard provides essential dimensions, finish, tolerances, and testing requirements. Because of the absence of strict standards, manufacturers produce welding outlet fittings of their own proprietary designs. These fittings must comply with the codes governing the systems in which the fittings are to be installed. The fittings, when installed in accordance with the manufacturers' recommendations, include the required reinforcement. The dimensions of these fittings vary; standardized dimensions and properties must be obtained from the manufacturers. Also, designers must consider the appropriate parameters (e.g., stress intensification factors). Figure A2.4 shows several types of welding fittings, which are proprietary; the terminology used varies with the manufacturer. The fittings are produced in carbon and alloy steels under the ASTM specifications for forgings permitted by applicable codes.

TRAPS

Steam Traps

The function of a steam trap is to discharge condensate from steam piping or steam heating equipment without permitting live steam to escape. Some principal types of steam traps are:

- Float
- Thermostatic
- Thermodynamic
- Inverted bucket

The float type (Fig. A2.5) consists of a chamber containing a float-and-arm mechanism which modulates the position of a discharge valve. As the level of condensate in the trap rises, the valve is opened to emit the condensate. This type of valve tends to discharge a steady stream of liquid since the valve position is proportional to the rate of incoming condensate. Because the discharge valve is below the waterline, float-type steam traps must employ a venting system to discharge noncondensable gases. This is generally accomplished with a thermostatic element which opens a valve when cooler noncondensable gases are present but closes the valve in the presence of hotter steam. The thermostatic steam trap (Fig. A2.6) contains a thermostatic element which opens and closes a valve in response to fluid temperature. Condensate collected upstream of the valve is subcooled, cooling the thermostat, which, in turn, exposes the discharge port. When the cooler condensate is discharged and the incoming condensate temperature approaches the saturation temperature, the thermostat closes the discharge port. Because of its principle of operations, the thermostatic trap operates intermittently under all but maximum condensate loads.

The *inverted bucket* steam trap (Fig. A2.7) consists of a chamber containing an inverted bucket (the opening at the bottom) which actuates a discharge valve through a linkage. The valve is open when the bucket rests at the bottom of the trap. This allows air to escape during warm-up until the bottom of the bucket is sealed by rising condensate. The valve remains open as long as condensate is flowing, and trapped air bleeds out through a small vent in the top of the bucket. When steam enters the trap, it fills the bucket, causing the bucket to float so it rises and closes the valve. The steam slowly escapes through the bucket vent and condenses, thus allowing the bucket to sink and reopen the valve for condensate flow. Small amounts of air and noncondensable

FIGURE A2.8 Thermodynamic steam trap (with integral strainer). (*Spirax Sarco Inc.*)

gases (such as carbon dioxide) that enter the trap during normal operation are also vented through the small opening in the top of the bucket, which prevents the trap from becoming air-bound.

The *thermodynamic steam* trap is illustrated in Fig. A2.8. In this type of trap, flashing of the hot condensate tends to force a small piston into the discharge opening when the temperature of the condensate approaches within about 30°F (15°C) of the saturation temperature. As soon as the condensate collected in the drain system cools sufficiently below the flash temperature, the trap opens and discharges the accumulated water until the temperature of the condensate once more approaches the saturation temperature and flashes, thereby closing the trap and again repeating the cycle. A small orifice permits a continuous discharge of steam, flashed vapor, or noncondensable gas when the trap is closed.

Single orifices are sometimes used to remove condensate from high-pressure, high-temperature steam lines. Where the drains are required only in bringing the line up to temperature, the use of orifices, in conjunction with valves, is particularly desirable.

Air (drain) traps are used to discharge condensed liquid—from a gas system. The drain trap operates on the same principle as the float steam trap does, except that the drain trap does not contain a thermostatic clement.

STRAINERS

Strainers are used in piping systems to protect equipment sensitive to dirt and other particles that may be carried by the fluid. During system start-up and flushing, strainers may be placed upstream of pumps to protect them from construction debris that may have been left in the pipe. Figure A2.9 depicts a typical start-up

strainer. Permanent strainers may be installed upstream of control valves, traps, and instrutments to protect them from corrosion products that may become dislodged and carried throughout the piping system.

Strainers are available in a variety of styles, including wye and basket.

The *wye strainer* (Fig. A2.10) is generally used upstream of traps, control valves, and instruments. The wye strainer resembles a lateral branch fitting with the strainer element installed in the branch. The end of the lateral branch is removable, to permit servicing of the strainer. Also, a blow-off connection may be provided in the end cap to flush the strainer.

FIGURE A2.9   Conical start-up strainer.

Strainer Screen
FIGURE A2.10   Wye strainer.

FIGURE A2.11   Basket strainer.

Basket strainers (Fig. A2.11) are generally used where high flow capacity is required. The basket strainer is serviced by removing the cover, which yields access to the basket. Basket strainers are also available in a duplex style which consists of two parallel basket strainers and diverting valves, which permit diversion of the flow through one of the strainer elements while the other element is being serviced—an essential feature where flow cannot be interrupted.
EXPANSION JOINTS

Expansion joints are used in piping systems to absorb thermal expansion where the use of expansion loops is undesirable or impractical. Expansion joints are available in slip, ball, metal bellows, and rubber bellows configurations.

Slip-type expansion joints (Fig. A2.12a) have a sleeve that telescopes into the body. Leakage is controlled by packing located between the sleeve and the body. Leakage is minimal and can be near zero in many applications. A completely leak-free seal cannot be ensured; thus these expansion joints are ruled out where zero leakage is required. The packing is subject to wear due to cyclic movement of the sleeve when connected piping expands and contracts. Thus, these joints require periodic maintenance, either to compress the packing by tightening a packing gland or to replace or replenish the packing. Replacement of the packing rings is necessary when leakage develops in a joint that has an adjustable packing gland which has been tightened to its limit. Some designs provide for packing replenishment rather than replacement. These are usually called *gun-packed* or *ram-packed* slip joints. Since the packing can wear away, some packing material may be picked up in the line fluid. This rules out the use of slip joints in systems, where such contamination of fluid cannot be tolerated.

Slip-type expansion joints are particularly suited for lines having straight-line (axial) movements of large magnitude. Slip joints cannot tolerate lateral offset or angular rotation (cocking) since this would cause binding, galling, and possibly leakage due to packing distortion. Therefore, the use of proper pipe alignment guides is essential.

Ball expansion joints (Fig. A2.12b) consist of a socket and ball with a sealing mechanism placed between them. The seals are of rigid materials, and in some designs a pliable sealant may be injected into the cavity located between the ball and socket. The joints are capable of absorbing angular and axial rotation; however, they cannot accommodate movement along the longitudinal axis of the joint. Therefore, an offset must be installed in the line to absorb pipe axial movement.

Bellows-type expansion joints (Fig. A2.13) do not have packing; thus they do not have the potential leakage or fluid contamination problems sometimes associated with slip joints. Likewise, they do not require the periodic maintenance (lubrication and repacking) that is associated with slip joints. Bellows joints absorb expansion and contraction by means of a flexible bellows that is compressed or extended. They can also accommodate direction changes by various combinations of compression on one side and extension on an opposing side. Thus, they can adjust to lateral offset and angular rotation of the connected piping. However, they are not capable of absorbing torsional movement. Typically, the bellows is corrugated metal and is welded to the end pieces. To provide the requisite flexibility, the metal bellows is considerably thinner than the associated piping. Thus these expansion joints are especially susceptible to rupture by overpressure. A bellows can also fail because of metal fatigue if the accumulated flexing cycles exceed the designed fatigue life
FIGURE A2.12 (*a*) Slip-type expansion joint. (*Yarway Co.*) (*b*) Typical ball expansion joint. (*Barco Co.*)
**FIGURE A2.13** Metal bellows expansion joint.

FIGURE A2.14 Rubber expansion joint.

(cyclic life) of the bellows or if the flexing extremes exceed the designed compression and extension limits.

Rubber expansion joints (Fig. A2.14) are similar in design to metal bellows expansion joints except that they are constructed of fabric and wire-reinforced elastomers. They are most suitable for use in cold water service where large movements must be absorbed (e.g., condenser circulating water).

THREADED JOINTS

Threaded joints are normally used in low-pressure small-bore, nonflammable service, although threaded iron pipe is commonly used in domestic gas piping and threaded joints up to NPS 12 (DN 300) have been used in low-pressure liquid service.

For quality joints, it is essential to have smooth, clean threads. A proper form for a pipe threading die is shown in Fig. A6.27. Because cut-thread surfaces are somewhat imperfect, thread sealants (pipe dope) and lubricants are often used to ensure a leak-tight joint. Lubricants such as linseed oil or a compound containing powdered zinc or nickel are sufficient to produce a leak-tight joint in well-made threads. Imperfect threads may require white lead or plumber's tape to provide a good seal. In high-pressure piping where leakage cannot be tolerated, the threaded joints may be seal-welded. Where seal welding is employed, all exposed threads should be covered to prevent cracking in the weld.

Dimensional Standards. Dimensional standards for threads are established in ASME Standard B1.20.1. This standard specifies dimensions, tolerances, and gauging for tape and straight pipe threads, including certain special applications. The normal type of pipe joint employs a tapered external and tapered internal thread. But straight pipe threads are used to advantage for certain types of pipe couplings, grease cup, fuel and oil fittings, mechanical joints for fixtures, and conduit and hose couplings.

Pressure-Tight Joints

Pressure-tight joints for low-pressure service are sometimes made with straight internal threads and the American standard taper external threads. The ductility of the coupling enables the straight thread to conform to the taper of the pipe thread. In commercial practice, straight-tapped couplings are furnished for standard-weight (schedule 40) pipe NPS 2 (DN 50) and smaller. If taper-tapped couplings are required for standard-weight pipe sizes NPS 2 (DN 50) and smaller, line pipe in accordance with API 5L should be ordered. The thread lengths should be in accordance with the American Standard for Pipe Threads, ASME B1.20.1. Taper-tapped couplings are furnished on extra-strong (schedule 80) pipe in all sizes and on standard-weight NPS 2½ (DN 65) and larger.

Dry-seal pipe threads machined in accordance with ASME B1.20.3 are also employed for pressure-tight joints, particularly where the presence of a lubricant or sealer would contaminate the flow medium. Threads are similar to the pipe threads covered by ASME B1.20.1; the essential difference is that, in dry-seal pipe threads, the truncation of the crest and root is controlled to ensure metal-to-metal contact coincident with or prior to flank contact, thus eliminating spiral leakage paths. Dry-seal pipe threads are used in refrigerant systems and for fuel and hydraulic control lines in aircraft, automotive, and marine service. Thread sizes up to NPS 3 (DN 75) are covered by ASME B1.20.3.

Hose Nipples and Couplings. Hose coupling joints are ordinarily used with a gasket and made with straight internal and external loose-fitting threads. There are several standards of hose threads having various diameters and pitches, one of which is based on the American standard pipe thread. With this thread series, it is possible to join small hose sizes ½ to 2 in, inclusive, to ends of standard pipe having American standard external taper pipe threads, by using a gasket to seal the joint. ASME B1.20.7 applies to the threaded parts of hose couplings, valves, nozzles, and all other fittings used in direct connection with hose intended for fire protection or for domestic and industrial general services. However, fire hose coupling dimensions and threads vary with fire districts, and the local fire authority must be consulted. Figure A2.15 illustrates a typical fire hose coupling.
FIGURE A2.15 Typical fire hose coupling.

Bolted Joints

The use of bolted joints is advantageous in the following circumstances:

- The components cannot be serviced in line.
- The components being joined are not capable of being welded.
- Quick field assembly is required.
- The component or pipe section must be frequently removed for service.

Bolted piping components are manufactured in accordance with several national standards. Also, several manufacturers produce proprietary bolted connections

TABLE A2.17 Dimensions of Typical Commercial Cast-Iron Companion Flanges Manufactured in Accordance with ASME B16.1-1989

which offer cost and time savings over conventional flanged connections. However, proprietary designs must be used within the limitations of the applicable codes.

Ductile and Cast-Iron Flanges. Cast-iron flanges are produced in accordance with ASME B16.1. The standard establishes dimensional requirements, pressure ratings, materials, and bolting requirements. The pressure-temperature ratings and materials requirements for cast-iron flanges are the same as those for cast-iron flanged fittings. The pressure-temperature ratings are given in Table A2.6. The dimensions for Class 125 and Class 250 cast-iron flanges are listed in Table A2.17. XDimensions for bolting are listed in Table A2.18. Note that the Class 125 and Class 250 flanges can be mated with ASME B16.5 Class 150 and Class 300 steel flanges, respectively. When a Class 150 flange is bolted to a Class 125 cast-iron flange (a flat-faced flange), the steel flange should be flat-faced.

Ductile iron flanges and flanged fittings are manufactured in conformance with

   * All 125-lb cast-iron standard flanges have a plain face.

   † Dimensional standards have not been established for malleable-iron companion flanges; they are generally produced to the same dimensions as cast-iron flanges of the same class.

   ‡ Minimum thickness of Class 250 flanges includes ¹⁄₁₆-in raised face.

the following standards:

ASME B16.42   Ductile Iron Pipe Flanges and Flanged Fittings—Class 150 and 300.

ANSI/AWWA   C110/A21.10, C115/A21.15 and C153/A21.53, are listed earlier under ductile and cast iron fittings.

Steel and Nickel-Alloy Flanges.   Steel and nickel-alloy flanges up to NPS 24 are produced in accordance with ASME B16.5. Steel flanges NPS 26 (DN 650) through NPS 60 (DN 1500) are produced in accordance with ASME B16.47. Also, orifice flanges are produced in accordance with ASME B16.36. The standards specify materials, dimensions, pressure-temperature ratings, and recommendations for bolting and gasketing. Flanges manufactured to ASME B16.5 and B16.47 may be cast or forged. Also, blind flanges may be fabricated from specific plate materials. The most commonly used materials are forged carbon steel (ASTM A105) and forged low-alloy and stainless steel (ASTM A182). The standards cover seven pressure classes (Classes 150, 300, 400, 600, 900, 1500, and 2500) in a variety of styles and materials. Figures A2.16 and A2.17 show typical flange styles. The dimensions of each style within each pressure class are held constant irrespective of the material. Therefore, within each pressure class, the pressure-temperature rating varies with the material properties (see Figs. A2.1, A2.2, and A2.3).

Proprietary Bolted Connections.   There are various proprietary bolted pipe joining systems produced that are not formally addressed by any standard. Under the various piping codes, pressure-retaining components not covered by standards specifically cited as acceptable for use under the "Code" may be used provided their design is proved by analysis or proof testing or a combination of both.

Flange Types

Flanges differ in method of attachment to the pipe, i.e., whether they are screwed, welded, or lapped. Contact surface facings may be plain, serrated, grooved for ring joints, seal-welded, or ground and lapped for metal-to-metal contact. Some common

types of joints and facings are shown in Fig. A2.18. In Section VIII, Unfired Pressure Vessels, of the ASME Boiler and Pressure Vessel Code, three types of circular flanges are defined, and these are designated as loose-type (Fig. A2.17), integral-type (Fig. A2.16), and optional-type flanges. Under the code, the welds and other details of construction shall satisfy the dimensional requirements stated therein.
FIGURE A2.16 Typical integral flange (welding neck flange).

Loose-Type Flanges. This (slip-on) type covers those designs in which the flange has no direct connection to the nozzle neck or the vessel or pipe wall and those designs where the method of attachment is not considered to give the mechanical strength equivalent of integral attachment.

Integral-Type Flanges. This type covers designs in which the flange is cast or forged integrally with the nozzle neck or the vessel or pipe wall, butt-welded thereto, or attached by other forms of arc or gas welding of such a nature that the flange
FIGURE A2.17 Typical loose flanges (threaded and slip-on).

and nozzle neck or vessel or pipe wall is considered to be the equivalent of an integral structure. In welded construction, the nozzle neck or the vessel or pipe wall is considered to act as a hub.

Optional-Type Flanges. This type covers designs where the attachment of the flange to the nozzle neck or the vessel or pipe wall is such that the assembly is considered to act as a unit, which shall be calculated as an integral flange, except that for simplicity the designer may calculate the construction as a loose-type flange, provided that stipulated load values are not exceeded.

It is important in flange design to select materials and to proportion dimensions of bolts, flanges, and gaskets to ensure that the necessary compression will be maintained on the joint faces over the expected life of the equipment.

Several distinct phases of the problem are involved: (1) type of flange facing, (2) finish of contact surfaces, (3) gasket type and proportions, (4) bolt load required to secure and maintain a tight joint, and (5) proportions of flange needed to support the bolt load.

Types of Flange Facing. There are numerous types of contact facings for flanges, the simplest of which is the plain face provided with a "smooth tool finish." Class 125 cast-iron flanged fittings are provided with this type of facing. For steel flanges
FIGURE A2.18 Commonly used flanged joints. (*a*) Screwed flange to fitting joint, plain face; (*b*) screwed flange pipe joint, male-and-female face; (*c*) lapped pipe to fitting joint, square corner; (*d*) lapped pipe to pipe joint, round corner; (*e*) ring and groove joint, welding neck flange to fitting; (*f*) lapped pipe to fitting joint, Sarlun seal welded; and (*g*) lapped pipe to fitting joint, Sargol seal welded.

and fittings, the typical facings (Fig. A2.19) are taken from the American Standard for Steel Pipe Flanges and Flanged Fittings, ASME B16.5 and ASME B16.47. The raised face, the lapped, and the large male-and-female facings have the same dimensions, which provide a relatively large contact area. Where metal gaskets are used with these facings, the gasket area should be reduced to increase the gasket compression.

The flange-facing types illustrated in Fig. A2.19 range in size and contact area in the following order: large tongue-and-groove, small tongue-and-groove, small

male-and-female, and ring joint. Because of the small gasket contact area, a tight joint may be secured with the ring-type facing using low bolting loads, thereby resulting in lowered flange stresses (ASME B16.5). The Sargol and Sarlun facings, which have lips for seal welding, are used frequently for severe service conditions. Seal welding is not always performed since, if it is properly made, a tight joint often can be maintained without the welded seal, thus facilitating disassembly. Typical facing dimensions for Sarlun and Sargol joints are shown in Fig. A2.20. Special types of facing of individual design intended for a specific service are numerous. Economic considerations generally make it desirable to use a standard facing wherever possible.

Selection of the type of facing depends to a considerable extent on the nature of the service. However, it is not possible to determine exactly which facing should be used. Prior experience is usually relied on as a guide. Plain-face joints with red rubber gaskets have been found satisfactory for temperatures up to 220°F (105°C), whereas serrated raised-face joints with graphite-steel-composition gaskets are commonly used for temperatures up to 750°F (400°C). For high temperatures and pressures, faces giving a high contact pressure for a given bolt load are customary, such as the tongue-and-groove and ring joints. However, with high contact pressures, the gasket load must be checked to ensure that the gasket is not overcompressed.

An equally successful joint for most types of service can be made by using a profile-serrated metal gasket contacting the flange facing, which may be the plain male-to-male raised-face type.

Contact Surface Finish. The surface finish is an important factor in determining the extent to which a gasket must flow to secure an impervious seal. Bolting that results in adequate gasket flow to form a satisfactory seal with a smooth contact surface may be inadequate to secure a tight joint with a rough surface. The finish may vary from that produced by rough casting surfaces to that produced by grinding and lapping. Less gasket flow will be necessary for the latter than for the former. The finish most frequently provided on cast-iron and steel pipe flanges is the smooth tool finish. A serrated finish frequently is provided for steel flanges, particularly when using a graphite-composition gasket with a wide contact area such as is furnished on raised, lapped, or large tongue-and-groove facings. The serrated finish consists of spiral or concentric grooves, usually about 1/64 in (0.4 mm) deep with 12.5 serrations per cm (32 serrations per inch). Where metal gaskets are used, a smooth surface produced by grinding or lapping is usually provided. The Sargol and Sarlun facings mate metal to metal without a gasket, in which case a mirrorlike finish is necessary. This is usually produced by grinding and lapping. It is evident that the surface finish varies with the type of contact face and gasket used and, therefore, should be specified accordingly.

Gaskets

Since it is expensive to grind and lap joint faces to obtain fluid-tight joints, a gasket of some softer material is usually inserted between contact faces. Tightening the bolts causes the gasket material to flow into the minor machining imperfections, resulting in a fluid-tight seal. A considerable variety of gasket types are in common use. Soft gaskets, such as cork, rubber, vegetable fiber, graphite, or asbestos, are usually plain with a relatively smooth surface. The semimetallic design combines metal and a soft material, the metal to withstand the pressure, temperature, and attack of the confined fluid and the soft material to impart resilience. Various designs involving corrugations, strip-on-edge, metal jackets, etc., are available. In addition to the plain, solid, and flat-surface metal gaskets, various modified designs and cross-sectional shapes of the profile, corrugated, serrated, and other types are used. The object in general has been to retain the advantage of the metal gasket but to reduce the contact area to secure a seal without excessive bolting load. Effective gasket widths are given in various sections of the ASME Boiler and Pressure Vessel Code.

Gasket Materials. Gasket materials are selected for their chemical and pressure resistance to the fluid in the pipe and their resistance to deterioration by temperature. Gasket materials may be either metallic or nonmetallic. Metallic ring-joint gasket materials are covered by ASME Standard B16.20, Ring-Joint Gaskets and Grooves for Steel Pipe Flanges. Nonmetallic gaskets are covered in ASME Standard B16.21, Nonmetallic Gaskets for Pipe Flanges. Typical selections of gasket materials for different services are shown in Table A2.19.

Gasket Compression. In the usual type of high-pressure flange joint, a narrow gasket face or contact surface is provided to obtain higher unit compression on the gasket than is obtainable on full-face gaskets used with low-pressure joints. The compression on this surface and on the gasket if the gasket is used, before internal

TABLE A2.19 Selections of Gasket Materials for Different Services

Fluid	Application	Gasket material*
Steam (high pressure)	Temp up to 1000°F (538°C)	Spiral-wound comp. asbestos or graphite
	Temp up to 1000°F (538°C)	Steel, corrugated, or plain
	Temp up to 1000°F (538°C)	Monel, corrugated, or plain
	Temp up to 1000°F (538°C)	Hydrogen-annealed furniture iron
	Temp up to 1000°F (538°C)	Stainless steel 12 to 14 percent chromium, corrugated
	Temp up to 1000°F (538°C)	Ingot iron, special ring-type joint
	Temp up to 750°F (399°C)	Comp. asbestos, spiral-wound
	Temp up to 600°F (316°C)	Woven asbestos, metal asbestos
	Temp up to 600°F (316°C)	Copper, corrugated or plain
Steam (low pressure)	Temp up to 220°F (105°C)	Red rubber, wire inserted

	Temp up to 700°F (371°C)	Comp. asbestos
	Weak solutions	Red rubber
	Hot	Thin asbestos
	Cold	Sheet lead

* Several gasket manufacturers have introduced nonasbestos, nonmetallic gasket materials for use in high-temperature service. These materials are proprietary, and therefore the manufacturers should be consulted for specific applications.

pressure is applied, depends on the bolt loading used. In the case of standard raised-face joints of the steel-flange standards, these gasket compressions range from 28 to 43 times the rated working pressure in the Class 150 to 400 standards, and from 1 to 28 times in the Class 600 to 2500 standards for an assumed bolt stress of 60,000 psi (4200 kg/cm^2). For the lower-pressure standards, using composition gaskets, a bolt stress of 30,000 psi (2100 kg/cm^2) usually is adequate. The effect of applying the internal pressure is to decrease the compression on the contact surface, since part of the bolt tension is used to support the pressure load.

The initial compression required to force the gasket material into intimate contact with the joint faces depends upon the gasket material and the character of the joint facing. For soft-rubber gaskets, a unit compression stress of 4000 psi (280 kg/cm^2) to 6000 psi (420 kg/cm^2) usually is adequate. Laminated asbestos gaskets in serrated faced joints perform satisfactorily if compressed initially at 12,000 psi (850 kg/cm^2) to 18,000 psi (1260 kg/cm^2). Metal gaskets such as copper, Monel, and soft iron should be given initial compressions considerably in excess of their yield strengths. Unit pressures of 30,000 psi (2100 kg/cm^2) to 60,000 psi (4200 kg/cm^2) have been used successfully with metal gaskets. Various forms of corrugated and serrated metal gaskets are available which enable high unit compression to be obtained without excessive bolt loads. These are designed to provide a contact area that will flow under initial compression of the bolts so as to make an initially pressure-tight joint, but at the same time the compressive stresses in the body of the gasket are sufficiently low as to be comparable to the long-time load-carrying ability of the bolting and flange material at high temperatures.

The residual compression on the gasket necessary to prevent leakage depends on how effective the initial compression has been in forming intimate contact with the flange joint faces. Tests show that a residual compression on the gasket of only 1 to 2 times the internal pressure, with the pressure acting, may be sufficient to prevent leakage where the joint is not subjected to bending or to large and rapid temperature changes. Since joints in piping customarily must withstand both these disturbing influences, minimum residual gasket compressions of 4 to 6 times the working pressure should be provided for in the design of pipe joints.

Relation of Gaskets to Bolting. There is a tendency, as indicated in the ASME Rules for Bolted Flanged Connections, to assign lower residual contact-pressure ratios ranging from about 1 for soft-rubber gaskets to 6 or 7 for solid-metal gaskets. Whereas these are said to have proved satisfactory service for heat-exchanger and pressure-vessel flanges, the more severe service encountered by pipe flanges due to bending moments and large temperature changes is considered by many to warrant designing on the basis of the larger residual gasket compression ratios recommended in the previous paragraph. The lack of understanding of the mechanics of gasket action, the variety of gasket materials, shapes, widths, and thicknesses; the variety of facings used; the variation in flange stiffness; and the uncertainties in bolt pull-up are among the factors that render difficult a precise solution to the problem of gasket design.

Rules for bolting and flange design are contained in Sections III and VIII of the ASME Boiler and Pressure Vessel Code.

Bolting

Bolting material for cast-iron flanges is listed in ASME B16.1. Generally, ASTM A307, grade B material is suitable. For steel flanges, acceptable bolting material is listed in ASME B16.5.

Threading.   Bolts and nuts normally are threaded in accordance with ASME B1.1 Standard for Unified Screw Threads. In diameters 1 in and smaller, Class 2A fits on the bolt or stud and Class 2B on the nut applies with the coarse thread series. In diameters 1⅛ in and larger, the eight-pitch-thread series applies with the same fit. Grade 7 bolts are threaded by roll threading after heat treatment. Roll threading cold-works the surface uniformly. The resulting compressive stresses provide substantially increased fatigue strength at the thread root, which is usually the weakest point. The thread root is the weakest point because it is the smallest cross-sectional area in the bolt. The stressed area A of a bolt is computed from

$$A = \frac{0.7854(D - 0.9743)^2}{N}$$

where D is the nominal bolt diameter and N represents the threads per inch.

Bolts with fine threads will exhibit a slightly higher proof strength (about 10 percent) than bolts with coarse threads (as illustrated in Fig. A2.21), provided that the length of engagement with the mating internal thread is sufficient to guarantee a tensile failure through the bolt rather than failure by thread stripping.

In practical bolt assemblies, fine threads are considered weaker because of reduced thread height. Fine threads have limited application for threaded assemblies. They should be used for adjustment rather than as a clamping force.
FIGURE A2.21   Comparison of proof strength of fine and coarse threads, SAE Grade 5, ¾-in bolts.

Dimensions

The dimensions applicable to bolting materials are given in ASME B16.5, American Standard Pipe Flanges and Flanged Fittings.

Securing and Tightening.   For the average low- and medium-pressure installations, bolts are made in staggered sequence with wrenches which will usually result in adequately tight joints. For the high-pressure and -temperature joints, it becomes increasingly important to make up each stud to a definite tension. Torque wrenches are sometimes used for this purpose.

In exceptional cases where a more positive method is desired, the studs may be tightened until a definite elongation has been attained. For this condition, an initial cold tension of 30,000 psi (2100 kg/cm^2) to 35,000 psi (2460 kg/cm^2) in each stud is recommended. Since the modulus of elasticity of stud material is about 30×10^6 psi (2.1×10^6 kg/cm^2), a tension of 30,000 psi (2100 kg/cm^2) would result in an elongation 0.1% of effective length. The effective length is the distance between nut faces plus one nut thickness. Special studs with ground ends are required to make micrometer measurements for this purpose. After the joint has been in service, periodic checks of the actual cold lengths as compared with the tabulated lengths will detect any permanent elongation of the studs. Permanent elongation will indicate

TABLE A2.20 Turning Efforts to Tighten Eight-Pitch-Thread Bolts

overstressing, relaxation, and creep. When these conditions become severe, new studs may be required to maintain the joint properly.

Special thread lubricants are available for temperatures both below 500°F (260°C) and from 500°F (260°C) to 1000°F (540°C). Such lubricants not only facilitate initial tightening but also permit easier disassembly after service.

Table A2.20 illustrates the turning effort required for tightening well-lubricated threads and bearing surfaces. Tests with no lubricant on threads and bearing surfaces may increase torque requirements by 75 to 100 percent to secure a given bolt stress.

For more information on bolted joints, see Chap. A7.

WELDED AND BRAZED JOINTS

Welded and brazed joints are the most commonly used methods for joining piping components because these joints are stronger and more leak-tight than threaded

and flanged joints. Furthermore, they do not add weight to the piping system as flanges do, and they do not require an increase in pipe wall thickness to compensate for threading, as threaded joints do.

Pipe-Weld Joint Preparation and Design

Butt Welds.   The most common type of joint employed in the fabrication of welded pipe systems is the circumferential butt joint. It is the most satisfactory joint from the standpoint of stress distribution. Its general field of application is pipe to pipe, pipe to flange, pipe to valve, and pipe to fitting joints. Butt joints may be used for all sizes, but fillet-welded joints can often be used to advantage for pipe NPS 2 (DN 50) and smaller.

The profile of the weld edge preparations for butt welds may be any configuration the welding organization deems suitable for making an acceptable weld. However, to standardize the weld edge preparation on butt-welded commercial piping components, standard weld edge preparation profiles have been established in ASME B16.25. These weld edge preparation requirements are also incorporated into the standards governing the specific components (e.g., B16.9, B16.5, B16.34). Figures
Nominal pipe wall thickness t	End preparation

A2.22, A2.23, and A2.24 illustrate the various standard weld edge profiles for different wall thickness.

On piping, the end preparation is normally done by machining or grinding. On pipe of heavier wall thicknesses, machining is generally done on post mills. On carbon and low-alloy steels, oxygen cutting and beveling are also used, particularly on pipe of wall thicknesses below ½ in (12 mm). However, the slag should be removed by grinding prior to welding.

Because of fairly broad permissible eccentricity and size tolerances of pipe and fittings, considerable mismatch may be encountered on the inside of the piping. Limitations on fit-up tolerances are included in several piping codes. For severe service applications, internal machining may be required to yield proper fit-up. When one is machining the inside diameter, care should be taken to ensure that minimum wall requirements are not violated. Table A2.21 lists the counterbore dimensions typically specified.

When piping components of unequal wall thickness are to be welded, care should be taken to provide a smooth taper toward the edge of the thicker member. The length of the taper desirable is normally 3 times the offset between the components, as outlined in ASME Boiler and Pressure Vessel Code Sections-I and III, and ASME B31.1, Power Piping Code. The two methods of alignment which are recommended are shown in Fig. A2.25.
FIGURE A2.25 Recommended welding-end sections for pipe, valves, and fittings of unequal thickness. (*a*) Preferred method (centerlines coincide); (*b*) permissible (circumferential points only).

The wall thickness of cast-steel fittings and valve bodies is normally greater than that of the pipe to which they are joined. To provide a gradual transition between piping and components, the ASME Boiler and Pressure Vessel Code and the ASME

Code for Pressure Piping permit the machining of the cylindrical ends of fittings and valve bodies to the nominal wall thickness of the adjoining pipe. However, in no case is the thickness of a valve permitted to be less than $0.77t_{min}$ at a distance of $1.33t_{min}$ from the weld end, where t_{min} is the minimum valve thickness required by ASME B16.34. The machined ends may be extended back in any manner, provided that the longitudinal section comes within the maximum slope line indicated in Fig. A2.25. The transition from the pipe to the fitting or valve end at the joint must be such as to avoid sharp reentrant angles and abrupt changes in slope.

End Preparation for Inert-Gas Tungsten-Arc Root-Pass Welding. The pipe end bevel preparations shown in Fig. A2.24 are considered adequate for shielded metal-arc welding, but they pose some problems in inert-gas tungsten-arc welding. When this process is used, extended U or flat-land bevel preparations are considered more suitable since the extended land reduces the heat sink, thereby affording better weld penetration. The end preparations apply to inert-gas tungsten-arc welding of carbon- and low-alloy steel piping, stainless-steel piping, and most nonferrous piping materials. On aluminum piping, the flat-land bevel preparations are preferred by some fabricators.

Backing Rings. Backing rings are employed in some piping systems, particularly where pipe joints are welded primarily by the shielded metal-arc welding process with covered electrodes. For example, a significant number of pipe welds for steam power plants and several other applications are made with the use of backing rings. On the other hand, in many applications backing rings are not used, since they may restrict flow, provide crevices for the entrapment of corrosive substances, enhance susceptibility to stress corrosion cracking, or introduce still other objectionable features. Thus, there is little, if any, use made of backing rings in most refinery piping, radioactive service piping, or chemical process piping.

The use of backing rings is primarily confined to carbon- and low-alloy steel and aluminum piping. Carbon-steel backing rings are generally made of a mild carbon steel with a maximum carbon content of 0.20 percent and a maximum sulfur content of 0.05 percent. The latter requirement is especially important since high sulfur in deposited weld metal (which could be created by an excessive sulfur content in such rings) may cause weld cracks. Split backing rings are satisfactory for service piping systems. For the more critical service applications involving carbon- and low-alloy steel piping, solid flat or taper-machined backing rings are preferred in accordance with the recommendations shown in Pipe Fabrication Institute Standard ES1 and illustrated in Fig. A2.24 and Table A2.21.

When a machined backing ring is desired, it is a general recommendation that welding ends be machined on the inside diameter in accordance with the Pipe Fabrication Institute standard for the most critical services—and then only when pierced seamless pipe that complies with the applicable specifications of the American Society for Testing and Materials is used. Such critical services include high-pressure steam lines between boiler and turbines and high-pressure boiler feed discharge lines, as encountered in modern steam power plants. It is also recommended that the material of the backing ring be compatible with the chemical composition of the pipe, valve, fitting, or flange with which it is to be used. Where materials of dissimilar composition are being joined, the composition of the backing ring may be that of the lower alloy.

On turned-and-bored and fusion-welded pipe, the design of the backing ring and internal machining, if any, should be a matter of agreement between the

customer and the fabricator. Regardless of the type of backing rings used, it is recommended that the general contour of the welding bevel shown in Fig. A2.24 be maintained.

When machining piping for backing rings, the resulting wall thickness should be not less than that required for the service pressure. Wherever internal machining for machined backing rings is required on pipe and welding fittings in smaller sizes and lower schedule numbers than those listed in Table A2.21, weld metal may have to be deposited on the inside of the pipe in the area to be machined. This is to provide satisfactory contact between the machined surface on the pipe inside and the machined backing ring. For such cases, the machining dimension should be a matter of agreement between the fabricator and the purchaser.

Whenever pipe and welding fittings in the sizes and schedule numbers listed in Table A2.21 have plus tolerance on the outside diameter, it also may be necessary to deposit weld metal on the inside of the pipe or welding fitting in the area to be machined. In such cases, sufficient weld metal should be deposited to result in an ID not greater than the nominal ID given in Table A2.21 for the particular pipe size and wall thickness involved.

Experience indicates that machining to dimension C for the pipe size and schedule number listed in Table A2.21 generally will result in a satisfactory seat contact of 7/32 in (5.5 mm) minimum (approximately 75 percent minimum length of contact) between pipe and the 10° backing ring. Occasionally, however, it will be necessary to deposit weld metal on the inside diameter of the pipe or welding fitting in order to provide sufficient material for machining a satisfactory seat.

In welding butt joints with backing rings, care should be exercised to ensure good fusion of the first weld pass into the backing ring in order to avoid lack of weld penetration or other types of stress-raising notches.

Consumable Insert Rings..   The chemical composition of a piping base metal is established primarily to provide it with certain mechanical, physical, or corrosion resisting properties. Weldability characteristics, if considered at all, are of secondary concern. On the other hand, the chemical composition of most welding filler metals is determined with primary emphasis on producing a sound, high-quality weld. The steelmaking process employed in the manufacture of welding filler metals permits closer control of the composition range, which is usually considerably narrower than would be practical for the piping base metal where much larger tonnages of steel are involved. On some base metals, the welding together by fusion of only the base-metal compositions may lead to such welding difficulties as cracking or porosity. The addition of filler metal tends to improve weld quality. However, in inert-gas tungsten-arc welding, the addition of welding filler metal from a separate wire, which the welder feeds with one hand while manipulating the tungsten-arc torch with the other, is a cumbersome process and interferes with welding ease. The welder may leave areas with lack of penetration, which generally are considered unacceptable as can be seen, e.g., in the rules of the ASME Boiler and Pressure Vessel Code. Since some types of serious weld defects are detected only with difficulty during inspection (if they are detected at all), it is extremely important to provide the easiest welding conditions for the welder to produce quality welds. One technique to produce high-quality welds is to employ consumable insert rings of proper composition and dimensions. Consumable insert rings which are available commercially are shown in Fig. A2.26. The three primary functions of consumable insert rings are to (1) provide the easiest welding conditions and thereby minimize the effects of undesirable welding variables caused by the "human" element, (2) give the most favorable weld contour to resist cracking resulting from weld-metal

shrinkage and hot shortness, or brittleness, in hot metal, and (3) produce metallurgically the soundest possible weld-metal composition of desirable strength, ductility, and toughness properties.

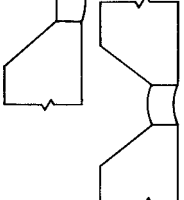
The best welding conditions are obtained where the flat-land and extended U-bevel preparations are used. These joint preparations are particularly helpful where welding is done in the horizontal fixed pipe position (5G), since they ensure a flat or slightly convex root contour and provide by far the greatest resistance to weld cracking in those alloys particularly susceptible to microfissuring.

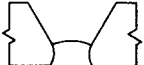
The weld-root contour conditions to be expected from different bevel preparations and consumable insert rings are illustrated in Fig. A2.27. Where sink is not acceptable, it is considered obligatory to use consumable insert rings with the special flat-land or extended U-bevel preparation. In horizontal-rolled (IG) and vertical-position (2G) welding, the insert ring should be placed concentrically into the beveled pipe.

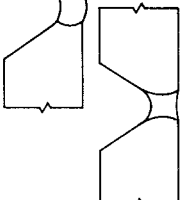
In horizontal fixed-position (5G) welding, the insert ring should be placed eccentric to the centerline of the pipe (as shown in Fig. A2.28). In this position, the insert ring compensates for the downward sag of the molten weld metal and aids in obtaining smooth, uniform root contour along the inner diameter and the joint.
FIGURE A2.26 Commercial consumable insert rings used in pipe welding (MIL-I-23413). Style D: for NPS 2 and larger. On Schedule 5 for NPS 5 and larger; style E: for NPS less than 2. On Schedule 5 for NPS less than 5.

Fillet Welds

Circumferential fillet-welded joints are generally used for joining pipe to socket joints in sizes NPS 2 (DN 50) and smaller. Figure A2.29 illustrates three typical fillet-welded joints. These types of welds are subjected to shearing and bending stresses, and adequate penetration of the pieces being joined is essential. This is particularly important with the socket joint, since the danger of washing down the end of the hub may obscure, by reason of fair appearance, the lack of a full and sound fillet weld. This condition is one which cannot be detected in the finished weld by the usual visual inspection. Additionally, a 1/16-in (1.5-mm) gap (before welding) must be maintained between the pipe end and the base of the fitting to allow for differential expansion of the mating elements.

There are service applications in which socket welds are not acceptable. Piping systems involving nuclear or radioactive service or corrosive service with solutions which promote stress corrosion cracking or concentration cell action generally






Welding conditions	Consumable insert ring	Position	Inside pipe contour			Permissible concavity at inside of pipe

FIGURE A2.27   Root-contour conditions which can be expected as the result of normal pipe welding with the gas tungsten-arc welding process. In 5G (horizontal-fixed) position welding the insert ring is positioned eccentric to the centerline of the pipe, as illustrated in Fig. A2.28.

require butt welds in all pipe sizes with complete weld penetration to the inside of the piping.

Brazed Joints

Lap or shear-type joints generally are necessary to provide capillary attraction for brazing of connecting pipe. Square-groove butt joints may be brazed, but the results are unreliable unless the ends of the pipe or tube are accurately prepared, plane and square, and the joint is aligned carefully, as in a jig. High strengths may be obtained with butt joints if they are properly prepared and brazed. However, owing to the brittleness of the brazing alloy, they are not normally applicable.

The alloys generally used in brazing exhibit their greatest strength when the thickness of the alloy in the lap area is minimal. Thin alloy sections also develop the highest ductility. For brazing ferrous and nonferrous piping with silver- and copper-base brazing alloys, the thickness of the brazing alloy in the joint generally should not be more than 0.006 in (0.15 mm) and preferably not more than 0.004 in (0.1 mm). Thicknesses less than 0.003 in (0.07 mm) may make assembly difficult, while those greater than 0.006 in (0.15 mm) tend to produce joints having lowered strength. The brazing of certain aluminum alloys is similar in most respects to the brazing of other materials. However, joint clearances should be greater because of a somewhat more sluggish flow of the brazing alloys. For aluminum, a clearance of 0.005 to 0.010 in (0.12 to 0.25 mm) will be found satisfactory. Care must be exercised in fitting dissimilar metals, since the joint clearance at brazing temperature is the controlling factor. In these cases, consideration must be given to the relative expansion rates of the materials being joined.

The length of lap in a joint, the shear strength of the brazing alloy, and the average percentage of the brazing surface area that normally bonds are the

* The thickness of the bell S shall in all instances be equal to, and generally exceed by at least 10 percent, the nominal wall thickness of the pipe or fitting of which it is a part.

† Cored holes may be tapered an additional 0.06 in in diameter.

‡ In the event of ovalness of the plain end outside diameter, the mean diameter measured by a circumferential tape shall not be less than the minimum diameter shown in the table. The minor acis shall not be less than the above minimum diameter plus an additional minus tolerance of 0.04 in for NPS 8–12, 0.07 in for NPS 14–24, and 0.10 in for NPS 30–48.

§ K_1 and K_2 are the dimensions across the bolt holes. For sizes 2 and 2¼ in, both flange and gland may be oval shaped. For NSP 3–48, the gland may be polygon shaped.

¶ Mechanical joints require the use of specially designed bolts. See ANSI/AWWA C111/A21.11-1985.

principal factors determining the strength of brazed joints. The shear strength may be calculated by multiplying the width by the length of lap by the percentages of bond area and by taking into consideration the shear strength of the alloy used. An empirical method of determining the lap distance is to take it as twice the thickness of the thinner or weaker member joined. Normally this will provide adequate strength, but in cases of doubt, the fundamental calculations should be employed.

Such detailed determinations are generally unnecessary for brazed piping, since commercial brazing fittings are available in which the length of lap is predetermined at a safe value. For brass and copper pipe, cast or wrought bronze and wrought copper fittings are available. A bore of correct depth to accept the pipe is provided, and midway down this bore may be a groove into which, at the time of manufacture, a ring of brazing alloy is inserted. Since the alloy is preplaced in fittings with such a groove, separate feeding of brazing alloy by hand is generally unnecessary.

JOINING DUCTILE OR CAST-IRON PIPE

Bell-and-Spigot Joint

This joint for underground cast-iron pipe was developed as long ago as 1785. Standard dimensions are shown in Table A2.22.

The joint may be made up with lead and oakum, sulfur compounds, or cement. Lead and oakum constitute the prevailing joint sealer for sanitary systems. Bell-and-spigot joints are usually reserved for sanitary sewer systems. These joints are not used in ductile iron pipe.

Mechanical (Gland-Type) Joint

This modification of the bell-and-spigot joints, as designated in Federal Specification WW-P-421 and ANSI/AWWA C111/A21.11, is illustrated in Table A2.23. This joint is commonly used for low and intermediate-pressure gas distribution systems, particularly those conveying natural gas or dry manufactured gas. Mechanical joints are also used for water lines, sewage, and process piping. In the mechanical (gland-type) joint shown in Fig. A2.30, the lead and oakum of the conventional bell-and-spigot joint are supplanted by a stuffing box in which a rubber or composition packing ring, with or without a metal or canvas tip or canvas backing, is compressed by a ductile cast-iron follower ring drawn up with bolts. In addition to making an inherently tight joint even under considerable pressure, this arrangement has the advantage of permitting relatively large lateral deflections (3½° to 7°), as well as longitudinal expansion or contraction. For more details, refer to AWWA C600, Standard for Installation of Ductile-Iron Water Mains and Their Appurtenances.
FIGURE A2.30   Mechanical (gland-type) joint for cast-iron pipe.

Tyton Joint

The Tyton joint is designed to contain an elongated grooved gasket. The inside contour of the socket bell provides a seat for the circular rubber in a modified bulb-shaped gasket. An internal ridge in the socket fits into the groove of the gasket. A slight taper on the plain end of the pipe facilitates assembly.

Standard dimensions are given in Table A2.24. The maximum joint deflection angle is 5° for sizes through NPS 12 (DN 300), 4° for NPS 14 (DN 350) and NPS 16 (DN 400), and 3° for NPS 18 (DN 450), NPS 20 (DN 500), and NPS 24 (DN 600). Either all-bell U.S. standardized mechanical joint fittings or bell-and-spigot all-bell fittings with poured or cement joints can be used with Tyton joint pipe.

Mechanical Lock-Type Joint

For installations where the joints may tend to come apart owing to sag or lateral thrust in the pipeline, a mechanical joint having a self-locking feature is used to resist end pull. This joint is similar to the gland-type mechanical joint except that in the locked joint the spigot end of the pipe is grooved or has a recess to grip the gasket. Although only slight expansion or contraction can be accommodated in this type of joint, it does allow the usual 3½° to 7° angular deflection. The lock-type joint finds application aboveground in the process industries and in river crossings on bridges or trestles, as well as in submarine crossings or in unusually loose or known marshy soils. Where the locking feature is on the spigot rather than on the bell, this type of pipe can be used with the regular line of mechanical joint fittings.

Mechanical Push-On-Type Joint

Where a low-cost mechanical joint is desired, the roll-on type can be used. In this joint, a round rubber gasket is placed over the spigot end and is pulled into the bell by mechanical means, thus pulling the ring into place in the bottom of the bell. Outside the rubber gasket, braided jute is wedged behind a projecting ridge in the bell. This serves to confine the gasket under pressure in the joint. A bituminous compound is used to seal the mouth of the bell and to aid in retaining the hemp and the rubber gasket. Either bell-and-spigot or mechanical (gland-type) fittings are used with this line of pipe. Push-on joints are made in accordance with ANSI/AWWA C111/A21.11.

Mechanical Screw-Gland-Type Joint

This type of mechanical joint for cast-iron pipe makes use of a coarse-threaded screw gland drawn up by means of a spanner wrench to compress a standard rubber or composition packing gasket. The joint allows from 2° to 7° angular deflection, as well as expansion or contraction without danger of leaks. A lead ring, inserted in the bell ahead of the gasket, seals off the contents of the line from the gasket. The ring also provides an electric circuit through the joint for thawing out frozen underground mains and service lines by the electrical method. The screw-gland joint is used in piping which conveys water, gas, oil, and other fluids at considerable pressure. The gaskets and lead rings are interchangeable with those used in equivalent lines of mechanical joints of the bolted-gland type. A full line of fittings is available for use with screw-gland pipe.

* Includes weight of bell.

Ball-and-Socket Joints

For river crossings, submarine lines, or other places where great flexibility is necessary, ductile cast-iron pipe can be obtained with ball-and-socket joints of the mechanical-gland types, as shown in Fig. A2.31. Provision is made for longitudinal expansion and contraction, and a positive stop against disengagement of the joint is a feature of the design. As much as 15° angular deflection can be accommodated without leakage. This

FIGURE A2.31 Ball-and-socket mechanical joint for cast-iron pipe.

pipe is heavy enough to remain underwater where laid without requiring river clamps or anchorage devices. The pipe may be pulled across streams with a cable, since the joints are positively locked against separating, or it may be laid directly from a barge, bridge, or pontoons, without the services of a diver. The mechanical ball-and-socket joint is suitable for use with water, sewage, air, gas, oil, and other fluids at considerable pressure. Either bell-and-spigot or mechanical (gland-type) fittings can be used with this line of pipe, although the integral ball present on the spigot end of some designs has to be cut off before the pipe can be inserted in a regular bell.

Universal Pipe Joints

This type of cast-iron pipe joint (shown in Fig. A2.32) has a machined taper seat which obviates the need for caulking or for a compression gasket. The joint is pulled up snugly with two bolts, after which the nuts are backed off slightly, thus enabling the lock washers to give enough to avoid overstressing the socket or lugs. Pipe is made in 12- to 20-ft (3.5- to 6-m) lengths to the usual pressure

FIGURE A2.32 Universal cast-iron pipe joint.

classes and can be bought as Type III under Federal Specification WW-P-421. Universal-joint fittings are available for use with the pipe. This type of joint is used to some extent in pipe diameters of NPS 4 (DN 100) to NPS 24 (DN 600) for underground water supply systems; but it is not considered suitable for gas service, and it does not permit much angular displacement or expansive movement.

Compression-Sleeve Coupling

The type of joint shown in Fig. A2.33 is used with plain-end pipe of either cast iron or steel. It is widely known under the trade names of Dresser coupling and Dayton coupling. Compression sleeve couplings are used extensively for air, gas, oil, water, and other services above- or underground. With a joint of this type, it is necessary to anchor or brace solidly at dead ends or turns to prevent the line from pulling apart. Compression couplings and fittings with screwed packing glands are available for use with small-size cast-iron or steel pipe. In welded transmission lines for oil or gas where any significant change in temperature is expected, a certain
FIGURE A2.33 Compression sleeve (Dresser) coupling for plain-end cast-iron or steel pipe.

percentage of the joints may be made up with compression couplings instead of welding in order to allow for expansion.

Grooved Segmented-Ring Coupling

The type of split coupling shown in Fig. A2.34 is used with either ductile cast-iron or steel pipe that has grooves near the ends which enable the coupling to grip the pipe, in order to prevent disengagement of the joint. The couplings are manufactured in a minimum of two segments for small pipe sizes and several segments for large pipe sizes. Grooved-end fittings are available for use with the couplings. With proper

FIGURE A2.34 Victualic coupling for grooved-end cast-iron or steel pipe.

FIGURE A2.36   High-hub cast-iron flanges with bitumastic to protect the exposed threads.

choice of gasket material, the joint is suitable for use above- or underground with nearly any fluid or gas. The joint's advantages are its

• Ability to absorb minor angular and axial deflections
• Ability to increase gasket sealing force with increased system pressure

Refer to AWWA C.606, Standard for Grooved and Shouldered Joints.

TABLE A2.25   Standard Dimensions of Class 125 Flanged Joints for Silver Brazing with Centrifugally Cast Pipe
Nominal pipe size	Pipe	Flanges					Bolts	
	Outside diameter A	Outside diameter C	Thickness* D	Bolt circle E	Weight each (lb)		Number	Diameter
2	2.50	6	¾	4¾	4		4	⅝
3	3.96	7½	1	6	7		4	⅝
4	4.80	9	1⅛	7½	13		8	⅝
6	6.90	11	1¼	9½	17		8	¾
8	9.05	13½	1⅜	11¾	27		8	¾
10	11.10	16	1½	14¼	38		12	⅞
12	13.20	19	1½	17	58		12	⅞

* Thickness D is slightly heavier than for standard cast-iron flanges in ASME B16.1-1989.

- Simplicity for rapid erection or dismantling for systems requiring frequent disassembly.

The coupling is also available in a style where grooving of the pipe ends is not required. Joint separation is prevented by the use of hardened steel inserts (teeth) which grab the mating pipe ends.

Flanged Joints

Flanged ductile or cast-iron pipe is used aboveground for low and intermediate pressures in water-pumping stations, gas works, power and industrial plants, oil refineries, booster stations for water, and gas and oil transmission lines. Cast iron flanges usually are faced and drilled according to ASME B16.1. For flanged joints in a ductile iron pipe, refer to ASME B16.42, ANSI/AWWA C110/A21.10, C111/A21.11, C115/A21.15, and C153/A21.53. Cast-iron pipe is made both with integrally cast flanges and with threaded companion flanges for screwing onto the pipe (as shown in Figs. A2.35 and A2.36). In the latter case, the outside diameter of the pipe conforms to iron pipe size (IPS) dimensions to allow for the threads provided. It is available in sizes NPS 3 (DN 50) through NPS 24 (DN 600) and in length to 18 ft (5.5 m). For lengths less than 3 ft (1 m), in sizes NPS 3 (DN 50) through NPS 12 (DN 300), the flanges may be cast integrally with the pipe, rather than screwed on the pipe, at the manufacturer's option.

Standard dimensions of flanged joints for silver brazing are shown in Table A2.25.

CONCRETE, CEMENT, AND CEMENT-LINED PIPE

Nonreinforced Concrete Pipe

Nonreinforced concrete pipe for the conveyance of sewage, industrial waste, and storm water is made in sizes from NPS 4 to NPS 36 (DN 100 to DN 900). It is produced in accordance with ASTM Specification C14, Standard Specifications for Concrete Sewer Storm Drain and Culvert Pipe.

Nonreinforced-concrete drain tile is used for land drainage and for subsurface drainage of highways, railroads, airports, and buildings. It is made in sizes from NPS 4 through 36 (DN 100 through 900) in accordance with ASTM Specification C412, Standard Specification for Concrete Drain Tile, and AASHO M178, Standard Specification for Concrete Drain Tile. Drain tile is available in the standard quality, extra-quality, and special-quality classifications.

Perforated concrete pipe used for under-drainage is made in accordance with ASTM Specification C444, Specifications for Perforated Concrete Pipe. This pipe is also made in sizes NPS 4 through 36 (DN 100 through 900) and is available in the standard-strength and extra-strength classification.

Concrete irrigation pipe, used for the conveyance of irrigation water under low hydrostatic heads and for land drainage, is made in sizes NPS 4 through 24 (DN 100 through 600) in accordance with ASTM Specification C118, Standard Specifications for Concrete Pipe for Irrigation or Drainage.

Nonreinforced-concrete irrigation pipe for use with rubber-type gasket joints is made for conveyance of irrigation water at water pressures of 1 bar (35 ft of head) or higher depending on the diameter. Such pipe is made in sizes NPS 6 through 24 (DN 100 through 600) in accordance with ASTM Specification C505, Specifica-

tions for Nonreinforced Concrete Irrigation Pipe with Rubber Type Gasket Joints. Physical and dimensional requirements of standard-strength bell-and-spigot nonreinforced-concrete sewer pipe are tabulated in Table A2.26.

Jointing. Rubber-gasketed joints for C14 and C76 pipe are covered by ASTM Specification C443, Joints for Circular Concrete Sewer and Culvert Pipe, Using Flexible, Watertight, Rubber-Type Joints.

Reinforced-Concrete Pipe

Reinforced-concrete pipe for the conveyance of sewage, industrial wastes, and storm water and for the construction of culverts is made in sizes from NPS 12 to 144 (DN 300 through 3600). Reinforced-concrete pipe may or may not be manufactured for use with rubber gaskets to seal the joints. It is usually manufactured in accordance with the following specifications:

- ASTM C76, Specifications for Reinforced Concrete Culvert, Storm Drain and Sewer Pipe
- AASHO M170, Specifications for Reinforced Concrete Culvert, Storm Drain and Sewer Pipe
- Federal SS-P-375-Pipe, Concrete (Reinforced, Sewer)

Reinforced-concrete pipe may be made with either tongue-and-groove or bell-and-spigot joints. When made for use with rubber gaskets, the joints must conform to ASTM Specification C443 or AASHO Specification M198, Specifications for Joints for Circular Concrete Sewer and Culvert Pipe, Using Flexible Watertight, Rubber-Type Gaskets.

Concrete pipe is available also in both an arch and an elliptical cross section. These pipes are made in accordance with the following specifications:

- ASTM C506, Specifications for Reinforced Concrete Arch Culvert, Storm Drain and Sewer Pipe
- ASTM C507, Specifications for Reinforced Concrete Elliptical Culvert, Storm Drain and Sewer Pipe

In each of the standards covering reinforced-concrete pipe, five strength classes are defined in terms of minimum three-edge bearing load at a crack width of 0.01 in (0.25 mm) and at the ultimate strength of the pipe.

The strength class required for a given installation is determined by computing the earth load and live load which will be transferred to the pipe under the conditions anticipated. This load is then converted to an equivalent three-edge bearing load by dividing it by a bedding factor. The bedding factor depends upon installation conditions and is always greater than 1.0.

Reinforced and Prestressed-Concrete Pressure Pipe

Reinforced-concrete pressure pipe is discussed in detail in Chap. A8.

Cement-Lined Steel, Ductiles, and Cast-Iron Pipe

Refer to Chap. B9 of this handbook.

Cement-lined pipe is well established for use in cold-water lines. Substantial

* Shorter lengths may be used for closures and specials.

† When pipe is furnished having an increase in thickness over that given in column 2, the diameter *at the inside* of the socket shall be increased by an amount equal to twice the increase of the barrel.

‡ This measurement shall be taken ¼ in from the outer end of the socket.

§ Not included in ASTM Specification C14.

quantities of cement-lined steel pipe are used for other applications where corrosion is more of a problem. The largest user, by far, is the petroleum industry in oil field flow lines, pipelines, tubing, and casing. Cement-lined pipe is particularly suitable for these applications because of the presence in the oil fields of saltwater, hydrogen sulfide, carbon dioxide, and other corrosive material. Other applications include lines in salt works for handling brine, discharge lines in coal mines for carrying highly corrosive sulfur water, lines in paper and pulp mills for handling diluted acids and corrosive waste liquids, and lines in process plants where water or other liquids must be kept free from iron contamination or rust.

Cement-lined pipe is generally joined with screwed seal rings which prevent the corrosive liquid from coming in contact with steel. Flanged joints are also extensively used. Some prefabrication is done of piping assemblies involving welding of the steel joints. Field joining of the preassembled welded assemblies is then done with flanged ends. Cement of course must not be at the pipe ends being welded. After welding, these ends are filled with mortar.

CHAPTER A3
PIPING MATERIALS

James M. Tanzosh
Supervisor, Materials Engineering
Babcock & Wilcox
Barberton, Ohio

The selection of materials for piping applications is a process that requires consideration of material characteristics appropriate for the required service. Material selected must be suitable for the flow medium and the given operating conditions of temperature and pressure safely during the intended design life of the product. Mechanical strength must be appropriate for long-term service, and resist operational variables such as thermal or mechanical cycling. Extremes in application temperature can raise issues with material capabilities ranging from brittle fracture toughness at low temperatures to adequacy of creep strength and oxidation resistance at the other end of the temperature spectrum.

In addition, the operating environment surrounding the pipe or piping component must be considered. Degradation of material properties or loss of effective load-carrying cross section can occur through corrosion, erosion, or a combination of the two. The nature of the substances that are contained by the piping is also an important factor.

The fabricability characteristics of the materials being considered must also be taken into account. The ability to be bent or formed, suitability for welding or other methods of joining, ease of heat treatment, and uniformity and stability of the resultant microstructure and properties all of a given piping material contribute toward or detract from its attractiveness and economy. The selection process should lead to the most economical material that meets the requirements of the service conditions and codes and standards that apply.

Applicable design and construction codes such as the ASME Boiler and Pressure Vessel Code and the ASME B31 Pressure Piping Code identify acceptable materials for piping systems within their jurisdiction. These codes specify the design rules, allowable design stresses, and other properties required to accomplish the design task. However, the information supplied is generally only adequate and intended to assure safe operation under the thermal and mechanical conditions expected under steady-state and sometimes (as in nuclear construction) cyclic operation. These codes do not directly and explicitly address the many other environmental and material degradation issues that should be considered by design and materials engineers in arriving at a piping system that is not only safe to operate but will

offer long-term, reliable service and function. Thus, simply designing to "the Code" when selecting materials can sometimes lead to premature end-of-life of piping system components.

This chapter will attempt to identify the important metallurgical characteristics of piping materials and how they can affect or be affected by operation of all of the other materials available to the engineer. Carbon and low-alloy steels come closest to being the ideal construction material. Due to the fact that the majority of piping applications employ iron-based metals, these will be emphasized in this chapter.

MATERIAL PROPERTIES OF PIPING MATERIALS

The behavior of piping material can be understood and predicted by studying a number of properties of the material. Appreciation of how a material will perform must extend all the way down to the atomic components of the material. Metals are crystalline in structure, composed of atoms in precise locations within a space lattice.

The smallest component of the crystalline structure is called a *unit cell,* the smallest repeating building block of the material. For example, iron and iron-based alloys exist in two unit cell forms, the body-centered cubic (BCC) and the face-
FIGURE A3.1   The three most common crystal structures in metals and alloys. (*a*) Face-centered cubic (FCC); (*b*) body-centered cubic (BCC); (*c*) hexagonal close-packed (HCP).

centered cubic (FCC) structure, shown in Fig. A3.1. They are differentiated in the way the atoms are arranged in repeating patterns. The body-centered cubic structure is represented by a cube with atoms at all eight corners, and one atom in the center of the cube. The face-centered lattice is represented by atoms at the eight corners of the cube, plus one atom located at the center of each of the cube's six faces. The crystal structure naturally assumed by a material dictates some of the fundamental properties of the material. For example, FCC materials are generally more ductile than BCC materials. This is basically because FCC crystals are the most tightly packed of metallic structures and, as such, allow for more planes of atoms to slide across one another with the least amount of resistance (the fundamental atomic motion involved in what is called *plasticity*).

Metallic materials consist of these and other ordered crystal structures. Some metals, most notably iron, change their crystal structure as temperature varies.

Structure may also change as certain other elements are added in the form of alloying additions. These changes are used to advantage by metallurgists and are the basis for developing and manipulating important material behavior, such as the heat treatability of carbon and low alloy steels.

Plastics may be defined as synthetic materials whose chief component is a resin or resin equivalent. The term *plastic* covers a very broad range of materials that contain, as an essential ingredient, one or more organic polymetic substances. They possess large molecular weight, formed by the chemical combination of carbon-hydrogen atom chains (monomers to polymers). The atomic structure is thus ordered and predictable, but dissimilar from that of metals. Many plastics have greater strength per unit weight than metal, but suffer due to lower impact strength, chemical stability, and thermal and aging stability. However, plastics fill an important niche in the piping engineer's repertoire.

Ceramic materials are composed of the oxides of metal arranged in ordered atomic structures similar to that of metals. The atomic constituents are electronically different, resulting in rigid, predictable behavior, but with an inherent lack of plasticity compared to metals.

Glasses form the other extreme of the atomic structure spectrum. Their atomic makeup is essentially that of a liquid; the structure is actually a solid with no ordered arrangement of atoms.

These atomic characteristics (i.e., the natural arrangement of the atoms, as well as the specific elements involved and their electronic characteristics) establish the fundamental properties of engineering materials. The properties that a engineer requires to design and construct a piping system are a manifestation of the longer-range effects of atomic structure. These properties fall into three categories: chemical, mechanical, and physical.

Chemical Properties of Metals

Chemical properties are herein defined as those material characteristics that are dictated by the elemental constituency of the solid. This is usually measured by the relative atomic weight percent of the various elements (metals or nonmetals) or compounds within the material.

Metals are are not usually used in their pure form. Rather, secondary elements are purposely added to improve or modify their behavior. This addition of secondary elements is called *alloying*, and the elements added fall into two categories, based on the relative size of the atoms. Atoms significantly smaller than those of the parent metal matrix fit into spaces between the atoms in the lattices' interstices and are called *interstitial alloying elements*. Carbon added to iron, creating steel, is the most common example. Larger-sized atoms will substitute for parent metal atoms in their matrix locations, thus the name *substitutional alloying elements*. Examples of this include zinc substituting for copper atoms in copper, creating brass; and tin substituting for copper atoms, creating bronze alloys.

Pure metals possess relatively low strength. Adding an alloying element will increase the strength of a metal's atomic matrix because the atomic lattice is strained locally by the foreign atom, creating a larger impediment for the sliding of planes of atoms across one another during plastic flow. This is true whether the alloying element is interstitial or substitutional; however, the former generally serve as better lattice strengtheners. Strength properties are often improved to the detriment of ductility. Proper alloying, combined with appropriate metal processing and heat treatment, results in optimization of material properties.

Elements are also added to metals to improve or modify their corrosion or oxidation characteristics, or to improve manufacturability (e.g., machineability) and/or electrical properties, among other effects. However, it is important to note that alloying done to optimize one material property may act to the detriment of others.

Carbon steels, the most common of the construction materials, always contain the elements carbon, manganese, phosphorous, sulfur, and silicon in varying amounts. Small amounts of other elements may be found either entering as gases during the steel-making process (hydrogen, oxygen, nitrogen), or introduced through the ores or metal scrap used to make the steel (nickel, copper, molybdenum, chromium, tin, antimony, etc.). The specific effect of each of these elements on steel properties will be addressed later in the chapter. Addition of significant quantities of the interstitial element carbon will result in high strength and hardness—but to the detriment of formability and weldability. A great amount of research has gone into the development of the principal metals used in piping design and construction; thus the specification limits must be vigorously adhered to in order to assure reliability, predictability, and repeatability of material behavior.

The number of elements alloyed with a parent metal, and the acceptable range of content of each, are identified in the material specification (e.g., ASTM, API, ASME). Tests appropriate for determining the elemental constituency of an alloy have been standardized and are also described in ASTM specifications. The material specifications also stipulate whether the chemical analysis of an alloy may be reported by analyzing a sample of the molten metal, or taken from a specimen removed from the final product. The former is commonly referred to as a *ladle* analysis, and the latter as a *product* or *check* analysis. This "chemistry" of a construction material is reported on a material test report which may be supplied by the material manufacturer upon request.

Mechanical Properties of Metals

Mechanical properties are critically important to the design process. They are defined as the characteristic response of a material to applied force. The standardized test methods for measuring these properties are described in ASTM specifications.

Properties fall into two general categories, strength and ductility. Some properties, such as material toughness, are dependent on both strength and ductility. The most widely known and used material properties, as defined by ASTM, are described in the following paragraphs.[1]

Modulus of Elasticity (Young's Modulus).   The modulus of elasticity is the ratio of normal stress to corresponding strain for tensile or compressive stresses. This ratio is linear through a range of stress, known as Hooke's law. The material behavior in this range is elastic (i.e., if the applied load is released the material will return to its original, unstressed shape). The value of the slope in the elastic range is defined as *Young's Modulus*.

The modulus of elasticity is measured using the tension test, the most widely used test applied to engineering materials. The test consists of applying a gradually increasing load in either tension or compression, in a testing machine, to a standardized test specimen (Fig. A3.2). The applied load is continuously monitored, as is test specimen elongation or contraction under load. These measured quantities are generally represented on a coordinate axis, called a stress-strain curve (Fig. A3.3). The modulus of elasticity and other strength properties are established from this

curve. Values of the modulus of elasticity for a number of construction materials are given in Table A3.1

Yield Strength. When a specimen is loaded beyond the point where elastic behavior can be maintained the specimen will begin to deform in a plastic manner. Most materials do not abruptly transform from purely elastic to purely plastic behavior. Rather, a gradual transition occurs as represented by a curve, or *knee*, in the stress-strain curve. Lacking an abrupt and easily definable point representing transition from elastic to plastic behavior, several standardized methods have been defined by ASTM to determine the yield strength used as the engineering property. The most common is termed the *0.2 percent offset method*. In this approach a line is drawn parallel to the elastic portion of the curve anchored to a point displaced 0.2 percent along the strain axis. (Fig. A3.4). The yield strength corresponds to the calculated value of the load indicated at the intersection point of the drawn line, divided by the original cross-sectional area in the gauge length of the tensile specimen. By convention, this test is performed at a constant rate of strain, and is reported as newtons per square meter, or as pounds per square inch of cross section in English units.

FIGURE A3.2 Tension-test specimens. (*a*) Strip specimen showing measurements which are taken to determine elongation; (*b*) standard round specimen with 2-in gauge length.
FIGURE A3.3 Stress-strain diagram.

Ultimate Tensile Strength. Upon further increase of applied load under constant strain rate, the specimen will continue to stretch until the loss of load-carrying cross section caused by specimen thinning during the test (due to Poisson's ratio) cannot withstand further load increase. The ultimate tensile strength constitutes the maximum applied load divided by the original specimen cross-sectional area.

Elongation and Reduction of Area. The ductility of the test specimen can be established by measuring its length and minimum diameter before and after testing. Stretch of the specimen is represented as a percent elongation in a given length (usually 2 or 8 in) and is calculated in the following manner:

$$\text{Percent elongation} = \frac{(\text{final length} - \text{original length})}{\text{original length}} \times 100$$

The diameter of the test specimen will decrease, or *neck down*, in ductile materials. Another standard measure of ductility is the reduction of area of the specimen, defined as follows:

$$\text{Percent reduction of area} = \frac{(\text{original cross-sectional area} - \text{final area})}{\text{original area}} \times 100$$

(A3.1)

Hardness.   This is a measure of the material's ability to resist deformation, usually determined by a standardized test where the surface resistance to indentation is measured. The most common hardness tests are defined by the indentor type and size, and the amount of load applied. The hardness numbers constitute a non-dimensioned, arbitrary scale, with increasing numbers representing harder surfaces. The two most common hardness test methods are Brinell Hardness and Rockwell Hardness, with each representing a standardized test machine with its own unique hardness scales. Hardness loosely correlates with ultimate tensile strength in metals (Fig. A3.5). Approximate hardness conversion numbers for a variety of material types, including steels, can be found in ASTM Specification E140.
FIGURE A3.4   Offset method of determining yield strength.

Toughness.   Sudden fracture, exhibiting little ductility in the vicinity of the break, occurs in certain metals when load is rapidly applied. The capability of a material to resist such a brittle fracture is a measure of its toughness.

Highly ductile materials (those possessing an FCC lattice, for example) exhibit considerable toughness across a full range of temperatures. Other materials, such as BCC-based carbon steels, possess a level of toughness that is dependent on the metal temperature when the load is applied. In these metals, a transition from brittle to ductile behavior occurs over a narrow range of temperatures.

The two most common methods used to measure metal toughness are the Charpy
FIGURE A3.5   Conversion chart for Brinell and Rockwell hardness numbers, giving corresponding tensile strength for steel. Based on hardness conversion table. (*SAE Handbook*, 1964.)

Impact test, defined in ASTM specification E 23, and the Drop-Weight test, defined in ASTM E 208. The Charpy test employs a small machined specimen with a machined notch that is struck by a pendulum weight (Fig. A3.6). The energy loss to the pendulum as it passes through and breaks the specimen (Fig. A3.7), measured in kilojoules or ft · lb of force, is a measure of the toughness of the specimen. Typical impact behavior versus test temperature is shown in Fig. A3.8.

The Drop-Weight test is similar in principle but employs a larger specimen with a brittle, notched weld bead used as the crack starter (Fig. A3.9). A weight is dropped from a height onto the specimen, which had been cooled or heated to the desired test temperature. The test determines the *nil-ductility transition temperature* (NDTT), defined as the specimen temperature when, upon striking, the crack propagates across the entire specimen width.

The Charpy brittle transition temperature (sometimes called the *Charpy fix temperature)* and the Drop Weight NDTT are both important design considerations for those materials that can exhibit poor toughness and that may operate in lower temperature regimes. In pressure vessel and piping design codes, limits are placed on material minimum use temperature based on adding an increment of margin over and above the Charpy fix or NDTT. Operating at or above this elevated temperature is then usually sufficient to avoid brittle, catastrophic failure, as for example is the case when at a temperature on the ''upper shelf'' of the Charpy V-notch toughness-versus-temperature curve.

On subsize specimens the length, notch angle, and notch radius are constant (see Fig. 6); depth (D), notch depth (N), and width (W) vary as indicated below.
NOTE 1—Circled specimen is the standard specimen (see Fig. 6).
NOTE 2—Permissible variations shall be as follows:

Cross-section dimensions	±1 % or ±0.075 mm (0.003 in.), whichever is smaller
Radius of notch	±0.025 mm (0.001 in.)
Depth of notch	±0.025 mm (0.001 in.)
Finish requirements	2 µm (63 µin.) on notched surface and opposite face; 4 µm (125 µin.) on other two surfaces

FIGURE A3.6 Charpy (simple beam) subsize (Type A) impact test specimens. (ASTM Specification E23.)
FIGURE A3.7 Charpy V-notch specimen placement during strike by testing anvil. (ASTM Specification E23.)

Fatigue Resistance. The ability of a metal to resist crack initiation and further propagation under repeated cyclic loading is a measure of its fatigue resistance. Several standardized test methods have been developed to test metals, machined to particular geometries, where applying a repeating load range. Loads are generally applied through bending, cantilevered, or push-pull load application in suitably outfitted testing machines. Either constant applied stress or strain ranges can be employed to determine material response.

The most common representation of fatigue test data is an *S-N* curve, relating stress (*S*) required to cause specimen failure in a given number of cycles (*N*) (Fig.
FIGURE A3.8 Transition temperature range and transition temperature in Charpy impact test.
FIGURE A3.9 Drop-weight test specimen with brittle weld deposit on specimen face; machined notch to act as crack starter. Impact load applied from side opposite weld deposit. (ASTM Specification E208.)

A3.10a). These tests are generally performed on smooth specimens, but they can also be run with stress-concentrating mechanisms such as notches machined into the specimen surface. The effect of stress concentrations on fatigue life cycles can also be estimated from the smooth specimen *S-N* curve by calculating the intensified stress due to the particular geometry, and intersecting the curve at that point on the stress axis.

As the applied load range decreases, ferritic steels exhibit a point at which an infinite number of cycles can be absorbed without causing failure. This level of stress is called the *endurance limit.* Many of the other metals do not exhibit this behavior, but rather exhibit an increasing, but finite, number of cycles to failure with decreasing cyclic load (Fig. A3.10b).

The fatigue resistance of a material at a given applied stress or strain range is a function of a number of variables, including material strength and ductility. Results may vary significantly for different surface finishes, product forms of the same material (Fig. A3.11), material internal cleanliness, test specimen orientation, and levels of residual stress, among other factors. Variations in the test environment can also have a profound effect on test results (Fig. A3.12). Therefore, fatigue test results characteristically exhibit significant scatter.

Fatigue design curves are generated from test data by applying large safety margins to the average property curve. In U.S. design codes, the fatigue design curve is commonly generated by taking the lesser of $\frac{1}{20}$ times the cycles to failure, or $\frac{1}{2}$ of the stress to cause failure. A new curve is constructed taking the lower bound of these two factored curves.

When considering metal fatigue in design, a further safety margin is often also applied against the cycles-to-failure at a given stress amplitude. For example, if a component is continuously cycled over the same stress range, a design limit on allowable cycles may correspond to the cycle life multiplied by a factor such as 0.8. This is a common safety margin employed in vessel and piping design.

As is normally the case, components may experience a wide variety of cyclic
FIGURE A3.10   *S-N* curves that typify fatigue test results (*a*) for testing medium-strength steels and (*b*) showing typical curve shape for ferrous and nonferrous materials. S_L is the endurance limit. (*Atlas of Fatigue Curves*, American Society for Metals, ©1986.)

stress ranges, at various temperatures, over their life. The effect of this array of cyclic parameters on fatigue life can be estimated by an approach referred to as *life fraction summation*. In this design practice, the percentage of life used up in cycling at a certain stress range is calculated, corresponding to the ratio of the number of actual service duty cycles to the total number of cycles to failure at that
FIGURE A3.11 Fatigue characteristics (*S-N* curve) for cast and wrought 1040 steel in the normalized and tempered condition, both notched and unnotched. R. R. Moore rotating beam tests, $K_t =$ 2.2. (*Atlas of Fatigue Curves*, ASM.)

stress range. This calculation is performed for all of the various stress ranges/duty cycles anticipated. The fractions thereby calculated are summed and compared to the design limit (1.0 with no safety margin, or 0.8 or some other value depending on the design safety factor that applies).

Elevated Temperature Tensile and Creep Strength. Tensile tests are performed at elevated temperatures to characterize the material's yield and ultimate tensile
FIGURE A3.12 Effect of alternating stresses with and without corrosion for ferrous material that normally exhibits an endurance limit. (*Atlas of Fatigue Curves*, ASM.)
FIGURE A3.13   Creep time versus elongation curves at a given temperature.

properties at potential use temperatures above room temperature. A heating chamber is combined with a conventional tensile testing machine, and special strain measuring extensometers are used that are capable of withstanding the test temperatures. Generally, as temperature increases, yield and ultimate strengths decrease, and ductility increases.

Creep is defined as the time-dependent deformation of a material that occurs under load at elevated temperatures. The test is performed by holding a specimen, similar in configuration to a tensile specimen, at a uniform temperature and a constant load (usually using a dead weight) and allowing the specimen to gradually elongate to ultimate failure. The practice is defined in ASTM Specification E 139.

The simplest test method records only the applied stress (based on original test specimen cross section), time to failure, and total elongation at failure. This is called a *stress rupture test*. If periodic measurements of strain accumulation versus test duration are also taken, the test is referred to as a *creep-rupture test*.

A representation of typical creep strain-versus-time data is shown in Fig. A3.13. Three stages of creep behavior are exhibited. Upon initial loading, instantaneous straining occurs. Almost immediately, the rate of creep strain accumulation (creep rate) is high but continuously decreasing. The test then progresses into a phase where the strain rate slows and becomes fairly constant for a long period of time. Finally, with decreasing load-bearing cross section of the specimen due to specimen stretching and necking, applied stress begins to increase steadily, as does the creep rate, until failure occurs. These three regions are termed the primary, secondary, and tertiary stages of creep. The intent of safe design practice is to avoid the third stage, where strain accumulations are rapid and material behavior less predictable.

After accumulating a number of rupture data points (i.e., time to failure of a metal at various applied stresses), the data is generally represented as a stress rupture curve (Fig. A3.14). Each curve represents the time to failure at various applied stresses, at a given test temperature. Another useful property that can be measured in these tests is the creep rate during the second stage of creep, for a given applied stress and temperature. This, along with time to onset of the tertiary creep stage, are useful properties to the design engineer and are used in establishing allowable design tension stresses in design codes.

FIGURE A3.14 Typical stress-to-rupture curves.

Metals that experience creep will accumulate a progressively larger amount of microscopic damage to the structure of the material. Damage is first observed microscopically as small cavities, or voids, that begin appearing in the grain boundaries of the metal, particularly at triple points (i.e., where three grains come together). Further progression of damage entails formation of more voids along many of the adjacent grain boundaries, until ultimately they link together to form grain boundary microcracks. With more time, these form larger macrocracks that lead to ultimate failure of the metal component.

The determination of a metal's degree of creep damage, and its consequence on the continued safe operation of the component, has developed into a sophisticated science referred to as component condition assessment, or estimation of remaining life. This will be addressed in more detail later in the chapter.

A practice essentially identical to cyclic fraction life summation used in fatigue design can be employed in material creep analysis to estimate the percentage of creep life expended. Here the individual life fraction corresponds to the amount of time a component spends at a given stress and temperature, compared to the total time to failure given on the stress rupture curve for the same applied stress and temperature. All of these fractions for all the operating conditions are then added together, and compared to an appropriate design limit (1.0 or less).

Physical Properties of Metals

Physical properties are those, other than mechanical properties, that pertain to the physics of a material. Physical properties of importance to the materials and design engineer are material density, thermal conductivity, thermal expansion, and specific heat.[2]

Density. Density is the ratio of the mass of a material to its volume. In vessel and piping design, the density of a construction material versus its strength per unit area of cross section is often an important consideration.

Thermal Conductivity. This is the characteristic ability of a material to transmit energy in the form of heat from a high-temperature source to a point of lower temperature. The ability to transmit heat is usually expressed as a coefficient of

thermal conductivity (k) whose units are a quantity of heat transmitted through a unit thickness per unit time per unit area per unit difference in temperature.

For example:

$$k = \frac{\mathrm{Btu\cdot ft}}{\mathrm{h\cdot ft^2\,°F}} \qquad \text{or} \qquad \frac{\mathrm{cal\cdot cm}}{\mathrm{sec\cdot cm^2\,°C}} \tag{A3.2}$$

The lower the value of k, the more resistant the material is to the flow of thermal energy. Good insulators possess low coefficients of thermal conductivity.

Thermal conductivity is a function of the temperature of the material. For example, the coefficient of thermal conductivity of carbon steel decreases as its temperature increases, thereby decreasing its ability to transfer heat energy. Austenitic stainless steels, on the other hand, increase in k value with temperature. However, they remain lower than carbon steels in normal piping system temperature ranges.

Thermal Expansion. Expressed as the coefficient of linear expansion, thermal expansion is a ratio of the change in length per degree of temperature, to a length at a given standard temperature (such as room temperature, or the freezing point of water). The units of the coefficient are length of growth per unit length per degree of temperature. The value of the coefficient varies with temperature.

Specific Heat. This is a measure of the quantity of heat required to raise a unit weight of a material one degree in temperature.

Some values of physical properties of a number of materials of interest are given in Table A3.2 and Table A3.3.

Other Metallurgical Properties of Metals

In addition to the properties already described, other characteristics of metals can have an important effect on the design process. These may profoundly affect the uniformity, achievable level, or stability of mechanical strength and ductility over long periods of usage.

Grain Size.   Upon solidification from the molten state, metals take crystalline form. Rather than a single, large crystal, the material consists of many small crystals that initiate independently and nearly simultaneously from separate nuclei sites. These individual crystals are called *grains*, and their outer surfaces are called *grain boundaries*. Grains form initially during the solidification process, but they may also reform, grow, or rearrange while in the solid state.

Some properties of many engineering metals are very dependent on grain size (Fig. A3.15). For example, austenitic stainless steels, such as Type 304 (18% Cr-8% Ni-Fe), possess excellent creep strength when the material has a coarse grain structure, but very poor strength with fine (small) grains.

If this same austenitic material is plas-tically cold-worked, these grains will be-come distorted and possess high levels

FIGURE A3.15 Sketch illustrating individual grain growth from nuclei and dendrites.

of lattice strain and residual stress. Subsequent heat treatment can cause the crystal lattice to reform unstrained grains initiating at lattice defects which act as nuclei. The process, called *recrystallization*, results in an initially very small grain size as the nucleated stress-free grains begin to grow. If heavily strained material is placed into elevated temperature service at temperatures sufficient to cause recrystalliza-tion, it will initially exhibit good creep strength until the grains begin to reform,

upon which the result is very poor creep rupture strength. The material will only return to its prestrained creep-strength level if additional heat treatment is performed, resulting in further grain growth.

Grain size is a material characteristic that is sometimes directly inspected in the base material testing and certification process. The test entails retrieving a piece of the material and then metallographically polishing and etching the specimen with a weak acid solution, which reveals the grain boundaries under magnification. The test is described in ASTM Specification E 112. Grain size can be measured and reported a number of ways. The most commonly used method involves reporting grain size as an ASTM grain size number (n), corresponding to the exponent of the following equation:

$$\text{Number of grains per square inch viewed} = 2^n \text{ at 100 magnifications}$$

ASTM has correlated this grain size number, which increases as grain diameter decreases, to a series of photographs representing the grain structure at 100 magnifications. The grain size number can then be estimated by visual comparison. Examples of this comparative standard are shown in Fig. A3.16.

Fine-grained carbon- and low-alloy steels tend to possess better notch toughness and ductility than coarse-grained steel. As noted earlier, as operating temperature increases into the creep regime, engineering material strength properties are usually enhanced with coarser grains. Although this is an oversimplified (and perhaps overstated) rule of thumb, it is important for the engineer to take grain size into account for critical structures.

Hardenability. This is a property of certain steels that allows them to be strengthened, or hardened, by *heat treating*. In carbon and alloy steels, for example, this hardening is accomplished by heating the material to a temperature above about 1550°F (843°C), where the material completely changes its crystal structure from BCC to FCC. When this is followed by rapid cooling or quenching, usually in water or oil, the result is a crystal structure akin to the original BCC, but distorted along one of the unit cell directions. In the case of steels the result is a martensitic structure possessing a lattice, termed a *body-centered tetragonal* (BCT), with a larger volume per unit cell than the starting BCC.

The maximum hardness achieved in a quenched structure is primarily a function of the steel's carbon content: the higher the carbon content, the greater the hardness. The depth into the material to which a high hardness is achieved for a given quenching operation is a function of the total alloy content within the steel. The substitutional alloying element nickel has perhaps the strongest effect on increasing the depth to which hardness extends.[3] Other elements creating similar if less potent effects are manganese and boron, substitutional and interstitial alloying elements, respectively.

Standard specimens and procedures have been adopted for testing the hardenability of steels. The test rates a combination of the highest hardness achievable and the depth to which significant elevation of hardness occurs. It is called the *Jominy End-Quench test* and is performed using a 1-in-diameter cylindrical specimen machined from the metal in question and heated to a temperature in its austenitic phase (FCC) region. The heated specimen is removed from the heating oven and quickly set in a water-quenching fixture, operating under prescribed conditions of water temperature and flow rate, quenching only the cylinder end face. Upon cooling, the cylinder is parted longitudinally (axially) down the center, and a series of Rockwell hardness readings are taken from the quenched edge. A hardness scan
FIGURE A3.16 ASTM grain size charts for classification of steels. 100 magnifications. (*Reproduced by permission of ASTM.*)

for several alloy steels is shown in Fig. A3.17. The Jominy test procedure is defined in ASTM A 255.

Many other metal alloys harden or strengthen with special aging or tempering heat treatments. However, this trait is normally not referred to as hardenability. These will be discussed in more detail later in the chapter.

Property Stability. The mechanical properties of materials may degrade with service time. In particular, alloys that depend on heat treatment or cold working
FIGURE A3.17   Jominy end-quench hardenability curves for various 0.40 percent carbon steels. (*Molybdenum Steels Iron Alloys*, Archer et al., Climax Molybdenum Company.)

to develop their strength may weaken if operated for long times at elevated temperatures. The actual exposure to service temperatures acts as a continuation of the heat-treating process, albeit at a significantly reduced rate of effect. In many engineering metals, this effect is actually a property degradation due to overtempering of the material.

A number of thermodynamic relationships exist that relate material strength and time and temperature of exposure for carbon and alloy steels. The most famous and widely used of these is the *Hollomon-Jaffe Parameter* (HJP). It is defined as the following:

$$\text{HJP} = (T + 273)(C + \log t) \times 10^{-3} \qquad (A3.3)$$

where T is temperature in degrees Celsius, t is time in hours, and C is a constant, usually around 20 for carbon steels.[4] Using this equation and solving for HJP for a given set of time and temperature conditions, the engineer can determine the time at a different temperature of interest that can result in an equivalent metallurgical effect.

A limitation exists on the range of temperatures over which the predictive capability of the Holloman-Jaffe equation can be considered reliable. Phenominologically, the same metallurgical processes must be in effect over the range of temperatures under consideration. For example, if a phase change occurs, or if other important microstructural constituents, such as carbides, are not stable at the two temperatures being compared, the correlation is not valid.

Design codes using allowable design stresses based on creep properties of the metals, by the nature of the long-term rupture tests involved, take these degrading tendencies into account. However, it is not always appreciated that the time-dependent properties, such as ultimate tensile strength and yield strength, can be decreased significantly below the starting property level by the same long-term service. This fact would be important to an engineer concerned with designing a high-temperature structure that must tolerate shock loads, such as seismic effects, that can occur near the end-of-life of the component.

More on degradation of properties and the mechanisms involved is discussed later in this chapter.

METALLIC MATERIALS

Metals are divided into two types: ferrous, which includes iron and iron-base alloys; and nonferrous, covering other metals and alloys. Metallurgy deals with the extraction of metals from ores and also with the combining, treating, and processing of metals into useful engineering materials. This section presents the fundamental metallurgical concepts and practices associated with the most common engineering metals, and outlines metallurgical considerations appropriate in the selection process of metals for piping system construction.

Ferrous Metals

Metallic iron, one of the most common of metals, is very rarely found in nature in its pure form. It occurs in the form of mineral oxides (Fe_2O_3 or Fe_3O_4), and as such it comprises about 6 percent of the earth's crust. The first step in the production of iron and steel is the reduction of the ore with coke and limestone in the blast furnace. In this process, the oxygen is removed from the ore, leaving a mixture of iron and carbon and small amounts of other elements as impurities. Coke is the reducing element and source of heat. The limestone ($CaCO_3$) acts as a fluxing agent which combines with impurities of the ore in the molten state and floats them to the top of the molten metal pool, where they can be removed as slag. The product removed from the blast furnace is called *pig iron* and is an impure form of iron containing about 4 percent carbon by weight percent. Liquid pig iron cast from the blast furnace is sometimes used directly for metal castings. More often, however, the iron is remelted in a cupola, or furnace, to further refine it and adjust its composition.[5]

Cast Iron

Pig iron that has been remelted is known as *cast iron*, a term applicable to iron possessing carbon in excess of 2 weight percent. Compared with steel, cast iron is inferior in malleability, strength, toughness, and ductility. On the other hand, cast iron has better fluidity in the molten state and can be cast satisfactorily into complicated shapes. It is also less costly than steel. The most important types of cast iron are white and gray cast irons.

White cast iron is so known because of the silvery appearance of its fracture surface when broken. In this alloy, the carbon is present in the form of iron carbide (Fe_3C), also known as *cementite*. This carbide is chiefly responsible for the high

hardness, brittleness, and poor machineability characteristic of white cast iron. Chilled iron, a form of white cast iron, is cast against metal chills that cause rapid cooling, promoting the formation of cementite. Consequently, a structure is obtained which possesses high wear- and abrasion-resistance, the principal attribute of the material, but retains white cast iron's characteristic brittleness.

Malleable cast iron is the name given to white cast iron that has been heat-treated to change its cementite into nodules of graphite. The iron becomes more malleable because, in this condition, the carbon as carbide no longer exists continuously through the metal matrix.

Gray iron is a widely used type of cast iron. In this alloy, the carbon predominantly exists in the form of graphite flakes. The typical appearance of a fracture of this iron is gray since the graphite flakes are exposed. The strength of gray iron depends on the size of the graphite particles and the amount of cementite formed together with the graphite. The strength of the iron increases as the graphite crystal size decreases and the amount of cementite increases. This material is easily machined. A wide range of tensile strengths can be achieved by alloying gray iron with elements, such as nickel, chromium, and molybdenum.

Another member of the cast-iron family is so-called *ductile* iron. It is a high-carbon magnesium-treated product containing graphite in the form of spheroids. Ductile iron is similar to gray cast iron in machineability, but it possesses superior mechanical properties. This alloy is especially suited for pressure castings. By special procedures (casting against the chill) it is possible to obtain a carbide-containing, abrasion-resistant surface with an interior possessing good ductility.[5]

Steel

Steel is defined as an alloy of iron with not more than 2.0 weight percent carbon. The most common method of producing steel is to refine pig iron by oxidation of impurities and excess carbon, which have a greater affinity for oxygen than iron.

The principal reduction methods used are the basic oxygen process (BOP) and the electric furnace process, each representing a type of furnace in which the refining takes place. The BOP primarily uses molten pig iron as the initial furnace charge; the electric furnace can use a charge of selected steel scrap. Another process, called the basic open-hearth process, is no longer in use in the United States. Although it constituted the major steel producing process for decades, it has succumbed to the more advanced and economical BOP and electric furnaces.[6]

The pig iron is reduced to the desired steel composition through use of acid and/or basic reactions with fluxing agents, heat, oxygen, and time. Excess carbon is oxidized and lost as gas; impurities float to the surface. Often desired alloying elements are added to the molten pool. The steel can be further refined by using one of various methods of vacuum degassing. As the name suggests, the molten steel is passed through a vacuum chamber with the purpose of removing entrained gases such as oxygen, hydrogen, and carbon dioxide. This operation is performed when extra steel purity is desired, and it results in improved and more uniform properties in the final product form.

The molten steel is then cast into molded ingots, which are then further reduced by hot working in rolling and drawing operations. Alternately, the molten steel may be directly cast into continuous smaller billet or hollow products. The latter process is called *continuous casting* and has become the preferred method of making steel since it avoids the costly ingot reduction operations.

Alloying additions are made, if required, to the molten steel either while in the

reducing furnace as already noted, in the ladle into which the steel is put, or in the ingot into which steel is poured from the ladle.

While the steel is molten in the furnace, oxygen is forcibly injected into it to refine the charge. The oxygen combines with excess carbon and is released as a gas. Excess oxygen is, however, unavoidably left in the molten steel. This results in the formation of oxide inclusions in the steel, or porosity, which appear upon solidification. The process of removing the oxygen is known as *deoxidizing practice*. Deoxidation is achieved by adding silicon, aluminum, or other deoxidizing agents to the molten steel, the amount of which determines the degree of deoxidation and the type of steel seated. The common names given to these various steel types are *killed steel*, *semikilled steel*, and *rimmed steel*.

Steel of the killed type is deoxidized almost completely; that is, sufficient deoxidizing agent is added to the molten pool to combine with all the excess entrained oxygen. The result is a large number of tiny oxides in the melt. The lack of gas in the molten pool gives the effect of ''killing'' any visible bubbling activity of the steel, thus the name. Killed steel has a more uniform composition than any of the other types, and usually possesses the best formability at room temperature. A fine-grained structure results from this practice because the many oxides formed act as initiation sites of new grains upon solidification and subsequent recrystallization. This fine-grained character offers toughness superior to the other types of steel.

Rimmed steel employs no purposeful addition of deoxidizing agents, and is characterized by relatively violent bubbling and stirring action in the ingot mold. This type exhibits a marked variation in composition across and from top to bottom of the ingot. The outer rim or outer edge of the solidified ingot is relatively pure and ductile material. The amounts of carbon, phosphorous, sulfur, and nonmetallic inclusions in this rim are lower than the average composition of the whole ingot. The amount of these constituents in the inner portion or core is higher than the ingot average. This type of steel costs less to make than the other types and is widely used for structural applications, where good surface appearance of the final product is desired.

Semikilled steel is only partially deoxidized with silicon, aluminum, or both, taking advantage of the positive attributes of killed and rimmed steel.

After casting, or *teaming* into the ingot molds, the steel is normally further reduced in size and modified in shape by mechanical working. The majority of the reduction process is done hot. During hot working, sufficient heat is maintained to ameliorate the working effects and maintain a structure that is relatively soft and ductile throughout the reduction process.

The steel in the form of ingot, slab, bar, or billet is first brought to the proper temperature throughout and is then passed through rolls or dies. The flow of metal is continuous and preferentially in one (longitudinal) direction. The cross-sectional area is reduced, and the metal is shaped the desired form. The internal structure of the steel is also favorably affected. The working reduces the grain size of the material, and tends to homogenize the overall structure, compared with cast or unworked steel.

Processes used to manufacture pipe and tube are addressed in another chapter.

PHYSICAL METALLURGY OF STEEL

Like all other metals, iron and steel are crystalline in structure, composed of atoms in a fixed lattice. As noted earlier, iron may exist in one of two cubic forms, body-centered (BCC) or face-centered (FCC).

At room temperature, pure iron is composed of a body-centered cubic lattice. In this form it is known as *alpha* iron, also called *ferrite*, which is soft, ductile, and magnetic. When heated above about 1415°F (768°C), alpha iron loses its magnetism but retains its body-centered crystalline structure. This temperature is called the *Fermi temperature*. The crystal structure changes to face-centered cubic at about 1670°F (910°C), at which temperature alpha iron is transformed to *gamma* iron, the FCC form, and remains nonmagnetic. As temperature rises further, another phase change occurs at 2570°F (1410°C), when *delta* iron is formed. This phase is again body-centered like that of the low-temperature alpha iron. It is stable to the melting temperature. In cooling very slowly from the liquid state, the phases reappear in reverse order.

The solid-state transformations of atomic structure, which occur in pure iron during heating to and cooling from the melting point, are called *allotropic* changes. The temperatures at which these changes take place are known as *transformation* or *critical* temperatures.

When carbon is added to iron and steel is produced, the same changes in phase occur, but a more complex relationship with temperature occurs. The effects of varying amounts of carbon content in iron on phase stability as temperature varies is represented in Fig. A3.18. This diagram is called an *equilibrium phase diagram*, and in this case is the very familiar iron-carbon (Fe-C) phase diagram. With this diagram, one can determine which stable phase the steel will assume at a given composition and temperature. Likewise, the effect of increasing or decreasing the amount of carbon content in iron on these critical temperatures can be predicted.

Phase diagrams are plotted in weight or atomic percent (horizontal axis) versus temperature (vertical axis). A single-phase region usually represents an area of high concentration of a single element, or an intermetallic single phase stable over a range of composition and temperature. Between these single-phase regions are regions where multiple phases coexist, in relative amounts at any given temperature approximated by the proximity of the specific composition to the single-phase regions. On the Fe-C diagram, single-phase regions are represented by those marked as alpha, gamma, and delta, and Fe_3C or cementite, which is a stable intermetallic phase.

The critical transformation temperatures in steel are the A_1, corresponding to about 1335°F (724°C), and A_3 referred to as the lower and upper critical temperatures of steel. The A_3 constitutes the boundary with the gamma phase, and its temperature varies with carbon content. The lower critical temperature, on the other hand, stays constant over the entire range of steel compositions.

These critical temperatures, as well as the entire phase diagram, represent transformations that occur under controlled, very slow cooling and heating (i.e., equilibrium) conditions. More rapid heating and cooling rates, like those encountered in normal steel processing, change these critical temperatures upward and downward, respectively. Additions of other alloying elements also will shift the critical transformation points.

It is the effective use by the metallurgist of the knowledge contained on this and similar phase diagrams that allows for the manipulation of properties of engineering materials by varying their chemistry and heat treatment. For steel, the principal phases and their properties are briefly summarized in the following list:

Austenite: A single-phase solid solution of carbon in gamma iron (FCC). It exists in ordinary steels only at elevated temperatures, but it is also found at room temperatures, but it is also found at room temperature in certain stainless steels
FIGURE A3.18 Iron-carbon equilibrium diagram.

(e.g., 18 Cr–8 Ni type) classified as *austenitic* stainless steels. This structure has high ductility and toughness.

Ferrite: Alpha iron (BCC), containing a small amount of carbon (0.04–0.05 percent) in solid solution. This phase is soft, ductile, and relatively weak.

Cementite: Iron carbide, Fe_3C, a compound containing 6.67 percent carbon, which is very hard and extremely brittle. Cementite appears as part of most steel structures, the form of which depends on the specifics of the heat treatment which the steel has received (see pearlite).

Pearlite: A mixture of alternating plates of iron carbide (cementite) and ferrite (lamellar structure), which form on slow cooling from within the gamma range.

This condition generally represents a good blend of strength, ductility, and fair machineability. It is the equilibrium structure in steel.

Bainite: A mixture of ferrite and cementite, which is harder and stronger than pearlite. It forms by the transformation of austenite in many steels during fairly rapid cooling, but not fast enought to cause martensite formation. The structure consists of ferrite and iron carbide, but unlike pearlite, the aggregate is nonlamellar.

Martensite: The hardest constituent achievable by heat-treating of steels, it is formed by the rapid cooling of austenite to a temperature below the *martensite start* or M_s temperature. Martensite consists of a distorted cubic unit cell (body-
FIGURE A3.19 Isotherm transformation diagrams for AISI 1050 (*a*) and AISI 4340 (*b*). (From I-T Diagrams, *United States Steel*, ©1963.)

centered tetragonal) which contains substantial quantities of carbon in interstitial solution in the lattice. The M_s temperature varies with steel composition.

These latter two microstructural constituents, bainite and martensite, will not be found on the Fe-C phase diagram because they are the direct result of cooling steel at an accelerated rate, which prevents atomic diffusion required to maintain equilibrium conditions.

The effects of nonequilibrium cooling of a steel are represented on an *isothermal transformation* diagram, or a *time-temperature transformation* (T-T-T) diagram. An example of each is shown in Fig. A3.19. The horizontal axis of the diagram is time, usually log scale; the vertical axis is temperature. A single diagram represents a given steel alloy composition and depicts the various equilibrium and nonequilibrium phases that will be formed, and their mix, with a given cooling rate from a starting temperature in the austenitic phase region. The diagram is used by entering it at the alloys temperature at time = 0, represented as a point of the vertical axis. The cooling rate describes the time/temperature path taken by the material from the starting point, through the field of transformation phases, to the final point of sample cooling. The metallurgical phases or constituents in the final state can thus be predicted. The continuous path followed between the two points also has a bearing on final microstructure. The T-T-T diagram is similar to the equilibrium phase diagram in that single and multiple phase fields are depicted. However, it differs from the equilibrium diagram in that it is a dynamic representation of phase formation with time. Thus quickly cooling to a given temperature above the M_s will result, for example, in coexistence of austenite, ferrite and, cementite (A, F, and C on the figure). However, as time progresses at that temperature, the austenite continues to decompose into more ferrite and cementite, until complete transformation is achieved. Cooling to below the M_s temperature causes tranformation to martensite. If the path of cooling had intersected the ''nose'' of the T-T-T curve, some ferrite will form and be combined with the martensite in the final microstructure, since martensite can only be formed by quenching austenite. The ferrite that formed on cooling is stable and unaffected by further cooling.

ALLOYING OF STEEL

The alloying of carbon steel with other elements to obtain a wide range of desired properties is a mature science. The following summarizes the known effects of adding certain elements to steel[7]:

Carbon: In general, increasing the carbon content of steel alloys produces higher ultimate strength and hardness but may lower ductility and toughness. Carbon also increases air-hardening tendencies and weld hardness. In low-alloy steel for high-temperature applications, the carbon content is usually restricted to a maximum of about 0.15 percent in order to assure optimum ductility for welding, expanding, and bending operations. An increasing carbon content lessens the thermal and electrical conductivities of steel.

Phosphorus: High phosphorus content has an undesirable effect on the properties of carbon steel, notably on shock resistance and ductility (see the section on temper embrittlement). Phosphorus is effective, however, in improving machineability. In steels, it is normally controlled to less than 0.04 weight percent.

Silicon: Used as a deoxidizing agent, silicon increases the tensile strength of

steel without increasing brittleness when limited to less than about 2 percent. Silicon increases resistance to oxidation, increases electrical resistivity, and decreases hysteresis losses. Thus it is used for electrical applications. Adding silicon may reduce creep rupture strength.

Manganese: Manganese is normally present in all commercial steels. The manganese combines with sulfur, thus improving hot-working characteristics. In alloy steels, manganese decreases the critical cooling rate to cause a hardened or martensitic structure and thus contributes to deep-hardening.

Nickel: As an alloying element in alloy steels, nickel is a ferrite strengthener and toughener and is soluble in all proportions. Nickel steels are easily hardened because nickel lowers the critical cooling rate necessary to produce hardening on quenching. In heat-treated steel, nickel increases the strength and toughness. In combination with chromium, nickel produces alloy steels possessing higher impact and fatigue resistance than can be obtained with straight carbon steels.

Chromium: As an alloying element in steel, chromium is miscible in iron as a solid solution, and forms a complex series of carbide compounds. Chromium is essentially a hardening element and is frequently used with a toughening element such as nickel to produce superior mechanical properties. At higher temperatures, chromium contributes increased strength and is ordinarily used in conjunction with molydenum. Additions of chromium significantly improve the elevated temperature oxidation resistance of steels.

Molybdenum: In steel, molybdenum can form a solid solution with the iron and, depending on the molybdenum and carbon content, can also form a carbide. A deeper hardening steel results. The molybdenum carbide is very stable and is responsible for matrix strengthening in long-term creep service.

Vanadium: This element is one of the strong carbide formers. It dissolves to some degree in ferrite, imparting strength and toughness. Vanadium steels show a much finer grain structure than steels of a similar composition without vanadium.

Boron: Boron is usually added to steel to improve hardenability; that is, to increase the depth of hardening during quenching.

Aluminum: Aluminum is widely used as a deoxidizer in molten steel and for controlling grain size. When added to steel in controlled amounts, it produces a fine grain size.

Sulfur: Present to some degree in all steel (less than 0.04 weight percent), sulfur forms a nonmetallic inpurity that, in large amounts, results in cracking during forming at high temperatures (hot shortness). Combining it with managanese forms a MnS compound that is relatively harmless.

Copper: Copper dissolves in steel and strengthens the iron as a substitutional element. The use of copper in certain alloys increases resistance to atmospheric corrosion and increases yield strength. However, excessive amounts of copper (usually above 0.3 percent are harmful to elevated temperature performance since the lower melting point element segregates to grain boundaries and locally melts (liquates), causing intergranular separation under applied stress.

In general, when used in combination, alloying elements may complement each other and give greater overall benefits than when used singly in much larger quantities.

CLASSIFICATION OF STEELS

There are literally hundreds of wrought grades of steel that range in composition with the variation of the many major and minor alloying elements. The simplest of these classes is known as plain carbon steel, with carbon varying between approximately 0.05 and 1.0 weight percent. Within this broad range fall three general groups according to carbon content; they are defined as follows:

1. Low carbon steels—0.05 to 0.25 percent carbon
2. Medium carbon steels—0.25 to 0.50 percent carbon
3. High carbon steels—0.50 percent and greater carbon content

Alloy steels are generally considered to be steels to which one or more alloying elements, other than carbon, have been added to give them special properties that are different than those of straight carbon steels. From the standpoint of composition, steel is considered to be an alloy steel when amounts of manganese, silicon, or copper exceed the maximum limits for the carbon steels, or when purposeful addition of minimum quantities of other alloying elements are added. These could be chromium, molybdenum, nickel, copper, cobalt, niobium, vanadium, or others.

The next higher class of alloyed steel useful to the piping industry is ferritic and martensitic stainless steels. These are steels alloyed with chromium contents above about 12 percent. Because of the chromium, these materials possess good corrosion resistance. They retain a ferritic (BCC) crystal structure, allowing the grades to be hardened by heat treatment.

When sufficient nickel is added to iron-chromium alloys, an austenitic (FCC) structure is retained at room temperature. Austenitic stainless steels possess an excellent combination of strength, ductility, and corrosion resistance. These steels cannot be hardened by quenching, since the austenite does not transform to martensite.

A stronger type of stainless steel has been developed which takes advantage of precipitation reactions within the metal matrix made possible by addition of elements such as aluminum, titanium, copper, and nitrogen. These materials are referred to as precipitation—hardenable stainless steels. Both martensitic and austenitic stainless steels can be enhanced in this manner.

As annealed, these materials are soft and readily formed. When fully hardened, through aging heat treatments, they attain their full strength potential.

STEEL HEAT-TREATING PRACTICES

Various heat treatments can be used to manipulate specific properties of steel, such as hardness and ductility, to improve machinability, to remove internal stresses, or to obtain high strength levels and impact properties. The heat treatments of steel commonly employed—annealing, normalizing, spheroidizing, hardening (quenching), and tempering—are briefly described in the following paragraphs.[8]

Annealing

Several types of annealing processes are used on carbon and low-alloy steel. These are generally referred to as *full annealing, process annealing*, and *spheroidizing annealing*.

In full annealing, the steel is heated to just above the upper critical (A_3) temperature, held for a sufficient length of time to fully austenitize the material structure, and then allowed to cool at a slow, controlled rate in the furnace. The microstructure of fully annealed low-carbon steel consists of ferrite and pearlite. A full anneal provides a relatively soft, ductile material, free of internal stresses.

Process annealing sometimes referred to as *stress-relieving*, is carried out at temperatures below the lower critical (A_1) temperature. This treatment is used to improve the ductility and decrease residual stresses in work-hardened steel.

The usual purpose of spheroidizing is to soften the steel and improve its machinability. Heating steel that possesses a pearlite microstructure for a long time at just below the lower critical temperature, followed by very slow cooling, will cause spheroidization. This is an agglomeration of the iron carbide, which eventually assumes a spheroidal shape. The properties of this product normally represent the softest condition that can be achieved in the grade of steel being heat-treated.

The austenitic stainless steels are annealed differently from carbon steels. First, since they posses a fully austenitic structure, the temperature used is not related to a critical transformation temperature. Rather, the intent of the annealing is to remove residual strain in the lattice, recrystallize the metal grains, and to dissolve any iron and chromium carbides that may exist in the matrix material. The temperature selected is usually at or above 1900°F (1038°C). Second, the cooling rate from the annealing temperature is normally as rapid as possible. This suppresses the reformation of carbides at the austenitic grain boundaries during cooling. Formation of grain boundary carbides results in local depletion of chromium in the matrix in the vicinity of the carbides, rendering this thin band of material susceptible to attack in a number of corrosive media. This susceptible condition is referred to as sensitization, and the resultant corrosion is termed intergranular attack.

The temperature range in which carbides are most apt to form in austenitic stainless steels is between about 850 and 1500°F (454 and 816°C). Slow cooling through or holding in this zone will sensitize the steel. The degree of sensitization that will occur can be greatly reduced by adding small amounts of elements that possess a stronger tendency to form carbides than the chromium. Two such elements, niobium and titanium, are added to form the so-called stabilized austenitic stainless steels. Alternately, the carbon content can be held as low as possible, thereby resulting in as few carbides as possible. These are termed the *L grade* stainless steels.

Ferritic and martensitic stainless steels will also be adversely affected by slow cooling from annealing temperatures. When slow cooled, or held in the temperature range of 750 to 950°F (400 to 510°C), these materials embrittle (see discussion on "474°C" embrittlement).

Normalizing

This carbon and low-alloy steel heat treatment is similar to the annealing process, except that the steel is allowed to cool in air from temperatures above the upper critical temperature. Normalizing relieves the internal stresses caused by previous working. While it produces sufficient softness and ductility for many purposes, it leaves the steel harder and with higher tensile strength than after annealing. Normalizing is often followed by tempering.

Hardening (Quenching)

When steels of the higher-carbon grades are heated to produce austenite and then cooled rapidly (quenched), the austenite transforms into martensite. Martensite is

formed at temperatures usually below about 400°F (204°C), depending on the carbon content and the type and amount of alloying steel. It is the hardest form of heat-treated steel and has high strength and resistance to abrasion. Martensitic steels have poor impact strength and are difficult to machine.

Tempering

Tempering is a secondary heat treatment performed on some normalized and almost all hardened steel structures. The object of tempering is to remove some of the brittleness by allowing certain solid-state transformations to occur. It involves heating to a predetermined level, always below the lower critical temperature, followed by a controlled rate of cooling. In most cases tempering reduces the hardness of the steel, increases its toughness, and eliminates residual stresses. The higher the tempering temperature used for a given time, the more pronounced is the property change. Some steels may become embrittled on slowly cooling from certain tempering temperatures. Steels so affected are said to be *temper-brittle*. To overcome this difficulty, steels of that type are cooled rapidly from the tempering temperature. Temper embrittlement is covered elsewhere in this chapter.

DEGRADATION OF MATERIALS IN SERVICE

A number of metallurgically based processes can occur in steels which contribute to loss of engineering strength, and even premature failure. Several of these are addressed in the following paragraphs.

Aging of Properties

A number of steels that have accumulated considerable service time are known to have experienced changes in their properties, usually to their detriment. This phenomenon has been called *aging*, and occurs in materials that are heat-treated or cold-worked to achieve high strength levels and to be used at elevated temperatures. These materials are potentially more susceptible to failure after the condition has developed.

''Aging'' in this case should not be confused with the same term used to represent the purposeful heat treatment performed to some types of nonferrous alloys. In the context being addressed here, aging refers to that normally very slowly progressing metallurgical reaction that occurs in a number of alloys while at operating temperatures for extended periods of time. Some specific types of this behavior (i.e., temper embrittlement and ''885'' embrittlement) are addressed in the paragraphs that follow.

Components that experience considerable service time contain materials that have aged with time. The materials of special interest are those that regularly experience higher operating temperatures; for example, ferritic steels above 900°F (482°C) and austenitic stainless steels at or above 1000°F (538°C). A study sponsored by the ASME Boiler and Pressure Vessel Code attempted to identify and quantify these effects. The effort was the result of concerns for near end-of-life seismic loadings in elevated-temperature nuclear boilers.

Data gathered from a number of sources have shown that the room and elevated temperature yield strengths of both ferritic and austenitic steels may degrade after

long exposure times. Ultimate tensile strength is affected, but to a lesser degree. The yield strength reductions can amount to as much as 40 percent in ferritic and 20 percent in austenitic steels.

Creep tests have also been run after long-term (e.g., 10,000 h) static exposure to elevated temperatures. No substantial negative effect on creep properties were noted in these tests.

In the case of ASME Boiler and Pressure Vessel Code and ASME B31.1 Power Piping Code design and construction, the degradation of yield strength does not generally violate or invalidate the conservatism built into their design rules, as manifest by the allowable design stresses. For example, in Section 1 of the ASME Boiler Code, addressing design and construction of power boilers, the material design allowable stresses for wrought materials are established by applying the following factors to base material properties. The lowest calculated value of all the following is assumed as the design allowable stress at a given temperature:

- ¼ specified minimum tensile strength at room temperature
- ⅔ specified minimum yield strength at room temperature
- ¼ tensile strength at the temperature of interest above room temperature
- ⅔ yield strength at the temperature of interest above room temperature
- 67 percent of the average stress to cause rupture in 100,000 h
- 80 percent of the minimum stress to cause rupture in 100,000 h
- 100 percent of the stress to produce 0.01 percent strain in 1000 h

In this manner, short-term properties, stress rupture strength, and creep rate are all taken into account. Typically, at the lower end of the temperature use range, the factored tensile and yield strength controls, and at higher temperatures, the creep properties set the allowable stresses.

Since most aging occurs at the higher temperatures, tensile and yield strength degradation does not normally cause concern. However, if large shock loads can occur late in component life (as is possible under seismic conditions), these short-term, time-independent properties can be critical to the components' continued safe operation.

As an illustration of the effect reduced yield strength has on fatigue, consider that with a lower yield strength, more plastic strain will result from a given high thermal, or mechanically induced stress. Since these stresses are usually due to operational transients, stress reversals can occur during continued operation (i.e., temperature stabilization at steady state, or ultimately, component shutdown). The greater the plastic strain cycle, the greater the damage, and the sooner the failure.

It is clear that as components experience increasing service time, they become less resilient to significant operational transients. That is, materials are less likely to withstand these transients than earlier in their life, not only because more cycles have continued to accumulate (toward an end-of-life limit), but also because material strength properties are degrading with time.

Temper Embrittlement

Temper embrittlement is a phenomenon that occurs in carbon and alloy steels when aged in the temperature range roughly between 660 and 1020°F (350 and 550°C). The property most significantly affected is toughness. The time in which this occurs is a function of the steel's chemical composition, heat treatment condition, fabrication

history, and service temperature. The most severe degradation occurs in weld regions. Due to the extensive use of Cr–Mo steels in the petrochemical and power boiler industries, most of the studies have concentrated on this family of materials.

It has been recognized for some years that a steel's susceptibility to temper embrittlement is due to the existence and amount of the trace elements antimony (Sb), phosphorous (P), tin (Sn), and arsenic (As), with P and Sn having the greatest effect. Other elements that may contribute to reduced toughness are silicon, manganese, and copper. Beneficial effects can be gained by additions of molydbenum and aluminum. The obvious dependency of temper embrittlement severity and chemistry has led to the development of a number of embrittlement *factors*.[9]

Bruscato made the first attempt to combine the effects of various elements into a single factor, known as the *embrittlement factor X*, which is expressed as follows:

$$X = \frac{1}{100}(10P + 5Sb + 4Sn + As) \qquad (A3.4)$$

The concentration of elements is in parts per million (ppm).

Miyano and Adachi arrived at a *J*-factor defined as:

$$J = (\%Si) + (\%Mn) \times (\%P) + (\%Sn) \times 10^4 \qquad (A3.5)$$

Finally, Katsumata et al, asserted that the following embrittlement factor (E.F.) was appropriate for 2¼ Cr–1Mo and 3 Cr–1Mo steels.

$$E.F. = (\%Si) + (\%Mn) + (\%Cu) + (\%Ni) \cdot Y$$

$$Y = \frac{1}{100}(10P + 5Sn + Sb + As) \qquad (\text{in ppm})$$

$$Y = \frac{1}{100}(10P + 5Sn + Sb + As) \qquad (\text{in ppm})$$

All of these are useful in assessing the relative susceptibility of various steel compositions to temper embrittlement. In all cases, the larger the factor, the more susceptible the particular heat of steel is to embrittlement.

The type of heat treatment applied to the materials may also affect a material's susceptibility to temper embrittle. For example, a number of experimenters have confirmed that 2¼ Cr–1 Mo alloy steels' susceptibility increases as austenitizing temperature used during its heat treatment increases. Inversely, susceptibility is lowest after an intercritical hold, at a temperature between the lower and upper critical temperature (Ac_1 and Ac_3, respectively). This effect is believed to be associated with the grain size achieved during the hold time, a larger grain being more detrimental. Although intercritically treated materials are less susceptible to temper embrittlement, they are weaker in the as-heat-treated condition.

In a parallel fashion, the degree of embrittlement, as measured by loss of toughness or shift of nil ductility temperature, is decreased if the material is more substantially tempered prior to the embrittling treatment. In this context, "tempered" represents the planned heat treatment that typically follows a normalizing or austenitizing and rapid quenching operation. A longer or higher temperature temper results in a softer, less strong, and more ductile condition, usually accompanied by good fracture toughness.

Luckily, the temper embrittled condition is reversible. Heat treatment for short periods of time at temperatures well above the upper critical will result in reestablishing nearly virgin properties in these materials.

Hydrogen Attack

Hydrogen attack is one of the most important problems with materials used in ammonia synthesis, oil refining, and coal gasification equipment.[9]

The first major failure of an ammonia convertor attributable to hydrogen damage was in 1933. Since then more failures and untold damage to materials have accumulated, with the majority of damage occurring in the welds or weld heat-affected zones of these components.

When carbon and low-alloy steels are held in hydrogen at high temperature and pressure for an extended period of time, these materials can suffer degrading effects to their tensile and creep rupture properties. This is accompanied by the formation of intergranular fissures, blisters on the surface, and loss of carbon content (decarburization). The phenomenon is called *hydrogen attack* and is generally attributed to the formation of methane (CH_4) within the steel.

The microstructural damage occurs when methane bubbles form and grow around precipitates at the grain boundaries within the material. The continued growth of the bubbles causes grains to separate along their boundaries and the bubbles, or voids, to coalesce. The rate of growth of the bubbles is a function of the ease by which the steel carbides give up carbon atoms to the intruding hydrogen atoms to form the methane. The more stable the carbide, the slower this reaction will take place. Thus, it has been long recognized that additions of chromium and molybdenum, both strong carbide stablizers, improves hydrogen-attack resistance of steels. Addition of other carbide-stabilizing elements such as titanium and tungsten has also assisted in reducing susceptibility.

Weld regions are more susceptible to hydrogen damage because they possess less stable carbides. It is also readily apparent that carbon content of the base material is an important variable in determining the susceptibility of a steel to hydrogen damage. In general, steels used in this service are kept below 0.20 weight percent carbon content. Certain other elements, such as nickel and copper, are known to also have a detrimental effect.

Nelson curves have proven indispensable in the selection of materials in hydrogen service. These curves (see Fig. A3.20. for an example) were originally based on experience gathered over several decades, and have been revised as new experience has been gained. These curves identify a ''safe'' regime in which an alloy will perform acceptably at various temperatures and hydrogen partial pressures. Where these curves have proven unconservative have been associated with weld heat-affected zones that had been inadequately postweld heat-treated (PWHT). The high residual stresses and high hardness left in the weld region contribute to accelerated damage. For this reason, most specifications for hydrogen service equipment stipulate a maximum hardness in weld regions that will assure adequacy of the PWHT. The limit is usually placed at 210 Brinell hardness, corresponding approximately to a 100,000 psi (690 Ma) ultimate tensile strength.

Austenitic stainless steels are essentially immune to hydrogen damage. The numerous sites within the FCC lattice in which the hydrogen atoms can be safely accommodated, and the inherent ductility of the lattice, gives austenitic materials this freedom from hydrogen damage. However, when stainless overlay weld metal has been used over carbon or low-alloy vessel steels, hydrogen-induced cracking can occur at the weld fusion line just inside the ferritic material.

''885°F'' (474°C) Embrittlement

One of the limitations of ferritic stainless steels (those alloys of iron possessing greater than about 14 pecent chromium) has been the loss of toughness at room
FIGURE A3.20 The classic Nelson diagram indicating the choice of steel warranted to avoid hydrogen attack as a function of operating temperature and partial pressure of hydrogen. Austenitic materials are satisfactory at all temperatures and pressure from hydrogen damage. (Dunn et al., *Molybdenum's Place in the Pressure-Vessel Field*, Climax Molybdenum Company.)

temperature that occurs after these materials are exposed for long times to temperatures in the range of 610 to 1000°F (320 to 538°C). This is commonly referred to as *885°F (474°C) embrittlement*, corresponding approximately to the temperature at which many of the alloys degrade the fastest.

The compositional effects in commercial alloys on 885°F (474°C) embrittlement have not been systematically investigated. However, it is clear that the degree of embrittlement increases as chromium content increases. The effects that other elements may have is not clear. Of these, most important is carbon, and it has been reported as having from no effect to a retarding effect on embrittlement.

This phenomenon results in increased hardness and strength, with a corresponding decrease in ductility, fracture toughness, and a decrease in corrosion resistance. Loss of toughness can be particularly severe, and in fact has tended to relegate the use of this class of alloy to temperature regimes below which significant embrittlement can occur.

Graphitization

Graphitization is a time- and temperature-dependent nucleation and growth process, in which iron carbide in the form of pearlite first spheroidizes, and later forms graphite nodules. There are two general types:

1. Formation of randomly, relatively uniformly distributed graphite nodules in the steel. This reduces the room temperature mechanical strength somewhat, but does not affect the creep-rupture strength at elevated temperature.

2. A concentrated formation of graphite most frequently along the edges of the heat-affected zone of weldments. This is referred to as chain graphite, since a plane of nodules exists paralleling the weld bead contours.

The formation of these nodules, when aligned through the wall of a pressure part, creates planes of weakness, subject to rupture. Fracture characteristically occurs without prior warning.

The first graphitization failure of a low-carbon steam piping material occurred in the early 1940s. The failure occurred after five and a half years of service in a steam line made of aluminum-killed carbon-molydenum steel. The fracture surface was located approximately ¹⁄₁₆ in (1.6 mm) from the fusion zone of a butt weld. The failure precipitated numerous and extensive research programs to understand the key variables of the mechanism and to determine the steels which would resist graphitization.

Research has helped in the understanding of the problem, and led to restrictions adopted by the various design codes on use of materials subject to graphitization. Carbon steel and carbon-molybdenum grades are the most susceptible to this degradation process, with the latter being more so. Relative susceptibility of these two grades is also dependent on the steel's aluminum content; the more aluminum, the greater the susceptibility. Additions of chromium in amounts as low as 0.5 weight percent make the steel essentially immune to graphitization.

The ASME Code permits the use of carbon and carbon-molybdenum steels in ASME Section 1 boiler applications up to 1000°F (538°C). A cautionary note is provided in the allowable stress tables of Section I indicating the carbon steels and carbon-molybdenum steels may be susceptible to graphitization at temperatures above about 800 and 875°F (427 to 468°C), respectively. ASME B31.1 has a similar precautionary note specifying limits of 775 and 850°F (413 and 454°C), respectively. Graphitization is a mechanism dependent on diffusion and is not associated with a precise temperature of initiation (it occurs sooner at higher temperatures). Thus, the differences between the design codes only reflect different levels of conservatism in dealing with the failure mode. Many manufacturers extend even more severe restrictions, some prohibiting the use of these steels in piping applications outside the boiler or pressure vessel where rupture creates a serious safety hazard. Substitution of chromium-containing steel grades, such as SA.335 P2(½Cr-½Mo), P11 (1¼Cr-½Mo), and P22 (2¼Cr-1Mo), is normally recommended for these applications. Grade P91 (9Cr-1Mo-V) is increasingly being used in high-temperature applications where use of P11 and P22 is not desirable due to their reduced mechanical strength.

Intergranular Attack

When an unstabilized austenitic stainless steel is held at a temperature within the range of 850 to 1500°F (454 to 816°C), chromium carbides will quickly and preferentially form at the austenitic grain boundaries. The formation of these carbides deletes the surrounding grain matrix of chromium atoms, rendering the thin zone adjacent to grain boundary susceptible to corrosive attack in aqueous environments. This condition is called *sensitization*, and the resulting corrosion is termed *intergranular attack* (IGA). When also in the presence of local high-tension stresses, the result can be *intergranular stress corrosion cracking* (IGSCC). Avoidance of

these failure mechanisms is best achieved by minimizing sensitization (fast cool from anneal; stabilized or L-grade steels), and eliminating local stresses.

The area of piping components most often attacked is weld regions. Sensitization can readily occur in a narrow band of base material in the heat-affected zone, caused by the heat of the weld pool. Corrosion of this area has been called *knife line attack* due to the characteristic appearance of a thin crack along a weld edge.

Sigmatization

A hard, brittle, nonmagnetic phase will form in some Fe-Cr and Fe-Ni-Cr alloys upon prolonged exposure to temperatures between about 1100 and 1475°F (593 and 800°C). Those austentic stainless steels containing higher alloy content, such as type 310 (25% Cr–20% Ni) are susceptible, as well as any grades that possess residual ferrite in their microstructure, a constituent which will transform to sigma, preferentially at grain boundaries.

The most deterimental effect of sigma is reduction of toughness. Charpy V-notch impact toughness can degrade to less than 10 ft · lb (14 joules) at room temperature if as much as 10 percent of the volume of material transforms. Toughness is usually not significantly degraded at higher temperatures, above about 1000°F (538°C).

Chemically, sigma is not as resistant to oxidizing media as the austenite, such as acidic environments, thus, the materials will undergo intergranular attack.

At normal metal operating temperatures in power plants, sigmatization of pressure piping made of these high-alloy materials takes very long times to form. Once formed, the phase can be redissolved by subjecting the material to an annealing heat treatment.

Creep Damage and Estimation of Remaining Creep Life

The type of damage observed in components operating at high temperatures, and high stress, typically progresses in stages occurring over a considerable period of time. Elongation or swelling of the component may be observed. Material damage manifests itself in the microstructure in characteristic form at grain boundaries. Voids will form first, which then subsequently link up to form cracks. These cracks increase in size or severity as the end-of-life condition is approached. Severe-damage indications invariably signal the need for near-term corrective action. Such corrective action may entail repair or replacement of the component in question, depending upon the extent of the damage and the feasibility of repair. It is important to note that, except in the most severe cases, damage is not readily detectable by the naked eye, or even by conventional nondestructive techniques such as ultrasonic, magnetic particle, or liquid penetrant examination methods.

The degree of microstructural damage can be assessed by conventional metallographic procedures that may either take a destructive sampling approach or use nondestructive in-place (in-situ) methods. Since the determination of the structural damage allows for a ready estimation of expended creep-rupture life, these inspection methods have recently been adopted to piping and other structural components. The power piping industry, in particular, has seen a wholesale application of metallographic examination to components that have experienced extensive time in elevated temperature service. Several serious steam line ruptures have caused deaths, serious injury, and significant lost operating time at fossil energy power plants. The

steam lines that have come under the greatest scrutiny are reheat superheater piping which, based on their relatively large diameters and thin walls, had been made from rolled and welded plate. The failures have been associated with the longitudinal weld regions, which are inherently more susceptible to problems due to danger of latent defects (lack of fusion, slag entrapment, solidification cracks), and the variability in mechanical properties across the welds heat-affected zone.

Destructive sampling of material surfaces of suspected creep-damaged components, to allow for metallographic examination, has evolved to the point where there can be minimal disturbance to surrounding material. Test samples are either trepanned through thickness or smaller silver (boat-shaped) samples are removed by sawing, electro discharge machining, or other methods. However, arc gouging or any other form of heat-producing mechanism must be avoided. It not only can significantly metallurgically alter surrounding material but also can damage the destructive sample, sometimes rendering it unusable for microscopic analysis. The small samples, once properly removed, are metallographically prepared in the standard fashion. These are then examined at high magnification in metallurgical microscopes for evidence of creep damage. The area from which this sample was removed must be weld repaired, employing the required preheat, postweld heat treatment, and weld inspections.

Alternately, an evaluation of microstructure can be performed in place on the component surface, in the area of interest using a procedure called *replication*, which provides, in a manner of speaking, a fingerprint image of the surface. The area to be examined is first carefully polished to a mirrorlike finish using ever-increasing fineness of sandpapers or grinding disks, and then polishing compounds. The surface is then etched with an appropriate acid. A thin, softened plastic film is then applied to the surface. Upon drying, the film hardens, retaining the microstructure in relief. When properly done by skilled technicians, the resolution of the metal structure at magnifications up to 500X or higher is almost equal to that achieved on an actual metal sample. The disadvantage of the replication method is that only the surface of the material can be examined, leaving any subsurface damage undetected. However, this method has proven useful when applied to weld regions, or other high-stressed areas where damage is suspected.

Remaining creep-life determination done in this fashion is not exact; the correlation between the type and degree of damage, and expended creep life is only approximate. In most cases, follow-up inspection several years hence is necessary to determine the rate of damage progression. Usually, when a network of microcracks has been generated, it is time to consider repair or replacement.

The science of estimating the expected growth rate of these cracks by creep evolved very rapidly in the 1980s. Armed with sufficient baseline creep data of a given alloy, formulas have been developed that can predict creep crack growth rates reasonably accurately. Analysis can also be made whether a pipeline would ''leak before break''; that is, weep fluid for a time prior to catastrophic rupture. All of these tools are available to the piping designer and to operating management, but will not be discussed in any greater detail in this chapter.

Oxide Thickness and Estimation of Remaining Creep Life

Another method for estimating remaining creep life of certain high-temperature tubing and piping components considers the amount of metal oxide scale that has formed on the metals surface. Understandably, this method only applies when the tubular items contain relatively benign substances under oxidizing conditions. It

has found its use in steam-carrying piping and components. This method is based on the knowledge that a given thickness of oxide scale on the tube or pipe surface represents growth for a certain time at some temperature. Since oxide growth kinetics of many alloys are well characterized, the effective temperature at which the tube was operating for a known time (service life) can be estimated. The combination of effective temperature and time can then be compared to the typical creep life of the alloy at an applied stress or stresses that are known to have acted on the component during its service life.

As noted, the two principal tools needed by the metallurgist to estimate life using the oxide measurement technique are (1) steam oxidation data for the alloy in question, and (2) uniaxial creep-rupture data for that alloy across the temperature range of interest. This latter information can be found for many of the most widely
FIGURE A3.21 Variation of Larson-Miller rupture parameter with stress for wrought 1¼ Cr ½ Mo-Si steel. (*Evaluation of the Elevated Temperature Tensile and Creep-Rupture Properties of ½ Cr-½ Mo, 1 Cr-½ Mo, and 1¼ Cr-½ Mo-Si Steels,* ASTM Data Series Publication DS50.)
FIGURE A3.22 Variation of Larson-Miller parameter with stress for rupture of annealed 2¼ Cr-1 Mo steel. (*Supplemental Report on the Elevated-Temperature Properties of Chromium-Molybdenum Steels*, ASTM Data Series Publication DS 652.)

used ferrous alloy piping materials in ASTM references. The specific steps followed in this approach are as follows:

1. Oxide thickness is measured either metallographically on a sample or using specialized ultrasonic techniques. Operating time is known.

2. The effective operating temperature is determined from the oxidation data. The effective temperature is defined as the constant temperature that the particular tube metal would have had to have operated at for the known service time to have resulted in the measured oxide thickness. (This is an approximation, since the tube or pipe would have operated at various temperatures, perhaps even in upset conditions well above the design temperature limit.)

3. The hoop stress is calculated using an appropriate formula, knowing the tube or pipe size and operating pressure.

4. The Larsen-Miller Parameter (LMP) is calculated for the service time and effective temperature of the subject tube. The LMP is defined as:

$$\text{LMP} = T(20 + \log t) \times 10^{-3} \tag{A3.6}$$

Where *T* is temperature in degrees Rankine and *t* is time in hours. This is a simple factor representing the actual condition of the operating component.

5. Uniaxial creep-rupture data is obtained for the alloy in question. Examples of data for 1¼Cr-½Mo-Si and 2¼Cr-1Mo, taken from creep data sources ASTM DS50 and DS652 are shown as Fig. A3.21 and Fig. A3.22. This rupture data is normally represented by curves of minimum and average behavior, and lists applied stress versus LMP.

6. The ASTM rupture curve is entered on the stress axis at the level of appropriate calculated operating stress (from step 3). In this manner, the LMP representing the expected minimum and average total creep life at that stress is determined.

7. The operating LMP calculated in step 4 is compared to the LMPs derived in step 6. The differential in time represented by these parameters can be easily calculated from the Larsen-Miller formula, and the percentage of expended life versus minimum and average expected life can be determined by taking a ratio of these values.

This method for estimating remaining creep life has found its greatest use in the fossil power boiler industry, particularly for ferritic alloy steam piping and superheater tubing. Since a great majority of the operating power boilers in the United States are approaching their originally intended lifetime, the method is critical for establishing when major repair or replacement is necessary to restore the unit to safer and more reliable operation.

MATERIAL SPECIFICATIONS

The American Iron and Steel Institute (AISI) and the Society of Automotive Engineers (SAE) have devised a standardized numbering system for the various classes of carbon and alloy steels that has gained widespread acceptance in North America.

This system employs a four-digit number for carbon and low-alloy steels, and a three-digit number for stainless steels. Regarding the former, the first two digits represents the major alloying elements of the grade. The final two digits represent the nominal carbon content of each alloy, in hundreds of weight percent. For example, 10XX represents simple carbon steels, and 41XX stands for steels with chromium-molybdenum as the major alloying elements. In both classes, a specific grade possessing a nominal carbon content of 0.20 percent would be, respectively, 1020 and 4120. In this fashion the many possible alloy steels can be systematically identified.

Table A3.4 lists the carbon and alloy steel grades categories recognized by AISI and SAE.

The stainless steels are assigned a three-digit code by AISI. Those austenitic stainless steels composed of chromium, nickel, and manganese are the 2XX series. Chromium-nickel austenitic stainless steels are 3XX; ferritic and martensitic stainless steels are 4XX. In the case of stainless steels, the last two digits represent a unique overall composition rather than the level of carbon.

Due to increasing international technical community involvement and cooperation, and with each country possessing its own alloy numbering system, a worldwide universal system of material identification was needed. The Unified Numbering System (UNS) was the result. In this system a letter is followed by a five-digit

intended purpose. The American Society for Testing and Materials (ASTM), the American Society of Mechanical Engineers (ASME), and the American Petroleum Institute (API) have generated a series of comprehensive material specifications that extend this control. Table A3.5 lists the more common ASME specification and grade numbers for the common piping system materials of construction. Table A3.6 gives equivalencies between selected piping material grades in ASME with the Unified Numbering System (UNS).

Copper and Copper Alloys

The use of copper and copper alloys is limited to temperatures below the lower recrystallization temperature for the particular alloy. This is the temperature at which cold-worked specimens begin to soften. This recrystallization is usually accompanied by a marked reduction in tensile strength. Typical classes of wrought copper-based materials are given in Table A3.7.

Brasses containing 70 percent or more of copper may be used successfully at temperatures up to 400°F (200°C), while those containing only 60 percent of copper should not be used at temperatures above 300°F (150°C).

TABLE A3.9 Nickel and Nickel-Based Pipe and Tubing Alloy Specifications

ASME specifications	UNS grade number	Characteristics
SB-161	N02200	Nickel 200; 99% Ni
SB-161	N02201	Low Carbon
SB-163/SB-407	N08800	Alloy 800 Tubing (Ni-Fe-Cr)
SB-163/SB-165	N04400	70-30 Ni-Cu Monel
SB-163/SB-167	N06600	Alloy 600 (Ni-Cr-Fe)
SB-163/SB-167	N06690	Alloy 690 (60-30-10)
SB-163/SB-423	N08825	Alloy 825

The ASME Boiler and Pressure Vessel Code limits the use of brass and copper pipe and tubing (except for heater tubes) to temperatures not to exceed 406°F (208°C). The ASME B31 Code for Pressure Piping also limits brass and copper pipe and tubing to this temperature for steam, gas, and air piping.

Table A3.8 lists a number of ASME specifications for copper and copper alloy piping and tubing.

Nickel and Nickel Alloys

Nickel is a tough, malleable metal that offers good resistance to oxidation and corrosion. When nickel is combined with copper as the secondary element, the well-known series of Monel alloys are created. Nickel, Monel, and various modifications of these materials are used in piping systems, turbine blading, valves, and miscellaneous power plant accessories handling steam.

The presence of even a small amount of sulfur in a reducing environment will result in embrittlement as temperatures of 700–1200°F (370–650°C).

Source: *American Society for Metals, Metals Handbook,* Vol. 1, 8th Ed., p 917.

By addition of Cr, Co, Mo, Ti, Al, or Nb, the high temperature strength and creep resistance of the nickel-base materials can be substantially increased. However, these alloys possess low ductility values and require special care in forming of these materials, even at elevated temperatures.

Table A3.9 lists a number of ASME specifications for nickel-based alloy piping and tubing.

Aluminum and Aluminum Alloys

Aluminum and many of its alloys are highly resistant to atmospheric corrosion and to attack by many chemical agents, with the exception of strong alkalis. However, they are subject to galvanic attack if coupled with more noble materials.

Additions of alloying elements increases strengh, but to the detriment of thermal and electrical conductivity, and lowers the material's melting point. Alloying with Cu, Mg, and Si creates heat-treatable alloys that are age-hardenable. Maximum strength can usually be achieved by heating to about 300 to 500°F (150 to 260°C). Effects of working or precipitation hardening can be removed by annealing at temperatures of 600 to 800°F (315 to 425°C).

A system has been devised to designate alloys of aluminum based on the major alloying constituent. See Table A3.10.

Typical classes of wrought aluminum-based materials are given in Table A3.11. The UNS number for each alloy is easily determined by taking the alloy number given in Table A3.11 and preceding it with A9. Thus, for example, the UNS numbers for alloy 6061 is A96061.

Appendix A5 provides a list of material specifications which are acceptable for design and construction of piping systems within the jurisdiction of the ASME Boiler and Pressure Vessel Code and the ASME B31, Code for Pressure Piping. Appendix A6 lists some international material specifications for piping.

CHAPTER A4
PIPING CODES AND STANDARDS

Mohinder L. Nayyar, P.E.
ASME Fellow

Codes usually set forth requirements for design, materials, fabrication, erection, test, and inspection of piping systems, whereas standards contain design and construction rules and requirements for individual piping components such as elbows, tees, returns, flanges, valves, and other in-line items. Compliance to code is generally mandated by regulations imposed by regulatory and enforcement agencies. At times, the insurance carrier for the facility leaves hardly any choice for the owner but to comply with the requirements of a code or codes to ensure safety of the workers and the general public. Compliance to standards is normally required by the rules of the applicable code or the purchaser's specification.

Each code has limits on its jurisdiction, which are precisely defined in the code. Similarly, the scope of application for each standard is defined in the standard. Therefore, users must become familiar with limits of application of a code or standard before invoking their requirements in design and construction documents of a piping system.

The codes and standards which relate to piping systems and piping components are published by various organizations. These organizations have committees made up of representatives from industry associations, manufacturers, professional groups, users, government agencies, insurance companies, and other interest groups. The committees are responsible for maintaining, updating, and revising the codes and standards in view of technological developments, research, experience feedback, problems, and changes in referenced codes, standards, specifications, and regulations. The revisions to various codes and standards are published periodically. Therefore, it is important that engineers, designers, and other professional and technical personnel stay informed with the latest editions, addenda, or revisions of the codes and standards affecting their work.

While designing a piping system in accordance with a code or a standard, the designer must comply with the most restrictive requirements which apply to any of the piping elements.

In regard to applicability of a particular edition, issue, addendum, or revision of a code or standard, one must be aware of the national, state, provincial, and local laws and regulations governing its applicability in addition to the commitments made by the owner and the limitations delineated in the code or standard. This

chapter covers major codes and standards related to piping. Some of these codes and standards are discussed briefly, whereas others are listed for convenience of reference.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The American Society of Mechanical Engineers (ASME) is one of the leading organizations in the world which develops and publishes codes and standards. The ASME established a committee in 1911 to formulate rules for the construction of steam boilers and other pressure vessels. This committee is now known as the ASME Boiler and Pressure Vessel Committee, and it is responsible for the ASME Boiler and Pressure Vessel Code. In addition, the ASME has established other committees which develop many other codes and standards, such as the ASME B31, Code for Pressure Piping. These committees follow the procedures accredited by the American National Standards Institute (ANSI).

ASME BOILER AND PRESSURE VESSEL CODE

The ASME Boiler and Pressure Vessel Code contains 11 sections:

Section I Power Boilers

Section II Material Specifications

Section III Rules for Construction of Nuclear Power Plant Components

- Division 1 Nuclear Power Plant Components
- Division 2 Concrete Reactor Vessel and Containments
- Division 3 Containment Systems and Transport Packaging for Spent Nuclear Fuel and High-Level Radioactive Waste

Section IV Heating Boilers

Section V Nondestructive Examination

Section VI Recommended Rules for Care and Operation of Heating Boilers

Section VII Recommended Rules for Care of Power Boilers

Section VIII Pressure Vessels

- Division 1 Pressure Vessels
- Division 2 Pressure Vessels (Alternative Rules)
- Division 3 Alternative Rules for Construction of High-Pressure Vessels

Section IX Welding and Brazing Qualifications

Section X Fiber-Reinforced Plastic Pressure Vessels

Section XI Rules for In-Service Inspection of Nuclear Power Plant Components

Code Cases: Boilers and Pressure Vessels

Code Cases: Nuclear Components

Primarily, Sections, I, II, III, IV, V, VIII, IX, and XI specify rules and requirements for piping. Section II, V, and IX are supplementary sections of the code because they have no jurisdiction of their own unless invoked by reference in the code of record for construction, such as Section I or III.

Editions and Addenda

Code editions are published every three years and incorporate the additions and revisions made to the code during the preceding three years.

Colored-sheet addenda, which include additions and revisions to individual sections of the code, are published annually. Before the 1986 edition of the code, addenda were published semiannually as summer and winter addenda.

Interpretations

ASME issues written replies to inquiries concerning interpretation of technical aspects of the code. The interpretations for each individual section are published separately as part of the update service to that section. They are issued semiannually up to the publication of the next edition of the code. Interpretations are not part of the code edition or the addenda.

Code Cases

The Boiler and Pressure Vessel Committee meets regularly to consider proposed additions and revisions to the code; to formulate cases to clarify the intent of the existing requirements; and/or to provide, when the need is urgent, rules for materials or construction not covered by existing code rules. The code cases are published in the appropriate code casebook: (1) *Boiler and Pressure Vessel* and (2) *Nuclear Components*. Supplements are published and issued to the code holders or buyers up to the publication of the next edition of the code.

Code case(s) can be reaffirmed or annulled by the ASME Council. Reaffirmed code case(s) can be used after approval by the council. However, the use of code case(s) is subject to acceptance by the regulatory and enforcement authorities having jurisdiction. A code case once used for construction may continue to be used even if it expires later or becomes annulled. An annulled code case may become a part of the addenda or edition of the code or just disappear after its annulment because there may not be any need for it.

ASME SECTION I: POWER BOILERS

Scope

ASME Section I has total administrative jurisdiction and technical responsibility for boiler proper; refer to Fig. A4.1. The piping defined as boiler external piping (BEP) is required to comply with the mandatory certification by code symbol stamping, ASME data forms, and authorized inspection requirements, called Administrative Jurisdiction, of ASME Section I; however, it must satisfy the technical
FIGURE A4.1 ASME Section I jurisdictional limits and clarifications for jurisdiction over boiler external piping (BEP) and nonboiler external piping (NBEP). *(Figure PG-58.3.1, ASME Section I).*

requirements (design, materials, fabrication, installation, nondestructive examination, etc.) of ASME B31.1, Power Piping Code.[1]

Effective Edition, Addenda, and Code Cases

Code editions are effective on—and may be used on or after—the date of publication printed on the title page. Code addenda are effective on—and may be used on or after—the date of issue. Revisions become mandatory as minimum requirements six months after such date of issuance, except for boilers (or pressure vessels) contracted for before the end of the six-month period.

Use of revisions and code cases that are less restrictive than former requirements of the applicable edition and addenda shall not be made without assurance that they have been accepted by the proper authorities in the jurisdiction in which the power boiler (component) is to be installed. Use of code cases is permissible beginning with the ASME council approval date published on the code case.

ASME SECTION II: MATERIALS

Scope

ASME Section II consists of four parts, three of which contain material specifications and the fourth the properties of materials which are invoked for construction of items within the scope of the various sections of the ASME Boiler and Pressure Vessel Code and ASME B31, Code for Pressure Piping. Therefore, ASME Section II is considered a supplementary section of the code.

Part A: Ferrous Material Specifications. Part A contains material specifications for steel pipe, flanges, plates, bolting materials, and castings and wrought, cast, and malleable iron. These specifications are identified by the prefix SA followed by a number such as SA-53 or SA-106.

Part B: Nonferrous Material Specifications. Part B contains materials specifications for aluminum, copper, nickel, titanium, zirconium, and their alloys. These specifications are identified by the prefix SB followed by a number such as SB-61 or SB-88.

Part C: Specifications for Welding Rods, Electrodes, and Filler Metals. Part C contains material specifications for welding rods, electrodes and filler materials, brazing materials, and so on. These specifications are identified by the prefix SFA followed by a number such as SFA-5.1 or SFA-5.27.

Part D: Properties. Part D covers material properties of all those materials that are permitted per Sections I, III, and VIII of the ASME Boiler and Pressure Vessel Code.

Subpart 1 contains allowable stress and design stress intensity tables for ferrous and nonferrous materials for pipe, fittings, plates, bolts, and so forth. In addition, it provides tensile strength and yield strength values for ferrous and nonferrous materials, and lists factors for limiting permanent strain in nickel, high-nickel alloys, and high-alloy steels.

Subpart 2 of Part D has tables and charts providing physical properties, such as coefficient of thermal expansion, moduli of elasticity, and other technical data needed for design and construction of pressure-containing components and their supports made from ferrous and nonferrous materials.

Effective Edition, Addenda, and Code Cases

The application of ASME Section II is mandatory only when referenced by other sections of the ASME Boiler and Pressure Vessel Code, ASME B31, Code for Pressure Piping, and various other industry codes and standards.[2]

The applicable edition and addenda of ASME Section II shall correspond to the edition and addenda of the referencing code or standard.

Use of a later or the latest edition and addenda of ASME Section II is permissible provided it is acceptable to the enforcement authorities having jurisdiction over the site where the component is to be installed.

For items within the scope of ASME Section XI, the effective edition and addenda of ASME Section II shall be in accordance with the requirements of ASME Section XI.

In case of nonnuclear items or applications, the effective edition addenda and code case shall be determined as described for ASME Section I.

Use of code cases related to materials for ASME Section III applications may be made in accordance with the recommendations of Regulatory Guide 1.85, Materials Code Case Acceptability, ASME Section III, Division 1. The code cases, as approved with or without limitations and listed in Regulatory Guide 1.85, may be used. The code case(s) not listed as approved in Regulatory Guide 1.85 by the U.S. Nuclear Regulatory Commission (NRC) may only be used after seeking approval from the NRC.

ASME SECTION III: NUCLEAR POWER PLANT COMPONENTS

Scope

Division 1 of ASME Section III contains requirements for piping classified as ASME Class 1, Class 2, and Class 3. ASME Section III does not delineate the criteria for classifying piping into Class 1, Class 2, or Class 3; it specifies the requirements for design, materials, fabrication, installation, examination, testing, inspection, certification, and stamping of piping systems after they have been classified Class 1, Class 2, or Class 3 based upon the applicable design criteria and Regulatory Guide 1.26, Quality Group Classifications and Standards for Water-Steam, and Radio-Waste-Containing Components of Nuclear Power Plants. Subsections NB, NC, and ND of ASME III specify the construction requirements for Class 1, Class 2, and Class 3 components, including piping, respectively. Subsection NF contains construction requirements for component supports, and a newly added Subsection NH contains requirements for 1 Class 1 Components in Elevated-Temperature Service. Subsection NCA, which is common to Divisions 1 and 2, specifies general requirements for all components within the scope of ASME Section III.

Division 3 of ASME Section III is a new addition to the code and contains requirements for containment systems and transport packaging for spent nuclear fuel and high–level radioactive waste.

The construction requirements for ASME Class 1, Class 2, and Class 3 piping are based on their degree of importance to safety, with Class 1 piping being subjected to the most stringent requirements and Class 3 to the least stringent requirements. It is noted that a nuclear power plant does have piping systems other than ASME Class 1, Class 2, and Class 3, which are constructed to codes other than ASME Section III. For example, the fire protection piping systems are constructed to National Fire Protection Association (NFPA) standards, and most of the nonnuclear piping systems are constructed to ASME B31.1, Power Piping Code.

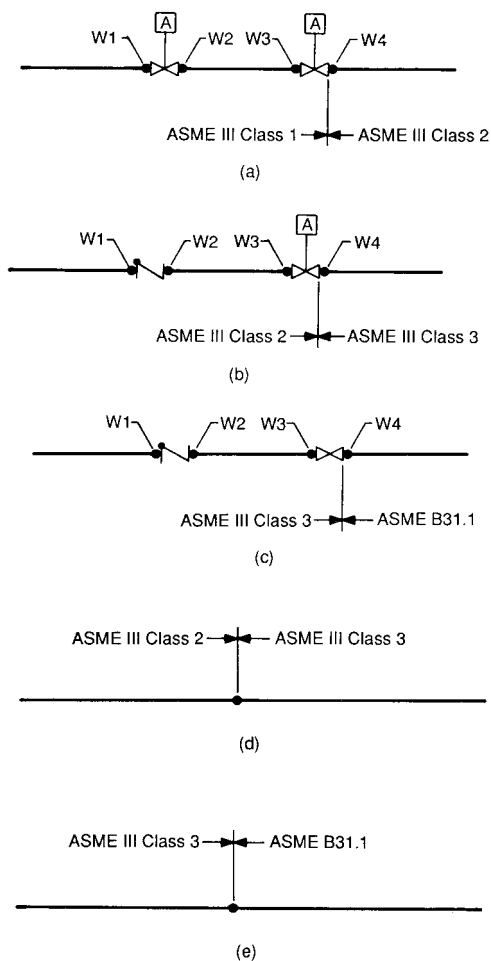
When joining piping systems or components of different classifications, the more restrictive requirements shall govern, except that connections between piping and


FIGURE A4.2 Code jurisdiction at interface welds between ASME III piping and components, and ASME/ANSI B31.1 piping. (*a*) Welds W1, W2, and W3 are between ASME III Class 1 piping and ASME III Class 1 valves/components. These welds shall comply with the requirements for ASME III Class 1 components. Weld W4 is between ASME III Class 1 valve and ASME III Class 2 piping. This weld shall comply with the requirements for ASME III Class 2 components; (*b*) Welds W1, W2, and W3 are between ASME III Class 2 piping and ASME III Class 2 valves/components. These welds shall comply with the requirements for ASME III Class 2 components. Weld W4 is between ASME Class 2 valve/component and ASME III Class 3 piping. This weld shall comply with the requirements for ASME III Class 3 components; (*c*) Welds W1, W2, and W3 are between ASME III Class 3 piping and ASME III Class 3 valves/components. These welds shall comply with the requirements for ASME III Class 3 components. Weld W4 is between ASME III Class 3 valve/component and ASME B31.1 piping. This weld shall comply with the requirements of ASME B31.1; (*d*) The connecting weld between two different ASME III classes of piping shall comply with more stringent requirements of the connecting classes of piping. In this case, the weld shall meet the requirements for ASME III Class 2 components; (*e*) The connecting weld between ASME III Class 3 and ASME B31.1 piping shall comply with more stringent requirements of ASME III Class 3 piping.

other components such as vessels, tanks, heat exchangers, and valves shall be considered part of the piping. For example, a weld between an ASME Class 1 valve and ASME Class 2 piping shall be made in compliance with the requirements of Subsection NC, which contains rules for ASME Class 2 components, including piping (refer to Fig. A4.2).

Effective Edition, Addenda, and Code Cases

Selection of effective editions and addenda of ASME Section III shall be based upon the following guidelines:

Only the approved edition(s) and addenda of ASME Section III, incorporated by reference in 10 CFR 50.55a, Paragraph (b) (1) are to be used for construction of items within the scope of ASME Section III.

The latest published edition and addenda of ASME Section III may not be approved by the U.S. NRC; therefore, their use can only be made after seeking special permission from the U.S. NRC. Refer to 10 CFR 50.55a, Codes and Standards from time to time to find which edition and addenda of ASME Section III have been approved by the U.S. NRC.

As per Subsubarticle NCA-1140, in no case shall the code edition and addenda dates established in the design specifications be earlier than three years prior to the date the nuclear power plant construction permit application is docketed. In addition, the guidelines of preceding paragraphs shall apply[3]:

Code editions and addenda later than those established in the design specification and documents per the above-delineated approach may be used provided they are approved for use. Also, specific provisions within an edition or addenda later than those established in the design specifications and documents may be used provided all related requirements are met.

All code items, including piping systems, may be constructed to a single code edition and addenda, or each item may be constructed to individually specified code editions and addenda.

The use of code case(s) is optional. Only the U.S. NRC–approved code cases with or without limitations or additional requirements published in the following regulatory guides may be used without a specific request to the U.S. NRC for approval:

> *Regulatory Guide 1.84:* Design and Fabrication Code Case Acceptability ASME Section III, Division 1.

> *Regulatory Guide 1.85:* Materials Code Case Acceptability ASME Section III, Division 1.

The code cases not listed as approved in Regulatory Guides 1.84 and 1.85 may be used only after seeking permission from the U.S. NRC for the specific application.

ASME SECTION V: NONDESTRUCTIVE EXAMINATION

Scope

ASME Section V comprises Subsection A, Subsection B, and mandatory and non-mandatory appendixes. Subsection A delineates the methods of nondestructive examination, and Subsection B contains various ASTM standards covering nondestructive examination methods that have been adopted as standards. The standards contained in Subsection B are for information only and are nonmandatory unless specifically referenced in whole or in part in Subsection A or referenced in other code sections and other codes, such as ASME B31, Pressure Piping Code.

The nondestructive examination requirements and methods included in ASME Section V are mandatory to the extent they are invoked by other codes and standards or by the purchaser's specifications. For example, ASME Section III requires radiographic examination of some welds to be performed in accordance with Article 2 of ASME Section V.[5]

ASME Section V does not contain acceptance standards for the nondestructive examination methods covered in Subsection A. The acceptance criteria or standards shall be those contained in the referencing code or standard.

Effective Edition, Addenda, and Code Cases

The applicable edition and addenda of ASME Section V shall correspond to the edition and addenda of the referencing code.

ASME SECTION VIII: PRESSURE VESSELS

Scope

The rules of ASME Section VIII constitute construction requirements for pressure vessels. Division 2 of ASME Section VIII delineates alternative rules of construction to Division 1 requirements. However, there are some differences between the scopes of the two divisions. Recently added Division 3 provides Alternative Rules for Construction of High-Pressure Vessels.

The rules of ASME Section VIII apply to flanges, bolts, closures, and pressure-relieving devices of a piping system when and where required by the code governing the construction of the piping. For example, ASME B31.1 requires that the safety and relief valves on nonboiler external piping, except for reheat safety valves, shall be in accordance with the requirements of ASME Section VIII, Division 1, UG-126 through UG-133.

Effective Edition, Addenda, and Code Cases

Editions are effective on—and may be used on or after—the date of publication printed on the title page.

Addenda are effective on—and may be used on or after—the date of issue. Addenda and revisions become mandatory as minimum requirements six months after date of issuance, except for pressure vessels contracted for prior to the end of the six-month period.

Code cases may be used beginning with the date of their approval by the ASME. Use of revisions and addenda and code cases that are less restrictive than former requirements must not be made without assurance that they have been accepted by the proper authorities in the jurisdiction where the pressure vessel is to be installed.

ASME SECTION IX: WELDING AND BRAZING QUALIFICATIONS

Scope

ASME Section IX consists of two parts—Part QW and Part QB—which deal with welding and brazing, respectively. In addition, ASME Section IX contains mandatory and nonmandatory appendixes.

ASME Section IX requirements relate to the qualification of welders, welding operators, brazers, and brazing operators and the procedures used in welding and brazing. They establish the basic criteria for welding and brazing observed in the preparation of welding and brazing requirements that affect procedure and performance.

ASME Section IX is a supplemental code. The requirements of ASME Section IX apply when referenced by the governing code or standard or when specified in purchaser's specification. It is usually referenced in other sections of the ASME Boiler and Pressure Vessel Code and the ASME B31, Pressure Piping Code.

Effective Edition, Addenda, and Code Cases

The applicable edition and addenda of ASME Section IX shall correspond to the edition and addenda of the referencing code. However, the later or the latest edition or addenda of ASME Section IX may be used, provided it is acceptable to the enforcement authorities having jurisdiction.

For safety-related items of an operating nuclear power plant, application of ASME Section IX will be in accordance with the requirements of ASME Section XI, Rules for Inservice Inspection of Nuclear Power Plant Components.

For nonsafety-related items, the following guidelines apply:

- Editions are effective and may be used on or after the date of publication on the title page.
- Addenda are effective and may be used on or after the date of issue.
- Addenda and revisions become mandatory as minimum requirements six months after the date of issue, except for pressure vessels or boilers contracted for prior to the end of the six-month period.
- Code cases may be used beginning with the date of their approval by the ASME.
- Use of revisions and addenda and code cases that are less restrictive than former requirements must not be made without assurance they have been accepted by the proper authorities in the jurisdiction where the item is to be installed.

ASME SECTION XI: RULES FOR IN-SERVICE INSPECTION OF NUCLEAR POWER PLANT COMPONENTS

Scope

ASME Section XI comprises three divisions, each covering rules for inspection and testing of components of different types of nuclear power plants. These three divisions are as follows:

ASME Section XI, Division 1: Rules for Inspection and Testing of Components of Light-Water-Cooled Plants

ASME Section XI, Division 2: Rules for Inspection and Testing of Components of Gas-Cooled Plants

ASME Section XI, Division 3: Rules for Inspection and Testing of Components of Liquid-Metal-Cooled Plants.

Since the publication of the first edition of ASME Section XI in 1971, significant changes and additions have been incorporated, and as such, the organization of the later versions of ASME Section XI, Division 1, is considerably different from that of the first edition.

ASME Section XI, Division 1, provides the rules and requirements for in-service inspection and testing of light-water-cooled nuclear power plants. The rules and requirements identify, as a minimum, the areas subject to inspection, responsibilities, provisions for accessibility and inspectability, examination methods and procedures, personnel qualifications, frequency of inspection, record-keeping and report requirements, procedures for evaluating inspection results, subsequent disposition of results of evaluations, and repair requirements.

Division 1 also provides for the design, fabrication, installation, and inspection of replacements. The jurisdiction of Division 1 of ASME Section XI covers individual components and complete power plants that have met all the requirements of the construction code, commencing at that time when the construction code requirements have been met, irrespective of physical location.

When portions of systems or plants are completed at different times, the jurisdiction of Division 1 shall cover only those portions on which all of the construction code requirements have been met. Rules of ASME Section XI apply to ASME Classes 1, 2, 3, and MC components and their supports, core support structures, pumps, and valves.

Rules of ASME Section XI, Division 1, apply to modifications made to ASME III components and their supports after all of the original construction code requirements have been met.

Rules of ASME Section XI, Division 1, apply to systems, portions of systems, components, and their supports not originally constructed to ASME Section III requirements but based on their importance to safety if they were classified as ASME Classes 1, 2, 3, and MC.

Effective Edition, Addenda, and Code Cases

Section 10 CFR 50.55a, Codes and Standards, of the Code of Federal Regulations requires compliance with ASME Section XI for operating nuclear power plants. In addition, 10 CFR 50.55a, Paragraph (b)(2) delineates the editions and addenda of ASME Section XI that are approved for use. Only the approved editions and addenda of ASME Section XI are to be used. The latest published edition and addenda may not be approved by the U.S. NRC; therefore, they can only be used after seeking special permission from the U.S. NRC.

It is recommended that one refer to 10 CFR 50.55a from time to time to determine which edition and addenda of ASME Section XI have been approved by the U.S. NRC and which edition and addenda may be applicable to a nuclear power plant at a particular time.

The requirements of 10 CFR 50.55a are based on the construction permit (CP) docket date and the operating license (OL) date of the nuclear plant.

Code editions and addenda later than those established for a particular application in conformance with the requirements of 10 CFR 50.55a may be used provided they are approved and all related requirements of respective editions or addenda are met.

While establishing a particular edition and addenda of ASME Section XI, consider the limitations and modifications to the specific editions and addenda delineated in Paragraph (b)(2) of 10 CFR 50.55a, and ensure compliance to those limitations and modifications, as applicable.

For repairs and replacements, the applicable edition and addenda shall be the one in effect for that in-service inspection (ISI) interval during which the repairs

and replacements are to be made. Refer to articles IWA-4000 and IWA-7000 of ASME Section XI.

Applicable Code Cases

Like the code edition and addenda, code cases are regularly reviewed by the U.S. NRC. The U.S. NRC–approved code cases with or without limitations or additional requirements are published in the Regulatory Guide 1.147, In-Service Inspection Code Case Acceptability of ASME Section XI, Division 1.[4]

Acceptance or endorsement by the U.S. NRC staff applies only to those code cases or code case revisions with the date of ASME Council approval, as shown in the Regulatory Guide 1.147.

ASME B31: CODE FOR PRESSURE PIPING

Starting with Project B31 in March 1926, the first edition of American tentative Standard Code for Pressure Piping was published in 1935. In view of continuous industry developments and increases in diversified needs over the years, decisions were made to publish several sections of the Code for Pressure Piping. Since December 1978, the American National Standards Committee B31 was reorganized as the ASME Code for Pressure Piping B31 Committee under procedures developed by the ASME and accredited by ANSI.

Presently, the following sections of ASME B31, Code for Pressure Piping are published:*

ASME B31.1	Power Piping
USAS B31.2	Fuel Gas Piping
ASME B31.3	Process Piping
ASME B31.4	Liquid Transportation Systems for Hydrocarbons, Liquid Petroleum Gas, Anhydrous Ammonia, and Alcohol
ASME B31.5	Refrigeration Piping
ASME B31.8	Gas Transmission and Distribution Piping Systems
ASME B31.9	Building Services Piping
ASME B31.11	Slurry Transportation Piping Systems

ASME B31.1: POWER PIPING CODE

Scope

ASME B31.1, Power Piping Code, prescribes requirements for the design, material, fabrication, erection, test, and inspection of power and auxiliary service piping

---

* USAS B31.2 was withdrawn in 1988, but it is available for historical and reference purposes.

systems for electric generation stations, industrial and institutional plants, central and district heating plants, and district heating systems. It does not apply to piping systems covered by other sections of the Code for Pressure Piping, and other piping which is specifically excluded from the scope of this code.[7]

As explained earlier, the BEP is required to meet administrative jurisdictional requirements of ASME Section I; however, pipe connections meeting all other requirements of ASME B31.1 but not exceeding nominal pipe size (NPS) ½ may be welded to boiler external pipe or boiler headers without inspection and stamping required by ASME Section I.

Nonboiler external piping is defined as all the piping covered by ASME B31.1 with the exception of BEP. The nonboiler external piping must be constructed in accordance with the requirements of this code.

In addition to the piping systems covered by other sections of ASME B31, Pressure Piping Code, ASME B31.1 does not cover the following:

- Economizers, heaters, pressure vessels, and components covered by the ASME Boiler and Pressure Vessel Code (except the connecting piping not covered by the ASME Boiler and Pressure Vessel Code shall meet the requirements of ASME B31.1)
- Building heating and distribution steam piping designed for 15 psig (100 kPa gauge) or less, or hot-water heating systems piping designed for 30 psig (200 kPa gauge) or less
- Piping for roof and floor drains, plumbing, sewers, and sprinkler and other fire-protection systems
- Piping for hydraulic or pneumatic tools and their components downstream of the first stop valve off the system distribution header
- Piping for marine or other installations under federal control
- Piping covered by other sections of ASME B31 and ASME Section III
- Fuel gas piping within the scope of ANSI Z 223.1, National Fuel Gas Code
- Pulverized fuel piping within the scope of NFPA

The requirements of this code apply to central and district heating systems for distribution of steam and hot water away from the plants whether underground or elsewhere, and geothermal steam and hot water piping both to and from wellheads.

The construction of fuel gas or fuel oil piping brought to plant site from a distribution system inside the plant property line is governed by the requirements of ASME B31.1 when the meter assembly is located outside the plant property line. In cases where the meter assembly is located within the plant property line, the requirements of this code shall apply to the fuel gas and fuel oil piping downstream from the outlet of the meter assembly (see Fig. A4.3).

This code also applies to gas and oil systems piping other than that shown in Fig. A4.3. It covers air systems, hydraulic fluid systems piping, and the steam-jet cooling systems piping which are part of the power plant cycle. In addition, building services within the scope of ASME B31.9 but outside the limits of Paragraph 900.1.2 of B31.9 are required to be designed in accordance with ASME B31.1.

Effective Edition, Addenda, and Code Cases

Prior to the publication and implementation of ASME Section III for construction of nuclear power plant components, in some nuclear power plants the safety-related
(a)
(b)

FIGURE A4.3 Jurisdiction of ASME B31.1, B31.4, and B31.8 Over Fuel Gas and Fuel Oil Piping.

piping systems now classified as ASME Classes 1, 2, and 3 were constructed to earlier versions of AMSE B31.1. Therefore, the repairs and replacements of those safety-related piping systems may be made in accordance with the edition and addenda of ANSI B31.1 used for the original construction or the later edition and addenda of ANSI B31.1. Refer to Article IWA-4000 and Article IWA7000 of ASME Section XI for requirements related to repairs and replacements, respectively.

For power piping systems other than the nuclear safety-related piping systems constructed and new piping systems to be constructed to ASME B31.1, the following guidelines shall be used to determine the effective edition and addenda of ASME B31.1:

Editions are effective and may be used on or after the date of publication printed on the title page. Addenda are effective and may be used on or after the date of publication printed on the title page

The latest edition and addenda, issued six months prior to the original contract date for the first phase of the activity covering a piping system(s) shall be the governing document for design, materials, fabrication, erection, examination, and

testing activities for the piping system(s) until the completion of the work and initial operation.[7] Unless agreement is specifically reached between the contracting parties, no code edition and/or addenda shall be retroactive.

Code cases may be used after they have been approved by the ASME Council. The provisions of a code case may be used even after its expiration or withdrawal, provided the code case was effective on the original contract date and it was used for original construction or was adopted prior to completion of work and the contracting parties agreed to its use.

Do not use revisions and code cases that are less restrictive than former requirements without having assurance that they have been accepted by the proper authorities in the jurisdictions where the piping is to be installed.

USAS B31.2: FUEL GAS PIPING

In 1955 a decision was made to publish separate code sections of B31, Code for Pressure Piping. Consequently, Section 2 of B31.1-1955 was updated and revised to publish as USAS B31.2—1968, Fuel Gas Piping. No edition of this code section was published after 1968. This code was withdrawn in 1988.

Scope

USAS B31.2 covers the design, fabrication, installation, and testing of piping systems for fuel gases such as natural gas, manufactured gas, and liquefied petroleum gas (LPG); air mixtures above the upper combustible limit; LPG in the gaseous phase; or mixtures of these gases.

This code applies to fuel gas piping systems both within and between the buildings, from the outlet of the consumer meter assembly, and to and including the first pressure-containing valve upstream of the gas utilization device.

This code does not apply to:

- Vacuum piping systems
- Fuel gas piping systems with metal temperatures above 450°F or below −20°F
- Fuel gas piping systems within petroleum refineries, loading terminals, natural gas processing plants, bulk plants, compounding plants, or refinery tank farms, and so forth within the scope of USAS B31.3
- Fuel gas piping systems in power and atomic energy plants within the scope of USAS B31.1
- Fuel gas piping systems within the scope of USAS B31.8
- Fuel gas piping systems within the scope of USAS Z21.30
- Piping systems within the scope of USAS Z106.1
- Proprietary items of equipment, apparatus, or instruments, such as compressors, gas-generating sets, and calorimeters
- Design and fabrication of pressure vessels covered by the ASME Boiler and Pressure Vessel Code
- Support structures and equipment such as stanchions, towers, building frames, pressure vessels, mechanical equipment, and foundations

- Piping systems for conveying premixed fuel gas-air mixtures which are in the combustible or inflammable limits or range

Effective Edition, Addenda, and Code Cases

USAS B31.2 is no longer used. It can be used for installations which were constructed in compliance with 1968 edition of this code, if permitted by the authorities having the jurisdiction.

ASME B31.3: PROCESS PIPING

Scope

This code prescribes requirements for the materials, design, fabrication, assembly, erection, examination, inspection, and testing of piping within the property limits of facilities engaged in the processing or handling of chemical petroleum or related products. Figure A4.4 provides an illustration of the scope of ASME B31.3. The requirements of ASME B31.3 apply to piping for all fluids, including raw, intermediate, and finished chemicals; petroleum products, gas, steam, air, and water; fluidized solids; and refrigerants.

In case of packaged equipment, the interconnecting piping with the exception of refrigeration piping shall be in compliance with the requirements of ASME B31.3. The refrigeration piping may conform to either ASME B31.3 or ASME B31.5.

The requirements of ASME B31.3 do not apply to piping systems designed for internal gauge pressures at or above 0 but less than 15 (100 kPa gauge) psig provided the fluid handled is nonflammable, nontoxic, and not damaging to human tissue and its design temperature is from $-29°C$ ($-20°F$) through $180°C$ ($366°F$).

The following piping and equipment are not required to comply with the requirements of ASME B31.3:

- Power boiler and the boiler external piping
- Piping covered by ASME B31.4, B31.8, or B31.11, although located on the company property
- Piping covered by applicable governmental regulations
- Piping for fire-protection systems
- Plumbing, sanitary sewers, and storm sewers
- Tubes, tube headers, crossovers, and manifolds of fired heaters which are internal to the heater enclosures
- Pressure vessels, heat exchangers, pumps, compressors, and other fluid-handling or processing equipment, including internal piping and connections for external piping

Effective Edition, Addenda, and Code Cases

The effective edition, addenda, and code cases shall be determined similarly to the approach delineated for ASME B31.1 for piping systems other than the nuclear safety-related piping systems.

ASME B31.4: LIQUID TRANSPORTATION SYSTEMS FOR HYDROCARBONS, LIQUID PETROLEUM GAS, ANHYDROUS AMMONIA, AND ALCOHOLS

Scope

Section B31.4 of the ASME Pressure Piping Code prescribes requirements for the design, materials, construction, assembly, inspection, and testing of piping transporting liquids such as crude oil, condensate, natural gasoline, natural gas liquids, liquefied petroleum gas, liquid alcohol, liquid anhydrous ammonia, and liquid petroleum products between producers' lease facilities, tank farms, natural-gas processing plants, refineries, stations, ammonia plants, terminals, and other delivery and receiving points.

The scope of ASME B31.4 also includes the following:

- Primary and associated auxiliary liquid petroleum and liquid anhydrous ammonia piping at pipeline terminals (marine, rail, and truck), tank farms, pump stations, pressure-reducing stations, and metering stations, including scraper traps, strainers, and prover loops

- Storage and working tanks, including pipe-type storage fabricated from pipe and fittings, and piping interconnecting these facilities

- Liquid pertroleum and liquid anhydrous ammonia piping located on property which has been set aside for such piping within petroleum refinery, natural gasoline, gas processing, ammonia, and bulk plants

- Those aspects of operation and maintenance of liquid pipeline systems relating to the safety and protection of the general public, operating company personnel, environment, property, and the piping systems

ASME B31.4 does not apply to

- Auxiliary piping such as water, air, steam, lubricating oil, gas, and fuel

- Pressure vessels, heat exchangers, pumps, meters, and other such equipment, including internal piping and connections for piping except as limited by Paragraph 423.2.4 (b) of ASME B31.4

- Piping designed for internal pressures:
  a. At or below 15 psi (100 kPa) gauge pressure regardless of temperature
  b. Above 15 psi (100 kPa) gauge pressure if design temperature is below $-20°F$ ($-29°C$) or above 250°F (120°C)

- Casing, tubing, or pipe used in oil wells, wellhead assemblies, oil and gas separators, crude oil production tanks, other producing facilities, and pipelines interconnecting these facilities

- Petroleum refinery, natural gasoline, gas processing, ammonia, and bulk plant piping, except as covered within the scope of the code

- Gas transmission and distribution piping

- The design and fabrication of proprietary items of equipment, apparatus, or instruments, except as limited by this code

- Ammonia refrigeration piping systems provided for in ASME B31.5, Refrigeration Piping Code
- Carbon dioxide gathering and field distribution systems

The rules of this code provide for protection of the general public and operating company personnel, for reasonable protection of the piping system against vandalism and accidental damage by others, and for reasonable protection of the environment.

Effective Edition, Addenda, and Code Cases

To determine the effective edition, addenda, and code cases for an application within the jurisdiction of ASME B31.4, follow the requirements delineated for ASME B31.1 for piping systems other than nuclear safety-related piping systems.

ASME B31.5: REFRIGERATION PIPING

Scope

This section of ASME B31, Pressure Piping Code, contains requirements for the materials, design, fabrication, assembly, erection, testing, and inspection of refrigerant and secondary coolant piping for temperatures as low as $-320°F$ ($-195.5°C$), except when other sections of the code cover requirements for refrigeration piping.
    ASME B31.5 does not apply to the following:

- Self-contained or unit systems subject to the requirements of Underwriters' Laboratories (UL) or other nationally recognized testing laboratories
- Water piping
- Piping designed for external or internal gauge pressure not exceeding 15 psig (100 kPa)

Effective Edition, Addenda, and Code Cases

To determine the effective edition, addenda, and code cases for piping systems within the jurisdiction of ASME B31.5, follow the guidelines delineated for nonnuclear piping systems within the jurisdiction of ASME B31.1.

ASME B31.8: GAS TRANSMISSION AND DISTRIBUTION PIPING SYSTEMS

Scope

A pipeline or transmission line is defined as that pipe which transmits gas from a source or sources of supply to one or more large-volume customers or to a pipe used to interconnect sources of supply. ASME B31.8 prescribes requirements for

the design, fabrication, installation, testing, and safety aspects of operation and maintenance of gas transmission and distribution piping systems, including gas pipelines, gas compressor stations, gas metering and regulation stations, gas mains, and service lines up to the outlet of the customer's meter set assembly.

Also included within the scope of ASME B31.8 are gas storage equipment of the closed-pipe type, fabricated or forged from pipe or fabricated from pipe and fittings, and gas storage lines.

The requirements of ASME B31.8 also apply to the use of elements of piping systems, including but not limited to pipe, valves, fittings, flanges, bolting, gaskets, regulators, pressure vessels, pulsation dampeners, and relief valves.

The requirements of ASME B31.8 are applicable to operating and maintenance procedures of existing installations and to the update of existing installations.

ASME B31.8 does not apply to the following:

- Design and manufacture of pressure vessels covered by the ASME Boiler and Pressure Vessel Code
- Piping with metal temperatures above 450°F (232°C) or below −20°F (−29°C)
- Piping beyond the outlet of the customer's meter set assembly (refer to ANSI Z223.1 and NFPA 54)
- Piping in oil refineries or natural gasoline extraction plants, gas-treating plant piping other than the main gas stream piping in dehydration, and all other processing plants installed as part of a gas transmission system, gas manufacturing plants, industrial plants, or mines (see other applicable sections of the ASME Code for Pressure Piping, B31)
- Vent piping to operate at substantially atmospheric pressures for waste gases of any kind
- Wellhead assemblies, including control valves, flow lines between wellhead and trap or separator, or casing and tubing in gas or oil wells
- The design and manufacture of proprietary items of equipment, apparatus, or instruments
- The design and manufacture of heat exchangers
- Liquid petroleum transportation piping systems (refer to ANSI/ASME B31.4)
- Liquid slurry transportation piping systems (refer to ASME B31.11)
- Carbon dioxide transportation piping systems
- Liquefied natural gas piping systems (refer to NFPA 59 and ASME B31.3)

Effective Code Edition, Addenda, and Code Cases

To determine the effective edition, addenda, and code cases to be invoked for an application or piping systems within the jurisdiction of ASME B31.8, follow the criteria delineated for piping systems within the scope of ASME B3 1.1:

No edition and addenda shall be applied retroactively to existing installations insofar as design, fabrication, installation, and testing at the time of construction are concerned. Further, no edition and addenda shall be applied retroactively to established operating pressures of existing installations, except as provided for in Chapter V of ASME B31.8.

ASME B31.9: BUILDING SERVICES PIPING

Scope

ASME B31.9 applies to the following building services:

- Water for heating and cooling
- Condensing water
- Steam or other condensate
- Steam
- Vacuum
- Compressed air and other nontoxic and nonflammable gases

The requirements of this code also apply to boiler external piping for steam boilers with 15 psig (103.5 kPa) maximum pressure and for water heating units having 160 psig (1104 kPa) maximum pressure and 250°F (121°C) maximum temperatures. It is noted that the boiler external piping exceeding the above limits of pressure and temperature fall within the scope of ASME B31.1 and ASME Section I.

   This code places size and thickness limitations on the piping made of different materials. The requirements of this code shall apply to the piping of up to and including those sizes and thicknesses. These limitations are as follows:

- *Carbon steel:* NPS 30 (DN 750) in O.D. and 0.500 in (12.7 mm) wall
- *Stainless steel:* NPS 12 (DN 300) and 0.500 in (12.7 mm) wall
- *Aluminum:* NPS 12 (DN 300)
- *Brass and copper:* NPS 12 (DN 300) (12.125 in or 308 mm O.D. for copper tubing)
- *Thermoplastics:* NPS 14 (DN 350)
- *Ductile iron:* NPS 18 (DN 450)
- *Reinforced thermosetting resin:* NPS 14 (DN 350)

Piping made of other materials permitted by this code may also be used for building services.

   The piping within the working pressure or temperature limits shown in Table A4.1 shall be designed and constructed in compliance with the requirements of ASME B31.9.

TABLE A4.1   Working Pressure and Temperature Limits of ASME B31.9

Pressure limit		Temperature limit	
Service	Pressure	Service	Temperature
Steam and condensate	150 psig (1000 kPa)	Steam and condensate	366°F (186°C)
Air and gas	150 psig (1000 kPa)		
Liquids	350 psig (2300 kPa)	Gases and vapors	200°F (93°C)
		Nonflammable liquids	250°F (121°C)
Vacuum	1 atm external pressure (100 kPa)	Minimum temperature (all services)	0°F (−18°C)

ASME B31.9 does not cover requirements for economizers, heaters, pumps, tanks, heat exchangers, and other equipment within the scope of ASME Boiler and Pressure Vessel Code.

Effective Code Edition, Addenda, and Code Cases

For any specific application, the effective edition, addenda, and code cases of ASME B31.9 shall be determined in accordance with the approach followed for ASME B31.1.

ANSI/ASME B31.11: SLURRY TRANSPORTATION PIPING SYSTEMS

Scope

Like ASME B31.4, this section of ASME B31, Pressure Piping Code, specifies minimum requirements for the design, materials, construction, assembly, inspection,
FIGURE A4.5 Scope of ANSI/ASME B31.11 Facilities Indicated by Solid Lines are within the Scope of ANSI/ASME B31.11. *(Source Figure 1100.11, ANSI/ASME B31.11).*

testing, operation, and maintenance of piping transporting aqueous slurries of non-hazardous materials, such as oil, mineral ores, and concentrates, between a slurry processing plant or terminal and a receiving plant or terminal. The requirements of ASME B31.11 also apply to the following:

1. Primary and auxiliary slurry piping at storage facilities, pipeline terminals, pump stations, and pressure-reducing stations, including piping up to the first valve of attached auxiliary water lines
2. Slurry piping storage facilities and other equipment located on property which has been set aside for the slurry transportation system
3. Those aspects of operation and maintenance of slurry transportation piping systems which relate to the safety and protection of the general public, operating company personnel, environment, property, and the piping systems.

Refer to Fig. A4.5 for facilities within the scope of ANSI/ASME B31.11.

Effective Code Edition, Addenda, and Code Cases

The effective edition, addenda, and code cases applicable for piping within the scope of ANSI/ASME B31.11 shall be determined in accordance with the guidelines delineated for ASME B31.

ASME PERFORMANCE TEST CODES

The ASME Performance Test Codes (PTC) were originally known as Power Test Codes. These codes provide standard directions and rules for conducting and reporting tests of specific materials such as fuels, equipment, and processes or functions related to power plants. Listed here are some Performance Test Codes which may be of interest in regard to piping:

PTC 1-91	General Instructions
PTC 2-80	Definitions and Values (R 1985)
PTC 4.1-64	Steam Generating Units (R 1991)
PTC 4.3-68	Air Heaters (R 1991)
PTC 4.4-81	Gas Turbine Heat Recovery Steam Generators (R 1992)
PTC 6A-82	Appendix A to Test Code for Steam Turbine (R 1995)
PTC 7-49	Reciprocating Steam-Driven Displacement Pumps (R 1969)
PTC 7.1-62	Displacement Compressors, Vacuum Pumps, and Blowers (R 1969)
PTC 10-65	Compressors and Exhaustors (R 1992)
PTC 12.2-83	Code on Steam Condensing Apparatus (R 1988)
PTC 12.3-77	Deaerators (R 1995)

PTC 12.4-92	Moisture Separator Reheaters
PTC 14-70	Evaporating Apparatus (R 1991)
PTC 16-58	Gas Producers and Continuous Gas Generators (R 1991)
PTC 18-92	Hydraulic Turbines
PTC 19.2-87	Pressure Measurement Instruments and Apparatus
PTC 19.3-74	Temperature Measurement Instruments and Apparatus (R 1986)
PTC 19.5-72	Application Part II of Fluid Meters
PTC 19.16-65	Density Determination of Solids and Liquids
PTC 19.17-65	Determination of the Viscosity of Liquids Instruments and Apparatus
PTC 22-85	Gas Turbine Power Plants
PTC 25-94	Pressure Relief Services
PTC 32.1-69	Nuclear Steam Supply Systems (R 1992)

AMERICAN NATIONAL STANDARDS INSTITUTE

The American National Standards Institute (ANSI) was earlier known as the American Standards Association (ASA). For a short period of time, from 1967 to 1969, it was called the United States of America Standards Institute (USASI).

ANSI provides a forum for development or obtaining a consensus for approval of standards having national impact and serves as a focal point for distribution of national and other standards, including those developed and issued by the International Organization for Standardization (ISO) and foreign governments. Development and approval functions are performed by committees representing a cross section of affected interests, such as engineering societies, manufacturers, trade institutes, fabricators, builders, universities, unions, insurance companies, and government agencies. Many of the committees are chaired or sponsored by engineering societies, such as ASME and the Institute of Electrical and Electronics Engineers (IEEE).

Safety is the basic objective of the engineering design and construction requirements contained in standards developed, approved, and distributed by ANSI. The ANSI standards include prohibition for practices considered unsafe and cautions where advisory warnings, instead of prohibitions, are deemed necessary.

This chapter provides a brief discussion of various sections of ASME B31, Pressure Piping Code, which was earlier known as ANSI B31, Pressure Piping Code. It is envisioned that other ANSI standards may eventually become known as ASME standards; however, they shall be subjected to approval of the ANSI. The following ANSI standards contain provisions related to piping.

ANSI Standards

| A13.1-96 | Scheme for the Identification of Piping Systems |
| A112.1.2-91 | Air Gaps in Plumbing Systems |

A112.6.1M-88	Supports for Off-the-Floor Plumbing Fixtures for Public Use
A112.18.1M-96	Plumbing Fixture Fittings
A112.19.IM-94	Enameled Cast Iron Plumbing Fixtures
A112.19.3M-87	Stainless Steel Plumbing Fixtures (designed for residential use) (R1996)
A112.21.1M-91	Floor Drains
A112.21.2M-83	Roof Drains (revision of ANSI A112.21.2-1971)
A112.36.2M-91	Cleanouts (revision of ANSI A112.36.2-1983)
AG-1-94	Code on Nuclear Air and Gas Treatment
B1.1	Unified Inch Screw Threads
B1.20.1-83	Pipe Threads General Purpose (Inch) (revision and redesignation of ASME/ANSI B2.1-1968) (R1992)
B1.20.3-76	Dryseal Pipe Threads (Inch) (revision and redesignation of B2.2-1968) (R1991)
B16.1-89	Cast Iron Pipe Flanges and Flanged Fittings
B16.3-92	Malleable Iron Threaded Fittings; Classes 150 and 300
B16.4.92	Cast Iron Threaded Fittings; Classes 125 and 250
B16.5-96	Pipe Flanges and Flanged Fittings
B16.9-93	Factory-Made Wrought Steel Butt-Welding Fittings
B16.10-92	Face-To-Face and End-To-End Dimensions of Valves
B16.11-96	Forged Steel Fittings, Socket-Welding and Threaded
B16.12-91	Cast Iron Threaded Drainage Fittings
B16.14-91	Ferrous Pipe Plugs, Bushings, and Locknuts with Pipe Threads
B16.15-85	Cast Bronze Threaded Fittings; Classes 125 and 250
B16.18-84	Cast Copper Alloy Solder Joint Pressure Fittings (R1994)
B16.22-95	Wrought Copper and Copper Alloy Solder Joint Pressure Fittings
B16.23-92	Cast Copper Alloy Solder Joint Drainage Fittings

B16.24-91	Bronze Pipe Flanges and Flanged Fittings; Classes 150 and 300
B16.25-97	Butt-Welding Ends
B16.26-88	Cast Copper Alloy Fittings for Flared Copper Tubes
B16.28-94	Wrought Steel Butt-Welding Short Radius Elbows and Returns
B16.29-94	Wrought Copper and Wrought Copper Alloy Solder Joint Drainage Fittings
B16.32-92	Cast Copper Alloy Solder Joint Fittings for Solvent Drainage Systems
B16.33-90	Manually Operated Metallic Gas Valves for Use in Gas Piping Systems up to 125 psig (sizes ½ through 2)
B16.34-96	Valves—Flanged, Threaded, and Welding End
B16.36-96	Orifice Flanges
B16.38-85	Large Metallic Valves for Gas Distribution (manually operated, NPS 2 ½ to 12, 125 psig maximum) (R1994)
B16.39-86	Malleable Iron Threaded Pipe Unions; Classes 150, 250, and 300 (R1994)
B16.40-85	Manually Operated Thermoplastic Gas Shutoffs and Valves in Gas Distribution Systems (R1994)
B16.41-83	Functional Qualification Requirements for Power-Operated Active Valve Assemblies for Nuclear Power Plants (R1989)
B16.42-87	Ductile Iron Pipe Flanges and Flanged Fittings; Classes 150 and 300 (R1997)
B16.44-95	Manually Operated Metallic Gas Valves for Use in House Piping Systems
B16.45-87	Cast Iron Fittings for Sovent Drainage Systems
B16.47-96	Large Diameter Steel Flanges NPS 26 through NPS 60
B18.2.1-96	Square and Hex Bolts and Screws (Inch Series) Including Hex Cap Screws and Lag Screws; Supplement 1318.2.1
B18.2.2-87	Square and Hex Nuts (Inch Series)
B18.2.3.1M-79	Metric Hex Cap Screws (R1995)
B18.2.3.2M-79	Metric Formed Hex Screws (R1995)
B18.2.3.3M-79	Metric Heavy Hex Screws (R1995)
B18.2.3.4M-84	Metric Hex Flange Screws (R1995)

B18.2.3.5M-79	Metric Hex Bolts; Errata-May 1981 (R1995)
B18.2.3.6M-79	Metric Heavy Hex Bolts (R1995)
B18.2.4.1M-79	Metric Hex Nuts, Style 1 (R1995)
B18.2.4.2M-79	Metric Hex Nuts, Style 2 (R1995)
B18.2.4.3M-79	Metric Slotted Hex Nuts (R1995)
B18.2.4.4M-82	Metric Hex Flange Nuts (R1993)
B18.2.4.5M-79	Metric Hex Jam Nuts (R1990)
B18.2.4.6M-79	Metric Heavy Hex Nuts (R1990)
B18.5-90	Round Head Bolts (Inch Series)
B18.5.2.1M-81	Metric Round Head Short Square Neck Bolts (R1995)
B18.5.2.2M-82	Metric Round Head Square Neck Bolts (R1993)
B18.15-85	Forged Eyebolts (R1995)
B18.18.1M-87	Inspection and Quality Assurance for General Purpose Fasteners (R1994)
B18.18.3M-87	Inspection and Quality Assurance for Special Purpose Fasteners (R1993)
B18.18.4M-87	Inspection and Quality Assurance for Fasteners for Highly Specialized Engineered Applications (R1993)
B18.21.1-72	Lock Washers (Inch Series)
B18.21.2M-94	Lock Washers (Metric Series)
B18.22M-81	Metric Plain Washers (R1990)
B18.22.1-65	Plain Washers (reaffirmation and redesignation of ASA 1327.2-1965) (R1990)
B32.5-77	Preferred Metric Sizes for Tubular Metal Products Other than Pipe (R1988)
B32.6M-84	Preferred Metric Equivalents of Inch Sizes for Tubular Products Other than Pipe (revision of ANSI B32.6-1977) (R1994)
B36.10M-96	Welded and Seamless Wrought Steel Pipe (revision of ANSI B36.10)
B36.19M-85	Stainless Steel Pipe (revision of ANSI B36.19)
MFC-1M-91	Glossary of Terms Used in the Measurement of Fluid Flow in Pipes
MFC-6M-87	Measurement of Fluid Flow in Pipes Using Vortex Flow Meters

MFC-7M-87	Measurement of Gas Flow by Means of Critical Flow Venturi Nozzles (R1992)
N45.2.1-80	Cleaning of Fluid Systems and Associated Components for Nuclear Power Plants
N278.1-75	Self-Operated and Power-Operated Safety-Related Valves Functional Specification Standard, Reactor Plants and Their Maintenance (R 1992)
NQA-1-1997	Quality Assurance Program Requirements for Nuclear Facilities
TDP-1-85	Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Fossil)
TDP-2-85	Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Revision of ASME Standard No. TWDPS-1-1973, Part 2) (Nuclear)

ANSI Guides/Manuals

1986	Guide for Gas Transmission and Distribution Piping Systems-1986; Addenda 1-1986, Addenda 2-1987, Addenda 3-1987
B31 Guide-77	Corrosion Control for ANSI B31.1, Power Piping Systems
B31 Guide-91	Manual for Determining the Remaining Strength of Corroded Pipelines (a supplement to ASME B31 Code for Pressure Piping)
1001-88	Performance Requirements for Pipe Applied Atmospheric Type Vacuum Breakers
1003-93	Performance Requirements for Water Pressure Reducing Valves
1037-90	Performance Requirements for Pressurized Flushing Devices (Flushometers) for Plumbing Fixtures
1045-87	Performance Standard and Installation Procedures for Aluminum Drain, Waste, and Vent Pipe with End Cap Components

Other ASME/ANSI Publications

The following is a list of additional ASME/ANSI publications which are of interest to people engaged in piping design, construction, operation, and maintenance activities:

B16.20-93	Metallic Gaskets for Pipe Flanges— Ring Joint, Spiral-Wound and Jacketed
B16.21-92	Nonmetallic Flat Gaskets for Pipe Flanges

AMERICAN SOCIETY FOR TESTING AND MATERIALS

The American Society for Testing and Materials (ASTM) is a scientific and technical organization that develops and publishes voluntary standards on the characteristics and performance of materials, products, systems, and services. The standards published by the ASTM include test procedures for determining or verifying characteristics, such as chemical composition, and measuring performance, such as tensile strength and bending properties. The standards cover refined materials, such as steel, and basic products, such as machinery and fabricated equipment. The standards are developed by committees drawn from a broad spectrum of professional, industrial, and commercial interests. Many of the standards are made mandatory by reference in applicable piping codes.

The ASTM standards are published in a set of 67 volumes. Each volume is published annually to incorporate new standards and revisions to existing standards and to delete obsolete standards. Listed here are the 67 volumes, divided among 16 sections, published by the ASTM.

Section 1: Iron and Steel Products

Volume 01.01	Steel—Piping, Tubing, Fittings
Volume 01.02	Ferrous Castings; Ferroalloys
Volume 01.03	Steel—Plate, Sheet, Strip, Wire
Volume 01.04	Steel—Structural, Reinforcing, Pressure Vessel, Railway
Volume 01.05	Steel—Bars, Forgings, Bearing, Chain, Springs
Volume 01.06	Coated Steel Products
Volume 01.07	Shipbuilding

Section 2: Nonferrous Metal Products

Volume 02.01	Copper and Copper Alloys
Volume 02.02	Aluminum and Magnesium Alloys

Volume 02.03	Electrical Conductors
Volume 02.04	Nonferrous Metals—Nickel, Cobalt, Lead, Tin, Zinc, Cadmium, Precious, Reactive, Refractory, Metals, and Alloys
Volume 02.05	Metallic and Inorganic Coatings; Metal Powders, Sintered P/M Structural Parts

Section 3: Metals Test Methods and Analytical Procedures

Volume 03.01	Metals—Mechanical Testing: Elevated and Low-Temperature Tests, Metallography
Volume 03.02	Wear and Erosion, Metal Corrosion
Volume 03.03	Nondestructive Testing
Volume 03.04	Magnetic Properties; Metallic Materials for Thermostats, Electrical Heating and Resistance, Heating, Contacts, and Connectors
Volume 03.05	Analytical Chemistry of Metals, Ores, and Related Materials (I)
Volume 03.06	Analytical Chemistry of Metals, Ores, and Related Materials (II)

Section 4: Construction

Volume 04.01	Cement, Lime, Gypsum
Volume 04.02	Concrete and Aggregates
Volume 04.03	Road and Paving Materials, Pavement Management Technologies
Volume 04.04	Roofing, Waterproofing, and Bituminous Materials
Volume 04.05	Chemical-Resistant Materials; Vitrified Clay, Concrete, Fiber-Cement Products; Mortars; Masonry
Volume 04.06	Thermal Insulation; Environmental Acoustics
Volume 04.07	Building Seals and Sealants; Fire Standards; Building Constructions
Volume 04.08	Soil and Rock; Dimension Stones; Geosynthetics
Volume 04.09	Wood

Section 5: Petroleum Products, Lubricants, and Fossil Fuels

Volume 05.01	Petroleum Products and Lubricants (1): D 56-D 1947
Volume 05.02	Petroleum Products and Lubricants (II): D 1949-D 3601
Volume 05.03	Petroleum Products and Lubricants (III): D 3602-latest; Catalysts
Volume 05.04	Test Methods for Rating Motor, Diesel, and Aviation Fuels
Volume 05.05	Gaseous Fuels; Coal and Coke

Section 6: Paints, Related Coatings, and Aromatic

Volume 06.01	Paint—Tests for Formulated Products and Applied Coatings
Volume 06.02	Paint—Pigments, Resins, and Polymers; Cellulose
Volume 06.03	Paint—Fatty Oils and Acids, Solvents, Miscellaneous; Aromatic Hydrocarbons

Section 7: Textiles

Volume 07.01	Textiles (I): D76-D3219
Volume 07.02	Textiles (II): D3333-latest

Section 8: Plastics

Volume 08.01	Plastics (I): C 177-D 1600
Volume 08.02	Plastics (II): D 1601-D 3099
Volume 08.03	Plastics (III): D 3100-latest
Volume 08.04	Plastic Pipe and Building Products

Section 9: Rubber

Volume 09.01	Rubber, Natural, and Synthetic—General Test Methods; Carbon Black
Volume 09.02	Rubber Products, Industrial—Specifications and Related Test Methods; Gaskets; Tires

Section 10: Electrical Insulation and Electronics

Volume 10.01	Electrical Insulation (I) D69-D2484
Volume 10.02	Electrical Insulation (II) D2518-latest

Volume 10.03	Electrical Insulating Liquids and Gas; Electrical Protective Equipment
Volume 10.04	Electronics (I)
Volume 10.05	Electronics (II)

Section 11: Water and Environmental Technology

Volume 11.01	Water (I)
Volume 11.02	Water (II)
Volume 11.03	Atmospheric Analysis; Occupational Health and Safety
Volume 11.04	Pesticides; Resource Recovery; Hazardous Substances and Oil Spill Responses; Waste Management; Biological Effects

Section 12: Nuclear, Solar, and Geothermal Energy

| Volume 12.01 | Nuclear Energy (I) |
| Volume 12.02 | Nuclear, Solar, and Geothermal Energy |

Section 13: Medical Devices and Services

| Volume 13.01 | Medical Devices, Emergency Medical Services |

Section 14: General Methods and Instrumentation

Volume 14.01	Analytical Methods—Spectroscopy; Chromatography; Computerized Systems
Volume 14.02	General Test Methods, Nonmetal; Laboratory Apparatus; Statistical Methods; Appearance of Materials; Durability of Nonmetallic Materials
Volume 14.03	Temperature Measurement

Section 15: General Products, Chemical Specialties, and End Use Products

Volume 15.01	Refractures; Carbon and Graphite Products; Activated Carbon
Volume 15.02	Glass; Ceramic Whitewares
Volume 15.03	Space Simulation; Aerospace and Aircraft; High Modulus Fibers and Composites

Volume 15.04	Soap; Polishes; Leather; Resilient Floor Coverings
Volume 15.05	Engine Coolants; Halogenated Organic Solvents; Industrial Chemicals
Volume 15.06	Adhesives
Volume 15.07	End Use Products
Volume 15.08	Fasteners
Volume 15.09	Paper; Packaging; Flexible Barrier Materials; Business Copy Products

Section 00: Index

Volume 00.01	Subject Index and Alphanumeric List

AMERICAN GAS ASSOCIATION

The following publications of the American Gas Association (AGA) are of interest to people associated with the design, construction, operation, and maintenance of gas systems piping.

Z223.1-92	National Fuel Gas Code, Fifth Edition
Z22.3-92	National Fuel Gas Code Handbook, Second Edition

AMERICAN PETROLEUM INSTITUTE

The American Petroleum Institute (API) publishes specifications (Spec.), bulletins (Bull.), recommended practices (RP), standards (Std.), and other publications (Publ.) as an aid to procurement of standardized equipment and materials. These publications are primarily intended for use by the petroleum industry. However, they can be and are used by others in that they are referenced in a code or invoked in the purchase order/specification governing the design and construction of piping systems. For example API Specification 5L and the API Standard 605 are referenced in ASME B31.1, Power Piping Code.

The following documents, which relate to piping, are published by the API.

Specifications (Spec.)

Spec. 2B-96	Specification for the Fabrication of Structural Steel Pipe
Spec. 6D-94	Specification for Pipeline Valves (Gate, Plugs, Ball, and Check Valves)

Spec. 5L-95	Specification for Line Pipe
Spec. 5LC-91	Specification for CRA Line Pipe
Spec. 6FA-94	Specification for Fire Test for Valves
Spec. 6FC-94	Specification for Fire Test for Valves with Automatic Backseats
Spec. 15HR-95	Specification for High Pressure Fiberglass Line Pipe
Spec. 15LE-95	Specification for Polyethylene Line Pipe (PE)
Spec. 15LR-90	Specification for Low Pressure Fiberglass Line Pipe
Spec. 5B-88	Specification for Threading, Gauging, and Thread Inspection of Casing, Tubing, and Line Pipe Threads; Thirteenth Edition, Supplement 1, July 1990
Spec. 6FA-94	Specification for Fire Test for Valves
Spec. 6B-92	API specification for Fire Test for End connections
Spec. 6FC-94	Specification for Fire Test for Valves with Automatic Backseats
Spec. 6FD-95	Specification for Fire Test for Check Valves
Spec. 14A-94	Specification for Subsurface Safety Valve Equipment
Spec. 14D-94	Specification for Wellhead Surface Safety Valves and Underwater Safety Valves for Offshore Service

Bulletins (Bull.)

Bull. 5C3-94	Bulletin on Formulas and Calculations for Casing, Tubing, Drill Pipe, and Line Pipe Properties
Bull. 6AF-95	Bulletin on Capabilities of API Flanges Under Combinations of Load
Bull. 6F2-94	Bulletin on Fire Resistance Improvements for API Flanges

Recommended Practices (RP)

RP 5A3	Recommended Practice on Threaded Compounds for Casing, Tubing, and Line Pipe
RP 5A5-97	Recommended Practice for Field Inspection of New Casing, Tubing, and Plain-End Drill Pipe
RP 5B1-96	Recommended Practice for Gauging and Inspection of Casing, Tubing, and Line Pipe Threads

RP 5L1-96	Recommended Practice for Railroad Transportation of Line Pipe
RP 5L2-87	Recommended Practice for Internal Coating of Line Pipe for Noncorrosive Gas Transmission Service
RP 5L3-96	Recommended Practice for Conducting Drop-Weight Tear Tests on Line Pipe
RP 51-5-75	Recommended Practice for Marine Transportation of Line Pipe; First Edition
RP 5L6-79	Recommended Practice for Transportation of Line Pipe on Inland Waterways; First Edition
RP 5L7-88	Recommended Practices for Unprimed Internal Fusion Bonded Epoxy Coating of Line Pipe
RP 5L8-96	Recommended Practice for Field Inspection of New Line Pipe
RP 6G-82	Recommended Practice for Through Flowline (TFL) Pump Down Systems
Bull 6AF-95	Technical Report on Capabilities of API Flanges under Combinations of Load
Bull 6AF1-91	Bulletin on Temperature Derating of API Flanges Under Combinations of Loading
Bull 6RS-90	Standardization of Valves and Wellhead Equipment
RP 1OE-94	Recommended Practice for Application of Cement Lining to Steel Tubular Goods, Handling, Installation, and Joining; Third Edition ISO 10409
RP 11V7-90	Recommended Practice for Repair, Testing, and Setting Gas Lift Valves; First Edition
RP 15TL4-93	Recommended Practice for Care and Use Fiberglass Tubulars
RP 17B-88	Recommended Practice for Flexible Pipe
RP 520 PTI-93	Recommended Practice for Sizing, Selection, and Installation of Pressure-Relieving Devices in Refineries, Part I—Sizing and Selection
RP 520 PT II 94	Recommended Practice Sizing, Selection, and Installation of Pressure-Relieving Devices in Refineries, Part II—Installation
RP 574-90	Inspection of Piping, Tubing, Valves, and Fittings; First Edition (Replaces Guide for Inspection of Refinery Equipment Chapter XI)

RP 1102-93	Recommended Practice for Liquid Petroleum Pipelines Crossing Railroads and Highways
RP 1107-91	Recommended Pipe Line Maintenance Welding Practices
RP 1109-93	Recommended Practice for Marking Liquid Petroleum Line Facilities
RP 1110-97	Recommended Practice for Pressure Testing of Liquid Petroleum Pipelines

Standards (Std.)

Std. 526-95	Flanged Steel Pressure-Relief Valves Seat
Std. 527-91	Seat Tightness of Pressure Relief Valves
Std. 594-91	Wafer and Wafer-Lug Check Valves
Std. 598-90	Valve Inspection and Testing
Std. 599-94	Metal Plug Valves—Flanged and Welding End
Std. 600-91	Steel Gate Valves—Flanged and Butt-Welding Ends
Std. 602-93	Compact Steel Gate Valves—Flanged, Threaded, Welding, and Extended Body Ends
Std. 603-91	Class 150, Cast, Corrosion-Resistant, Flanged-End Gate Valves
Std. 607-93	Fire Test for Soft-Seated Quarter Turn Valves
Std. 608-95	Metal Ball Valves—Flanged, Threaded and Welding Ends
Std. 609-91	Lug and Wafer Type Butterfly Valves
Std. 1104-94	Welding of Pipelines and Related Facilities; Seventeenth Edition

Publications (Publ.)

Publ. 1113-93	Developing a Pipeline Supervisory Control Center

AMERICAN WATER WORKS ASSOCIATION

The American Water Works Association (AWWA) publishes standards that cover requirements for pipe and piping components used in water treatment and distribution systems, including specialty items such as fire hydrants. It also publishes several

AWWA manuals relative to design, installation, operation, management, and training. The AWWA standards are used for design, fabrication, and installation of large-diameter piping for water systems not covered by ASME Boiler and Pressure Vessel Code, ASME B31, Code for Pressure Piping, and other codes. Conformance to AWWA standards is required either by being referenced in the codes governing the construction of water systems piping or by the enforcement authorities having jurisdiction over the water systems piping.

Refer to Table C1.2 of Chapter C1, Part C of this handbook for a comprehensive listing of AWWA publications and standards dealing with piping.

AMERICAN WELDING SOCIETY

The American Welding Society (AWS) publishes handbooks, manuals, guides, recommended practices, specifications, and codes. The specifications for filler metals are in the AWS A5 series. The filler metal specifications are usually cited in design documents. The welding procedures are in the D10 series. The AWS handbook is published in five volumes and is intended to be an aid to the user and producer of welded products.

The following is a list of AWS publications directly related to piping. The AWS A5 series filler metal specifications are not included in the list since they can be used for a multitude of items other than piping.

AWS Welding Handbook

Volume 1	Fundamentals of Welding
Volume 2	Welding Processes
Volume 3	Welding Processes
Volume 4	Engineering Applications—Materials
Volume 5	Engineering Applications—Design Brazing Manual, Soldering Manual
AWS A3.0	Soldering Manual, Brazing Handbook, Welding Terms and Definitions, including Terms for Brazing, Soldering, Thermal Spraying, and Thermal Cutting
AWS A5.01	Filler Metal Procurement Guidelines
AWS D10.4	Recommended Practices for Welding Austenitic Chromium-Nickel Stainless Steel Piping and Tubing
AWS D10.6	Recommended Practices for Gas Tungsten Arc Welding of Titanium Pipe and Tubing
AWS D10.7	Recommended Practices for Gas Shielded Arc Welding of Aluminum and Aluminum Alloy Pipe
AWS D10.8	Recommended Practices for Welding of Chromium-Molybdenum Steel Piping and Tubing

AWS D10.10	Recommended Practices for Local Heating of Welds in Piping and Tubing
AWS D10.11	Recommended Practices for Root Pass Welding of Pipe Without Backing
AWS D10.12	Recommended Practices for Procedures for Welding Low Carbon Steel Pipe

AIR-CONDITIONING AND REFRIGERATION INSTITUTE

The Air-Conditioning and Refrigeration Institute (ARI) publishes standards, guidelines, and directories of certification. Some of these standards and guidelines, listed here, may be used for design and construction of refrigeration piping systems.

Standards

720-88	Refrigerant Access Valves and Hose Connectors
750-87	Thermostatic Refrigerant Expansion Valves
760-87	Solenoid Valves for Use with Volatile Refrigerants
770-84	Refrigerant Pressure Regulating Valves

Guidelines

| C-95 | Guideline for ARI Recommended Dimensions of Steel Solder/Braze Fittings |

AMERICAN SOCIETY OF HEATING REFRIGERATING AND AIR-CONDITIONING ENGINEERS

The following standards, guidelines, and handbooks published by the American Society of Heating Refrigeration and Air Conditioning Engineers (ASHRAE) relate to piping:

Standards

| 41.3-89 | Standard Method for Pressure Measurement |
| 41.4-84 | Standard Method for Measurement of Proportion of Oil in Liquid Refrigerant |

41.6-94	Standard Method for Measurement of Moist Air Properties
41.7-84	Standard Method for Measurement of Flow of Gas
41.8-89	Standard Methods of Measurement of Flow of Liquids in Pipes Using Orifice Flowmeters

Guidelines

| 1-89 | Guidelines for Commissioning of HVAC Systems |
| 2-86 | Guidelines for Engineering Analysis of Experimental Data |

Handbooks

1993 ASHRAE Handbook Fundamentals I-P Edition

1993 ASHRAE Handbook Fundamentals SI Edition

1995 ASHRAE Handbook HVAC Applications IP Edition

1995 ASHRAE Handbook HVAC Applications SI Edition

1992 ASHRAE Handbook HVAC Systems and Equipment IP Edition

1992 ASHRAE Handbook HVAC Systems and Equipment SI Edition

1994 ASHRAE Handbook Refrigeration Systems and Applications I-P Edition

1994 ASHRAE Handbook Refrigeration Systems and Applications SI Edition

AMERICAN SOCIETY OF SANITARY ENGINEERS

The American Society of Sanitary Engineers (ASSE) publishes many standards, some of which are ANSI approved. The following is a list of standards which contain requirements related to sanitary piping.

Standards

1001-88	Performance Requirements for Pipe Applied Atmospheric Type Vacuum Breakers
1003-93	Performance Requirements for Water Pressure Reducing Valves
1005-86	Performance Requirements for Water Heaters Drain Valves 3″ IPS
1029-94	Performance Requirements for Dual Check Valve Type Backflow Preventers

1032-80	Performance Requirements for Dual Check Valve Type Backflow Preventers for Carbonated Beverage Dispensers
1037-90	Performance Requirements for Pressurized Flushing Devices (Flushometers) for Plumbing Fixtures
1045-87	Performance Standard and Installation Procedures for Aluminum Drain, Waste, and Vent Pipe with End Cap Components
1046-90	Performance Requirements for Thermal Expansion Relief Valve
1048-93	Performance Requirements for Double Check Detector Assembly Backflow Preventer
1047-93	Performance Requirement for Reduced Pressure Detector Backflow Preventer
1050-91	Performance Requirements for Air Admittance Valves for Plumbing DWV Systems Stack Type Devices
1051-90	Performance Requirements for Air Admittance Valves for Plumbing Drainage Systems Fixture and Branch Devices
1052-93	Performance Requirements for Hose Connection Backflow Preventers
1056-93	Performance Requirements for Back Siphonage Backflow Vacuum Breakers

AMERICAN SOCIETY OF CIVIL ENGINEERS

The following documents, which are published by the American Society of Civil Engineers (ASCE), contain information related to piping. The contents of these documents can be used in design and construction of appropriate piping systems.

12-92.1.1	Standard Guidelines for the Design of Urban Subsurface Drainage
13-93.1.1	Standard Guidelines for Installation of Urban Subsurface Drainage
14-94.1.1	Standard Guidelines for Operation and Maintenance of Urban Subsurface Drainage
15-93.1.1	Standard Practice for Direct Design of Buried Precast Concrete Pipe Using Standard Installations

Publications Guideline for the Seismic Design of Oil and Gas Pipeline Systems (1984)

Report on Pipeline Location, 1965 Edition

AMERICAN SOCIETY FOR NONDESTRUCTIVE TESTING

The American Society for Nondestructive Testing (ASNT) publishes recommended practices concerning procedures, equipment, and qualification of personnel for nondestructive testing. The following practice is cited in several codes and standards which contain requirements for piping:

SNT-TC-1A-92	Recommended Practice for Nondestructive Testing Personnel Qualification

AMERICAN IRON AND STEEL INSTITUTE

The following publications of the American Iron and Steel Institute (AISI) provide design guidelines for use of stainless steel in piping systems.

E-3-89	Welded Steel Pipe Steel Plate Engineering Data
E-6-84	Handbook of Steel Pipe
SG-862-90	Modern Sewer Design

AMERICAN NUCLEAR SOCIETY

The following American Nuclear Society (ANS) standards contain requirements for nuclear power plant piping systems:

8.9-87	Nuclear Criticality Safety Criteria for Steel Pipe Intersection Containing Aqueous Solutions of Fissile Materials
51.10-91	Auxiliary Feedwater System for Pressurized Water Reactor
56.2-84	Containment Isolation Provisions for Fluid Systems after a LOCA
56.3-77	Overpressure Protection of Low Pressure Systems Connected to the Reactor Coolant Pressure Boundary
56.4-83	Pressure and Temperature Transient Analysis for Light Water Reactor Containment

56.8-94	Containment System Leakage Testing Requirements
58.2-88	Design Basis for Protection of Light Water Nuclear Power Plants Against Effects of Postulated Pipe Rupture
59.51-89	Fuel Oil Systems for Emergency Diesel Generators

BUILDING OFFICIALS CONFERENCE OF AMERICA

The Building Officials Conference of America (BOCA) publishes a series of national codes, manuals, training aids, and other documents which contain technical requirements and other information related to piping. The following is a partial list of these publications:

National Codes

National Building Code
National Mechanical Code
National Plumbing Code
National Private Sewage Disposal Code
National Fire Prevention Code
National Energy Conservation Code

Manuals

BOCA National Code Interpretations
Fire Protection Systems Workbook
Plumbing Materials and Sizing Selector

DUCTILE IRON PIPE RESEARCH ASSOCIATION

The following documents published by the Ductile Iron Pipe Research Association contain guidelines, requirements, and other technical information related to ductile iron piping systems:

Pipe Material Comparison Booklet
Ductile Iron Pipe Characteristics/Applications
Design of Ductile Iron Pipe on Supports
Ductile Iron Pipe for Wastewater Applications
Cement-Mortar Linings for Ductile Iron Pipe
Direct Tapping Comparison Study

Ductile Iron Pipe Energy Savings

Ductile Iron Pipe

Flanged Ductile Iron Pipe

Gasket Materials Used for Ductile Iron Pipe in Water and Sewage Service

Linings Available for Ductile Iron Pipe & Fittings

Thrust Restraint Design for Ductile Iron Pipe

Truck Loads on Pipe Buried at Shallow Depths

Bridge Crossings with Ductile Iron Pipe

Ductile Iron Pipe Subaqueous Crossings

Hydraulic Analysis of Ductile Iron Pipe

Stray Current Effects on Ductile Iron Pipe

Polyethylene Encasement: Effective, Economical Protection for Ductile Iron Pipe in Corrosive Environments

Direct Tapping of Ductile Iron Pipe Encased in Polyethylene

Tapping Tests on Ductile Iron Pipe

A Comparison of Engineering Considerations for Pressure Pipe

Ductile Iron Pipe versus pvc

Ductile Iron pipe vs. Steel Pipe

Polyethylene Encasement Installation Guide

Field Welding and Cutting Ductile Iron Pipe

It may also be prudent to list our web site address (http://www.dipra.org) here so that people that require information about ductile iron pipe can easily contact us.

Ductile Iron Pipe in Deep Trench Installations

Ductile Iron Pipe Installation Guide

Ductile Iron Pipe Subaqueous Crossings

Concentrated Consulting Engineering Programs

Polyethylene Encasements

Corrosion Control Seminars

Ductile Iron Pipe Thrust Restraint Design, 1986 Edition

Inside Diameter/Velocity and Headloss/Pumping Costs

EXPANSION JOINT MANUFACTURERS ASSOCIATION

The Expansion Joint Manufacturers Association (EJMA) publishes a handbook called the *Standards of the Expansion Joint Manufacturers Association.* The book contains manufacturing standard practices as well as comprehensive and detailed engineering data concerning pipe expansion joint types, installation layouts and locations, movements, forces, moments, cycle-life expectancy, and effects of corrosion, erosion, and testing.

FLUID CONTROLS INSTITUTE

The Fluid Controls Institute (FCI) publishes voluntary standards that have been developed by consensus of the member companies. The following is a list of the FCI publications:

FCI 68-1 78	Solenoid Valves for Gas Service
FCI 68-2 78	A Procedure in Rating Flow and Pressure Characteristics of Solenoid Valves for Liquid Service
FCI 69-1 89	Pressure Rating Standard for Steam Traps (R 1994)
FCI 70-2 91	Quality Control Standard for Control Valve Seat Leakage
FCI 73-1 95	Pressure Rating Standard for "Y" Type Strainers
FCI 74-1 90	Spring-Loaded Lift Disc Check Valve
FCI 75-1 79	Characteristics of Solenoid Valves (R 1991)
FCI 78-1 78	Pressure Rating Standard for Pipeline Strainer Other Than "Y" Type
FCI 79-1 86	Proof of Pressure Ratings for Pressure Reducing Regulators (R 1993)
FCI 81-1 85	Proof of Pressure Ratings for Temperature Regulators (R 1993)
FCI 82-1 85	Recommended Methods for Testing and Classifying the Water Hammer Characteristics of Electrically Operated Valves (R 1991)
FCI 84-1	Metric Definition of the Valve Flow Coefficient Cv
FCI 85-1 89	Production Testing for Steam Traps (R 1994)
FCI 86-1 93	Standard Solenoid Valve Terminology and Nomenclature
FCI 87-1 93	Classification and Operating Principles of Steam Traps
FCI 87-2 90	Power Signal Standard for Spring-Diaphragm Actuated Control Valves
FCI 87-2	Control Valves (R 1994)
FCI 89-1 92	Guide for Selection, Installation and Maintenance of Pipeline Strainers
FCI 91-1 94	Standard for Qualification of Control Valve Stern Seals to Most EPA Emission Guidelines for Volatile Organic Compounds

FACTORY MUTUAL ENGINEERING & RESEARCH CORPORATION

The Factory Mutual Engineering & Research Corporation is usually referred to as Factory Mutual (FM). FM performs examinations of equipment, materials, and services before listing them as ''approved'' in the guide *Approval Guide to Equipment, Materials and Services*. The following publications of FM may be of interest to people involved with fire protection systems piping:

Approval Guide to Equipment, Materials and Services

Automatic Sprinkler Systems

Fixed Extinguishing Systems

Oil Safety Shutoff Valves

Gas Safety Shutoff Valves

Supplemental Data

Property Loss Control Catalog

FLUID SEALING ASSOCIATION

The Fluid Sealing Association publishes various documents related to gaskets and seals used in mechanical joints to maintain leak-tightness of the fluid piping and ducting systems. These documents include the following:

Ducting Systems Technical Handbook

Nonmetallic Gasket Handbook

Compression Packings Handbook

Molded Packings Handbook

Rubber Expansion Joints/Flexible Pipe Connectors

Mechanical Seal Handbook

Glossary of Terms

HEAT EXCHANGE INSTITUTE

The Heat Exchange Institute (HEI) publishes voluntary standards developed to express the consensus of member companies concerned with the fabrication of heat exchangers and similar equipment. The following are typical of the standards published by this institute:

HE14	Method and Procedure for the Determination of Dissolved Oxygen
HE15	Standards for Closed Feedwater Heaters
HE17	Standards for Direct Contact Barometric and Low Level Condensers

HE18	Standard for Power Plant Heat Exchangers
HE18A	Standards for Steam Jet Vacuum Systems
HEI10	Standards for Steam Surface Condensers, 8th Edition

HYDRAULIC INSTITUTE

The following is the list of the Hydraulic Institute (HI) publications:

Hydraulic Institute Standards, 1994 Edition

ANSI/HI 1.1-1.5	Centrifugal Pumps
ANSI/HI 1.6	Centrifugal Pump Test
ANSI/HI 5.1-5.6	Sealless Centrifugal Pumps
ANSI/HI 2.1-2.5	Vertical Pumps
ANSI/HI 2.6	Vertical Pump Test
ANSI/HI 3.1-3.5	Rotary Pumps
ANSI/HI 3.6	Rotary Pump Test
ANSI/HI 4.1-4.6	Sealless Rotary Pumps
ANSI/HI 6.1-6.5	Reciprocating Power Pumps
ANSI/HI 6.6	Reciprocating Pump Test
ANSI/HI 7.1-7.5	Controlled Volume Pumps
ANSI/HI 8.1-8.5	Direct Acting (Steam) Pumps
ANSI/HI 9.1-9.5	Pumps General Guidelines

Engineering Data Book, 2nd Edition (1990)

The information previously contained in the *Pipe Friction Manual* has been incorporated into the *Engineering Data Book;* the *Pipe Friction Manual* is no longer available.

INSTITUTE OF ELECTRICAL AND ELECTRONICS ENGINEERS

The following standards published by the Institute of Electrical and Electronics Engineers (IEEE) are of interest to those involved in the design and construction of nuclear power plant piping systems:

| IEEE 323-83 | Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations |

IEEE 336-85	Standard Installation, Inspection, and Testing Requirements for Power, Instrumentation, and Control Equipment at Nuclear Facilities
IEEE 344-87	Recommended Practice for Seismic Qualification of Class IE Equipment for Nuclear Power Generating Stations
IEEE 352-87	Guide for General Principles of Reliability Analysis of Nuclear Power Generating Station Safety Systems
IEEE 379-94	Standard Application of the Single Failure Criterion to Nuclear Power Generating Station Safety Systems
IEEE 382-96	Standard for Qualification of Actuators for Power Operated Valve Assemblies with Safety-Related Functions for Nuclear Power Plants

INSTRUMENT SOCIETY OF AMERICA

The Instrument Society of America (ISA) develops and publishes periodicals, books, standards, recommended practices, monographs, references, and training aids pertaining to instruments and automated controls. The following publications of the ISA contain information related to piping:

Recommended Practices (RP)

RP 16.5-61	Recommended Practice for Installation, Operation, Maintenance Instructions for Glass Tube Variable Area Meters (Rotometers)
RP 31.1-77	Recommended Practice for Specification, Installation, and Calibration of Turbine Flowmeters
RP 42.1-92	Recommended Practice for Nomenclature for Instrument Tube Fittings
RP 60.9-81	Recommended Practice for Piping Guide for Control Centers
RP 75.18-89	Recommended Practice for Control Valve Position Stability
RP 75.21-89	Recommended Practice for Process Data Presentation for Control Valves
RP 75.23-95	Considerations for Evaluating Control Valve Cavitation

Standards

S 5.1-84	Instrumentation Symbols and Identification

S 5.2-76	Binary Logic Diagrams for Process Operations
S 5.3-83	Graphic Symbols for Distributed Control/Shared Display Instrumentation, Logic, and Computer
S 5.4-91	Standard Instrument Loop Diagrams
S 5.5-85	Graphic Symbols for Process Displays
S 7.0.01	Quality Standard for Instrument Air
S 12.4-70	Instrument Purging for Reduction of Hazardous Area Classification
S 18.1-79	Annunciator Sequences and Specifications (R 1985)
S 20-81	Specification Forms for Process Measurement and Control Instruments, Primary Elements, and Control Valves
S 26-68	Dynamic Response Testing of Process Control Instrumentation
S 37.3-75	Strain Gauge Pressure Transducers, Specifications, and Tests (R 1982)
S 37.5-75	Strain Gauge Linear Acceleration Transducers, Specifications, and Tests (R 1982)
S 37.6-76	Specifications and Tests of Potentiometric Pressure Transducers (R 1982)
S 37.8-77	Specifications and Tests for Strain Gauge Force Transducers (R 1982)
S 51.1-79	Process Instrumentation Terminology
S 67.01-94	Transducer and Transmitter Installation for Nuclear Safety Applications
S 67.02.01-96	Nuclear-Safety-Related Instrument Sensing Line Piping and Tubing Standards for Use in Nuclear Power Plants
S 67.03-82	Light Water Reactor Coolant Pressure Boundary Leak Detection
S 67.04-94	Setpoints for Nuclear Safety-Related Instrumentation
S 67.10-94	Sample-Line Piping and Tubing Standard for Use in Nuclear Power Plants
S 75.01-85	Flow Equations for Sizing Control Valves
S 75.02-96	Control Valve Capacity Test Procedure
S 75.03-92	Face-to-Face Dimensions for Integral Flanged Globe-Style Control Valve Bodies (ANSI Classes 125, 150, 250, 300, and 600)

S 75.04-95	Face-to-Face Dimensions for Flangeless Control Valves (ANSI Classes 150, 300, and 600)
S 75.05-83	Control Valve Terminology
S 75.07-87	Laboratory Measurement of Aerodynamic Noise Generated by Control Valves
S 75.08-85	Installed Face-to-Face Dimensions for Flanged Clamp or Pinch Valves
S 75.11-85	Inherent Flow Characteristic and Rangeability of Control Valves
S 75.12-93	Face-to-Face Dimensions for Socket Weld-End and Screwed-End Globe-Style Control Valves (ANSI Classes 150, 300, 600, 900, 1500, and 2500)
S 75.14-93	Face-to-Face Dimensions for Butt-Weld-End Globe Style Control Valves (ANSI Classes 4500)
S 75.15-94	Face-to-Face Dimensions for Butt-Weld-End Globe-Style Control Valves (ANSI Classes 150, 300, 600, 900, 1500, and 2500)
S 75.17-89	Control Valve Aerodynamic Noise Prediction Standard
S 75.19-95	Hydrostatic Testing of Control Valves (Formerly ASME/ANSI B16.37-80)
ISA MC96.1	Temperature Measurement Thermocouples (1982)
ISA RP2.1	Manometer Tables (1985)
ISA RP12.4	Pressurized Enclosures (1996)
ISA RP75.23	Considerations for Evaluating Control Valve Cavitation
ISA S75.16	Face-to-Face Dimensions for Flanged Globe-Style Control Valve Bodies (ANSI Classes 900, 1500, and 2500) (1994)
ISA S75.20	Face-to-Face Dimensions for Separable Flanged Globe-Style Control Valves (ANSI Classes 150, 300, and 600) (1991)
ISA S75.22	Face-to-Centerline Dimensions for Flanged Globe-Style Angle Control Valve Bodies (ANSI Classes 150, 300, and 600) (1992)
ISA S77.70	Fossil Fuel Power Plant Instrument Piping Installation (1995)

| ISA S84.01 | Application of Safety Instrumented Systems for the Process Industries (1996) |
| ISA DIRECT | Directory of Instrumentation, 1992 |

Handbook

ISA Handbook of Control Valves

MANUFACTURERS STANDARDIZATION SOCIETY OF THE VALVE AND FITTINGS INDUSTRY

The Manufacturers Standardization Society (MSS) publishes Standard Practices (SP) which provide a basis for common practice by the manufacturers, the user, and the general public. Compliance to the Standard Practices of MSS is required by reference in a code, specification, sales contract, law, or regulation. The MSS is also represented on the committees of other standardization groups, such as ANSI and ASME. Many of the ASME B16 series standards were originally developed as MSS Standard Practices. Once a Standard Practice is adopted as ANSI standard, it is discontinued as an MSS Standard Practice.

The following is a complete list of MSS Standard Practices published and in current use:

Standard Practices (SP)

SP-6-96	Standard Finishes for Contact Faces of Pipe Flanges and Connecting-End Flanges of Valves and Fittings
SP-9-97	Spot Facing for Bronze, Iron, and Steel Flanges
SP-25-93	Standard Marking System for Valves, Fittings, Flanges, and Unions
SP-42-90	Class 150 Corrosion Resistant Gate, Globe, Angle, and Check Valves with Flanged and Butt-Weld Ends
SP-43-91	Wrought Stainless Steel Butt-Welding Fittings, Including Reference to Other Corrosion Resistant Materials
SP-44-96	Steel Pipe Line Flanges (superseded by ASME B16.47)
SP-45-92	Bypass and Drain Connection Standard
SP-51-91	Class 15OLW Corrosion Resistant Cast Flanges and Flanged Fittings
SP-53-95	Quality Standard for Steel Castings and Forgings for Valves, Flanges, and Fittings and Other Piping Components

	Magnetic Particle Examination Method
SP-54-95	Quality Standard for Steel Casting for Valves, Flanges, and Fittings and Other Piping Components, Radiographic Examination Method (R 1990)
SP-55-96	Quality Standard for Steel Castings for Valves, Flanges, and Fittings and Other Piping Components, Visual Method for Evaluation of Irregularities
SP-58-93	Pipe Hangers and Supports—Materials, Design, and Manufacture
SP-60-91	Connecting Flange Joint Between Tapping Sleeves and Tapping Valves (R 1986)
SP-61-92	Pressure Testing of Steel Valves
SP-65-94	High Pressure Chemical Industry Flanges and Threaded Stubs for Use with Lens Gaskets
SP-67-95	Butterfly Valves
SP-68-97	High Pressure-Offset Seat Butterfly Valves with Offset Design
SP-69-96	Pipe Hangers and Supports—Selection and Application
SP-70-90	Cast Iron Gate Valves, Flanged, and Threaded Ends
SP-71-97	Cast Iron Swing Check Valves, Flanged and Threaded Ends
SP-72-92	Ball Valves with Flanged or Butt-Welding Ends for General Service
SP-73-91	Brazing Joints for Wrought and Cast Copper Alloy Solder Joint Pressure Fittings
SP-75-93	Specification for High Test Wrought Butt-Welding Fittings
SP-77-95	Guidelines for Pipe Support Contractual Relationships and Responsibilities of the Pipe Hanger Contractor with the Purchaser's Engineer or the Pipe Fabricator and/or Erector
SP-78-87	Cast Iron Plug Valves, Flanged and Threaded Ends
SP-79-92	Socket-Welding Reducer Inserts
SP-80-97	Bronze Gate, Globe, Angle, and Check Valves

SP-81-95	Stainless Steel, Bonnetless Flanged Knife Gate Valves
SP-82-92	Valve Pressure Testing Methods
SP-83-95	Class 3000 Steel Pipe Unions Socket-Welding and Threaded
SP-85-94	Cast Iron Globe and Angle Valves Flanged and Threaded Ends
SP-86-97	Guidelines for Metric Data in Standards for Valves, Flanges, Fittings, and Actuators
SP-87-91	Factory-Made Butt-Welding Fittings for Class 1 Nuclear Piping Applications (R 1986)
SP-88-93	Diaphragm Type Valves (R 1988)
SP-89-98	Pipe Hangers and Supports—Fabrication and Installation Practices
SP-90-86	Guidelines on Terminology for Pipe Hangers and Supports
SP-91-92	Guidelines for Manual Operation of Valves
SP-92-87	Valve User Guide
SP-93-87	Quality Standard for Steel Castings and Forgings for Valves, Flanges, and Fittings and Other Piping Components Liquid Penetrant Examination Method
SP-94-92	Quality Standard for Ferritic and Martensitic Steel Castings for Valves, Flanges, and Fittings, and Other Piping Components Ultrasonic Examination Method (R 1987)
SP-95-86	Swage(d) Nipples and Bull Plugs
SP-96-96	Guidelines on Terminology for Valves and Fittings
SP-97-95	Forged Carbon Steel Branch Outlet Fittings—Socket Welding, Threaded, and Butt-Welding Ends
SP-98-96	Protective Epoxy Coatings for the Interior of Valves and Hydrants
SP-99-94	Instrument Valves
SP-100-97	Qualification Requirements for Elastomer Diaphragms for Nuclear Service Diaphragm Type Valves
SP-101-89	Part-Turn Valve Actuator Attachment Flange and Driving Component Dimensions and Performance Characteristics

SP-102-89	Multi-Turn Valve Actuator Attachment Flange and Driving Component Dimensions and Performance Characteristics
SP-103-95	Wrought Copper and Copper Alloy Insert Fittings for Polybutylene Systems
SP-104-95	Wrought Copper Solder Joint Pressure Fittings
MS SP-105	Instrument Valves for Code Applications (Jan. 1, 1996)
MSS SP-106	Cast Copper Alloy Flanges and Flanged Fittings Class 125, 150 and 300 (Jan. 1, 1990)
MSS SP-107	Transition Union Fittings for Joining Metal and Plastic Products (Jan. 1, 1991)
MSS SP-108	Resilient-Seated Cast Iron-Eccentric Plug Valves (Jan. 1, 1996)
MSS SP-109	Welded Fabricated Copper Solder Joint Pressure Fittings (Jan. 1, 1997)
MSS SP-110	Ball Valves Threaded, Socket-Welding, Solder Joint, Grooved and Flared Ends (Jan. 1, 1996)
MSS SP-111	Gray-Iron and Ductile-Iron Tapping Sleeves (Jan. 1, 1996)
MSS SP-112	Quality Standard for Evaluation of Cast Surface Finishes Visual and Tactile Method (Jan. 1, 1993)
MSS SP-113	Standard Practice for Connecting Joint Between Tapping Machines and Tapping Valves (Jan. 1, 1994)
MSS SP-114	Corrosion Resistant Pipe Fittings Threaded and Socket Welding Class 150 and 1000 (Jan. 1, 1995)
MSS SP-115	Excess Flow Valves for Natural Gas Service (Jan. 1, 1995)
MSS SP-116	Service Line Valves and Fittings for Drinking Water Systems (Jan. 1, 1996)
MSS SP-117	Bellows Seals for Globe and Gate Valves (Jan. 1, 1996)
MSS SP-118	Compact Steel Globe and Check Valves Flanges, Flangeless, Threaded and Welding Ends (Chemical and Petroleum Refinery Service) (Jan. 1, 1996)
MSS SP-119	Belled End Socket Welding Fittings, Stainless Steel and Copper Nickel (Nov. 1, 1996)

MSS SP-120	Flexible Graphite Packing System or Rising Stern Steel Valves (Design Requirements) (March 1, 1997)
MSS SP-121	Qualification Testing Methods for Stem Packing for Rising Stem Steel Valves (March 1, 1997)
MSS SP-122	Plastic Industrial Ball Valves (Jan. 1, 1997)

NATIONAL FIRE PROTECTION ASSOCIATION

The National Fire Protection Association (NFPA) is a voluntary association of members representing all aspects of fire protection, such as professional societies, educational institutions, public officials, insurance companies, equipment manufacturers, builders and contractors, and transportation groups. The NFPA publishes codes, standards, guides, and recommended practices in a 12-volume set of books called the *National Fire Codes*. Conformance to the *National Fire Codes* may be required by federal, state, and local laws and regulations. Sometimes insurance companies may leave no choice for the owner/user of the facility but to comply with the fire protection and prevention requirements of the applicable National Fire Codes.

Volumes 1 through 8 contain actual text of the National Fire Codes and Standards. The requirements contained in these volumes have been judged suitable for legal adoption and enforcement. Volumes 9 through 11 contain recommended practices and guides considered to be good engineering practices. Volume 12 contains formal interpretations, tentative interim amendments, and errata that relate to the documents in Volumes 1 through 11.

Here is a list of NFPA publications. For specific NFPA Codes and Standards related to fire protection systems piping, refer to Chapter C2, Part C of this handbook.

National Fire Protection Association Publications

Technical Committee Documentation and Reports

Automatic Sprinkler Systems Handbook, Sixth Edition

Automatic Sprinkler and Standpipe Systems, Second Edition

Flammable and Combustible Liquids Code Handbook, Fifth Edition

Fire Litigation Handbook

SFPE Handbook of Fire Protection Engineering, First Edition

Fire Protection Guide to Hazardous Materials, Eleventh Edition

Fire Protection Handbook, Seventeenth Edition

Liquefied Petroleum Gases Handbook, Third Edition

Life Safety Code Handbook, Sixth Edition

National Electrical Code Handbook, Seventh Edition

National Fuel Gas Code Handbook, Second Edition

National Fire Codes and Standards, Volumes 1 through 12
Formal Interpretations, Volume 13

PIPE FABRICATION INSTITUTE

The Pipe Fabrication Institute (PFI) publishes advisory Engineering Standards (ES) and Technical Bulletins (TB) intended to serve the needs of the pipe-fabricating industry at the design level and in actual shop operations. The PFI standards contain minimum requirements; however, the designer or fabricator may consider specifying additional requirements beyond the scope of PFI publications. The use of PFI standards or bulletins is voluntary. A complete listing of PFI publications follows:

Engineering Standards (ES)

ES-1-92	Internal Machining and Solid Machined Backing Rings for Circumferential Butt Welds
ES-2-92	Method of Dimensioning Piping Assemblies
ES-3-81	Fabricating Tolerances (R 1990)
ES-4-85	Hydrostatic Testing of Fabricated Piping (R 1988)
ES-5-93	Cleaning of Fabricated Piping
ES-7-94	Minimum Length and Spacing for Welded Nozzles
ES-11-75	Permanent Marking on Piping Materials (R 1990)
ES-16-85	Access Holes, Bosses, and Plugs for Radiographic Inspection of Pipe Welds (R 1988)
ES-20-97	Wall Thickness Measurement by Ultrasonic Examination
ES-21-92	Internal Machining and Fit-Up of GTAW Root Pass Circumferential Butt Welds (R 1989)
ES-22-95	Recommended Practice for Color Coding of Piping Materials
ES-24-92	Pipe Bending Methods, Tolerances, Process, and Material Requirements
ES-25-93	Random Radiography of Pressure Retaining Girth Butt Welds
ES-26-93	Welded Load Bearing Attachments to Pressure Retaining Piping Materials
ES-27-94	''Visual Examination''—The Purpose, Meaning, and Limitation of the Term
ES-29-93	Abrasive Blast Cleaning of Ferritic Piping Materials

ES-30-86	Random Ultrasonic Examination of Butt Welds (R 1989)
ES-31-92	Standard for Protection of Ends of Fabricated Piping Assemblies
ES-32-93	Tool Calibration
ES-34-92	Painting of Fabricated Piping (R 1989)
ES-35-93	Nonsymmetrical Bevels and Joint Configurations for Butt Welds
ES-36-95	Branch Reinforcement Work Sheets
PFI ES-37	Loading and Shipping of Piping Assemblies (March 1, 1997)
PFI ES-39	Fabricated Tolerances for Grooved Piping Systems (Feb. 1, 1994)
PFI ES-40	Method of Dimensioning Grooved Piping Assemblies (Feb. 1, 1994)
PFI ES-41	Material Control and Traceability of Piping Components (Jan. 1, 1995)
PFI ES-42	Positive Material Identification of Piping Components Using Portable X-Ray Emission Type Test Equipment (Jan. 1, 1996)
PFI ES-44	Drafting Practices Standard (March 1, 1997)

Technical Bulletins (TB)

TB1-94	Pressure-Temperature Ratings of Seamless Pipe Used in Power Plant Piping Systems
TB3-93	Guidelines Clarifying Relationships and Design Engineering Responsibilities Between Purchasers' Engineers and Pipe Fabricator or Pipe Fabricator Erector (R 1988)
TB7-97	Guideline for Fabrication and Installation of Stainless Steel High Priority Distribution Systems

PLASTICS PIPE INSTITUTE

Those interested in the application of plastics piping systems may find the following Plastics Pipe Institute (PPI) publications of help:

PPI Handbook of Polyethylene Piping
Engineering Basics of Plastics Piping
Plastic Piping Manual

In addition, the PPI publishes technical reports (TR), technical notes (TN), recommendations (REC), statements (STA), and model specifications (MS) dealing with plastics piping.

Technical Reports (TR)

PPI TR2/6	Policies and Procedures for the Listing of Thermoplastic Pipe, Fittings and Fixture Materials when Evaluated under Constant Internal Pressure with Flow (ASTM F 948) (1987)
PPI TR-3	Policies and Procedures for Developing Recommended Hydrostatic Design Stresses for Thermoplastic Pipe Materials; Addendum—1992 (1992)
PPI TR-4	Recommended Hydrostatic Strengths and Design Stresses for Thermoplastic Pipe and Fittings Compounds; Correction Notice (1994)
PPI TR-5	Standards for Plastics Piping (1990)
PPI TR-7	Recommended Method for Calculation of Nominal Weight of Plastic Pipe (1988)
PPI TR-9	Recommended Design Factors for Pressure Applications of Thermoplastic Pipe Materials (1992)
PPI TR-11	Resistance of Thermoplastic Piping Materials to Micro- and Macro-Biological Attack (1989)
PPI TR13	Poly (Vinyl Chloride) (PVC) Plastic Piping Design and Installation (1973)
PPI TR14	Water Flow Characteristics of Thermoplastic Pipe (1992)
PPI TR18	Weatherability of Thermoplastic Piping (1973)
PPI TR19	Thermoplastics Piping for the Transport of Chemicals; Errata (1991)
PPI TR20	Joining Polyolefin Pipe (1973)
PPI TR21	Thermal Expansion and Contraction of Plastic Pipe; Errata (1974)
PPI TR-22	Polyethylene Plastic Piping Distribution Systems for Components of Liquid Petroleum Gases; Revision—1991 (1988)
PPI TR-30	Thermoplastic Fuel Gas Piping Investigation of Maximum Temperatures At-

	tained by Plastics Pipe Inside Service Risers (1988)
PPI TR-31	Underground Installation of Polyolefin Piping (1988)
PPI TR-32	Recommended Minimum In-Plant Quality Control Program for Production of Polyethylene Gas Distribution Piping Systems (1989)
PPI TR8	Installation Procedures for Polyethylene (PE) Plastic Pipe (1984)

Technical Notices (TN)

PPI TN-15	Resistance of Polyethylene Pipe to a Sanitary Sewage Environment (1992)
PPI TN-16	Rate Process Method for Evaluating Performance of Polyethylene Pipe (1992)
PPI TN2	Sealants for Polyvinyl Chloride (PVC) Plastic Piping (1970)
PPI TN8/8	Making Threaded Joints with Thermoplastic Pipe and Fittings (1973)
PPI TN12/3	Coefficients of Thermal Expansion Thermoplastic Piping Materials (1977)
PPI REC.A	Limiting Water Velocities in Thermoplastic Piping Systems (1971)
PPI REC.B	Thermoplastic Piping for the Transport of Compressed Air or Other Compressed Gases (1989)
PPI REC.C	Pressure Rating of PVC Plastic Piping for Water at Elevated Temperatures (1973)
PPI STA.L	Thermoplastic Piping in Fire Sprinkler Systems
PPI STA.H	Noise in Piping Systems (1988)
PPI.STA.N	Pipe Permeation (R 1990) (1984)
PPI STA.R	Technical Considerations When Using Polyethylene (PE) (1992)
PPI STA.S	Caution Statement on Heat Fusion Methods of Polyethylene Pipe and/or Fittings of Similar Colors (1991)
PPI MS-2	Model Specification for Polyethylene Plastic Pipe Tubing and Fittings for Natural Gas Distribution (1990)

STEEL STRUCTURES PAINTING COUNCIL

The Steel Structures Painting Council (SSPC) publishes specifications, which include surface preparation (SP), pretreatment (PT), paint application (PA), and paint and paint systems (PS). These specifications identify practical and economical methods of surface preparation and painting steel structures. They are used to clean and paint piping and other steel equipment. With the exception of paint and paint system specifications, the following are the commonly used SSPC specifications:

Surface Preparation (SP) Specifications

SSPC-Vis I-89	Pictorial Surface Preparation Standard for Painting Steel Surfaces
SSPC-Vis 2-82	Standard Method of Evaluating Degree of Rusting on Painted Steel Surfaces
SSPC-SP 1-82	Solvent Cleaning
SSPC-SP 2-95	Hand Tool Cleaning
SSPC-SP 3-95	Power Tool Cleaning
SSPC-SP 5-94	White Metal Blast Cleaning
SSPC-SP 6-94	Commercial Blast Cleaning
SSPC-SP 7-94	Brush-Off Blast Cleaning
SSPC-SP 8-91	Pickling
SSPC-SP 10-94	Near-White Blast Cleaning
SSPC-SP 11-95	Power Tool Cleaning and Base Metal

Pretreatment Specifications (PT)

SSPC-PT 1	Wetting Oil Treatment
SSPC-PT 2	Cold Phosphate Surface Treatment
SSPC-PT 3	Basic Zinc Chromate-Vinyl Butyral Washcoat
SSPC-PT 4	Hot Phosphate Surface Treatment

Paint Application (PA) Guides

SSPC-PA I-91	Shop, Field, and Maintenance Painting
SSPC-PA 2-91	Measurement of Dry Paint Thickness with Magnetic Gauges

TUBULAR EXCHANGER MANUFACTURERS ASSOCIATION

The Tabular Exchanger Manufacturers Association (TEMA) publishes standards for use by manufacturers and users. The following is a list of some Heat Exchange Institute (HEI) publications that may be of interest:

HEI 8	Standards for Power Plant Heat Exchangers, Second Edition
HEI 8A	Standards for Steam Jet Vacuum Systems, Fourth Edition
HEI 10	Standards for Steam Surface Condensers, Eighth Edition
HEI 10A	Standards for Steam Surface Condensers Addendum, Eighth Edition
HEI TSD	Standards and Typical Specifications for Deaerators, Fifth Edition

UNDERWRITERS LABORATORIES

The UL is a nonprofit organization that develops specifications and standards directed toward assuring the safety of materials, products, and equipment when used in accordance with the conditions for which they were designed. It also tests items for conformance to these and other nationally recognized standards and publishes lists of items approved as a result of the tests. The NFPA codes require that items to be used in fire protection and prevention systems be approved and listed. The UL-published *UL Fire Protection Equipment List* (such as a listing of fire-loop piping material and equipment manufacturers) is one of the publications normally used by those involved in piping associated with fire protection systems.

FOREIGN CODES AND STANDARDS

The basic principles of piping design and construction may not differ much from one country to another, but the requirements of country-specific codes and standards may vary substantially. Therefore, the personnel involved in the engineering design, construction, operation, and maintenance of piping systems must ensure that the requirements of applicable codes and standards are complied with to ensure the safety of the general public and workers associated with the facility.

The user is advised to verify the latest applicable version/edition of the code and/or standard before invoking their requirements for any application.
Appendix E10 provides a listing of British, DIN, Japanese, and ISO codes, standards, and specifications related to piping.

BRITISH STANDARDS AND SPECIFICATIONS

Pipe, Tube, and Fittings

Appendix E10, Table E10.B1 lists British standards and specifications for pipe, tube, and fittings.

Flanges, Bolts, Nuts, and Gaskets

Appendix E10, Table E10.B2 lists British standards and specifications for flanges, bolts, nuts, and gaskets.

Valves

Appendix E10, Table E10.B3 lists British standards and specifications for valves.

DIN STANDARDS AND SPECIFICATIONS

Pipe, Tube, and Fittings

Appendix E10, Table E10.D1 lists DIN standards and specifications for pipe, tube, and fittings.

Flanges, Bolts, Nuts, and Gaskets

Appendix E10, Table E10.D2 lists DIN standards and specifications for flanges, bolts, nuts, and gaskets.

Valves

Appendix E10, Table E10.D3 lists DIN standards and specifications for valves.

JAPANESE STANDARDS AND SPECIFICATIONS

Pipe, Tube, and Fittings

Appendix E10, Table E10.J1 lists Japanese standards and specifications for pipe, tube, and fittings.

Flanges, Bolts, Nuts, and Gaskets

Appendix E10, Table E10.J2 lists Japanese standards and specifications for flanges, bolts, nuts, and gaskets.

Valves

Appendix E10, Table E10.J3 lists Japanese standards and specifications for valves.

ISO STANDARDS AND SPECIFICATIONS

Pipe, Tube, and Fittings

Appendix E10, Table E10.I1 lists ISO standards and specifications for pipe, tube and fittings.

Flanges, Bolts, Nuts, and Gaskets

Appendix E10, Table E10.I2 lists ISO standards and specifications for flanges, bolts, nuts, and gaskets.

Valves

Appendix E10, Table E10.I3 lists ISO standards and specifications for valves.

Other chapters include reference to other international or foreign standards and specifications relevant to the piping and related components.

DEVELOPMENT OF COMMERCIAL PIPE-MAKING

There have been increasing societal demands for modern structures and facilities and concomitant increased emphasis on safety and reliability of equipment under all operating conditions. Piping manufacturing processes have been developed to provide the quality and reliability commensurate with these demands, together with economically feasible production methods. To meet the more stringent reliability goals, the quality control of the piping manufacturing process from the production of the raw material to the finished product is of significant importance. Driving the need for process quality improvement are the social and economic consequences of equipment failure in critical applications such as power generation, chemical and petroleum production, and transportation.

This chapter considers the methods by which different types of metallic pipe are produced. It also considers the various steel-making processes which are important to the ultimate quality of the manufactured pipe. For a discussion of pipes made of thermoplastic and fiberglass, refer to Part D of this handbook.

Historical Background

The history of pipe manufacturing goes back to the use of hollow wooden logs to provide water for medieval cities. The use of cast-iron pipes in England and France

became prevalent in the early nineteenth century. The first major cast-iron water pipeline for Philadelphia was obtained in 1817 and for New York in 1832. Distribution of gas for gaslights was initiated in England, using sheet iron drawn through a die to a cylindrical shape and with the edges welded together. In 1887 the first pipe was made of Bethlehem steel in the United States.

Seamless pipe manufacture was attempted in the mid–nineteenth century by various means; the Mannesmann process was developed in Germany in 1885 and operated commercially in England in 1887. The first seamless pipe mill in the United States was built in 1895.

In the early twentieth century, seamless tubes gained wide acceptance as the Industrial Revolution proceeded with automobiles, oil refineries, oil pipelines, oil wells, and fossil power generation boilers. At that time, the welded tube had not achieved the reliability of present-day electric resistance welded tubes.

The development of pipe and tube production methods, together with the development of steel alloys capable of withstanding the demanding environmental conditions of temperature, chemistry, pressure, and cyclic thermal and pressure load application have enabled pipe and tube to be used reliably in the most critical applications, ranging from Alaskan pipelines to nuclear power generation plants.

World Tubular Product Production Capability

World production and consumption of iron and steel tubular products makes up almost 14 percent of the worldwide crude steel conversion. World production of steel tubular products is continuously increasing to meet the demands of worldwide industrialization and growing population. The production of iron and steel tubular products vary depending on a wide range of worldwide economic factors such as oil exploration, power generation plant construction, and automotive production. For example, in economic climates where oil prices are low, there is less incentive to drill new oil wells. Consequently, the production of steel pipe for oil drilling casings would be reduced. Similar examples of steel pipe production as a function of economic climate can be seen in the power generation and automotive industries. Total world production of pipe is an integration of the effects of the local national economic climates throughout the world.

FERROUS PIPE-MAKING PROCESSES

Iron-Making

The making of steel for ferritic piping begins with the smelting of iron ore found in deposits in the crust of the earth throughout the world in forms such as hematite and magnetite. In preparation for the smelting process, the iron ore may be treated by any of several methods to convert it into a suitable form for introduction into the blast furnaces. One method is sintering, which converts ores into a porous mass called clinkers. Another is smelting, which is performed in a blast furnace. The process involves the chemical reaction of iron ore with limestone, coke, and air under heat, reducing the iron ore to iron. The ''pig'' iron obtained from the blast furnace is used as the basic component in the steel-making process.

Steel-Making

Steel for piping can be produced in several ways (Fig. A5.1), depending on the facilities available and the desired characteristic of the steel. Generally, steel requires
FIGURE A5.1 Piping steel-making processes.

the removal of carbon from the pig iron to a degree required by the carbon steel properties desired. Alloy steel also requires the addition of alloying elements such as chromium, nickel, manganese, and molybdenum to provide the special properties associated with the alloying element.

Bessemer Converter.   The Bessemer method of making steel (due to Sir Henry Bessemer in 1856) consisted of blowing a current of cold air through the molten pig iron, thereby using the oxygen in the air to burn carbon and other impurities from the melt. After burning out the carbon in the pig iron, the exact amount of carbon required for the steel is reintroduced into the heat.

Basic Oxygen Process.   The basic oxygen process (BOP) is essentially the same as the Bessemer process except that it uses pure oxygen (instead of air) together with burned lime converted from limestone. This process burns out the impurities more quickly and completely and provides for more precise control of the steel chemistry.

Open-Hearth Furnace.   The open-hearth furnace is used to produce much of the steel in the United States; however, it is being superseded by the basic oxygen process. Its significant advantage is the ability to use scrap steel as well as pig iron

as ferrous stock in producing steel. The open-hearth furnace is a large rectangular brick floor, or hearth, completely covered with a brick structure through which the charge of ferrous stock and limestone is introduced. It is fueled with coke gas, oil, or tar introduced through a burner playing a flame across the hearth while the products of combustion escape through the furnace wall away from the burner. An advantage of the open-hearth process is that testing for carbon content during the heating is possible, allowing adjustments to be made to the feed-stock at that time to control the chemistry of the product.

Electric Arc Furnace. The electric arc furnace is a large kettle-shaped chamber lined with fire brick, into which a charge of steel scrap with coke is melted by means of heat produced by an electric arc. Since no burning of fuel is required, the oxygen of the steel can be controlled and kept to a minimum. Alloying elements can be added without the fear of oxidation. Because of the control of heat time, temperature, and chemistry, the electric arc furnace is used in the production of high-quality alloy steels.

Argon Oxygen Process. The argon oxygen process (AOP) is used in the production of specialty steels with low carbon and sulfur and high chromium content. A charge of steel of almost the desired properties is introduced into a basic oxygen furnacelike vessel, and controlled amounts of oxygen and argon are introduced into the melt. This reducing process conserves valuable chromium.

Vacuum Degassing Process. When exceptionally high quality steel is required, steel can be ''degassed'' in a vacuum environment. This vacuum degassing process provides strong reduction in hydrogen, oxygen, nitrogen, inclusions, and contaminants such as lead, copper, tin, and arsenic.

Ingots, Blooms, and Billets. Ingots, blooms, and billets are the shapes into which the molten metal is solidified before using it in a particular pipe-making (or other) process. An ingot is poured from the molten steel and after solidification goes to the blooming mill to be rolled into square blooms, which are further formed onto bar rounds. Alternately, in the case of large pipe, the ingot may be formed into pierced billets to be used in the seamless tube-making process.

Continuous Casting Process. Although the development of the continuous casting process (Fig. A5.2) began in the nineteenth century, it was after World War II that its use became of great commercial interest. In the continuous casting process, molten steel is poured from the melting furnace to a ladle feeding a reservoir called a tundish. The tundish feeds a lubricated mold that has a cooled copper surface, and the solidifying steel is continuously drawn from the mold. In the case of piping steel, the mold is the shape of the billet or slab used in the tube-making process. There are many types of continuous casting processes, ranging from vertical to horizontal, with variations of bent sections in between. This process is now used in more than half the world's steel production. In Japan, 85 percent of the total steel produced is by the continuous casting process.

Pipe- and Tube-Forming Processes

There are basically two types of pipe- and tube-forming processes, namely, seamless and welded. Each process imparts unique properties to the pipe or tube. Seamless
FIGURE A5.2   Continuous casting process.

pipe or tube does not have the presence of a welded seam along the length of the pipe. This seam has traditionally been believed to be a potential weakness. The development of automated welding processes and quality control, however, has made this a virtually nonexistent concern. The control of thickness uniformity and concentricity is relatively easy with welded pipe and tube. In general, the seamless pipe is more expensive to produce. The classification of cylindrical tubular products in terms of either pipe or tube is a function of end use. This is discussed further under Tubular Product Classification.

Seamless Pipe.   Seamless tube and pipe (Fig. A5.3) are manufactured by first producing a hollow tube which is larger in diameter and thickness than the final tube or pipe. The billet is first pierced by either a rotary (Mannesmann) piercer or by a press piercing method. For tubes of small diameter, the mandrel mill process is used. For medium outside diameter tubes of carbon or low-alloy steel, the Mannesmann plug mill process is used. Large-diameter, heavy-wall carbon steel, alloy, and stainless pipe is manufactured by the Erhardt push bench process and vertical extrusion similar to the Ugine Sejournet type extrusion process. High-alloy and specially shaped pipe are manufactured by the Ugine Sejournet extrusion-type process. These processes are performed with the material at hot-metal-forming temperatures. Further cold processing may or may not be performed to obtain further dimensional accuracy, surface finish, and surface metallurgical structure.

   Mandrel (Pilger) Mill Process.   In the mandrel (pilger) mill process (Fig. A5.4), a steel billet is heated to forging temperature and placed between the rolls of a hot rotary piercing mill. A piercing point is placed at the center of the billet, and the rotating rolls are designed to advance the billet over the piercing point, thereby forming a hole through the center of the billet along its entire length as it advances
FIGURE A5.3   Seamless tube and pipe manufacturing processes.

into the tilted rolls. A mandrel of outside diameter approximately that of the inside finished pipe diameter is pressed into the pierced hole of the billet. This combination of mandrel and billet is placed between rolls of a pilger-mill having a cam-shaped contour revolving counter to the direction in which the billet is being forced by means of a hydraulic and pneumatic ram mechanism.

Second phase
rolling

Third phase
outlet

Fourth phase
recuperator
FIGURE A5.4   Mandrel (pilger) mill process.

In the pilger-mill, the rolls first grab the hot billet and after some rotation form a shaft. The pressure of the rolls forces the billet backward, and the resulting tube section is squeezed and smoothed out in the adjacent part of the roll groove. This process is equivalent to forging the billet against the mandrel and driving the billet and mandrel against the ram. After reaching the open portion of the cam shape, the ram mechanism again forces the billet into the rolls. Following the pilger-mill process, the tube is reheated and passed through a reducer or sizer to provide a more uniform diameter. The resulting tube or pipe is called *hot finished seamless*.

The pilger-mill process is slower than conventional drawing. However, since large reductions in diameter are possible in a single pass, the process is applied to the production of tubes of small diameter such as heat exchangers, fossil fuel boilers, and nuclear steam generators.

Mannesmann Plug-Mill Process. In the Mannesmann plug-mill process (Fig. A5.5) the billet may be pierced in two hot rotary piercers because of the greater reduction needed for medium-size pipe and tube. Following the piercing process, the pierced billet is placed in a plug-mill, which reduces the diameter by rotating the tube over a mandrel. Having some ovality, the tube is next inserted between the rolls of reelers which provide for dimensional correction and burnish the inside and outside diameters of the tube. Finally, after reheating, the tube reenters a reeler and sizing rollers to provide for greater dimensional uniformity.

The Mannesmann plug-mill process is a standard process for making large quantities of thin-wall stainless steel tube or pipe of uniform size and roundness throughout its entire length.

FIGURE A5.5 Mannesmann plug-mill process.

Ugine Sejournet Type Extrusion Processes. The Ugine Sejournet extrusion process (Fig. A5.6) is used for high-alloy steel tubes and pipe such as those of stainless steel and specially shaped pipe. A descaled billet, heated to approximately 2300°F (1260°C), is placed in the vertical press compartment with an extrusion die at its bottom. After applying a hydraulic ram to the billet, a piercing mandrel within the ram punches the billet, producing a cylinder from which the punch piece is ejected through the extrusion die opening. Following this, the ram is activated to apply pressure to the billet, and the billet is extruded through the annulus formed between the piercing mandrel and die cavity. In horizontal presses, piercing is done as a separate operation, or a hollow is used with a mandrel and die. The mandrels and dies are made of high-alloy steels containing tungsten, molybdenum, and chromium having Rockwell C hardness values of approximately 46. Powdered glass is the lubricant used in this process. Heavy-wall pipe in sizes NPS 8–48 (DN 200–1200), having a wall thickness ranging from 1 in (25 mm) to 6 in (150 mm), is extruded vertically to 45 ft (14 m) lengths using procedural steps in the Ugine Sejournet process and a graphite lubricant. These large extrusions of carbon-, alloy-, and

nickel-based materials include ASTM specifications A 106, Grades B & C; A 312; A 333; A 335; A 376; B 167; and B407. Heavy-wall pipe per ASTM A335, Grades P11, P22, and P91 is increasingly being used in power generation. In addition, heavy-wall pipe is utilized in offshore oil drilling and production.

Forged Seamless Pipe.   Forged pipe is used for large-diameter, NPS 10–30 (DN 250–750), and thickness, 1.5–4 in (40–100 mm), pipe, where equipment availability and cost for other seamless grades are limiting. There are two processes available for the production of forged seamless pipe, namely, forged and bored pipe and hollow forged pipe.

Forged and Bored Seamless Pipe.   In the forged and bored process a billet or ingot heated to forging temperature is elongated by forging in heavy presses or forging hammers to a diameter slightly larger than that of the finished pipe. After turning in a lathe to the desired outside diameter, the inside diameter is bored to the specified internal diameter dimensions. The resulting pipe can be made to very close tolerances. Sections 50 ft (15 m) long have been produced by this process.

Hollow Forged Seamless Pipe Erhardt Type Process.   The Erhardt process (Fig. A5.7), developed by Heinrich Erhardt in Germany in 1891, consists of heating a
FIGURE A5.7   Hollow-forged seamless pipe—Erhardt-type process.

square ingot to forging temperature, placing it into a circularly hollow die, and incompletely piercing it with a vertical piercing mandrel such that a cup shape is obtained. As a result of the piercing at forging temperature, the square ingot becomes the (circular) shape of the die. After reheating, the cup-shaped shell is mounted on a mandrel and pushed through a series of dies to the desired diameter and wall thickness, after which the cupped end is removed and the inside and outside pipe diameters are machined. This process is used for large-diameter and heavy-wall seamless pipe for boiler headers and main steam line piping. It can be applied to produce low and medium carbon steel pipe (ASTM A53, A106, A161, A179, A192, A210), stainless steel pipe (TP329, TP304, TP304L, TP321, TP347, TP316), and high nickel alloys (A333, A334).

Cold and Hot Finishing of Seamless Pipe and Tube.   Pipe that has been produced by the Mannesmann plug-mill, mandrel mill, Ugine Sejournet, or Erhardt forging process can be used as hot finished seamless steel pipe or tube if the application does not require further finishing. If further finishing is required, the pipe or tube may be further reduced by a cold reduction process (Fig. A5.8). If the cold reduction processes are used, the reduced tube must be heat-treated in a furnace such as a bright annealing furnace or in a continuous barrel furnace. Subsequent to the heat treatment of the cold finished pipe, the pipe must pass through a straightening process which corrects any nonstraight sections caused in the pipe by the heat treatment of cold reduced pipe. The straighteners are either a series of rolls

(a)

(b)
FIGURE A5.8 Cold and hot finishings of seamless pipe and tube.

through which the pipes pass cold or a device which bends the pipe at discreet locations along the pipe. The resulting product is called *cold finished seamless pipe* or *tube*.

In applications of tube to fossil fuel boilers, cold finishing is sometimes specified. Cold finishing improves the surface finish and dimensional accuracy. Some boiler manufacturers, however, consider the hot finished tube surface satisfactory and specify it as such because of its reduced cost.

Welded Pipe. Welded pipe is produced by forming a cylinder from flat steel sheets coming from a hot strip mill. The strip mill takes the square bloom from the blooming mill and reduces it into plates, skelp, or coils of strip steel to be fed into the particular welding process equipment. Butt-weld pipe is made by furnace heating and forge welding or by fusion welding using electric resistance, flash, submerged-arc welding, inert-gas tungsten-arc welding, or gas-shielded consumable metal-arc welding. The welded seam is either parallel to the tube axis or in a spiral direction about the tube centerline.

Furnace-Welded (Continuous or Butt-Welded) Pipe. This is a low-cost carbon steel pipe below 4-in diameter made of steel from open-hearth or basic oxygen Bessemer steel. In this process, skelp is heated to welding temperature in a continuous furnace and passed through forming and welding rolls, welding the strip edges at the same time the tube is formed. Strips can be consecutively resistance-welded to each other to form a continuous pipe.

Fusion-Welded Pipe. Fusion-welded pipe is produced by resistance-welding, induction-welding, or arc-welding.

Electric Resistance-Welded Pipe. In the electric resistance-welded (ERW) pipe process (Fig. A5.9), upon exiting the forming mill, the longitudinal edges of the cylinder formed are welded by flash-welding, low-frequency resistance-welding,
FIGURE A5.9   Electric resistance welded pipe process.

high-frequency induction-welding, or high-frequency resistance-welding. All processes begin with the forming of the cylinder with the longitudinal seam butt edges ready to be welded.

In the flash-welding process, the butted cylinder surfaces are placed in contact; a voltage is applied across the contact, causing metal flashing along the seam length and raising the steel temperature locally to the metal-forming temperature. After this, the seam edges are pressed together and a pressure fusion-weld is formed at a temperature lower than the steel melting point. The upset material along both the inside and outside of the seam is removed with a scarfing tool. This process is used to produce high-strength carbon steel pipe from NPS 4 to 36 (DN 100 to 900).

In the low-frequency resistance method, electric current and pressure are simultaneously applied, and the resulting heat causes melting of the edges. The resulting seam is similar to that from the flash-welding process and requires removal of the upset material. Postweld heat treatment may be desirable for stress relief, tempering, or recrystallization. This process is applied to pipe of outside diameters up to NPS 22 (DN 550).

High-frequency welding process, using an alternating current of more than 400,000 Hz, is similar to the low-frequency resistance welding process. The lower inductance path followed by the current produces a smaller high-temperature band that minimizes the amount of upset material. This process is used for pipe up to NPS 42 (DN 1050).

For production of small-diameter pipe at high rates of production, the high-frequency induction-welding process may be used. In this process, an induction coil raises the seam temperature to welding temperature. The rapid increase in temperature caused by the high-frequency current causes little upsetting because of the resulting control of temperature and fusion.

Several arc-welding processes are used in commercial welded pipe production. These include the submerged-arc-welding process, the inert-gas tungsten-arc-welding process, and the gas-shielded consumable metal-arc-welding process.

In the submerged-arc-welding process, bare wire consumable electrodes are added to the weld metal under a blanket of flux. The melting flux creates a protective atmosphere of inert gas and a slag blanket over the solidifying weld metal. In heavy-wall piping, simultaneous submerged arc seam welds on inner and outer sides of the pipe are sometimes used to build up the weld thickness to the desired level. In modern pipe production facilities, automated equipment is used to control all variables in the submerged arc process, including relative movement speed between pipe and welding heads, wire feed rate, welding current, and flux feed rate. Submerged-arc seam-welded pipe is used in critical high-temperature or high-pressure applications in the electrical power generation process and chemical industries.

For carbon steel and stainless steel pipe of smaller wall thickness, the inert-gas tungsten-arc-welding process is used. The weld is protected by an inert gas such as argon or helium, which forms a blanket over the weld metal. For thicker-wall pipe, a filler wire may be fed into the protective gas blanket. For thin-wall pipe, no filler is used. A number of variations in pipe forming before welding are used, including molding, pressing, or rolling strip into cylinders.

Spiral Welded Pipe.   Lightweight pipe for temporary or light operation duty such as in water systems applications may be made by the spiral-welded process. In this process, narrow strips of steel sheet are helically wound into cylinders. The edges of this strip can either be butting or overlapping and are welded by any of several electric arc-welding processes.

Cast Pipe

Cast-Iron Pipe.   There are four basic types of cast iron: white iron, gray iron, ductile iron, and malleable iron. White iron is characterized by the prevalence of carbides which impart high compressive strength, hardness, and resistance to wear. Gray cast iron has graphite in the microstructure, giving good machinability and resistance to wear and galling. Ductile iron is gray iron with small amounts of magnesium or cesium which bring about nodularization of the graphite, resulting in both high strength and ductility. Malleable iron is white cast iron which has been heat-treated to provide for ductility.

Cast-iron pipe is extensively used for underlying water, sewage, and gas distribution systems because of its long life expectancy. Specifications for this pipe can be found under Federal Specification W-W-P-421b-Pipe, Cast Iron, Pressure (for Water and Other Liquids). Cast-iron pipe is produced from four processes: vertical pit casting, horizontal casting, centrifugal sand mold casting, and centrifugal metal mold casting.

Vertical Pit Process.   The vertical pit process for producing pipe requires a sand mold formed into a pipe pattern of the outer surface of the pipe, into which a separately made core is placed. The molten iron is poured into the vertical annulus between the outer mold and the core. American Standard Specifications for Cast Iron Pit Cast Pipe for Water or Other Liquids are available in ASTM Specification A 377. Pit-cast pipe specifications for the gas industry may be found in American Gas Association (AGA) Standards for Cast Iron Pipe and Special Castings. ASTM Designation A142 provides specifications for pit-cast culvert pipe.

Horizontal Process.   In the horizontal cast-iron pipe process, horizontal outer molds are made in halves, with a core formed around a perforated horizontal bar. After the top half is placed on the bottom half, the molten iron is introduced in a manner preventing ladle slag from entering the mold.

Centrifugally Cast-Iron Pipe.   There are two types of centrifugal casting machines—horizontal and vertical. Pipe is most commonly produced in the horizontal machine. The centrifugal castings are formed after molten metal is poured into a

rotating mold. The mold continues its rotation until solidification of the metal is complete, after which the casting is removed. Molds can be made of sand or, for permanent molds, graphite, carbon, or steel. The centrifugal casting process provides a means of producing high-quality castings which are defect-free due to the absence of shrinking. These castings cool from the outside to the inside, providing a desirable directional solidification which results in cleaner and denser castings than those resulting from static casting methods.

Cast-Steel Pipe.   Cast-steel pipe is produced by either static or centrifugal casting processes. In the horizontal centrifugal casting machine, the molten steel is introduced into the rotating mold of sand, ceramics, or metal. Centrifugally cast pipe can be obtained in sizes up to NPS 54 (DN 1350). Application of this pipe can be found in paper mill rolls, gun barrels, and high-temperature and pressure service in refineries (temperatures above 1000°F or 538°C). This process is also used for high-nickel and high-nickel alloy pipes.

Cold-Wrought Steel Pipe.   Centrifugally cast stainless steel pipe can be cold expanded subsequent to casting by internally applied pressure to form cold-wrought pipe. The process, called hydroforging, applied to austenitic stainless steels provides for recrystallization and grain refinement of the centrifugally cast material grain structure.

NONFERROUS PIPE-MAKING PROCESSES

Aluminum and Aluminum Alloy Tube and Pipe

Aluminum tubular products include both pipe and tube. They are hollow-wrought products produced from a hollowed ingot by either extrusion or by welding flat sheet, or skelp, to a cylindrical form. General applications are available in alloys 1100, 2014, 2024, 3003, 5050, 5086, 6061, 6063, and 7075. For shell and tube heat exchanger applications, alloys 1060, 3003, 5052, 5454, and 6061 are available. Pipe is available only in alloys 3003, 6061, and 6063. The designation numbers indicate the particular alloying element contained in the aluminum alloy (such as copper, manganese, silicon, magnesium, and zinc) and the control of the impurities. The numerical designation system consists of four numbers, *abcd*, where *a* designates the major alloying element in the aluminum alloy: 1 for 99 percent pure aluminum, 2 for copper, 3 for manganese, 4 for silicon, 5 for magnesium, 6 for magnesium and silicon, 7 for zinc, and 8 for another element. Digit *b* designates an alloy modification for groups 2 through 8 and an impurity limit for group 1. Digits *c* and *d* indicate the specific alloy for groups 2 through 8 and the purity of group 1.

Copper and Copper Alloy Tube and Pipe

Copper tube and pipe have a wide range of application throughout the chemical, process, automotive, marine, food and beverage, and construction industries. Unified Numbering System (UNS) designations (CXXXXX) have been established for many alloys of copper. ASTM and ASME specifications have been developed for copper tube and pipe. Seamless pipe and tube are covered by ASTM B466, B315, B188, B42, B302, B75, B135, B68, B360, B11, B395, B280, B306, B251, B372, and B88. ASME specifications include SB466, SB315, SB75, SB135, SB111, SB395, and SB359.

Tubes and pipe of copper and copper alloys are produced by either of two processes—piercing and extrusion, or welding skelp formed into cylindrical shape. The seamless pipe or tube produced through the extrusion process is the most common commercial form of copper and copper alloy tubular products.

Hot Piercing Process. In the Mannesmann piercing process, a heated copper billet is first pierced, then rolled over a mandrel which determines the inside diameter of the pipe. Following the piercing operation, the pierced shell is drawn through a die and over a plug to obtain the finished outside and inside diameters.

Extrusion Process. In the extrusion process, the heated copper or copper alloy billets are formed into shells by heavy hydraulic presses. The hollowed-out billet is then extruded through a die and over a mandrel to form the outside and inside diameters of the pipe.

Cold-Drawing Process. The cold-drawing process uses mother pipe which is placed on a draw bench which pulls a cold tube through one or a multiplicity of dies and over a mandrel to reduce the pipe gradually to its finished dimensions.

Other Processes. Other processes of significance are the cup-and-draw process for large-diameter pipe and the tube-rolling process which reduces copper tubing by means of cold-working over a mandrel with oscillating tapered dies.

Nickel and Nickel-Alloy Pipe and Tube

Nickel and nickel-alloy pipe and tube, because of their high strength and generally good resistance to oxidation and corrosion, are used in the chemical industry and in steam-generation equipment for nuclear power-generation plants. Applications of nickel are found in tubes and pipe of pure nickel and binary and tertiary alloys of nickel, such as Ni-Cu (Monel 400 and Monel K-500), Ni-Mo and Ni-Si (Hastelloy B), Ni-Cr-Fe (Inconel 600 and Inconel 800), and Ni-Cr-Mo (Hastelloy C276 and Inconel 625) alloys. The alloys are used in applications requiring corrosion resistance to water, acids, alkalis, salts, fluorides, chlorides, and hydrogen chloride. The alloy must be carefully selected to provide for resistance to the specific corrosion media found in the environment.

Nickel and nickel-alloy pipe and tube are produced by the Ugine-Sejournet extrusion process, in which a shell is formed by hydraulic piercing of a billet by a ram and subsequent extrusion. Alternately, the billet may be initially pierced by means of drilling.

Titanium and Titanium-Alloy Tube and Pipe

Titanium and its alloys have provided the engineering designer with an important alternative to aluminum. They are lightweight and have high strength at moderately elevated temperatures, good toughness, and excellent corrosion resistance. Their applications have been found in a wide range of industries, including aerospace, heat-exchange equipment, chemical plants, and power-generation facilities.

There is a wide range of alloying systems to which titanium may be produced. The alloying elements possibly include aluminum, molybdenum, nickel, tin, manganese,

chromium, and vanadium. UNS numbers are used to identify the many available alloys and forms of titanium.

Titanium and alloys of titanium pipe and tube are produced from a melt of raw titanium ''sponge'' and alloying metals in a vacuum electric arc furnace. An ingot is obtained which is reduced to a billet. The billet provides the stock for the extrusion process, from which the tube or pipe is formed. The process consists of initially piercing the billet, then passing a heated shell through a die and over a mandrel.

COMMERCIAL PIPE AND TUBE SIZES

The standard pipe sizes and other pipe properties are given in App. E2 and E2M, and the standard tube sizes and other tube properties are given in App. E3 and E3M.

TUBULAR PRODUCT CLASSIFICATION

Pipe and tubing are considered to be separate products, although geometrically they are quite similar. ''Tubular products'' infers cylindrical products which are hollow, and the classification of ''pipe'' or ''tube'' is determined by the end use.

Piping Classification

Tubular products called pipe include standard pipe, conduit pipe, piling pipe, transmission (line) pipe, water-main pipe, oil country tubular goods (pipe), water-well pipe, and pressure pipe. Standard pipe, available in ERW or seamless, is produced in three weight (wall-thickness) classifications: standard, extra strong, and double extra strong (either seamless or welded). ASTM and the American Petroleum Institute (API) provide specifications for the many categories of pipe according to the end use. Other classifications within the end use categorization refer to the method of manufacture of the pipe or tube, such as seamless, cast, and electric resistance welded. Pipe and tube designations may also indicate the method of final finishing, such as hot finished and cold finished.

Tubing Classification

Pressure tubes are differentiated from pressure pipe in that they are used in externally fired applications while carrying pressurized fluid inside the tube.

Structural tubing is used for general structural purposes related to the construction industry. ASTM provides specifications for this type of tubing.

Mechanical tubing is produced to meet particular dimensional, chemical, and mechanical property and finish specifications which are a function of the end use, such as machinery and automotive parts. This category of tubing is available in welded (ERW) and seamless form.

SPECIALTY TUBULAR PRODUCTS

There are many specialty tubular products designed for special applications requiring unique manufacturing methods for production. Examples are the rifled boiler tube, the finned heat-exchanger tube, the duplex tube, and the double-wall tube.
FIGURE A5.10   Single rifled boiler tube.

The rifled boiler tube (Fig. A5.10) is used to provide an improved heat transfer surface on the inner surface of a boiler tube. The rifling twist, similar to that of a rifle, is produced by specially shaped mandrels over which the tube is drawn.

The finned heat exchanger (Fig. A5.11) tube provides improvement in thermal efficiency by providing an extended surface from the base tube surface. The extended surface is produced by turning the tube through special sets of dies which raise fins from part of the base tube material. These fins can be coarse or fine depending on the equipment developed for producing fins.

Duplex or composite tubes have been developed to provide a different material on the inside and outside of the tube to meet the requirements of a different environment on either side of the tube. One method of producing a composite tube is by providing a bimetal mother tube before the extrusion or drawing process. Careful development of this process will yield a composite tube with an excellent bond between the two materials.
FIGURE A5.11   Finned heat-exchanger tube.
FIGURE A5.12   Double-wall leak-detecting tube.

Double-wall tubes (Fig. A5.12) are used in applications requiring leak detection to avoid a catastrophic mixture of the fluids on either side of the tube. An inert detecting gas can be placed in the annulus between the two tubes to sense very small amounts of leakage from either tube so as to allow careful shutdown of the system. This tube is manufactured by inserting one tube inside the other, then drawing the combined tube through dies or over mandrels which provide a calibrated prestress between the two tubes. This type of tube was developed for application to a fast breeder reactor sodium-water steam generator.

ENGINEERING SELECTION OF PIPE MANUFACTURING METHODS

The selection of the appropriate pipe manufacturing method by the design engineering specification deserves consideration. For many applications, the codes and standards specified in the procurement contract provide for little room to select an optimal manufacturing method. The safest procedure is to obtain the price and schedule from suppliers before firming the piping specifications. At times the selection of the pipe with the best manufacturing process might be tempered by project cost or delivery considerations. In such cases, much is required of the engineer to consider whether lesser quality will be able to meet the desired reliability standard. It therefore is essential that the engineer is aware of the alternates and their operating history of success and failure before an appropriate alternative decision can be accepted. It must also be recognized that choices based on economic considerations alone may prove to be the more costly in the face of the downtime costs of failure.

CHAPTER A6
FABRICATION AND INSTALLATION OF PIPING SYSTEMS

Edward F. Gerwin, P.E.
ASME Fellow

INTRODUCTION

Background

The term *fabrication* applies to the cutting, bending, forming, and welding of individual pipe components to each other and their subsequent heat treatment and nondestructive examination (NDE) to form a unit (piping subassembly) for installation.

The term *installation* refers to the physical placement of piping subassemblics, valves, and other specialty items in their required final location relative to pumps, heat exchangers, turbines, boilers, and other equipment; assembly thereto by welding or mechanical methods; final NDE; heat treatment; leak testing; and cleaning and flushing of the completed installation.

Depending on the economics of the particular situation, fabrication may be accomplished in a commercial pipe fabrication shop, or a site fabrication shop, where portions of the piping system are fabricated into subassemblies or modules for transfer to the location of the final installation.

Commercial pipe shops have specialized equipment for bending and heat treatment which is not normally available at installation sites. They also have certain types of automatic welding equipment which permits welding to be performed more efficiently and economically than in field locations where fixed position, manual arc welding is most often employed.

As a general rule piping NPS 2½ (DN 65) and larger for nuclear and fossil power plants, chemical plants, refineries, industrial plants, resource recovery, and cogeneration units are most often shop fabricated. Piping NPS 2 (DN 50) and smaller is often shop fabricated where special heat treatment or cleaning practices may be required; otherwise it is field fabricated. Pipelines and other systems involving long runs of essentially straight pipe sections welded together are usually field assembled.

In recent years, the infusion of new bending technologies, new welding processes,

new alloys, fracture toughness limitations, and mandatory quality assurance (QA) programs have made piping fabrication and installation much more complex than in the past. Greater emphasis is being placed on written procedures for QA and quality control (QC) programs, special processes, and qualification and certification of procedures and personnel.

Improper selection of fabrication or installation practices can result in a system which will not function properly or will fail before its expected life span. Accordingly, fabrication and installation contractors must work closely with the designer and be aware of the mandatory requirements of the applicable codes, the unique requirements and limitations of the materials, and those of the fabrication and installation techniques being applied.

Codes and Standards Considerations

A great many codes and standards apply to piping. These are discussed in detail in Chap. A4.

It is incumbent on the fabricator and/or installer to be familiar with the details of these codes and standards since some codes have the force of law. As an example, the ASME B31.1 Power Piping Code[1] is referenced by ASME Section I Power Boilers[2] for piping classed as Boiler External Piping. The latter, which is law in most states and Canadian provinces, contains rules for code stamping, data reports, and third-party inspection. Piping under ASME Section III[3] also has legal standing. Most other piping codes are used for contractual agreements.

Most codes reference ASME Section V[4] for nondestructive examination methodology and ASME Section IX[5] for welding requirements.

Each of the codes covers a different piping application, and each has evolved in a different way over the years. For specific practices, some have mandatory requirements, while others only have recommendations. Heat treatment requirements may vary from one to another. The manner in which the code-writing bodies have perceived the hazardous nature of different applications has led to differing NDE requirements.

Generally, the codes are reasonably similar, but the owner, designer, fabricator, and installer must meet the specifics of the applicable code to ensure a satisfactory installation. It is essential that the designer be very familiar with the code being used and that purchasing specifications for material, fabrication, and installation be very specific. Reference to the code alone is not sufficient. In the design, a particular allowable stress for a specific material, grade, type, product form, and/ or heat-treated condition was selected. The specifications issued for material purchase and fabrication must reflect these specifies to assure that the proper materials and fabrication practices are used.

As an example: Type 304 stainless steel has a specified carbon content of 0.08 percent maximum. There is no specified minimum. Footnotes in the B31.1 Code Allowable Stress Tables for Type 304 indicate that for use over 1000°F (538°C), the allowable stresses apply only when the carbon content is 0.04 percent or higher. It is essential that this requirement be put in the purchasing specification if the design temperature exceeds 1000°F (538°C).

Similarly, in the B31.1 Code, low chrome alloy electric fusion welded pipe has differing allowable stresses depending upon whether the plate from which it was made was annealed or normalized and tempered. If this material is to be heated above the lower critical temperature during fabrication by hot bending or forming, the designer should specify a postbending heat treatment appropriate for the allowable stress level used in the design.

It is also incumbent upon the fabricator and/or installer to be very familiar with the applicable code. Each project should be reviewed in detail. "Standard shop practices" may not always produce the desired result. Communication between the designer, fabricator, and installer is essential. All should be familiar with the various standards used in piping design. Most piping systems are composed of items which conform to some dimensional standards such as ASME B36.10M[6] and ASME B36.19M for pipe, B16.5[7] for flanges, etc. Other dimensional standards are issued by the Manufacturers Standardization Society (MSS)[8] and the American Petroleum Institute (API).[9]

The Pipe Fabrication Institute (PFI)[10] publishes a series of Engineering Standards which outline suggested practices for various fabrication processes. These standards give excellent guidance for many aspects of piping fabrication not covered by the codes.

The American Welding Society (AWS)[11] publishes a number of recommended practices for welding of pipe in various materials.

Materials Considerations

Piping systems are fabricated from a great variety of metals and nonmetals, material selection being a function of the environment and service conditions. Materials must conform to the standards and specifications outlined in the governing code. Some codes such as ASME Section III impose additional requirements on materials beyond those in the material specifications. All fabrication and installation practices applied to these materials must be conducted so as to assure that the final installation exhibits all of the properties implicit in the design. For example, hot bending of certain austenitic stainless steels in the sensitization range will reduce their corrosion resistance if they are not subsequently heat-treated. Accordingly, a heat treatment to restore these properties should be specified.

Consideration must also be given to the various types of piping products, their tolerances, alloys, heat-treated conditions, weldability, and formability. Pipe is made by a variety of processes and depending on the method of manufacture can have differing tolerances.

Most product forms also come in a variety of alloys, and the choice of a fabrication process may be governed by the alloy. ASME Section IX has developed a system of P Numbers and Group Numbers. This system groups material specifications by chemical composition and/or physical properties. Those with like compositions and properties are grouped together to minimize the number of welding procedure qualifications required. This method of grouping can also be applied to other fabrication processes as well.

FABRICATION

Drawings

Installation Drawings. Current industry practice is for the designer to prepare plans and sections or isometric drawings of the required piping system. These, together with line specifications, outline all the requirements needed for the fabrication and installation. Usually the weld bevel requirements for field welds are specified to assure compatibility between all the system components to be field welded.

Frequently the shop welding bevels are left to the discretion of the fabricator, provided, of course, the required weld quality is attainable.

Location and numbers of field welds are an economic consideration of available pipe lengths, shipping or heat-treating limitations, and field installation limitations.

Shop Details.   A piping system prefabricated at a commercial pipe fabrication shop is usually divided into subassemblies or spools.

The manner in which a system is divided depends on many factors: available lengths of straight pipe, dimensional and weight limitations for shipping and heat treatment, field welding clearance requirements, and sometimes scheduling needs.

Bending, forging, special heat treatment, cleaning, and as much welding as possible are normally performed in the shop. Every attempt is made to minimize the number of field welds, but this must be balanced economically against the added costs of transportation and greater field rigging problems because of larger, heavier, more complex assemblies. Where the site conditions are adverse to normal field erection practices, much of the plant can be fabricated in modules for minimal onsite installation work. Once the number and locations of field welds have been decided, the fabricator will prepare detailed drawings of each subassembly.

Each subassembly drawing will show the required configuration; all necessary dimensions required for fabrication; reference to auxiliary drawings or sketches; size, wall thickness, length, alloy, and identification of the materials required; code and classification; reference to special forming, welding, heat treatment, NDE, and cleaning requirements; need for third-party inspection; weight and piece identification number. See Fig. A6.1.

Tolerances.   In order to assure installation of a system within a reasonable degree of accuracy, all the components involved must be fabricated to some set of tolerances on those dimensions which affect the system length. Tolerances on valve dimensions are given in B16.34,[12] those of welding fittings in B16.9,[13] and those for flanges and flanged fittings in B16.5, B16.1,[14] etc. The assembly of these components will result in "tolerance stack-up," which could have a significant impact on the overall dimensions, particularly in a closely coupled system.

Piping subassembly tolerances normally conform to PFI-ES-3 "Fabricating Tolerances."[15] Usually the terminal dimensions are held to ±⅛ in, but can be held more closely upon agreement with the fabricator.

In order to assure that tolerance stack-up is held to a minimum, the manner in which shop details are dimensioned should be carefully studied. As an example, assemblies with multiple nozzles can result in large deviations if these are dimensioned center to center. A better way is to select a base point and dimension all nozzles from this location. This assures that all nozzles are ±⅛ in (3.0 mm) from the base point. See Fig. A6.2.

For angle bends, terminal dimensions and often a chord dimension are required, since a small variation in angle with long ends can result in serious misalignment. See Fig. A6.3.

Sometimes assemblies which have been fabricated within tolerance may not fit in the field because of tolerance stack-ups on equipment to which they are attached. This will be addressed in the section, "Installation."

Procedures and Travelers.   The need to assure better control of fabrication processes has led the use of written procedures for most operations. Fabricators will have a library of written procedures controlling cutting, welding, bending, heat treatment, nondestructive examination, and testing. Welding procedures in most

FIGURE A6.1 Shop detail. (*Pullman Power Products Corporation*)
FIGURE A6.2　Dimensioning.

codes are qualified under ASME Section IX, which requires written Welding Procedure Specifications (WPSs) backed up by Procedure Qualification Records (PQRs). Similarly ASME Section V requires NDE to be performed to written procedures.

Frequently, piping fabricators use a system of travelers to control flow through the shop. This practice is well-suited to fabrication of piping subassemblies under QA or QC programs, where record keeping is required. It also affords the purchaser and the third-party inspector opportunities for establishing "hold points" where they may wish to witness certain operations or review certain records.

Fabrication Practices

Cutting and Beveling.　The methods of cutting plate or pipe to length can be classed as mechanical or thermal.

Mechanical methods involve the use of saws, abrasive discs, lathes, and pipe-cutting machines or tools. See Fig. A6.4.

Thermal methods are oxyfuel gas cutting or electric arc cutting. Oxyfuel gas cutting is a process wherein severing of the metal is effected by the chemical reaction of the base metal with oxygen at an elevated temperature. In the cutting torch, a fuel such as acetylene, propane, or natural gas is used to preheat the base metal to cutting temperature. A high-velocity stream of oxygen is then directed at the heated area resulting in an exothermic reaction and severing of the material. Oxyfuel gas cutting is widely used for cutting carbon steels and low alloys. It does, however, lose its effectiveness with increasing alloy content.

For higher alloy materials, some form of arc cutting is required. Plasma arc cutting is the process most frequently employed. It involves an extremely high temperature (30,000 to 50,000°K), a constricted arc, and a high-velocity gas. The torch generates an arc which is forced to pass through a small-diameter orifice and concentrate its energy on a small area to melt the metal. At the same time a gas such as argon, hydrogen, or a nitrogen-hydrogen mixture is also introduced at the orifice where it expands and is accelerated through the orifice. The melted metal is removed by the jetlike action of the gas stream.

FIGURE A6.3 Dimensioning a bend. (*Pullman Power Products Corporation*)
FIGURE A6.4   Pipe-cutting machine. (*Pullman Power Products Corporation*)

Because oxyfuel gas and arc cutting involve the application of heat, preheating may be advisable in some cases.

A very detailed description of oxyfuel gas and arc cutting is presented in *The Welding Handbook.*[16]

Weld end bevels can also be prepared by the mechanical or thermal methods just described. Both mechanical and thermal methods are used to apply the V bevel, which is used in the vast majority of piping applications. For compound and U bevels or those which may involve a counterboring requirement, horizontal boring mills are most appropriate. Various factors to be considered in selecting a weld end bevel are discussed in the section, ''Welding Joint Design.''

Forming.   The term *forming* as it relates to piping fabrication encompasses bending, extruding, swaging, lapping, and expanding. All of these operations entail the use of equipment normally only available in pipe fabrication shops. Although the availability of welding fittings in the form of elbows, tees, reducers, and lapped-joint stub ends may reduce the need for certain of these operations, economics may dictate their use, especially where special pipe sizes are involved.

Bending
Economics.   The use of bends versus welding fittings for changes in direction should be carefully evaluated from an economic viewpoint. Bends whose radii range from 3 to 5 times the nominal pipe diameter will offer the least pressure drop while still affording adequate flexibility to the system. Since each bend eliminates a welding fitting and at least one weld with its attendant examination, bending is very often the economic choice. In the case of special pipe sizes which are frequently used for main steam, reheat, and feedwater lines in large central power generating units, bending may be the only option available.

Limitations. The metal being bent should preferably exhibit good ductility and a low rate of strain hardening. Most metals used in piping systems fulfill these requirements. A successful bend is also a function of its diameter, thickness, and bending radius. As the diameter-to-thickness ratio increases and the bending radius decreases, there is greater probability of flattening and buckling. Each bending process has differing capabilities, so the selection of a bending process rests on the availability of equipment and/or practices capable of handling the material, diameter, thickness, and bending radius involved.

Accept and Reject Criteria. The codes have certain requirements for the acceptability of finished bends:

1. *Thinning:* In every bending operation the outer portion of the bend (extrados) stretches and the inner portion (intrados) compresses. This results in a thinning of the extrados and a thickening of the intrados. Because of uncertainties introduced by the pipe-manufacturing method, by the pipe tolerances, and by those introduced by the pipe-bending operation itself, it is not possible to exactly predetermine the degree of thinning. However, it can be approximated by multiplying the thickness before bending by the ratio:

$$\frac{R}{R + r} \tag{A6.1}$$

where r = the radius of the pipe (½ the outside diameter)
R = the radius of the bend

The codes require that the wall thickness at the extrados after bending be at least equal to the minimum wall thickness required for straight pipe. Accordingly, the fabricator must assure that the wall thickness ordered has sufficient margin for this effect.

Although the codes do not comment on the resulting increased thickness of the intrados, this thickness does serve to offset a portion of the increased stresses caused by internal pressure which are found at this location. (See *Theory and Design of Modern Pressure Vessels.*[17])

2. *Ovality:* A second acceptance criteria is ovality. During the bending operation, the cross section of the bend arc frequently assumes an oval shape whose major axis is perpendicular to the plane of the bend. See Fig. A6.5. The degree of ovality is determined by the difference between the major and minor axes divided by the nominal diameter of the pipe.

$$\text{Ovality} = \frac{D_{max} - D_{min}}{D_{nom}} \times 100$$

FIGURE A6.5 Bend ovality.

Where the bend is subject to internal pressure, the pressure tries to reround the cross section by creating secondary stresses in the hoop direction. Some codes consider an ovality of 8 percent acceptable in this case. Where the bend is subject to external pressure, the pressure tries to
collapse the cross section. The ASME B31.3 Code[18] recommends a 3 percent maximum ovality when the bend is subject to external pressure.

3. *Buckling:* Bending of pipe with large diameter-to-thickness ratios often results in buckling rather than thickening of the intrados, even where internal mandrels or other devices are employed to minimize it. The codes do not address this subject. It is, however, often the subject of "good workmanship" debates. The PFI gives a criterion which has been generally accepted. This appears in PFI ES-24.[19] An acceptable buckle is one where the ratio of the distance between two crests divided by the depth of the average crest to valley is equal to or greater than 12. See Fig. A6.6
Depth of average crest to valley is the sum of the outside diameters of the two adjoining crests divided by two, minus the outside diameter of the valley.

$$\text{Depth} = \frac{(OD)_1 + (OD)_3}{2} - (OD)_2$$

Ratio of the distance between crests to depth must be equal to or greater than 12.

$$\frac{A}{\text{Depth}} \geq \frac{12}{1}$$

FIGURE A6.6 Suggested pipe buckling tolerance. (*Pipe Fabrication Institute PFI ES-24*)

Bending Methods.   Pipe is bent by a variety of methods, using bending tables or bending machines, with and without the application of heat. The selection of one method over another is a function of economics, materials properties, pipe size, bending radius, and equipment availability. The arc length of the bend may be heated in order to reduce the yield strength of the material. Higher bending temperatures result in lowering the yield strength and reduction of the bending energy required.

Cold bending normally infers bending at ambient temperature, while hot bending infers the application of heat. However, definitions given in B31.1 and ASME Section III create an exception to this for *ferritic* materials. These codes define cold bending of *ferritic* steels as any operation where the bending is performed at a temperature 100°F (55°C) below the lower critical or lower. Ferritic materials undergo a phase change on heating and cooling. On heating, this change starts at a temperature called the *lower critical*. (See *Heat Treatment—Ferritic Steels*).

Ferrous Pipe and Tubes

1. *Cold bending:* Where sufficient quantities of repetitive bends are required, ferrous pipes and tubes up to NPS 10 or 12 (DN 250 or 300) with wall thickness of ½ in (12.7 mm) or less are most often bent at ambient temperature using some type of bending machine.

There are a great variety of cold bending machines available, with degrees of sophistication varying from simple manually operated single-plane bending devices to numerically controlled hydraulically operated machines capable of multiplane bends.

In ram-type bending, two pressure dies which are free to rotate are mounted in a fixed position on the machine frame. The pipe to be bent is positioned against these dies. A ram then presses a forming die against the pipe and the pressure dies wipe the pipe around the forming die. See Fig. A6.7. Ram bending is usually applied to heavier wall thicknesses.
FIGURE A6.7   Ram bender.

In compression bending the pipe is clamped to a stationary bending die and wiped around it by a follower. As in all bends, the extrados thins and the intrados thickens or compresses. The degree of compression is greater than the thinning in this method. Compression bending is usually limited to heavier walls and larger bending radii. See Fig. A6.8 to compare compression and draw bending.

In rotary draw bending the pipe is clamped to a rotating bending form and drawn past a pressure die which is usually fixed. See Fig. A6.9. The degree of thinning of the extrados is greater than the compression of the intrados. This method permits bending of thinner wall pipe and tubes at smaller bending radii. To accommodate lighter walls and tighter radii it is often advisable to provide internal support to minimize flattening or buckling. Usually this takes the form of an internal mandrel. As the diameter-to-thickness ratio increases and the bending radius decreases, mandrels using follower balls are employed. See Fig. A6.10.

Roll bending is often used for coiling. One of its great advantages is that the bending radius is not dependent on a fixed radius die, and consequently there is great flexibility in choosing a bending radius. In roll bending three power-driven rolls, usually in pyramid form, are used. The pipe to be bent is placed between the
FIGURE A6.8   Comparison of the essential elements of draw bending and compression bending. (*Metals Handbook*[20])

two lower rolls and the upper roll. Bending is accomplished by adjusting the rolls relative to each other as necessary to attain the required diameter. See Fig. A6.11.

Pipe can also be cold bent on a bending table in the manner described for hot bending below, except that for ferritic materials the bending temperature is kept at least 100°F (56°C) below the lower critical.

A postbending heat treatment for cold bends may be advisable for some alloys, degree of deformation, certain service conditions, or when mandated by code.

2. *Hot bending:* In those cases where suitable cold bending equipment is unavail-

FIGURE A6.9   Tooling for a draw bend application. (*Teledyne Pines*)
FIGURE A6.10   Cold bending ranges. (*Pipe Fabrication Institute PFI ES-24*)

able, hot bending may be employed. For hot bending of ferrous materials the pipe to be bent is usually heated to temperatures in the range of 1750 to 2050°F (954 to 1121°C). For austenitic materials these temperatures may introduce sensitization, and for ferritic materials they will exceed the critical temperature where metallurgical phase changes occur. See the section "Heat Treatment" for a discussion of these subjects.

FIGURE A6.11   Operating essentials in one method of three-roll bending. (*Metals Handbook*[20])

The traditional method of hot bending is performed on a bending table. Depending on the diameter-to-thickness ratio, the pipe to be bent may be packed with sand to provide more rigidity and thus reduce the tendency for buckling. A rule of thumb is to sand fill if the diameter-to-thickness ratio is 10 to 1 or greater for 5-diameter bends. However, when the diameter-to-thickness ratio approaches 30 to 1, sand begins to lose its effectiveness, and buckles will appear. As the diameter of the pipe increases, the probability of buckling will increase since the sand fill will not expand in proportion to the pipe, leaving a void between the pipe and packing. It becomes pronounced around NPS 24 (DN 600).

After the pipe has been packed with sand, it is placed in a specially designed bending furnace. The furnace is usually gas fired through ports along its length, placed to direct the flames around the pipe and avoid direct flame impingement. The furnace is controlled by thermocouples or pyrometers to assure that the required bending temperature is attained but not exceeded. Depending on the length of arc to be bent, it may be necessary to make the bend in more than one heat.

After the segment to be bent has attained the required temperature throughout its thickness, the pipe is placed on the bending table. One end is restrained by holding pins and the other is pulled around by block and tackle powered by a winch. As bending progresses, the arc is checked against a bending template. Reposi-

FIGURE A6.12   Hot bending on a table. (*Pullman Power Products Corporation*)

tioning of the holding pins may be necessary. See Fig. A6.12. For ferritic steels, it is recommended that the bending be completed above the upper critical temperature of the metal, usually about 1600 to 1725°F (870 to 940°C).

There are certain limits as to the combination of diameters, thicknesses, and bending radii which can be accommodated by the hot table bend method. PFI Standard ES-24 contains a chart of suggested limits for bend radius versus diameter to wall thickness ratios. See Fig. A6.13.

To fulfill the need for a bending process beyond the capabilities of hot table bending, the M. W. Kellogg Co. developed the increment bending process, which was further refined by Pullman Power Products Corp. In this process, one end of the pipe is fixed in an anchor box while a clamp connected to a hydraulic piston is attached to the other. A gas torch ring burner assembly is positioned at one end of the arc to be bent. The burner assembly is sized to heat a length of arc (increment) about 1 to 2 times the pipe wall thickness. The increment length is selected to be less than the buckling wave length of the pipe. The increment is then heated to bending temperature. Optical pyrometers are used to control the heating to assure that proper temperature is attained but not exceeded. At bending temperature the hydraulic piston pulls the clamped end a fixed amount to bend the heated increment. The increment is then water cooled, the torch ring moved to the next increment, and the process is repeated. As many as 350 increments may be required for a typical NPS 24 × ⅜-in (DN 600 × 9.5 mm), 90°, 5-diameter bend.

The process can produce bends in sizes from NPS 8 to 48 (DN 200 to 1200) with bending radii of 3 pipe diameters and larger in ferrous and nickel-alloy materials. Because the heat is applied from one side only, thicknesses are limited to 2 in (50 mm) and less.

In more recent years a more sophisticated piece of bending equipment has entered the pipe-bending field, notably the Induction Bender. In this process the increment to be bent is heated by an induction coil, and the bending operation is continuous. The pipe to be bent is inserted in the machine, and the start of the arc
FIGURE A6.13   Limits for hot bending on a table. *(Pipe Fabrication Institute PFI ES-24)*

is positioned under the induction coil. The portion of the pipe upstream of the coil is clamped to a rotating arm fixed to the required bend radius. The downstream portion of the pipe is pushed hydraulically through the coil, where it attains bending temperature. Since it is clamped to the rotating arm, a bending moment is imposed on the pipe and it bends as it moves through the coil. As soon as it has been bent, the heated section is cooled to restore its prior rigidity. The permissible rate of cooling is a function of material composition. Low-carbon steels and some low Cr molys may be water quenched. It is recommended that the 9Cr-1Mo-V material be cooled in still air.

The Induction Bender is manufactured in several sizes depending on the expected combinations of pipe size and bending radius. These range from NPS 3½ to 64 (DN 80 to 1600) and from 8 to 400 in (DN 200 to 10,000 mm) in radius. Since induction is used as the heating method, wall thicknesses as heavy as 4 in (100 mm) can be bent. (See Fig. A6.14a and 6.14b.)

3. *Nonferrous pipe and tubes:* Although most of the equipment used to bend ferrous materials is also used for bending nonferrous materials, the details of bending do differ from those for ferrous materials and also vary between the several nonferrous materials themselves. Accordingly, it is wise to obtain specific procedural information from the materials' producers or from other reliable sources such as the latest edition of *The Metals Handbook*.[20] Certain nonferrous materials can be hot bent.

Aluminum and aluminum alloys can be bent cold using the same types of bending equipment used for ferrous materials. Alloys in the annealed condition are easiest to bend, but care is required in selecting tooling because of the low tensile strength and high ductility of these materials. Alloys with higher tempers and heat-treatable alloys require larger bending radii for satisfactory results. It is seldom necessary to

heat aluminum for bending: however, non-heat-treated materials can be heated to 375°F (190°C) with minimal loss of properties, Heat-treated alloys require specific time-temperature control. More detailed information is available from the manufacturers of aluminum products.

Copper and copper alloy pipe and tube can be readily bent to relatively small radii. Although copper can be bent hot, the vast majority is done cold. For draw bending an internal mandrel is required and for other methods internal support is recommended. For very tight radii a snug-fitting forming block and shoe which practically surround the pipe at the point of bending are needed to preclude buckling.

Hot bending of copper and copper alloys particularly in larger diameters and walls is common. Pipes are usually sand-filled, and contoured bending dies are recommended. See Table A6.1. More information can be obtained from the Copper Development Association.[21]

Nickel and nickel-alloy pipe can be cold bent with the same type of bending equipment used for ferrous materials. Use of material in the annealed condition is preferred. For bends with radii 6 diameters and less, filler material or internal mandrels are required. Draw bending with internal mandrels is the preferred method for close-radius bending. Galling can become a problem, and chromium-plated or hard bronze-alloy mandrels should be used.

Nickel and nickel alloys can be hot bent using the same practices as for ferrous steels. Sand filling is appropriate. Care should be taken to assure that the sand and heating fuel are low in sulfur and that any marking paints or crayons or lubricants have been removed. These materials can be bent over a wide temperature range. See Table A6.2. The best bending is usually between 1850 and 2100°F (1010 to 1149°C). Other nickel alloys may exhibit carbide precipitation and should not be worked in the sensitization range. Postbending heat treatment may be required. For more information contact nickel product manufacturers such as Huntington Alloys.[22]

Titanium can be bent using draw bending equipment. However, those parts of the equipment which will wipe against the inner and outer surfaces of the pipe should be of aluminum bronze to minimize galling. For better formability, the pipe, the pressure die, and the mandrel should be heated to a temperature between 350 and 400°F (177 and 204°C). Unalloyed titanium can be hot worked in the temperature range of 1000 to 1400°F (538 to 760°C). Titanium alloy grade 12 requires a temperature range of 1400 to 1450°F (760 to 788°C). Heat treatment of titanium is recommended after forming. This is usually a furnace treatment at 1000 to 1100°F (538 to 593°C) for a minimum of ½ h for the unalloyed grades and 1 h for the alloy

TABLE A6.2   Temperature Range for Hot Bending of Nickel and Nickel Alloy Pipe and Tube

Material	Spec. no.	Alloy	Temperature range (°F)
Nickel	SB-161	N02200	1200–2300
Low carbon nickel	SB-161	N02201	1200–2300
Nickel-copper	SB-165	N04400	1700–2150
Ni-Cr-Fe	SB-167, SB-517	N06600, N06690	1850–2300
Ni-Fe-Cr	SB-407, SB-514	N08800, N08810	1850–2200

(grade 12). Prolonged exposure to temperatures in excess of 1100°F (593°C) will result in heavy scaling and require some type of descaling treatment.

Other Forming Operations.   Some additional forming operations which can be performed in a pipe shop are extrusion, swaging, and lapping. Extrusions involve forming outlets in pipe by pulling or pushing a hemispherical or conical die from the inside of the pipe through an opening in the wall. The work may be done hot or cold depending on the characteristics of the material. Ferritic steels, austenitic steels, and nickel alloys are usually formed hot; aluminum and copper are usually formed cold. In order to assure that the outlet will have sufficient reinforcement, it is necessary to increase the wall thickness of the header as a function of the outlet size desired. An increase of 30 percent may be needed for large outlet-to-header ratios.

Swaging involves the size reduction of pipe ends by forging, pressing, or rolling operations. The operation is usually used to produce reductions of one to two pipe sizes. Ferritic steels, austenitic steels, and nickel alloys are usually formed hot. Aluminum and copper are formed cold.

In lapped joints, a loose flange is slipped over the end of the pipe which is then heated to forging temperature, upset, and flared at right angles to the pipe axis. After heat treatment and cooling, the lapped section is machined on the face to attain a good gasket surface and on the back for good contact with the flange. The finished thickness of the lapped flange should be equal to or exceed the thickness of the pipe.

Layout, Assembly, and Preparation for Welding.   In fabrication shops, piping subassemblies are often assembled on layout tables. A projection of the subassembly is laid out on the table in chalk. This establishes the baseline for locating the components and terminal dimensions of the subassembly, and the components are assembled relative to the layout. Prior to fit-up, it is essential that all weld surfaces be properly cleaned of rust, scale, grease, paint, and other foreign substances which might contaminate the weld. If moisture is present, the weld joint should be preheated. For alloy steels the heat-affected zone (HAZ) which results from thermal cutting should be removed by grinding or machining.

Depending on the configuration of the subassembly and root opening required by the welding procedure, some allowance may be required for weld shrinkage in the longitudinal direction. Actual shrinkage is difficult to predict and can vary considerably because of the many variables involved. For most open butt and backing ring joints, one-half the root opening is a reasonable allowance. For joints

with other root configurations it may be as little as $\frac{1}{16}$ in (2.0 mm) for the lighter walls, increasing to as much as $\frac{5}{32}$ in (8 mm) for walls 4 to 5 in (100 to 127 mm) thick.

Each weld joint should be carefully aligned within required tolerances using alignment fixtures, spacers, or jigs if necessary. Poor alignment may result in a poor weld. Once alignment is attained, the joint is usually tack-welded to maintain the alignment. The process used for tacking is usually that being used for the root-pass weld. Numbers and size of tacks should be kept to a minimum, but if the subassembly is to be moved elsewhere for weld out, their size must be sufficiently large so as not to crack during the moving operation. Temporary lugs or spacer bars may also be used for this purpose provided they are of a compatible material, the temporary welds are removed, and the surface examined after removal to assure sound metal. Tack welds made by the shielded metal are welding (SMAW) or gas metal arc welding (GMAW) processes at the root of a weld should be removed or ground smooth since they can become a source of lack of fusion. For gas tungsten arc (GTAW) root welds, tacks usually fuse the adjacent lands to each other or to the insert, and filler metal is often not used. Tack welds are then fused into the weld during the root pass without further preparation. After tacking, the recommended practice is to complete the root pass and one or more weld out passes before starting to complete the weld by other processes to avoid burning through the relatively thin root.

Welding.   Welding constitutes the bulk of the work involved in fabrication of modern piping systems, so it is essential for all involved to have a good working knowledge of this subject.

Procedure and Personnel Qualifications.   All of the ASME Boiler and Pressure Codes and most of the ASME B31 Pressure Piping Codes reference ASME Section IX for the requirements for qualifying welding procedures and welding personnel. The ASME B31.4,[23] B31.8,[24] and B31.11[25] Codes also permit qualification to API-1104,[26] published by the American Petroleum Institute. ASME B31.5[27] permits qualification to AWS D10.9.[28]

The purpose of procedure qualification is to assure that the particular combination of welding process, base metal, filler material, shielding fluxes or gases, electrical characteristics, and subsequent heat treatment is capable of producing a joint with the required chemical and physical characteristics.

The purpose of personnel qualification is to assure that the welder or welding machine operator is capable of performing the operation in accordance with a qualified procedure in the required position.

Procedure Qualification.   ASME Section IX requires the preparation of a Welding Procedure Specification (WPS), which lists the various parameters to be used during welding. When each WPS is qualified, the parameters used in the qualification are recorded in a Procedure Qualification Record (PQR).

For each type of welding process, ASME Section IX has established a series of variables. These are base metal, filler metal, position, preheat, postweld heat treatment, shielding gases, joint configuration, electrical characteristics, and technique. Base metal must not only be considered from a chemical and physical properties point of view, but in piping, the diameter and thickness of the test coupon limits the qualification to certain sizes. Differing fluxes, use of solid or gaseous backing, and single- or multipass techniques are some of the other variables which must be considered. Careful study of Section IX, AWS D10.9, or of API 1104 as may be applicable is in order.

The variables for welding are classed as essential, supplementary essential, and nonessential. The manner in which the variables are classed can vary depending

on the welding process. That is, what may be classed as an essential variable for one may be a nonessential variable for one another. For a given process, each combination of essential variables must be qualified separately. A change in any one of them requires a new qualification.

When welds must meet certain fracture toughness requirements, the supplementary essential variables become essential and the procedure must be requalified for the particular combination of essential and supplementary essential variables.

Nonessential variables do not require requalification but should be referenced in the WPS.

Personnel Qualification.   The fabricator and/or installer must qualify each welder or welding operator for the welding processes to be used during production welding. The performance qualification must be in accordance with a qualified WPS. Each performance qualification is also governed by a series of essential variables which are a function of the welding process for which the welder is being qualified.

The welder or welding operator may be qualified by mechanical tests or in some cases by radiographic examination of the test coupon. The record of each performance qualification is kept on a Welder/Welding Operator Performance Qualification (WPQ). Under ASME Section IX rules, a qualified welder who has not welded in a specific process within a specified period of time must be requalified for that process. API 1104 and AWS D10.9 have similar requalification provisions.

Welding Processes.   Currently the most commonly used welding processes for fabrication of piping are SMAW, submerged arc welding (SAW), GTAW, GMAW, and flux core arc welding (FCAW). Some special applications may involve plasma arc welding (PAW) or electron beam welding (EBW), but their application to piping is still rare. However, any welding process which can be qualified under the requirements of ASME Section IX is acceptable. Detailed descriptions of these various processes and their variations may be found in the *Welding Handbook*.[16] This section will limit discussion to their application to piping.

For shop work, the best efficiency in all welding processes is attained when the pipe axis is horizontal and the piece is rotated so that welding is always done in the flat position. This is referred to as the 1G position. Other positions are 2G (pipe vertical and fixed, weld horizontal); 5G (pipe horizontal and fixed, weld a combination of flat, vertical, and overhead); and 6G (pipe inclined at 45° and fixed). See ASME Section IX.

Shielded Metal Arc Welding.   SMAW has been the mainstay for pipe welding for many years, but it is rapidly being displaced by newer, more efficient processes. It is a process where an arc is manually struck between the work and a flux-coated electrode which is consumed in the weld. The core wire serves as the filler material, and the flux coating disintegrates to provide shielding gases for the molten metal, scavengers, and deoxidizers for the weld puddle and a slag blanket to protect the molten metal until it is sufficiently cool to prevent oxidation. It can be used in all positions, for upward or downward progression, and for root pass welding depending on the flux composition. Each weld pass is about ⅛ in thick, and before subsequent passes are made the slag must be removed and the surface prepared by removing irregularities which could entrap slag during subsequent passes.

Submerged Arc Welding.   Unlike SMAW, SAW is an automatic or semiautomatic process. For circumferential welds in pipe the welding head is fixed for flat welding and the work is rotated under the head (1G position). It is used most efficiently in groove butt welds in heavy wall materials with pipe sizes NPS 6 (DN 150) and larger. The arc is created between the work and a bare solid wire or composite electrode which is consumed during the operation. The electrode comes

in coils. Shielding is accomplished by a blanket of granular, fusible material called a *flux* which covers the arc and molten metal by forming a slag blanket to prevent oxidation of the molten metal until it has sufficiently cooled. Particular wire-flux combinations are required to assure that the deposited weld has the needed chemical and physical properties. This process has the greatest deposition rate and accordingly is the preferred process wherever possible. Because of the high heat input, care must be taken to assure that the interpass temperature is controlled to minimize sensitization in austenitic stainless steels or loss of notch toughness in ferritic steels. High heat input can also result in excessive penetration, so this process cannot be used effectively for root pass welding unless the root is deposited against a backing ring or sufficient backing is provided by two or more weld passes made by the shielded metal arc or a gas-shielded arc process.

Gas Shielded Arc Welding. The term *gas-shielded arc welding* applies to those welding processes where the arc and molten metal are shielded from oxidation by some type of inert gas rather than by a flux.

1. *Gas tungsten arc welding:* GTAW is a form of gas-shielded arc welding where the arc is generated between the work and a tungsten electrode which is not consumed. The filler metal must be added from an external source, usually as bare filler rod or preplaced consumable insert. The filler metal is melted by the heat of the arc, and shielding gases are usually argon or helium. Alloying elements are always in the filler material. GTAW is considered to be the most desirable process for making root welds of highest quality. Techniques using added filler metal or preplaced filler metal as inserts are equally effective in manual and automatic applications.

Automatic versions can be used in all positions provided sufficient clearance is available for the equipment. Automatic versions also require tighter fit-up requirements since the equipment is set to specific parameters and will not recognize variations outside of these limits, such as a welder would do in manual applications.

In automatic GTAW, the welding head orbits the weld joint on a guide track placed on the pipe adjacent to the joint to be welded. The welding head contains motors and drive wheels needed to move the head around the track, a torch to create the arc, and a spool of filler wire. Welding current, voltage, travel speed, wire feed rate, and oscillation are controlled from an external source. These parameters may be varied by the operator as the welding head traverses the weld. Oscillation and arc energy can be adjusted to permit greater dwell time and heat input into the side walls. Automatic GTAW welds are usually deposited as a series of stringer beads to minimize the effects of high interpass temperature.

2. *Gas metal arc welding:* GMAW is a type of gas-shielded welding generally used in the manual mode but adaptable to automation. The filler wire is the electrode and is furnished in coils or spools of solid wire. Is is fed automatically into the joint, melted in the arc, and deposited in the weld groove. Alloying elements arc in the wire, and shielding gas may be argon, helium, nitrogen, carbon dioxide, or combinations thereof, depending on the application.

Depending on the equipment and the heat input settings, filler metal can be transferred across the arc is several modes. In *short-circuiting transfer*, the electrode actually touches the work where it short-circuits, melts, and restarts the arc. This process has low heat input and accordingly low penetrating power. It can often result in lack of fusion. Because of the low heat input, however, it can be effectively used for open-butt root pass welding.

In *spray transfer*, the heat input parameters are sufficiently high to transfer the molten electrode across the arc as small droplets. Argon or argon-rich gases are

used for shielding, resulting in a very stable spatterfree arc. Because of the high arc energy, it is normally used in the flat (1G) position. For all-position welding, a procedure which superimposes high amplitude pulses of current on a low-level steady-state current at regular intervals is often used. This results in a discrete transfer of metal with lower heat input needed for all-position welding.

3. *Flux core arc welding:* FCAW is a variation of GMAW where a composite electrode is substituted for the solid wire. The electrode is a tubular wire containing a flux material. Depending on the application, the arc may be self-shielding, or shielding gases may be used. Because of its high deposition rate this process is rapidly being developed for shop and field welding of piping.

Base Metal. Base metal is one of the essential variables for welding qualification. Because there are so many base metals to be welded, ASME Section IX has established a system of P Numbers and Group Numbers. Each base metal is assigned to a specific P Number depending on characteristics such as composition, weldability, and mechanical properties. Each P Number is further subdivided into Group Numbers depending on fracture toughness properties. See Table A6.3. When a procedure is qualified with a base metal within a particular P Number, it is also qualified for all other base metals within that P Number. When fracture toughness is a requirement, qualification is limited to base metals within the same P Number *and* Group Number. For example: A 106 Gr. B pipe is P No. 1 Gr. No. 1, while an A 105 flange is P No. 1 Gr. No. 2. Since both are P No. 1, qualification on either qualifies both when fracture toughness is not a factor. However, should fracture toughness become a requirement, a separate qualification would be required for each to itself and to each other.

Filler Metals. Electrodes, bare wire, wire-flux combinations, and consumable inserts which form a part of the finished weld are classed as filler materials. Most are covered by AWS and ASME specifications. See ASME Section II Part C.[29]

When the filler material is part of the electric circuit, it is designated as an

TABLE A6.3 ASME P Numbers and Group Numbers for Some Typical Piping Materials

Nominal composition	P No.	Group No.
Carbon Steel—65 ksi & under	1	1
—65 ksi to 75 ksi	1	2

electrode. If it is fed externally and melted by the heat of the arc, it is designated as a rod. Coated electrodes for SMAW come in straight lengths. Bare rods for GTAW come in straight lengths or spools. Electrode wire for GMAW and SAW are in spools or coils, while composite electrodes for FCAW are in spools.

Each specification incorporates a system of identification so that the filler materials manufactured by different suppliers which have equivalent characteristics are identified by the same number.

For qualification purposes, they are classified in ASME Section IX with F Numbers and A Numbers. Changes in filler metal from one F Number or A Number to another require requalification.

One of the problems associated with coated electrodes for SMAW is the introduction of hydrogen into the arc atmosphere and finished weld, resulting in hydrogen-induced cracking. To minimize this problem, low-hydrogen-type coatings are used, but these can absorb moisture from the atmosphere. Once a sealed can of electrodes is opened, the electrodes should be stored in an oven at about 250 to 350°F (120 to 175°C) or other temperature recommended by the manufacturer. Once removed from the oven, low-hydrogen electrodes should be maintained at 175°F (80°C) minimum until consumed. Baking to remove moisture is recommended for electrodes which have been out of the oven for several hours. Refer to the manufacturers' recommendations.

A problem associated with welding of fully austenitic stainless steel is microfissuring. To combat this problem the chemical composition of the filler material is adjusted to produce a weld deposit with small amounts of ferrite. ASME III requires that filler materials used in welding austenitic stainless steels contain a minimum of 5 percent ferrite. Ferrite, however, can be a problem at cryogenic and high temperatures. For cryogenic services the weld metal may not possess the fracture toughness capabilities of the base metal, and the ferrite content should be kept as low as possible. Alternatively, fully austenitic fillers may be required, but these are more crack-sensitive. For very high temperatures ferrite in the weld may convert to a brittle phase called *sigma*. For this reason applications over about 800°F (427°C) usually require a minimum of 3 percent ferrite for weldability but not exceeding 7 percent to minimize sigma formation.

Preheat and Interpass Temperature. Ferritic materials undergo metallurgical phase changes when cooling from welding to ambient temperature. Mild steels which contain no more than 0.20 percent carbon and 1 percent manganese can be welded without preheat when the thickness is 1 in (25 mm) or less. However, as the chemical composition changes by increases of carbon, manganese, and silicon or the addition of chromium and certain other alloying elements, preheating becomes increasingly important since the higher carbon and chrome molybdenum steels can develop more crack-sensitive martensitic, matensitic-bainitic, and other mixed phase structures when cooled rapidly from welding temperatures.

There is also a potential for hydrogen from SMAW electrode coatings or from moisture on the base metal surface to be dissolved in the weld. Also as the weld cools, stresses caused by shrinkage are imposed on the parts and distortion can result; and as thickness increases, thermal shock from the heat of welding can induce cracking more readily.

Preheating prior to welding is a solution to most of these problems. Preheating slows the cooling rate of the weld joint and results in a more ductile metallurigical structure in the weld metal and HAZ. It permits dissolved hydrogen to diffuse more readily and helps to reduce shrinkage, distortion, and possible cracking caused by the resultant residual stresses. It raises the temperature of the material sufficiently high to be above the brittle fracture transition zone for most materials.

The codes vary regarding preheat requirements. Some have mandatory require-

TABLE A6.4 Typical Preheat Requirements

P No.	Temp. (°F)	Composition/thickness limits
1	175	For *both* a max. specified carbon content >0.30% *and* thickness >1 inch.
	50	For all others.
3	175	For *either* a min. specified tensile strength >60 ksi, *or* thickness >½ in.
	50	For all others.
4	250	For *either* a min. specified tensile strength >60 ksi, *or* thickness >½ in.
	50	For all others.
5A and 5B	400	For *either* a min. specified tensile strength >60 ksi, *or both* a min. specified Cr content >6.0% *and* thickness >½ in.
	300	For all others.
6	400	For all materials.
7	50	For all materials.
8	50	For all materials.
9A	250	For all materials.
9B	300	For all materials.
10I	300	With a max. interpass temperature of 450°F.

Source: ASME B31.1 1995 ed.

ments while others give suggested levels. For example, for carbon steel welding, the B31.1 Code *requires* preheating to a temperature of 175°F (80°C) when the carbon content exceeds 0.30 percent *and* the thickness of the joint exceeds 1 in. B31.3 *recommends* preheating to 175°F (80°C) when the base metal specified strength exceeds 71 ksi *or* the wall thickness is equal to or greater than 1 in (25 mm). ASME III Section *suggests* a preheat of 200°F (95°C) when the maximum carbon content is 0.30 percent or less *and* the wall thickness exceeds 1½ in for P No. 1 Gr. No. 1, or 1 in (25 mm) for P No. 1 Gr. No. 2. It also suggests a 250°F (120°C) preheat for materials with carbon in excess of 0.30 percent and wall thicknesses exceeding 1 in (25 mm). The ASME B31.4 and B31.8 Codes require preheat based on carbon equivalents. When the carbon content (by ladle analysis) exceeds 0.32 percent, or the carbon equivalent (C + ¼ Mn) exceeds 0.65 percent, preheating is required. The reader is advised to consult the specific codes for preheating requirements. See Table A6.4 for some typical preheat requirements.

It should be noted that for the 9Cr-1Mo-V (P No. 5B Gr. 2) material some manufacturers suggest a preheat of 350°F (177°C) for GTAW and 400 to 450°F (204 to 232°C) for other types of welding regardless of thickness.

While it is preferred that preheat be maintained during welding and into the postweld heat treatment cycle without cooling, this may not always be practical. The B31.1 Code permits slow cooling of the weld to room temperature provided the completed weld deposit is a minimum of ⅜ in (9.5 mm) or 25 percent of the final thickness, whichever is less. For P No. 5B and P No. 6 materials some type of intermediate stress relief is required.

For the 9Cr-1Mo-V material it is recommended that the finished weld be heated

to 500°F (260°C), held at that temperature for 2 hours, and allowed to cool slowly in still air by wrapping it with insulating material.

Too much heat during welding can also be a problem. Where notch toughness is a requirement, prolonged exposure to temperatures exceeding 600°F (316°C) can temper the base metal. Controlling the interpass temperature is required to minimize this problem. Interpass temperature control means allowing the temperature of the joint to cool below some specified level before the next pass is deposited.

Because of its martensitic structure, a maximum interpass temperature of 600°F (316°C) should be observed when welding 9Cr-1Mo-V material.

In welding of austenitic stainless steels, sensitization of the base metal HAZ will result from the heat and welding. Here the solution is to weld with as low a heat input as possible at the highest possible speed to minimize the precipitation of carbides (sensitization). A maximum interpass temperature of 300 to 350°F (149 to 177°C) is usually employed.

Weld Joint Design

Butt Welds. A butt joint is defined as one in which the members being joined are in the same plane. The circumferential butt joint is the most universally used method of joining pipe to itself, fittings, flanges, valves, and other equipment. The type of end preparation may vary depending on the particular preferences of the individual, but in general the bevel shape is governed by a compromise between a root sufficiently wide to assure a full-penetration weld but not so wide as to require a great deal of filler metal.

In the shop, the inside surface of large-diameter pipe joints is often accessible. In this case the joint is most often double-welded (welded from both sides), and a double V bevel is used. For heavier walls, machined double U bevels can be used. However, the vast majority of piping butt welds must be made from one side only. For this situation the most frequently specified shapes are the V bevel, compound bevel, and U bevel, all of which can have varying angles, lands, and tolerances. See Fig. A6.15. Recent advances in SAW narrow-gap welding as applied to piping butt welds have cut the volume of filler metal significantly in pipe walls that are 2 in (51 mm) and thicker. The 30 or 37½° (60 or 75° included angle) V bevel is most often performed integrally with the cutting operation by machine, oxyfuel gas, or arc cutting. Other bevel shapes such as the compound V, U, J bevels, or combinations thereof require machining in lathes or boring mills.

1. *Alignment:* Alignment for butt welding can often be a frustrating task since it is influenced by the material; pipe diameter, wall thickness, out-of-roundness tolerances; welding process needs; and design requirements.

When a joint can be double welded, the effects of misalignment are minimized since both inner and outer weld surfaces can be blended into the base metal, and any remaining offsets can be faired out. ASME Section III gives a table of allowable offsets due to misalignment in double-welded joints. See Table A6.5. All resulting offsets must be faired to a 3:1 taper over the finished weld.

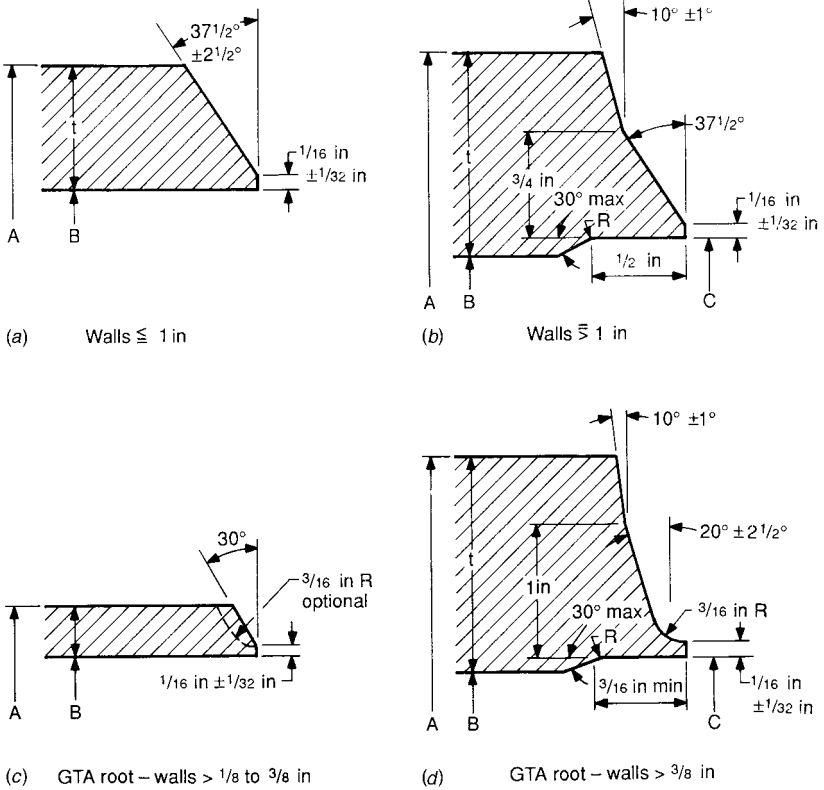
For single-welded joints alignment can be more difficult, since the inside surface is not accessible. The degree of misalignment is influenced by many factors and depending on the type of service application may or may not be significant. The various codes impose limits on inside-diameter misalignment. This is to assure that the stress intensification resulting from the misalignment is kept within a reasonable value. The B31.1 Code requires that the misalignment between ends to be joined not exceed ¹⁄₁₆ in (2.0 mm), unless the design specifically permits greater amounts. See Fig. A6.16. The B31.4 and B31.8 Codes do not require special treatment unless the difference in the nominal walls of the adjoining ends exceeds ³⁄₃₂ in (2.5 mm).


FIGURE A6.15 Typical weld end bevels. (*a*) Walls ≤ 1 in; (*b*) walls > 1 in; (*c*) GTA root walls > ⅛ to ⅜ in; (*d*) GTA root walls > ⅜ in.

ASME Section III on the other hand requires that the inside *diameters* of the adjoining sections match within ¹⁄₁₆ in (2.0 mm) to assure good alignment. Counterboring is usually required to attain this degree of alignment.

 The welding process and NDEs to be employed also bear on misalignment limits. Some welding processes can tolerate fairly large misalignments while others, notably

TABLE A6.5 Maximum Allowable Offset in Joints Welded from Both Sides

	Direction of joints	
Section thickness (in)	Longitudinal	Circumferential
Up to ½, incl.	¼*t*	¼*t*
Over ½ to ¾, incl.	⅛ in	¼*t*
Over ¾ to 1½, incl.	⅛	³⁄₁₆ in
Over 1½ to 2, incl.	⅛ in	⅛*t*
Over 2	Lesser of ¹⁄₁₆*t* or ⅜ in	Lesser of ⅛*t* or ¾ in

gas tungsten arc root pass welding with and without consumable inserts require closer tolerances. See PFI ES-21.[30] Radiographic or ultrasonic examinations of misaligned areas may show unacceptable indications if the degree of misalignment is too great.

A review of the tolerances permitted in the manufacture of various types of pipe, fittings, and forgings immediately reveals that in many situations the probable inside diameter and wall thickness variations will produce unacceptable misalignment situations. Out-of-roundness in lighter wall materials can add to the problem.

When most of the pipe comes from the same rolling and the fittings from the same manufacturing lot, variations in tolerances are minimal and the pipe and fittings can be assembled for most common applications without a great deal of adjustment. Out-of-round problems in lighter walls are handled with internal or external round-up devices.

To assure that all components will be capable of alignment in the field, it is common practice for the designer to specify that the inside diameters of all matching components be machine counterbored to some specified dimension. This practice is also desirable for shop welding of heavier wall piping subassemblies. PFI ES-21 contains a set of uniform dimensions for counterboring of seamless hot-rolled pipe ordered to A106 or A335 by NPS and schedule number. See Table A6.6.

The C dimension is determined from the following equation:

$$C = A - \tfrac{1}{32} \text{ in} - 2 \times t_m - 0.010 \text{ in}$$

where A = pipe outside diameter
   $\tfrac{1}{32}$ in = pipe outside diameter under tolerance
   t_m = mill minimum wall = $0.875t$
   t = mill nominal wall
   0.010 = a boring tolerance

This simplifies to:

$$C = A - 0.041 - 1.75t \text{ in} \tag{A6.2}$$
$$C = A - 1.04 - 1.75t \text{ mm} \tag{A6.2M}$$

The tolerance on C is $+0.010 - 0.040$ in ($+0.25$ mm, -1.02 mm).

Source: Pipe Fabrication Institute PFI ES-21.

For other types of seamless pipe, longitudinally welded pipe, forged and bored pipe, and other specialties, the tolerances on the outside diameter and wall thickness are different. The machining tolerance required for some welding processes may also be different. However, similar logic may be applied in determining C dimensions for these products. (See PFI ES-21.)

It should be noted from Table A6.6 that the tabulation applies to wall thickness greater than ½ in (12.7 mm). While one can calculate a C dimension for lighter walls, the combination of outside diameter tolerance and wall thickness tolerance will usually result in a calculated C which is often smaller than the actual bore of the pipe. The difference is most often relatively small, and the existing diameter will usually be suitable for alignment of most welds. In those cases where it is considered essential, the outside diameter at the end can be sized to provide stock for machining, but care is required to assure that the minimum wall is maintained. Where counterboring is used, the machined surface should taper into the existing inside surface at an angle of 30° maximum. See Fig. A6.17.

There are many instances where round-up devices and counterboring are insuffi- cient remedies for misalignment. On occasion it may be necessary to expand the ends where counterboring would violate minimum wall requirements. Most of the codes permit the use of weld metal deposits (weld buildup) both on the inside and outside surfaces of the weld end in order to attain the required alignment. In

FIGURE A6.17 Welding end transitions—maximum envelope. (*ASME Boiler and Pressure Vessel Code, Sec. III, 1995 ed.*)

using this alternative, consideration must be given to other factors such as radial shrinkage, imperfections in the weld buildup which may show on NDE, need for pre- and postweld heat treatment, and possible sensitization of austenitic stainless steels.

2. *Unequal wall thickness:* In most piping systems there are components such as valves, castings, heavier header sections, and equipment nozzles which are welded

to the pipe. In such instances the heavier sections are machined to match the lighter pipe wall and the excess thickness tapered both internally and externally to form a transition zone. Limits imposed by the various codes for this transition zone are fairly uniform. The external surface of the heavier component is tapered at an angle of 30° maximum for a minimum length equal to 1½ times the pipe minimum wall thickness and then at 45° for a minimum of ½ times the pipe minimum wall. Internally, either a straight bore followed by a 30° slope or a taper bore at a maximum slope of 1 to 3 for a minimum distance of 2 times the pipe minimum wall are required. See Fig. A6.17. The surface of the weld can also be tapered to accommodate differing thickness. This taper should not exceed 30°, although some codes limit the taper to 1 to 4. It may be necessary to deposit weld metal to assure that these limits are not violated.

Fillet Welds. Circumferential fillet welds are used in piping systems to join slip-on flanges and socket welding fittings and flanges to pipe. In welding slip-on flanges to pipe, the pipe is inserted into the flange and welded with two fillet welds, one between the outside surface of the pipe and the hub of the flange and the other

t_n = nominal pipe wall thickness

x_{min} = 1.09 t_n or thickness of the hub, whichever is smaller
FIGURE A6.18 Slip-on and socket welding flange welds. (*ASME B31.1, 1995 ed.*)

between the inside surface of the flange and the thickness of the pipe. See Fig. A6.18. Alignment is relatively simple since the pipe fits inside the flange. The B31.1 Code requires that the fillet between the hub and the pipe have a minimum weld leg of 1.09 times the pipe nominal wall or the thickness of the hub, whichever is smaller. The weld leg of the front weld must be equal to the pipe nominal wall or ¼ in, whichever is smaller. The gap between the outside diameter of the pipe and flange inside diameter may increase with size, so the size of the fillet leg should be adjusted to compensate for this situation.

Fillet welds are also used for circumferential welding of pipe to socket fittings. Socket weld fittings and flanges are available in sizes up to NPS 4 (DN 100) but are most frequently used in sizes NPS 2 (DN 50) and smaller. Alignment is not a problem since the pipe fits into the fitting socket. Some codes require that the fillet have uniform leg sizes equal to 1.09 times the pipe nominal wall or be equal to the socket wall, whichever is smaller. In making up socket joints it is recommended that the pipe not be bottomed in the socket before welding. B31.1 and ASME Section III suggest a ¹⁄₁₆-in (2.0 mm) gap. In high-temperature service especially, the pipe inside the socket will expand to a greater degree than the socket itself,

and the differential expansion may result in unwanted shear stress in the fillet and possible cracking during operation.

Intersection-Type Weld Joints.   Intersection-type weld joints occur when the longitudinal axes of the two components meet at some angle. Such is the case where nozzle, lateral, and wye intersections are fabricated by welding. Weld joints in these cases may be butt, fillet, or a combination thereof. Nozzles are made either by *set-on* or *set-through* construction. In set-on construction, the opening in the header pipe is made equal to the inside diameter of the branch pipe. The branch pipe is contoured to the outside diameter of the header and beveled so that the weld is made between the outside surface of the header and through the thickness of the branch. The through thickness weld is covered by a fillet weld to blend it into the header pipe surface. In set-through construction an opening is cut in the header pipe equal to the outside diameter of the branch pipe and beveled. The branch pipe is contoured to match the inside diameter of the header. See Fig. A6.19. The weld is between the outside surface of the branch and through the thickness of the header and is covered with a fillet weld to blend it into the outside surface of the branch. Either type of construction is acceptable; the usual practice is to use set-on since the volume of required weld metal is less. However, when the header is
FIGURE A6.19   Types of branch nozzle construction. (*a*) Set-on; (*b*) set-through; (*c*) set-on with reinforcing pad; (*d*) special drill through socket weld coupling.

made from a plate product which may contain laminations, set-through construction is preferred.

Small nozzles are frequently made with socket welding or threaded couplings set on the header. In these cases it is difficult to assure complete root penetration, and specially designed couplings which permit drilling through the bore to remove the root of the weld are often used. See Fig. A6.19.

Welded-nozzle construction cannot be used at the full rating of the pipe involved, and suitability for particular pressure temperatures must be verified by component design methods found in Part B of this book. In all cases there must be a through thickness weld of the branch to the header. Where reinforcing pads are used, they should also be joined to the header by a weld through their thickness. See Fig. A6.19 for typical details. In designing headers with multiple outlet nozzles, sufficient clearance is needed between adjacent nozzles to provide accessibility for welding. Nozzles with reinforcing pads or flanges need greater clearance. PFI ES-7[31] gives suggested minimum spacings.

Root Pass Weldings. The integrity of any weld rests primarily with the quality of the root pass. In double-welded joints the root pass serves as a backing for passes welded from the first side. Before welding begins from the opposite side, the root area is usually removed to sound metal. In most cases, however, pipe welds must be made from one side only, and the inside surface of the root weld is not accessible for conditioning.

Backing Rings. The earliest solution to root pass welding was the use of a backing ring using the SMAW process. This usually assured good penetration and is still used for many applications. However, commercial rings used with nominal pipe dimensions may result in unwanted flow restriction, crevices for entrapment of corrosion products, and notch conditions which could result in cracking during service. Prior to the introduction of GTAW root welding, piping systems which required the highest possible quality were welded using counterboring of the pipe to close tolerances and machined backing rings. This reduced problems significantly, but the crack potential still remained. See PFI ES-1[32]

Open Butt Root Welds. In petrochemical services backing rings often could not be used, and the practice of open butt welding with shielded metal arc electrodes was and still is used. Welders require considerably more skill. Welding is most often performed with E-XX10 electrodes, which are more controllable than the low-hydrogen types but are also more prone to porosity.

GTAW Root Welds. The introduction of GTAW represented a breakthrough in root pass welding. Because of the greater expense involved, its application is usually limited to applications requiring high-quality root welds. The weld end bevels are carefully prepared by machining and counterboring where necessary to meet the close tolerances required. The joint involves butted or open lands, and the weld is made with filler metal added or with a preplaced consumable insert. The latter have a decided advantage in that they eliminate a good deal of the variability introduced by hand feeding of filler wire. Consumable inserts come in a variety of shapes, each requiring somewhat differing fit-up tolerances. See PFI ES-21. Some types can be used for root pass welding in lighter wall materials (½ in and less) without the need for counterboring. Depending on the service, the inside surface of the molten weld puddle is often shielded from oxidation by an inert gas inside the pipe contained between dams. See Fig. A6.20. A small, controlled, positive pressure on the backing gas can aid in better controlling the shape of the root inside diameter.

When the root pass is made by the GTAW process, the resulting finished weld is relatively thin. In depositing the second and third passes, the first pass may be
Dams consist of rubber gaskets between
two flanges.

FIGURE A6.20   Typical shop purging arrangement.

remelted. As it resolidifies, it shrinks radially, resulting in a small concave depression on the inside of the weld. This condition is usually considered acceptable provided the resulting thickness through the finished weld is equal to or greater than the required minimum wall, and the concavity blends smoothly into the adjacent base metal.

GMAW Root Welds.   Many fabricators and/or installers take advantage of the low penetrating power of GMAW in the short-circuiting mode to use it for open-butt root pass welding where the quality level of GTAW root pass welding is not required. The balance of the weld is made by other processes. Care must be taken to assure that unmelted wire does not penetrate the joint and remain.

Welding of Ferrous Piping Materials

Carbon Steels.   Carbon steels are classed as P-No.1 by ASME Section IX. See Table A6.3. The vast majority of carbon steel pipe is used for services below 775°F (413°C). Joints are most often V bevels with commercial backing rings or open butt roots and are welded out with SMAW, SAW, GMAW, and FCAW. For services which require high quality, GTAW root welds with SMAW, SAW, and FCAW weld-outs are most prevalent. Most carbon steel filler metal is produced to weld 60,000- and 70,000-psi material. More often than not fabricators use the 70,000-psi filler for all carbon steel welding. For SMAW the most popular electrode is E-7018, although for open-butt root pass welding using SMAW, E-6010 is still the choice. FCAW welding is rapidly replacing SMAW because it can deposit at a much higher rate. Preheating and postweld heat treating are required depending on the carbon content and wall thickness. For typical preheat and postweld heat treatment requirements see Tables A6.4 and A6.7. When working to a specific code, be sure to use the requirements found in that code.

Carbon Molybdenum Steels.   Carbon molybdenum steels are classed as P-No 3. Currently this material has very little use because of unfavorable experience with graphitization at temperatures over 800°F (427°C).

Chromium Molybdenum Steels.   The chromium molybdenum steels are primarily used for service temperatures from 800 to 1050°F (427 to 565°C). They range from ½ Cr-½ Mo to 9 CR-1 Mo-V and are classed by ASME Section IX as P-No. 3, P-No. 4, and P-No. 5 A and 5 B. The preponderance of usage is in the 1¼ Cr-½ Mo-Si and 2¼ Cr-1 Mo grades. Welding usually consists of GTAW root welds with filler metal added or preplaced inserts. The balance of the weld is made by SAW for welds which can be performed in the 1G position and SMAW for fixed position welds. FCAW is rapidly overtaking SMAW for these materials also. See

TABLE A6.7 Some Typical Time and Temperature Cycles for Heat Treatment

P no.	Heating rate	Holding temperature range*				Minimum holding time at temperature	Cooling program
		SR or T	N	A	CST		
P-1	Above 800°F heat at a rate of 400°F/h divided by the thickness in inches but not faster than 400°F or less than 100°F	1100–1250°F	1600–1700°F	1500–1600°F	N/A	1 h/in of thickness but not less than 30 min or more than 2 h plus 15 min for each additional inch over 2 in	SR or T—Cool at 400°F/h divided by the thickness in inches but not faster than 400°F/h; need not be lower than 100°F/h down to 800°F
P-3	Same as P-1	1100–1250°F	1600–1700°F	1500–1600°F	N/A

Tables A6.4 and A6.7 for typical preheat and postweld heat-treatment requirements. Note that in B31.3 hardness limits are imposed to verify the adequacy of any heat treatment, and above-critical heat treatment may be necessary to attain the maximum hardness limit.

The 9Cr-1Mo-V material is a relatively recent addition to the list of chromium molybdenum steels for use in high-temperature service. Its great advantage over other chrome moly steels is its high-temperature strength. It has allowable stresses comparable with those of austenitic stainless steels. This results in a lesser wall thickness and consequently less weight to support and considerably less volume of filler material. A tighter line configuration can be anticipated because the lesser section modulous will result in smaller reactions at the terminals due to expansion loadings.

This material also has an advantage over austenitic stainless steels in that its coefficient of thermal expansion is less than that of the stainlesses, again resulting in lower end reactions for the same configuration.

On the down side, 9Cr-1Mo-V is typically a martensitic structure at room temperature and requires great care in bending, welding, and postbending and welding heat treatment.

For hot bending, a temperature of 1740 to 1920°F (950 to 1050°C) is preferred. Bending in the temperature range of 1560 to 1740°F (850 to 950°C) should be avoided. After hot bending, a normalize at 1900 to 1990°F (1040 to 1090°C) is required to put carbides back into solution. The normalize is followed by a tempering heat treatment between 1350 and 1440°F (730 and 780°C). Both are followed by cooling in still air.

Welding is extremely critical. The latest ASME Section II Part C, lists 9Cr-1Mo-V filler materials. SFA 5.5 lists E9018-B9 for SMAW electrodes, and SFA 5.28 lists ER90S-B9 for rods and electrodes for gas-shielded welding. Storage and handling of electrodes is very critical (see Filler Metals). Preheat and interpass temperatures and postwelding cooling should be scrupulously observed (see Preheat and Interpass Temperature). Postwelding stress relief is a necessity. The current ASME B31.1 Code requires a range of 1300 to 1400°F (700 to 760°C), but some literature indicates that a range of 1360 to 1440°F (740 to 780°C) may be more desirable for reasonable hardness and good ductility. The time at temperature should be 1 h per in of thickness, and heating and cooling rates above 800°F (427°C) should be limited to 100°F (55°C) per h.

Martensitic and Ferritic Stainless Steels. The martensitic and ferritic grades of stainless steels are not often encountered in piping systems. They are a group of steels with chromium contents ranging from 11.5 to 30 percent. Martensitic stainless steels are those which are capable of transformation to martensite under most cooling conditions and therefore can be hardened. Ferritic stainless steels on the other hand contain sufficient chromium and other ferrite formers such as aluminium, niobium, molybdenum, and titanium so that they cannot be hardened by heat treatment. ASME Section IX classes martensitic stainless steels as P-No.6 and ferritic stainless steels as P-No.7. The user should consult the *Welding Handbook*[16] for suggested welding processes and the applicable code for specific preheating and postweld heat-treatment requirements.

Austenitic Stainless Steels. Austenitic stainless steels are classed as P No. 8. Piping systems of austenitic stainless steels represent a fairly significant proportion of a fabricator's and/or installer's work, since they appear in nuclear power plants, chemical plants, paper mills, food processing facilities, and other applications where cleanliness and corrosion resistance are mandatory and even in fossil power plants where their high-temperature properties are needed. Most root welding is done by

the GTAW process, and the inside of the root is protected by purging with argon, helium, or nitrogen to prevent formation of hard chromic oxides. GTAW is used for weld-out in lighter walls, and combinations of GTAW, SMAW, and SAW are used for heavier sections. Filler metal must contain some ferrite to preclude microfissuring as described in the section "Filler Metals." To minimize the precipitation of carbides (sensitization) during welding, interpass temperatures are usually limited to 300 to 350°F (150 to 175°C). Heat treatment after welding is not mandatory. For corrosion services, heating during fabrication could be detrimental since it would serve to enhance sensitization. The effects of sensitization can be mitigated by a carbide solution heat treatment as described in the section "Heat Treatment." Low-carbon grades of stainless steels welded with L grade electrodes are also used in services where sensitization can be a problem.

Low-Temperature Steels. The term *low-temperature steel* is applied to a variety of steels which exhibit good notch toughness properties at temperatures down to cryogenic levels.

The B31.1 and B31.3 Codes permit the use of most steel down to −20°F (−29°C). Below this, certain grades of carbon and nickel steel with good toughness and austenitic stainless steels are needed. Welding procedures and welding filler metals must be tested to assure suitability for the intended service. B31.3 gives details of such requirements. Root pass welding using GTAW, with SMAW and SAW weld-out, is commonly used. Some FCAW is used in the carbon steels and low-nickel steels.

A preheat of 200°F (95°C) is suggested by B31.3 for low-nickel steels followed by a postweld heat treatment consisting of a stress relieve at 1100 to 1175°F (600 to 630°C) when the wall exceeds ¾ in (19 mm). For 9 percent nickel steel a preheat of 50°F (10°C) and a stress relieve at 1025 to 1085°F (552 to 585°C) followed by cooling at a rate greater than 300°F/h (167°C/h) down to 600°F (316°C) is required.

Certain nonferrous materials are also suitable for low-temperature service. See the following section.

Welding of Nonferrous Metals

Aluminum. Aluminum and aluminum alloys have high thermal conductivity, high coefficients of thermal expansion, and high fluidity in the molten state. The predominant welding methods used for joining them are GMAW and GTAW, both manually and in automatic modes. Joint designs are much like those used for ferritic metals, except that the included angles are usually 60 to 75°, increasing to 90 or 110° for welding overhead. The root pass may be welded against a permanent aluminum backing strip or removable stainless-steel backup or with an open butt or consumable insert. Joint cleanliness is very important, so oil, grease, and dirt must be removed. For heavy oxide, wire brushing or chemical cleaning may be required. Preheating is normally not needed but may be required when the mass of the parts is large enough to conduct the heat of welding away from the joint faster than it can be supplied by the arc. Depending on the welding process used, as the weld thickness increases from about ¼ to 1 in (19 to 25 mm), a preheat of 200 to 600°F (95 to 316°C) may be required. Since the properties and tempers of certain alloys may be affected, care should be exercised when preheat is applied. Shielding gases are usually helium or argon. For critical applications and heavier sections a mixture of 75 percent helium, 25 percent argon is recommended. Heat treatment after welding is not required.

It is important to remember that the annealing effect of the heat of welding can reduce the strength level of cold-worked and heat-treatable alloys. In this case the allowable stress value for the material in the annealed condition should be used

for design. An exception to this can be made in the case of heat-treatable materials when the finished weldment is subjected to the same heat treatment which produced the original temper and both the base metal and weld joint are similarly affected.

Aluminum and aluminum alloys are suitable for service temperatures down to −452°F (−269°C). See B31.3 for information on this subject.

Copper and Copper Alloys. Although copper and copper alloys can be welded by other processes, GTAW welding is commonly applicable for all-position welding of most copper and copper alloys. GMAW with pulsed current can also be used for some alloys. Shielding gases may be argon, helium, or mixtures thereof. Argon is preferred for walls to ⅛ in (3 mm), but a 75 percent helium, 25 percent argon mixture is most often used for heavier walls and weld positions other than flat (1G).

Like aluminum, the coppers have high thermal conductivity and high coefficient of thermal expansion. Accordingly, preheating is recommended to compensate for heat loss at the joint due to the metal mass and to reduce distortion. Welding current should not be used to compensate for heat loss. The degree of preheat is a function of alloy, welding process, and metal mass. More heat input is needed for the pure coppers, with decreasing amounts needed as the alloy content increases. Preheat should increase with wall thickness, from about 200°F (95°C) for ¼-in (6 mm) wall increasing to 750°F (400°C) minimum for walls ⅝ in (16 mm) and over. Surface cleanliness is very important, and some alloys require a chemical cleaning to remove oxides. Copper-nickel alloys are susceptible to hot cracking if sulfur is present.

The heat of welding will soften the HAZ of cold-worked material, and it will be weaker than the base metal. When precipitation-hardenable alloys are used, it is recommended that welding be done on base metal in the annealed condition and the entire weldment be given the precipitation-hardening heat treatment. For detailed information refer to the *Welding Handbook*,[16] the *Metals Handbook*,[20] or contact the Copper Development Association.

Many coppers are suitable for services down to −325°F (−199°C), See ASME B31.3.

Nickel and Nickel Alloys. Nickel and its alloys can be welded by SMAW, GTAW, and GMAW. SAW is limited to certain compositions. Welding is similar to austenitic stainless steels except that the molten metal is more sluggish and does not wet as well. Larger groove angles may be required. Preheat is not required, but welding at temperatures below 60°F (16°C) in the presence of moisture is not recommended. A low interpass temperature is suggested. For GTAW welding shielding gas is normally argon, but helium or an argon-helium mix may be used. The inside surface of GTAW root welds should be shielded with an inert gas. GMAW in the spray, pulsed, globular, or short-circuiting modes may be used with argon or argon-helium mixtures as shielding. Postweld heat treatment is not usually required. Many nickel and nickel alloys may be used down to −325°F (−199°C). For more detailed information refer to the *Welding Handbook*,[16] the *Metals Handbook*,[20] and ASME B31.3.

Titanium. Titanium and its alloys are normally welded using the GTAW and GMAW processes. It is vital that the HAZ and molten metal be protected from the atmosphere by a blanket of inert gas during welding. Most welding is done in a protective chamber purged with an inert gas or by using trailing shields. Precleaning is extremely important. Use of degreasers, stainless steel wire brushes, or chemical solutions may be required. Preheating or postweld heat treatment are not normally required. See the *Welding Handbook*[16] and the *Metals Handbook*.[20]

Dissimilar Metals. Until now we have discussed welding where both items being joined are essentially the same material and are joined with a filler metal of similar

chemistry and physical properties. Occasions arise where metals of different chemical composition and physical properties must be joined.

In joining dissimilar metals, normal welding techniques may be employed if the two base metals have melting temperatures within about 200°F (95°C) of each other. Otherwise different joining techniques are required.

In designing a welding procedure for dissimilar metals, a great many factors must be considered. Service conditions such as temperature, corrosion, and the degree of thermal cycling may apply. The effects of dilution of the two base metals by the filler and each other must be evaluated to assure a sound weld with suitable chemical, physical, metallurgical, and corrosion-resistant properties. Similarly, preheat and postweld heat treatment requirements for one base metal may not be suitable for the other.

It is usually necessary to qualify a separate welding procedure for the particular combination of base metals and filler material. ASME Section IX should be consulted for specifics.

As a general rule, when welding within a family such as ferritic to ferritic, austenitic to austenitic, or nickel alloy to nickel alloy, the filler metal may be of the same nominal composition as either of the base metals or of an intermediate composition. The filler metal normally used to weld the lower alloy is most often preferred.

The previous advice may not always hold true. It has been noted that when welding P 22 (2¼Cr-1Mo) to P 91 (9Cr-1Mo-V) using 2¼Cr filler metal at high temperatures, carbon migration from the 2¼Cr weld metal to the 9Cr base metal can produce a carbon-denuded zone at the interface, resulting in a weakened area. One recommendation is to "butter" the 9Cr side with a 5Cr filler metal, heat-treat the buttered segment, and complete the weld with 2¼Cr. Bear in mind that the 5Cr filler may not have high-temperature properties similar to the 2¼Cr, and design the weldment accordingly.

In welding dissimilar materials, selection of preheating and postweld heat treatment requires a great deal of care. What is desirable for one metal may be detrimental to another. Some compromise may be required.

Establishing a welding procedure for welding ferritic to austenitic steels requires careful consideration of the service conditions. For moderate service temperatures (below 800°F or 427°C), where the thickness of the ferritic side does not require postweld heat treatment, austenitic stainless steel electrodes are often the choice. Some prefer electrodes such as type 309 or 310 because of their higher chrome content. Because of the thickness involved, the ferritic member may require some type of postweld heat treatment. In this case the preferred method is to butter the ferritic weld surface with a nickel-chrome-iron (NiCrFe) filler metal such as ERNiCrMo-3 (see ASME Section II Part C SFA-5.14) and postweld heat-treat the buttered section as required for the ferritic composition. The buttered section is then prepared for welding, set up with the austenitic side, and the weld between the butter and austenitic base metal is completed with NiCrFe filler metal without subsequent postweld heat treatment. See Fig. A6.21.

For high-temperature service (above 800°F or 427°C) the buttering procedure just described is also recommended. There is a difference in coefficients of expansion between the ferritic and austenitic metals. This difference will result in expansion stresses above the yield point at the weld juncture while at operating temperature. At higher temperatures there is also greater probability of diffusion of carbon from the ferritic side to the austenitic side. The NiCrFe "butter" minimizes the carbon diffusion problem and has an expansion coefficient which is intermediate between the two base metals, thus reducing but not eliminating the thermal stress at the interface. Where a transition from ferritic to austenitic steels is required in high-

temperature applications involving cyclic services, a transition piece of a high-nickel alloy such as UNS N06600 with two welds is often used to reduce thermal fatigue damage.

In welding nonferrous metals to ferrous or other nonferrous metals, a filler metal with a melting point comparable to the lower melting point base metal is usually recommended.

Nickel and nickel alloys are invariably welded to ferrous metals with nickel-alloy filler metals. Sulfur embrittlement can be a problem with nickel to ferritic welds, just as it is in nickel-to-nickel welds. Copper-nickel and nickel-copper alloys should not be joined with filler materials containing iron or chromium since hot cracking may result.

Copper and copper alloys can be welded to carbon steel with silicon bronze or aluminum bronze electrodes, but the preferred method is to butter the carbon steel side with nickel and weld the copper to the nickel butter with nickel filler. This will preclude hot cracking of the copper because of iron dilution. The copper side may require preheat. Copper can easily be welded to nickel, copper-nickel, or nickel-copper filler metal. When welding nickel alloys which contain iron or chromium to copper, the nickel alloy should be buttered with nickel.

Aluminum and titanium generally cannot be welded to ferrous or other nonferrous metal using currently available welding procedures, and special joining procedures must be employed.

Clad, Metal-Coated, and Lined Pipe. There are instances when it is economically desirable to construct a piping system from relatively inexpensive material but with an interior surface having corrosion- or erosion-resistant properties. Clad pipe may be made by seam welding of clad plate, by weld metal overlay of the inside surface, or by centrifugal casting of a pipe with two metal layers. Lined pipe is made by welding a linear, sometimes as strips, to the inside surface of the pipe. Metal-coated pipe is made by dipping, metal spraying, or plating the entire pipe.

Before choosing construction which requires welding of clad, lined, or metal-coated pipe, such factors as filler metal compatibility, filler metal strength relative to the base metal strength, dilution of base metal into the finished weld, and need for postfabrication heat treatment must be considered. Because it is not possible to cover the great many combinations of base metals and cladding, lining, or metal coatings, some examples of the more common applications will be given.

For corrosion services, a carbon steel base material, clad or lined with austenitic stainless steel, is often used. The cladding is usually about $\frac{3}{32}$ to $\frac{5}{32}$ in thick. Where the inside of the weld is accessible, the preferred method is to weld the base metal from the outside with carbon steel filler metal, back-gouge the root from the inside, and weld the root from the inside with two or more passes of austenitic filler metal to minimize dilution from the base metal. See Fig. A6.22*a*.

Where the inside surface is not accessible, a backing strip of the same composition as the cladding, fillet welded to the cladding on the upstream side may be used. The root weld between the two clad surfaces and the austenitic backing strip is then made with austenitic filler metal. The root weld can also be made with the GTAW process using austenitic filler or preplaced inserts. The carbon steel should be removed for a sufficient distance back to preclude dilution into the root weld. In most instances, the balance of the weld is usually made with austenitic filler metal since it is not good practice to deposit carbon steel or low-alloy steel directly against the stainless steel deposit. See Fig. A6.22*b*. In some cases, nickel-base alloys are used for cladding where high-temperature corrosion is involved. The joints may be treated much like the austenitic cladding, except that appropriate nickel-base filler metals are used.

Some services require the use of carbon steel pipe nickel plated on the inside surface. Since the plating is relatively thin, different approaches are needed. First, as much fabrication as possible should be done prior to plating. For joints to be welded after plating, the ends to be prepared for welding should be buttered with nickel filler metal and machined to the required contour prior to plating. The root weld is made using the GTAW process with nickel filler metal. See Fig. A6.22*c*.

Some occasions require the use of aluminized pipe. Steel pipe is prefabricated and coated with aluminum by immersion in a bath of molten aluminum or by metal spray. Where the inside of the weld will not be accessible for metal spray, one method of joining is to counterbore the ends and use a solid machined backing ring which is fit and welded into one side of the joint prior to coating. After coating, the weld is made using an appropriate base metal process and filler, taking care not to blister the aluminum coating on the underside of the backing ring.

Galvanized steel pipe is often used for external corrosion applications. Since welding of galvanized pipe releases toxic vapors and since the welded area most often cannot be regalvanized, welding of galvanized pipe is not recommended. It is preferable that the assemblies be fabricated with provisions for mechanical joining in the field and then galvanized.

For services involving erosion, carbon steel pipe is often lined with cement or
FIGURE A6.22 Examples of welding clad, lined, and plated pipe. (*a*) Clad pipe welded from both sides; (*b*) clad pipe welded from one side only; (*c*) nickel-plated pipe.

some type of abrasion-resistant material which cannot be welded. In this case the joints are butted together to minimize the gap between the adjacent linings. The weld is then made between the two carbon steel weld bevels, recognizing that full penetration through the carbon steel joint may not be achieved and that additional thickness may be necessary for strength. The gap between the adjacent linings is usually not a problem if only erosion is present.

Brazing and Soldering

Brazing. For services involving the ASME Boiler and Pressure Vessel Code or the B31 Code for Pressure Piping, brazing procedures and brazers must be

qualified in accordance with ASME Section IX similar to welding procedures and welders. See the section ''Procedure and Personnel Qualification.''

There are a great many types of brazing processes. In establishing a brazing procedure, consideration must be given to the ability of the filler metal to produce suitable physical properties, its melting point and wettability, possible base metal and filler metal interactions, loss of base metal properties, increased sensitization to corrosion, increased hardness in the base metal due to brazing temperature, and the need for postbrazing heat treatments.

Since most piping materials can be welded, the use of brazing for joining is rather limited. It is most often used for joining coppers and for combinations of metals which cannot be welded.

Brazing is a process wherein the base metals do not melt, the filler metal has a liquidus above 840°F (450°C), and the filler metal wets the base metal and is drawn into the joint by capillary action.

Although butt or scarf joints can be used, a lapped joint with an overlap of 3 times the thickness of the thinner member gives the best joint efficiency and ease of fabrication. It should be noted that typical copper or brass fittings have a depth of socket based on the strength of tin-lead solders. When brazing is used, only a small percentage of that depth is needed. Required clearance between the faying surfaces usually vary from 0.001 to 0.010 in (0.025 to 0.25 mm) depending on the filler and flux combination used during the operation. The flux melts upon application of heat and is displaced by the molten filler metal. Flux residue should be removed after the operation is complete. Silver, copper-phosphorus, and copper-zinc filler metals are most often used for copper brazing.

Torch brazing is commonly used for fabrication and installation of copper piping systems. For torch brazing, the type of fuel gas selected is a function of the melting temperature required to melt the filler metal. For piping joints NPS 2 (DN 50) and larger, use of a second torch to preheat may be desirable.

In brazing metals with differing coefficients of expansion, it is preferable that the metal with the higher expansion coefficient form the socket and the metal of the lower expansion coefficient form the pipe or tube. Clearance between the parts at room temperature must be adjusted so there will be a suitable clearance at brazing temperature. On cooling, the greater contraction of the socket will put the joint in a compressive stress state.

Soldering. Unlike welding and brazing, ASME Section IX has no requirements for qualification of soldering procedures or personnel. Soldering is much like brazing in that the base metals are not melted, the faying surfaces are wetted by the filler, and the filler is drawn into the joint by capillary action. However, the melting point of the filler metal is lower than 840°F (450°C) usually between 450 and 500°F (230 and 260°C). Since the strength of soldering filler metals is considerably less than that of brazing fillers, a longer overlap is required to develop a joint equal to base metal strength. A clearance of about 0.003 in is preferred for optimum strength.

A good soldered joint depends again on the cleanliness of the faying surfaces. Fluxes are used to assist in the wetting action by removing tarnish films and to prevent oxidation. Rosin fluxes and organic fluxes are used for most materials. Inorganic fluxes may be required for certain other materials that can be soldered, while in some cases precoating of the material with a surface that can be soldered may be required. Most piping applications use tin-lead solders. These range in composition from 5 percent tin, 95 percent lead to 70 percent tin, 30 percent lead, with 50 percent tin, 50 percent lead the most common. Tin-antimony and tin-silver solders are also frequently used. For soldering aluminum, tin-zinc and zinc-aluminum are used.

For additional information refer to the *Welding Handbook*[16] and *The Theory and Technique of Soldering and Brazing of Piping Systems.*[33]

Heat Treatment

Purpose. Heat treatment during piping fabrication is performed for a variety of reasons (i.e., to soften material for working, to relieve fabrication stresses, to restore metallurgical and physical properties, etc.). During fabrication, ferritic steels undergo phase changes during heating and cooling, while the austenitic stainless steels and nonferrous piping materials do not; consequently differing criteria must be applied.

Ferritic Steels. Ferritic steels undergo a phase change on heating and cooling during fabrication operations because their principal component (iron) is allotropic; that is, it undergoes a change in crystalline structure with temperature. At room temperature iron favors a body-centered cubic (BCC) structure called *alpha iron*, but on heating to 1670°F (910°C) it changes to a face-centered cubic (FCC) structure called *gamma iron* and subsequently at 2534°F (1390°C) it reverts to a BCC called *delta iron*. The addition of carbon to the iron to form steel and additions of other elements such as chromium, manganese, molybdenum, and nickel to form alloys modify the temperatures at which transformation occurs and the manner in which the crystalline structure forms into grains.

As an example, a melt of 0.30 percent carbon steel will first begin to solidify as delta iron and a liquid, then at about 2680°F (1479°C) to an interstitial solid solution of carbon in gamma iron called *austenite*. At about 1500°F (815°C) this will transform into a mixture of austenite and ferrite, which at 1333°F (721°C) becomes ferrite and pearlite. Ferrite is alpha iron which contains small amounts of carbon (up to a maximum of about 0.02 percent) in solid solution. The excess carbon not in solid solution with the ferrite forms as iron carbide (Fe_3C) or cementite. The cementite forms as thin plates alternating with ferrite. This structure is known as *pearlite*.

The temperatures at which the transformations occur are called critical temperatures or transformation temperatures. The lower critical temperature, usually designated A_1, is that point on heating where the BCC ferrite and pearlite phase begins to transform to FCC austenitic structure, and the upper critical temperature, A_3, is the temperature at which the transformation is complete. Between these two points the structure is a mix of ferrite-pearlite and austenite. These temperatures are of importance in postbending and postwelding heat treatments as well as qualification of welding procedures.

The critical temperatures are a function of chemical composition and as such will vary with alloy. As an example, for 9Cr-1Mo-V, the lower critical is located between 1525 and 1560°F (830 and 850°C), and the upper critical is between 1650 and 1725°F (900 and 940°C). Some approximate methods of calculating critical temperature are found in *Welding Metallurgy*[34] and *The Making, Shaping and Treating of Steel.*[35] Some approximate lower critical temperatures are given in Table A6.8.

Critical temperatures are affected by heating and cooling rates. An increase in heating rate will serve to increase the transformation temperatures, while an increase in cooling rate will tend to depress them. The more rapid the rate of heating or cooling, the greater the variation from the critical temperature at equilibrium conditions. Most sources will indicate the lower and upper critical temperatures on heating as A_{c1} and A_{c3}, respectively, and the upper and lower on cooling as the A_{r3} and A_{r1}, respectively. In the case of our 0.30 percent carbon steel, cooling from the austenite phase through the critical range at a rate of 50°F/h (28°C/h) or less will result in the soft, ductile ferrite-pearlite structure. On the other hand, extremely

TABLE A6.8 Approximate Lower Critical Temperatures

Material	Approximate lower critical temperature [°F (°C)]
Carbon steel	1340 (725)
Carbon molybdenum steel	1350 (730)
1¼ Cr–½ Mo	1430 (775)
2¼ Cr–1 Mo, 3 Cr–1 Mo	1480 (805)
5 Cr–½ Mo	1505 (820)
9 Cr–1 Mo	1490 (810)

Source: From ASME B31.1 1995 ed.

rapid cooling from the austenite phase down to temperatures 600°F (316°C) or lower can result in an extremely hard structure called *martensite*. This is because the austenite FCC crystals did not have time to transform to BCC ferrite and cementite.

Heat treatments which are applied to ferritic steels are related to the critical temperatures and depending on which is applied will have differing results. These are annealing, normalizing, normalizing and tempering, and stress relieving. See Fig. A6.23.

Annealing is used to reduce hardness, improve machinability, or produce a more uniform microstructure. It involves heating to a temperature above the upper critical or to a point within the critical range, holding for a period of time to assure temperature uniformity, then following with a slow furnace-controlled cooling through the critical range.

Normalizing is used to refine and homogenize the grain structure and to provide more uniform mechanical properties and higher resistance to impact loadings. It involves heating to a temperature above the upper critical temperature, holding for a time to permit complete transformation to austenite, and cooling in still air from the austenitizing temperature.

A normalized structure may be pearlitic, bainitic, or even martensitic depending on the cooling rate. If there is a concern for excessive hardness and attendant low ductility, a tempering treatment may follow the normalizing treatment. Tempering involves heating to a temperature below the lower critical and slowly cooling to room temperature, much like a stress relief. The degree of tempering depends on the tempering temperature selected. The higher the tempering temperature, the greater the degree of softening.

A stress-relieving heat treatment is primarily intended to reduce residual stresses resulting from bending and welding. It involves heating to a temperature below the lower critical; holding for a predetermined time, depending on thickness and material, to permit the residual stresses to creep out; and then slowly cooling to room temperature.

Some typical time-temperature cycles are shown in Table A6.7.

Austenitic Stainless Steels.   Austenitic stainless steels do not undergo phase changes like the ferritic steels. They remain austenitic at all temperatures and so heat treatments usually do not apply. When austenitic stainless steels are to be used in corrosive services, cold working and heating for bending may significantly lower their corrosion resistance. Cold working may result in residual stresses, and heating operations can result in sensitization. Both factors contribute to intergranular stress corrosion cracking (IGSCC). When austenitic stainless steels are heated
FIGURE A6.23   Heat treatment cycles. (*a*) Anneal; (*b*) normalize; (*c*) stress relief; (*d*) normalize and temper.

in the range of about 800 to 1600°F (430 to 870°C), carbon in excess of about 0.02 percent will come out of solution and diffuse to the grain boundaries where it will combine with adjacent chromium to form chromium carbide ($Cr_{23}C_6$). This phenomenon is called *sensitization*. These grain boundaries are then preferentially attacked by corrosive media. The heat treatment often applied to cold-worked and sensitized stainless steels to restore corrosion resistance is a carbide solution heat treatment. In this procedure, the material is heated to a temperature above the sensitization range, usually about (1950 to 2100°F (1065 to 1150°C), and held there sufficiently long to permit the carbides to dissolve and the carbon to go back into solid solution. The material is then removed from the furnace and rapidly cooled through the sensitization range, preferably by quenching in water. The rapid cooling does not give the carbon sufficient time to come out of solution, and corrosion resistance is restored to the sensitized area.

Obviously carbide solution heat treatment is limited by the furnace size and quenching facilities. It is most freqently applied to bends but is also useful in reducing sensitization and residual stresses in welds.

Nonferrous Materials.   Bending and forming of nonferrous materials may result in undesirable work-hardening. Some nickel alloys may be subject to carbide precipitation when hot bent or formed. Materials that can be hardened by precipitation require other considerations. Depending on the final use, it may be desirable to perform some type of postbending or forming heat treatment. Because of the great many new materials being developed and used, it is suggested that the user contact the material manufacturers or material associations for their recommendations on the specific material and service.

Heat Treatment Methods.   Shop heat treatments are most often carried out in specifically designed heat treatment furnaces, but local stress relieving of welds may also involve induction, resistance, or torch heating.

Above critical heat treatments, such as annealing, normalizing, and normalizing and tempering for ferritic steel and carbide solution heat treatment for austenitic stainless steels, are performed in large heat-treatment furnaces. These same furnaces are also used for stress-relieving heat treatments of ferritic steels. Such furnaces are generally fired with natural gas, propane, or low-sulfur oil. Depending on their design, they may attain temperatures up to 2300°F (1260°C) which covers the entire spectrum of temperatures commonly encountered in piping applications. Heating and cooling rates and holding temperatures are automatically controlled. Larger furnaces may have two or more zones, each independently controlled. Records of furnace zone temperatures and material temperatures are obtained using recording potentiometers.

When assemblies are too large or furnaces are not available, local stress relieving of individual welds may be accomplished in the shop using electrical induction, electrical resistance, or gas torch heating.

Induction equipment involves alternating current frequencies of the order of 60 to 400 Hz. Induction generates heat within the wall of the pipe. This has the advantage of a more uniform temperature through the thickness with greater uniformity at the lower frequencies. The heat treatment cycle is controlled automatically with thermocouples attached directly on or adjacent to the weld. The weld and thermocouple are covered with insulating material. The induction field is generated in copper cables or solid or water-cooled copper coils external to the insulation. See Fig. A6.24.

Resistance heating involves the use of direct current in suitable lengths of nichrome heating wire. Various configurations and sizes of prefabricated heating elements consisting of heating wires separated by ceramic beads are available
FIGURE A6.24   Setup for preheat, maintenance of preheat during welding, and stress relief using induction heating.

commercially. Depending on the size, wall thickness, and desired heating temperature, multiple heating units and combinations of elements may be needed. The weld and heating elements are covered with insulating blankets to retain the heat. Since heating is from one side, a somewhat wider heating band on the outside may be needed to assure that the inside of the pipe attains the required temperature. Thermocouples attached directly to the weld or adjacent to it are used to control heating, holding, and cooling temperatures.

Torch heating can often be used for stress relieving, but where controlled heating and cooling rates are mandated, it may be less than satisfactory. Single torches may be used for pipe up to about NPS 3 (DN 80), but ring burners are needed for larger sizes.

Exothermic heating has been used in the field and is discussed in the section "Installation."

Heat Treatment Considerations

Furnace Heat Treatment.   To assure that heat treatments attain the results intended (i.e., correct heating and cooling rates, desired holding temperature in all parts, etc.), it is very important that all controlling and recording instruments be calibrated on a regular basis. The furnace should be inspected and a temperature survey made to assure that all locations within it are capable of attaining and maintaining specific temperatures within some reasonable tolerance. This is particularly important if the zone temperatures are used as the basis for acceptance of the heat treatment. If there is any concern, it might be advisable to attach thermocouples directly to the parts being heat-treated.

When piping subassemblies are placed in the furnace, they should be supported to permit exposure of the underside to the radiant and convection heating surface. Supports should be located so as to avoid sagging. Care should be taken to avoid any flame impingement directly on surfaces being heat-treated.

The ends of assemblies being heat-treated should be closed but not sealed to minimize oxidation of the inside surfaces. Occasions may arise where special surface finishes on the pipe inside surface or on flow meter sections could be adversely affected by oxidation caused by heat treatment. In such cases the inside of the assembly can be purged with an inert gas to minimize oxidation.

Assemblies should be so placed as to assure the uniform application of heat. Heating and cooling rates must be selected to assure heating through the full thickness and to minimize distortion caused by uneven heating. The faster the rate of heating or cooling, the more probability of distortion. Assemblies with massive flanges, fittings, or other unusual configurations should be treated more carefully than those with butt welds only. Many of the codes have specified heating and cooling rates which are considered reasonable.

Local Heat Treatment.   When an assembly is too large for a furnace to accommodate, it may be fabricated in sections which are individually furnace heat-treated and later joined by welding. The final butt welds may then be locally heat-treated in the same fashion as field welds. The most common practice is the use of induction or resistance heating. When preheating is an essential part of the welding operation, the induction or resistance equipment can be used for preheating, maintaining preheat during welding, and, finally, stress relieving.

A proper stress-relieving operation will assure that the weld and HAZ through the full thickness will attain the required temperature for the required time. The B31.1 Code requires that the heated band be at least 3 times the thickness of the thickest part being joined. With induction or resistance heating the heating elements themselves often have greater coverage. Depending on the massiveness of the joint being heated, one or more pieces of heating equipment may be needed. Controlling and recording thermocouples are located on or adjacent to the weld. Usually locally heat-treated shop welds are in the 5G position (pipe horizontal, weld vertical). For small pipe sizes, a single thermocouple located at the 12 o'clock position may suffice, but for larger diameters and heavier walls at least two and preferably four, located at 90° intervals, should be employed to assure uniformity of heating.

Judicious use of insulating material should be employed to minimize heat loss. When joining parts of differing masses, concentrate more heating effort on the more massive part.

If it is necessary to locally stress-relieve a branch connection, not only the branch weld itself but the entire circumference of the header for a distance of at least 2 times the header thickness on either side of the branch should be heated. Heating of the weld alone, while resulting in a satisfactory stress relief, could distort the header significantly.

Heating and cooling during local stress relief of pipe to pipe joints can be more rapid than for furnace applications since there is less chance of distortion unless, of course, the heating is not applied uniformly. Ends of the assembly should be closed but not sealed to reduce heat loss on the inside surface due to air flow. The main concern is assurance that the inside surface of the weld attains the required temperature for the required time.

Local stress relieving with torches or gas ring burners can be effectively employed but must be limited to situations where controlled heating and cooling rates are not a factor.

Code Requirements

Postbending and Postforming Requirements.   The designer of the piping system should specify the type of heat treatment required to assure appropriate physical, metallurgical, or corrosion-resistant properties. As an example, a normalize or normalize and temper may be required to assure certain notch toughness properties for nuclear or low-temperature applications, or a carbide solution heat treatment for cold-worked austenitic stainless steel may be required to preclude IGSCC. This should be agreed upon well before any fabrication starts.

The codes have certain mandatory heat treatment requirements which must be

observed as a minimum, normally a stress-relieving treatment. Such heat treatment is usually in accordance with the postweld heat treatment tables given in the applicable code. Differing requirements apply depending on whether the bending or forming was performed hot or cold. According to B31.3, cold bending is performed at a temperature below the transformation range (below the lower critical), and hot bending is performed at a temperature above the transformation range (above the upper critical). B31.1 and ASME Section III make the break between hot and cold bending at a temperature 100°F (38°C) below the lower critical.

B31.3 requires heat treatment after cold bending when (1) specified in the engineering design, (2) the calculated elongation will exceed 5 percent for materials requiring notch toughness properties, and (3) the calculated elongation will exceed 50 percent of the specified minimum elongation indicated in the material specification for P-No.1 through P-No.6 materials. For hot bending and forming, heat treatment is required for all thicknesses of P-Nos.3, 4, 5, 6, and 10A materials.

B31.1 and ASME Section III on the other hand require heat treatment after bending or forming in accordance with the postweld heat treatment table of the applicable code for P-No.1 materials with a nominal wall thickness exceeding ¾ in unless the bending or forming was completed above 1650°F (900°C). All ferritic alloy materials of NPS 4 (DN 100) or larger or with a nominal wall thickness of ½ in or greater which are hot bent or formed must receive an annealing, normalizing and tempering, or a tempering heat treatment to be specified by the designer, or if cold bent or formed, the heat treatment at the required time and temperature cycle specified in the postweld heat treatment table for the material involved.

The codes have no requirements for postbending or forming heat treatments of austenitic stainless steels or nonferrous materials.

Postwelding Heat Treatment Requirements.   Before applying any post-welding heat treatment (PWHT), it should be noted that for work under ASME Section IX, postwelding heat treatment is an essential variable for welding procedure qualification. For ferritic materials there are five possible conditions of heat treatment, each requiring separate qualifications. These are:

1. No PWHT

2. PWHT below the lower critical temperature (stress relief)

3. PWHT above the upper critical temperature (normalize or anneal)

4. PWHT above the upper critical temperature, followed by heat treatment below the lower critical temperature (normalize and temper)

5. PWHT between the upper and lower critical temperatures.

For other materials, two conditions apply: no PWHT or PWHT within a specified temperature range.

Accordingly, for shop work, it may be necessary to qualify welding procedures for several possible heat-treatment situations. For field work only the no heat treatment or stress-relieving situations will normally apply.

When required by the codes, heat treatment consists of a stress-relieving operation. Other heat treatments such as annealing, normalizing, or solution heat treatment may be applied but are not mandatory. However, the welding procedure must have been qualified for the heat treatment applied.

Each code has its own definition regarding governing thicknesses, its own exemptions, differing temperature and holding requirements, heating and cooling rates, etc., reflecting the differing concerns and needs of individual industries. The codes are also constantly evolving as the committees obtain and review new data. Accord-

ingly, the reader should refer to the applicable edition of the code of interest for requirements.

At the time of this writing, the following is a comparison of the heat treatment requirements for carbon steel materials.

B31.1 requires heat treatment of P-No. 1 Gr.Nos. 1, 2, and 3 in the temperature range of 1100 to 1200°F (600 to 650°C) for 1 h/in (1 h/25 mm) of thickness for the first 2 in (50 mm) plus 15 min for each additional inch over 2 in (50 mm), with a 15-min minimum. Exempted are welds with a nominal thickness of ¾ in (19 mm) or less, and a 200°F (95°C) preheat must be applied when either of the base metals exceed 1 in (25 mm). The nominal thickness is defined as the lesser of the thickness of the weld or the thicker of the base metals being joined at the weld. The thickness of the weld is further defined as the thicker of the abutting edges in a groove weld, the throat of a fillet weld, the depth of a partial penetration weld, and the depth of the cavity for repair welds. Thickness as it relates to branch welds is a function of the header thickness, the branch thickness, and reinforcing pad thickness.

B31.1 also requires controlled heating and cooling at temperatures above 600°F (316°C). The rate shall not exceed 600°F/h (335°C/h) or 600°F/h (335°C/h) divided by one-half the maximum thickness at the weld in inches, whichever is less.

Section III requires heat treatment of P-No. 1 materials in the temperature range of 1100 to 1250°F (600 to 675°C) for 30 min when the thickness is ½ in (12.7 mm) or less, for 1 h/in (1 h/25 mm) of thickness for thickness over ½ to 2 in (12.7 mm to 50 mm), and 2 h plus 15 min for each additional inch of thickness over 2 in (50 mm). In this case the thickness is defined as the lesser of (1) the thickness of the weld, (2) the thinner of the pressure retaining parts being joined, or (3) for structural attachment welds, the thickness of the pressure retaining material.

ASME Section III exempts P-No. 1 materials in piping systems from mandatory heat treatment based on thickness and carbon content. When the materials being joined are 1½ in (38 mm) or less, the following exemptions apply: (1) a carbon content of 0.30 percent or less with a nominal thickness of 1¼ in (32 mm) or less, (2) a carbon content of 0.30 percent or less with a nominal wall thickness of 1½ in (38 mm) when a preheat of 200°F (95°C) is applied, (3) a carbon content over 0.30 percent with a nominal wall thickness of ¾ in (19 mm) or less, and (4) a carbon content over 0.30 percent and a nominal wall of 1½ in (38 mm) or less when a preheat of 200°F (95°C) is applied.

ASME Section III also requires controlled heating and cooling. Above 800°F (430°C) the rate shall not exceed 400°F/h (225°C/h) divided by the maximum thickness in inches but not to exceed 400°F/h (205°C/h). The rate need not be less than 100°F/h (55°C/h). Time and temperature recordings must be made available to the Authorized Nuclear Inspector.

B31.5 requires heat treatment of P-No. 1 material greater than ¾ in (19 mm) in the temperature range of 1100 to 1200°F (600 to 650°C) for 1 h/in (1 h/25 mm) of wall thickness with a 1 h minimum. The governing thickness is the thicker of the abutting edges for butt welds and the throat thickness for fillet socket and seal welds. Controlled heating and cooling rates are specified.

B31.3 has similar requirements except that differing thickness definitions are applied to branch, fillet, and socket welds, and there are no specified heating or cooling rates.

B31.4 and B31.11 both require stress relieving when the wall thickness exceeds 1¼ in (32 mm), or 1½ in (38 mm) if a 200°F (95°C) preheat is applied. No specific temperature is specified. B31.8 on the other hand requires stress relief if the carbon content exceeds 0.32 percent, the carbon equivalent (C + ¼ Mn) exceeds 0.65 percent, or the wall thickness exceeds 1¼ in (32 mm). Carbon steels are to be heat treated at 1100°F (600°C) or higher as stated in the qualified welding procedure.

Requirements for postweld heat treatment of many different ferrous alloy steels are given in the various codes. As in the case of the carbon steels, there are variations in requirements from code to code.

In the case of welding dissimilar metals, the codes most often specify that the heat treatment which invokes the higher temperature requirement be applied to the weld joint. In applying this criteria many factors should be considered. See the section ''Dissimilar Metals'' for some options. Another possibility is to take advantage of longer-time and lower-temperature heat treatments permitted by some codes.

In the end, the best source of information for specific requirements regarding heat treatment is the particular code mandated by law or contract. Where none is invoked, the various codes can be used as guides.

Verification Activities—Inspection, Nondestructive Examination, Testing, and Quality Assurance and Quality Control

Introduction.   Activities involved in verifying that fabrication meets the specified quality level may be broadly categorized as inspection, NDE, testing and QA and QC.

The terms *inspection, examination*, and *testing* are still often used interchangeably. The ASME Boiler and Pressure Vessel Codes have begun to establish specific definitions for these terms. The B31 Codes present a mixture of usages, some following the ASME Boiler and Pressure Vessel Code lead, while others are less definitive. The reader is directed to the individual codes to see how these terms are used. In general, the ASME Boiler and Pressure Vessel Code practice will be followed in this section.

Inspection relates to those activities performed by the owner, the owner's agent, or a third party. All other activities are usually performed by fabricator personnel.

The term *examination* is applied to nondestructive methods of examination, while *testing* refers to traditional hydrostatic and pneumatic tests for leakage. QA and QC relate to in-plant or on-site programs, whose function is to control the various activities which affect quality.

Inspection.   Inspection, as used in ASME Section I, III and B31.1 for Boiler External Piping, covers those activities which the authorized inspector (AI) or authorized nuclear inspector (ANI) performs in verifying compliance with the applicable code. The AI or ANI is employed by a third party; is independent of the owner, fabricator, or installer; is an employee of a state or municipality in the United States, a Canadian province, or an insurance company authorized to write boiler insurance; and is qualified by written examination as required by state or provincial rules.

In the B31 Piping Codes, inspection is the verification activity performed by the owner or the owner's agent. Specific requirements for qualification of inspectors are outlined in the individual code sections.

The manner in which an inspector verifies compliance is generally left to the discretion of the individual. It may take the form of detailed visual examinations; witnessing of actual operations such as bending, welding, heat treatment, or NDEs; review of records; or combinations thereof. Much relies on the degree of confidence the inspector has in the fabricator's programs and personnel. B31.3 has mandatory sampling requirements for this activity.

Examination

Types of Examinations.   When used in the various codes, examination refers to the verification work performed by employees of the fabricator, much of which

falls into the category of NDE. NDEs most often referenced by code and applied to the fabrication and installation of piping components and systems are:

Visual

Radiographic

Ultrasonic

Liquid penetrant

Magnetic particle

Eddy current examination is often used to evaluate the quality of straight lengths of pipe as they are manufactured but is not often used in fabrication activities. Although not referenced by most codes, bubble testing, halogen diode probe testing, or helium pass spectrometer leak testing may be invoked by contract when, in the opinion of the designer, they will contribute to the integrity of the system. While these methods are referred to as leak tests, their methodology is outlined in Article 10 of ASME Section V Nondestructive Examination.

Accept-reject criteria and the extent to which the various NDEs are to be applied are in the applicable code.

The following are brief descriptions of NDEs as they apply to piping. For much more detailed information the reader is referred to various publications of the American Society for Nondestructive Testing (ASNT),[36] particularly the Nondestructive Testing Handbooks.

1. *Visual examination:* Visual examination is probably the oldest and most widely used of all examinations. It is used to ascertain alignment of surfaces, dimensions, surface condition, weld profiles, markings, and evidence of leaks, to name a few. In most instances the manner of conducting a visual examination is left to the discretion of the examiner or inspector, but more recently, written procedures outlining such things as access, lighting, angle of vision, use of direct or remote equipment, and checklists defining the observations required are being used. Visual examination takes place throughout the fabrication cycle along with QA and QC checks. At setup, this would consist of verifying materials, weld procedures, welder qualifications, filler metal, and weld alignment, and on completion of fabrication, such things as terminal dimensions, weld profile, surface condition, and cleanliness.

2. *Radiographic examination:* When the need for greater integrity in welding must be demonstrated, the most frequently specified examination is radiography. Since the internal condition of the weld can be evaluated, it is referred to as a *volumetric* examination.

Radiographic sources used for examination of piping are usually X-rays or gamma rays from radioactive isotopes. While X-ray equipment is often used, it has limitations in that it often requires multiple exposures for a single joint, and special equipment, such as linear accelerators, are needed for heavier thicknesses. Although X-ray machines produce films with better clarity, they are not as practical in the field because of space limitations and portability. In the field, radioactive isotopes are used almost exclusively because of their portability and case of access. For wall thicknesses up to about 2½ in (63.5 mm) of steel, the most commonly used isotope is iridium 192. Beyond this cobalt 60 is used for wall thickness up to about 7 in (179 mm).

Radioactive sources normally used in piping work range in intensity from a few curies up to about 100 curies. Each source decays in intensity in accordance with

its particular half-life. As the intensity decays, longer exposure times are required. Iridium 192 has a half-life of 75 days, while cobalt 60 has a 5.3-year half-life.

Radioactive sources have finite dimensions and as a result produce a shadow effect on the film. This is referred to as geometric unsharpness, and it is directly proportional to the source size and inversely proportional to the distance between the source and the film. ASME Section V has established limits for geometric unsharpness.

Ideally for pipe, the source is placed inside the pipe and at the center of the weld being examined, with film on the outside surface of the weld, thus permitting one panoramic exposure. Where geometric unsharpness precludes this practice, the source may be placed on the inside on the opposite wall and a portion of the weld is shot. Several exposures will be needed. The source may also be placed outside the pipe and the exposure made through two walls. Again this requires multiple exposures and longer exposure times. See Fig. A6.25.

A radiograph is considered acceptable if the required essential hole or wire size

A	B	C
Opposite wall	Panoramic	Double wall
Given: 1. 30-in dia. X 7-in wall C/S pipe
       2. 10 cu CO_{60} X 0.051 dia. source
       3. 50 cu CO_{60} X 0.125 dia. source
       4. 100 cu CO_{60} X 0.181 dia. source
       5. Max. allowable geometric unsharpness $Ug = \dfrac{Fd}{D} = 0.07$ in (ASME Sect. V Art. 2 para. T-274)
       6. Use Kodak "AA" Film with a 2.5 film density

    Min. SFD = 5.1 in for 10 cu AX 0.051 in dia.
               12.5 in for 50 cu X 0.125 in dia.
               18.1 for 100 cu X 0.181 in dia.

Using the parameter established in 1 above as well as 5 and 6, it would be possible to:

    (a) Use a 10-cu source as established in 2 above and shoot the pipe using the panoramic technique, sketch B above, with an exposure time of 3 hrs or

    (b) Use a 50-cu source as established in 3 above and shoot the pipe using the panoramic technique, sketch B above, with an exposure time of 1 hour 15 min or

    (c) Use a 100-cu source as established in 4 above and shoot the pipe using the opposite wall technique, sketch A above, with an exposure time of 50 min. As many as six exposures might be required—total 5 hrs.

FIGURE A6.25   Effect of source size on radiographic technique.

from the image quality indicator is visible on the film. See ASME Section V for information on this subject.

3. *Ultrasonic examination:* Ultrasonic examination is used in piping for the detection of defects in welds and materials as well as for determining material thickness. A short burst of acoustic energy is transmitted into the piece being examined and echoes reflect from the various boundaries. An analysis of the time and amplitude of the echo provides the examination results.

A clock in the equipment acts to initiate and synchronize the other elements. It actuates a pulsar to send a short-duration electrical signal to a transducer, usually at a frequency of 2.5 MHz. The transducer converts the electrical signal to mechanical vibration. The vibration as ultrasound passes through a couplant (such as glycerine) and through the part at a velocity which is a function of the material. As the sound reflects from various boundaries, it returns to the initiating transducer or sometimes to a second one where it is converted back to an electrical signal which is passed to a receiver amplifier for display on a cathode-ray tube. The horizontal axis of the display relates to time and the vertical axis relates to amplitude. The indication on the extreme left will show the time and amplitude of the signal transmitted from the transducer. Indications to the right will show the time and degree of reflection from various boundaries or internal discontinuities.

The ability of an ultrasonic examination to detect discontinuities depends a great deal on the part geometry and defect orientation. If the plane of the defect is normal to the sound beam, it will act as a reflecting surface. If it is parallel to the sound beam, it may not present a reflecting surface and accordingly may not show on the oscilloscope. Therefore, the search technique must be carefully chosen to assure that it will cover all possible defect orientations.

The most serious defect in a pipe butt weld is that which is oriented in the radial direction. The most commonly used technique for detecting such defects is the shear wave search. In this procedure, the transducer is located to one side of the weld at an angle to the pipe surface. The angle is maintained by a lucite block which transmits the sound from the transducer into the pipe. The sound will travel at an angle through the pipe and weld. Being at an angle, it will reflect from the pipe surfaces until it is attenuated. Any surface which is normal to the beam, however, will reflect a portion of the sound back to the transducer and show as an indication on the oscilloscope. See Fig. A6.26. If the beam angle and the material thickness are known, the reflecting surface can be located and evaluated.

Prior to and periodically during each search, the equipment is calibrated against artificial defects of known size and orientation in a calibration block. The block must be representative of the material being searched (i.e., an acoustically similar material, with appropriate thickness, outside contour, surface finish, and heat-treated condition).

A variation of ultrasonic examination can be used to measure material thickness. If the speed of sound within the material is known, the time it takes for the signal to traverse the thickness and return can be converted to a thickness measurement.

4. *Liquid penetrant examination:* Penetrant-type examinations are suitable for surface examinations only but are very sensitive. They require a fairly smooth surface, since surface irregularities such as grinding mark indications can be confused with defect indications. The surface to be examined is thoroughly cleaned with a solvent and then coated with a penetrating-type fluid. Sufficient time is allowed to permit the fluid to penetrate into surface discontinuities. The excess penetrant is removed by wiping with cloths until all evidence of the penetrant is removed. A developer which acts somewhat like a blotter is then applied to the surface. This
FIGURE A6.26   Ultrasonic shear wave search. (*a*) Search arrangement; (*b*) oscilloscope.

draws the penetrant out of the discontinuity, and it will appear on the surface as an indication. Obviously, the success of the examination depends on the visibility of the indication. To enhance this, the penetrant contains colored dyes which can be seen under normal light, or fluorescent dyes which are viewed under ultraviolet light. The most common case is a red dye penetrant with a white developer.

5. *Magnetic particle examination:* Magnetic particle examination is essentially a surface-type examination, although some imperfections just below the surface are detectable. This type of examination is limited to materials which can be magnetized (paramagnetic materials), since it relies on the lines of force within a magnetic field.

The item to be examined is subjected to a current which will produce magnetic lines of force within the item. The surface is then sprayed with a fine iron powder. The powder will align itself with the lines of force. Any discontinuity normal to the lines of force will produce a leakage field around it and a consequent buildup of powder which will pinpoint the defect. The examination must be repeated at 90° to detect discontinuities which were parallel to the original field.

There are a great many variations of magnetic particle examination depending on the manner in which the field is applied and whether the particles are wet or dry and fluorescent or colored.

Methodology.   The ASME Boiler and Pressure Vessel, B31.1 and B31.3, require certain NDEs to be performed in accordance with the methods described in ASME Section V Nondestructive Examination. The pipeline codes, B31.4, B31.8, and B31.11, refer to API-1104 for Radiographic Procedures. In some cases, particularly in visual examination, requirements are given but no specific methodology is stated. In others, alternative parameters or qualification requirements are given. The specific requirements of the individual codes should be consulted.

Qualification Requirements.   Qualification of procedures and personnel used in NDEs are required by most codes. When ASME Section V or API-1104 are invoked by the referencing code, a written procedure is required and it must be demonstrated to the satisfaction of the AI, ANI, owner, or owner's agent, whichever is applicable. Similarly personnel who perform NDEs must be trained, qualified, and certified. The most frequently invoked qualification document is SNT-TC-1A[37]; it is also accepted by B31.1 for qualification of personnel performing visual examinations. Some codes permit alternatives, such as AWS-QC-1.[38]

TABLE A6.9 Acceptance Standards for Visual Examination

The following indications are unacceptable:
1. Crack(s) on external surfaces
2. Undercut on surface greater than $\frac{1}{32}$ in (1.0 mm) deep
3. Weld reinforcement greater than specified in ASME Table 127.4.2
4. Lack of fusion on surface
5. Incomplete penetration (applies only when inside surface is readily accessible)
6. Any other linear indications greater than $\frac{3}{16}$ in (5.0 mm) long
7. Surface porosity with rounded indications having dimensions greater than $\frac{3}{16}$ in (5.0 mm) or 4 or more rounded indications separated by $\frac{1}{16}$ in (2.0 mm) or less edge to edge in any direction. Rounded indications are indications which are circular or elliptical with their length less than 3 times their width

Source: From ASME B31.1 1995 ed.

Extent of Examination.   The applicable code will define the extent of examination required for piping systems under its coverage. The degree of examination and the examination method and alternatives are a function of the degree of hazard which might be expected to occur in the event of failure. Pressure, temperature, toxicity of the fluid, and release of radioactive substances are some of the considerations. Added layers of examinations may be required as the perceived hazard increases.

Accept-Reject Criteria.   The applicable code will also define the items to be examined and the accept-reject criteria to be applied. Table A6.9 shows the acceptance standards applicable to the visual examination of butt welds under B31.1. Other piping codes have similar but not necessarily identical criteria.

Table A6.10 shows acceptance standards for radiographic examination. Indications interpreted as cracks, incomplete penetration, or lack of fusion are not permitted. Porosity and elongated indications are kept within certain limits. The acceptance standards for ultrasonic examination are similar.

TABLE A6.10 Acceptance Standards for Radiography

Welds that are shown by radiography to have any of the following types of discontinuities are unacceptable:
1. Any type of crack or zone of incomplete fusion or penetration
2. Any other elongated indication with a length greater than
    a. $\frac{1}{4}$ in (6.0 mm) for t up to $\frac{3}{4}$ in (19.0 mm)
    b. $\frac{1}{3}$ t for t from $\frac{3}{4}$ in (6.0 mm) to $2\frac{1}{4}$ in (57.0 mm) inclusive
    c. $\frac{3}{4}$ in (19.0 mm) for t over $2\frac{1}{4}$ in (57.0 mm) where t is the thickness of the thinner portion of the weld
3. Any group of indications in a line that have an aggregate length greater than t in a length of 12 t, except where the distance between successive indications exceeds 6L where L is the longest indication in the group
4. Porosity in excess of that shown as acceptable in Appendix A-250 of Section I of the Boiler and Pressure Vessel Code
5. Root concavity when there is an abrupt change in density indicated on the radiograph

Note: t pertains to the thickness of the weld being examined. If a weld joins two members having different thicknesses at the weld, t is the thinner of these thicknesses.
Source: ASME B31.1 1995 ed.

TABLE A6.11   Acceptance Standards for Magnetic Particle and Liquid Penetrant Examinations

---

The following relevant indications are unacceptable:
1. Any cracks or linear indications
2. Rounded indications with dimensions greater than $\frac{3}{16}$ in (5.0 mm)
3. Four or more rounded indications in a line separated by $\frac{1}{16}$ in (2.0 mm) or less edge to edge
4. Ten or more rounded indications in any 6 in^2 (3870 mm^2) of surface with the major dimension of this surface not to exceed 6 in (150 mm) with the area taken in the most unfavorable location relative to the indications being evaluated

---

Source: From ASME B31.1 1995 ed.

Both magnetic particle and liquid penetrant examinations have identical limits. See Table A6.11

Other types of NDEs, such as acoustic emission, bubble testing, and mass spectrometer testing, are not required by the various codes. They can be invoked by contract and the acceptance standards must be a matter of agreement between the contracting parties.

Testing.   All of the piping codes outline some type of pressure test to determine leak tightness. Since the completed piping system is usually subjected to some type of test in the field after installation, shop testing of subassemblies is infrequent. In those cases where the assembly cannot be field tested, where welds in the assembly will not be exposed for examination during the field test, and in other special situations, shop testing may be required. Shop testing must meet all of the requirements for field testing. See the section "Installation" for particulars.

Quality Assurance and Quality Control.   ASME Section III has very specific requirements for QA programs. ASME Section I has requirements for QC programs. The B31 Piping Codes do not require any formal written program at this time. Refer to these codes for detailed information on this subject.

Cleaning and Packaging.   Cleanliness of piping subassemblies is a matter of agreement between the fabricator and purchaser. As a minimum the fabricator will clean the inside of the subassembly of loose scale, weld spatter, machining chips, etc., usually with jets of compressed air. For those systems which require a greater degree of cleanliness several options are available. For specific information refer to PFI Standard ES-5 "Cleaning of Fabricated Pipe."[39] See also the following specifications published by the Steel Structures Painting Council:[40]

SSPC—SP 2 Hand Tool Cleaning

SSPC—SP 3 Power Tool Cleaning

SSPC—SP 6 Commercial Blast Cleaning

SSPC—SP 8 Pickling

SSPC—SP 10 Near-white Blast Cleaning

For ferritic steels the inside surfaces may be cleaned by turbinizing to remove loosely adhering mill scale and heavy rust. Wire brushing and grinding may also be employed for removal of more tightly adhering scale, rust, etc.; however, the most effective method for removal of tight scale is blasting with sand, shot, or grit.

For guidance on blasting methods and degrees of cleanliness refer to PFI Standard ES-29 ''Abrasive Blast Cleaning of Ferritic Piping Materials.''[41]

Pickling is an equally effective method of cleaning. It is most often used for cleaning large quantities of straight tubes prior to fabrication or small-size (about NPS 4) subassemblies where blasting is not as effective. Its application is limited by the availability and size of pickling tanks. A hot solution of sulfuric acid (H_2SO_4) is most commonly used, although cold hydrochloric acid (HCl) is also recommended. See SSPC—SP 8 ''Pickling.''

For the 9Cr-1Mo-V materials, aluminum-oxide or silicon-carbide grit, sand or vapor blasting is preferred. Steel shot or grit which has been previously used to clean iron-bearing materials should be avoided. Acid pickling should also be avoided since damaging hydrogen embrittlement may occur.

Austenitic stainless steels normally do not require cleaning except for a degreasing with solvent-saturated cloths to remove traces of greases or cutting oils. Subassemblies which have been heated for bending or which have been given a carbide solution heat treatment will have a tightly adhering chromic oxide scale. Pickling and passivating in a solution of hydrofluoric and nitric acid will remove the scale and passivate the exposed surface. Here again, the equipment for pickling may limit the size of the subassembly. See ASTM A 380 published by the American Society for Testing Materials.[42] Blasting may also be used, but new silica sand or aluminum-oxide grit is required. Sand or grit previously used on ferritic pipe will contaminate the pipe surface with iron particles, and it will subsequently rust. The blasted surface should be treated with a solution of nitric acid to passivate the surface.

For extreme cleanliness, steam degreasing and rinsing with demineralized water may be employed.

The external surfaces of pipe may be left as is, painted, or otherwise preserved. See PFI Standard ES-34 ''Painting of Fabricated Piping.''[43]

Depending on the need for maintaining rust-free interior surfaces, the pipe inside diameter may be coated with different preservatives, or desiccants may be employed during shipping and storage.

For shipping, the ends of subassemblies are equipped with some type of end protection to preclude damage to weld end bevels or flange faces during shipment and field handling. See PFI Standard ES-31 ''Standard for Protection of Ends of Fabricated Piping Assemblies.''[44]

During shop operations, it is common practice to move piping assemblies with overhead or floor cranes, usually with chain or wire rope slings. For austenitic stainless steels and nonferrous materials which could be damaged or contaminated, use of nylon slings is recommended.

INSTALLATION

Drawings

Drawings used for piping system installation may vary greatly. Often orthographic projections of the building showing several systems or single systems, depending on complexity, are used. In many cases single or multiple isometric drawings of a single system are used. These of course are not to scale but are convenient for planning, progress recording, or record keeping when required by quality programs. In all cases where prefabricated subassemblies are being erected, these drawings

will have been marked up to show the locations and mark numbers of the individual subassemblies, the location and designations of field welds, and the locations and markings of hangers.

Erection Planning

Planning is vitally important in installing a piping system. Many factors must be considered, among them accessibility to the building location, coordination with other work, availability and accessibility of suitable welding and heat treatment equipment, availability and qualification of welders and welding procedures, rigging, scaffolding, and availability of terminal equipment.

Each of the system components should also be carefully checked to assure correctness. Valves and other specialty items in particular should be checked to assure they are marked with flow arrows, that the handwheels or motor operators are properly oriented, and that the material to be welded is compatible with the material of the piping. Special valves for use in carbon steel systems are sometimes furnished as 5 percent chrome material, and thermowells are often not of the same chemical composition as the pipe. This may not be apparent from the drawings. Such a preliminary check will indicate the need for alternate welding procedures and preclude problems later.

The location of the work and accessibility to it should be viewed. It may not be possible to install an overly long subassembly after other equipment or building structure is in place. A common practice in the power field is to have large, heavy assemblies often found in the main steam and reheat lines of large central stations erected with the structure. In other cases, a preliminary review may show interferences from an existing structure, cable trays, ducts, or other piping which are not apparent from the drawings. The locations of the terminal points on equipment should be checked to assure that they are correct. The type, size, rating, or weld preparation of the connection should be checked to assure that it will match the piping. Solutions to any problems can be devised with the designer before work starts.

The ideal way to begin erection is to start at some major piece of equipment or at a header with multiple outlets. Install the permanent hangers if possible. If these are to be welded to the structure, some prudence should be exercised, since the final location of the line may warrant some small relocation to assure that the hanger is properly oriented relative to the piping in its final position. Obviously a certain number of temporary supports will be needed. Welding of temporary supports to the building structure or to the piping itself should be avoided or used only with the approval of the responsible engineers. Variable spring and constant-support-type hangers should normally be installed with locking pins in place, assuring that they function as a rigid support during the erection cycle. Where welded attachments to the pipe are involved, it is preferred that they be installed in the shop as part of the subassembly.

If possible, the major components of the system should be erected in their approximate final position prior to the start of any welding. This will reveal any unusually large discrepancies which may result from equipment mislocation, fabrication error, or tolerance accumulations. Adjustments or corrections can then be decided upon. Long, multiplane systems can absorb considerable tolerance accumulation without the need to modify any part. Short, rigid systems may not be able to accommodate any tolerance accumulation, and it may be necessary to rework one or more parts.

Cold Spring

Both the B31.1 and B31.3 Codes address cold springing in detail. Cold spring is the intentional stressing and elastic deformation of the piping system during the erection cycle to permit the system to attain more favorable reactions and stresses in the operating condition.

The usual procedure is to fabricate the system dimensions short by an amount equal to some percentage of the calculated expansion value in each direction. The system is then erected with a gap at some final closure weld, equal to the ''cut shorts'' in each direction. Forces and moments are then applied to both ends as necessary to bring the final joint into alignment. Once this is done, it is usually necessary to provide anchors on both sides of the joint to preserve alignment during welding, postweld heat treatment, and final examination. When the weld is completed and the restraining forces are removed, the resulting reactions are absorbed by the terminal points, and the line is in a state of stress. During start-up the line expands as the temperature increases, and the levels of stress and terminal reactions resulting from the initial cold spring will decrease. For the 100 percent cold sprung condition, the reactions and stress will be maximum in the cold condition and theoretically zero in the hot condition. It should be borne in mind that it is very difficult to assure that a perfect cold spring has been attained and for this reason the codes do not permit full credit in the flexibility calculations. Also remember that lines operating in the creep range will ultimately attain the fully relaxed condition. Cold spring merely helps it get there faster. Cold spring was historically applied to high-temperature systems such as main steam and hot reheat lines in central power stations, but this practice is not as prevalent anymore.

For those involved with the repair of lines which have been cold sprung, or which have achieved some degree of creep, caution should be exercised when cutting into such lines since the line will be in a state of stress when cold. The line should be anchored on either side of the proposed cut to prevent a possible accident.

Joint Alignment

In aligning weld joints for field welding it may be necessary to compromise between a perfect weld fit-up and the location of the opposite (downstream) end of the assembly. The weld bevel may not be perfectly square with the longitudinal axis of the assembly. Even a $\frac{1}{32}$-in (0.8 mm) deviation across the face of the weld bevel can result in an unacceptable deviation from the required downstream location if the joint is aligned as perfectly as possible. Often such a small gap can be tolerated in the welding. If, in order to maintain the downstream location, the gap at the joint is excessive, the joint should be disassembled, and the land filed or ground as needed to attain the required alignment of the weld joint while still maintaining the required downstream position. Flanged connections should be made up hand-tight so that advantage can be taken of the bolt-hole clearances to translate or rotate the assembly for better alignment of downstream connections.

Weld shrinkage of field welds may or may not be important in field assembly. In long flexible systems, they may be ignored. For more closely coupled systems, particularly those using GTAW root-pass welding, this factor should be considered. The degree of longitudinal shrinkage across a weld varies with welding process, heat input, thickness, and weld joint detail. See the section ''Layout, Assembly, and Preparation for Welding.'' In extreme cases closure pieces may be used. Here, the system is completed except for the final piece. A dummy assembly is then

fabricated in place and the closure assembly is fabricated to match the dimensions of the dummy assembly with weld shrinkage of the final welds taken into account.

Cutting, Bending, Welding, Heat Treatment, and Examination

Cutting, bending, and welding operations in the field parallel those used in the shop. See the section ''Fabrication.''

Mechanical and oxyfuel gas cutting are most commonly used in the field. Plasma cutting may occasionally be used.

Bending, if used at all, is limited to small-diameter piping using relatively simple bending equipment at ambient temperatures. Occasionally in order to correct for misalignment, larger-diameter ferritic piping is bent at temperatures below the lower critical. Please note that this procedure is limited to ferritic materials. Any application of heat to austenitic materials will result in sensitization and loss of corrosion properties. See the section ''Bending.'' For smaller pipe sizes, torches may be used to supply heat, but for larger, heavier-wall materials and where better temperature control is warranted, heat may be applied by induction or resistance heating units in the same manner as local stress relieving. See the section ''Local Heat Treatment.'' The heating units are applied to the section of the pipe to be bent. The section of the line upstream of the area to be bent should be anchored to preclude translation or rotation of the installed portion of the line. The anchor should preferably be not more than one or two pipe diameters from the area to be heated. Once the bend area has attained the required temperature, a bending force can be applied on the downstream leg of the pipe until the required bend arc has been obtained. Since most ferritic materials still have reasonably high yield strengths even at lower critical temperatures, care should be exercised. Large bending forces may damage the building structure or crack the line being bent. Apply a reasonable force for the conditions and allow the imposed stress in the bend arc to be relieved by the heat. Then repeat. Progress in this fashion until the required bend is accomplished. Some small amount of overbending may be required to offset the deflection which will occur in the unheated section of pipe between the heated arc and the pulling device. When the bend is completed and allowed to cool, all restraints may then be removed. Little if any force should be needed to align the downstream joint; otherwise additional bending may be needed to further correct the situation. No further heat treatment of the bend arc is needed since the temperatures applied in this bending method are below the lower critical temperature. Corrections to lines with large section modulus or where the required bend arc is large should preferably be made in a shop since better controls can be exercised.

Field welding is more often than not in a fixed position. Welders should be qualified in the 6G position since this qualifies for all positions.

Welding will be done using SMAW, GMAW, FCAW, and GTAW. Some welding processes can be automated using orbital welding techniques. Such practice can result in fewer repairs, provided the bevels and alignment are within tolerance and the welding parameters are carefully selected.

Field postweld heat treatment also follows the practices outlined in the section ''Heat Treatment'' for local stress-relieving of ferritic materials. This usually involves induction or resistance heating units with recording devices. For small pipe welds, torch heating using temperature-sensitive crayons to control temperature is sometimes used. Exothermic heating to stress-relieve welds is still used on occasion for outdoor applications where heating rates are not required to be controlled.

Exothermic materials are preformed to pipe contour and sized to reflect the wall thickness and desired stress-relieving temperature. They are placed around the weld and ignited, attaining temperature in 5 or 10 min. The actual maximum temperature attained may vary.

NDE in the field will follow the practices outlined in the section "Verification Activities." Radiography is usually limited to radioactive isotopes, although occasionally X-ray equipment may find a use. Most surface examination is conducted using liquid-penetrant methods, since magnetic particle equipment is not as convenient in the field. Ultrasonics are used for thickness verification and in certain situations as an alternative to radiography of welds when permitted by the governing code.

Mechanical Joints

Threaded joints probably represent the oldest method of joining piping systems. The dimensional standards for taper pipe threads are given in ASME B1.20.1.[45] This document gives all required dimensions including number of threads per inch, pitch diameter, and normal engagement lengths for all pipe diameters. Thread cutting should be regarded as a precise machining operation. A typical threading die is shown on Fig. A6.27. For steel pipe the lip angle should be about 25°, but for brass it should be much smaller. Improper lip angle results in rough or torn threads. Since pipe threads are not perfect, joint compounds are used to provide leak tightness. The compounds selected, of course, should be compatible with the fluid carried and should be evaluated for possible detrimental effects on system components. Manufacturers' recommendations should be followed.

FIGURE A6.27   Threading die.

Where the presence of a joint compound is undesirable, dryseal pipe threads in accordance with ASME B1.20.3[46] may be employed. These are primarily found in hydraulic and pneumatic control lines and instruments.

Flanged joints are most often used where disassembly for maintenance is desired. A great deal of information regarding the selection of flange types, flange tolerances, facings and gasketing, and bolting is found in B16.5. The limitations regarding cast-iron-to-steel flanges, as well as gasket and bolting selection, should be carefully observed. The governing code will usually have further requirements.

Gasket surfaces should be carefully cleaned and inspected prior to making up the joint. Damaged or pitted surfaces may leak. Appropriate gaskets and bolting must be used. The flange contact surfaces should be aligned perfectly parallel to each other. Attempting to correct any angular deviation perpendicular to the flange faces while making up the joint may result in overstressing a portion of the bolts and subsequent leakage. The proper gasket should be inserted making sure that it is centered properly on the contact surfaces. Bolts should be tightened hand-tight. If necessary for alignment elsewhere, advantage may be taken of the bolt hole

tolerances to translate or rotate in the plane of the flanges. In no case should rotation perpendicular to the flange faces be attempted. When the assembly is in its final location, bolts should be made up wrench-tight in a staggered sequence. The bolt loading should exert a compressive force of about twice that generated by the internal pressure to compensate not only for internal pressure but for any bending loads which may be imposed on the flange pair during operation. For a greater guarantee against leakage, torque wrenches may be employed to load each bolt or stud to some predetermined value. Care should be exercised to preclude loading beyond the yield point of the bolting. In other cases, special studs that have had the ends ground to permit micrometer measurement of stud elongation may be used. Flange pairs which are to be insulated should be carefully selected since the effective length of the stud or bolt will expand to a greater degree than the flange thicknesses, and leakage will occur. Thread lubricants should be used, particularly in high-temperature service to permit easier assembly and disassembly for maintenance.
FIGURE A6.28   Compression sleeve (Dresser) coupling for plain-end cast-iron or steel pipe.

There are a great variety of mechanical joints used primarily for buried cast-iron pipelines carrying water or low-pressure gas. They are primarily of the bell and spigot type with variations involving the use of bolted glands, screw-type glands, and various types of gasketing. The reader is referred to AWWA Standards C 111,[47] C 150,[48] and C 600,[49] and to catalogs for proprietary types. For reinforced concrete pipe, AWWA Standards C 300,[50] C 301,[51] and C 302,[52] should be consulted. Compression-sleeve couplings such as the Dresser coupling (see Fig. A6.28) and the Victualic coupling (see Fig. A6.29) are widely used for above- and below-ground services, both with cast-iron and steel pipe. Consult the manufacturers' catalogs for more information. Refer to Chap. A9 of this handbook.

Tubing

Copper, aluminum, steel, and stainless-steel tubing are frequently used in hydraulic, pneumatic, and sampling systems. Installation is most often concerned with protection of such materials from damage, since they are often associated with control systems. The manner of protection is left to the designer's judgment.

Lighter wall tubing is often bent using small compression-type benders. Tubing is joined to itself and to pipe-size fitting and components with a variety of proprietary tubing fittings which are described in Chap. A2. Some heavier-wall stainless-steel tubing is welded using specially designed socket welding fittings. GTAW welding with filler metal added is used for such applications.
FIGURE   A6.29 Victualic   coupling   for grooved-end cast-iron or steel pipe.

Pipe Supports

This section offers some thoughts on the installation of piping supports. The design, manufacture, and influence of supports on the system flexibility are outlined in Chaps. B4 and B5 of this book.

As pointed out earlier, economics and efficiency dictate that it is preferable to install the permanent supports for a system as the first step, thus minimizing the need for temporary supports. In so doing considerable judgment should be exercised, since there can be minor variations between the as-designed and as-installed line location. Resilient and constant-effort support should be locked with stops to preclude change in supporting effort as the line is being installed. Only after the line has been completely welded, tested, and insulated should the stops be removed. Once removed, the resilient and constant-effort supports should be carefully adjusted to their "cold" positions. This may take several iterations, since adjustment of any one will change the loading on the adjacent ones. Systems with multiple constant-effort supports can be especially troublesome. Since the support design is most often based on theoretical values of weight of the pipe, insulation, and the fluid, there will be some difference between the actual and calculated supporting effort. Where rigid supports are involved, this variation will be taken up automatically. Where a system is designed with multiple resilient or constant-effort supports, every effort should be made to incorporate one or more rigid supports in the design to absorb the variation between actual and theoretical loads. Otherwise it may be necessary, with the approval of the designer, to modify the spring load-carrying settings.

As the line goes to operating temperature, it should be carefully observed to assure that there are no unforeseen interferences with its required expansion, particularly at nearby structures, floor sleeves, or adjacent lines or by restrained branch connections. Some modification may be required to assure free expansion of the line. All resilient supports and constant-effort supports should be checked during initial start-up to assure that they are functioning properly, and after the line has

been at operating temperature for several hours, they should be checked to verify that they are in the required "hot" operating condition. It may be necessary to readjust some units to match the calculated "hot" loading. These settings should be checked on a regular basis for the first few weeks of service, particularly in systems operating in the creep range, since the temperature will begin to relieve locked-in construction stresses, and the line may choose a different, more relaxed location. Readjustments may be required. If after some time in service, the resilient and constant-effort supports still require significant adjustment (i.e., the system cannot be balanced), a complete review of the flexibility analysis, expansion calculations, weight calculations, hanger, design, and installation procedures should be made to determine the cause. Resilient and constant-effort support units which are not functioning in the spring range (i.e., they have become "solid" or "loose") may impose undesirably high stresses in the line if they are not corrected, which can lead to premature failure or significantly reduced system life.

Leak Testing

At one time, complex shapes were pressure-tested to determine their suitability for the service intended. This involved stressing the component to a point above service stresses, but below bursting stress, and was referred to as a pressure test. Currently most codes require some type of test to determine leak tightness rather than service suitability.

The most common method of leak testing for piping systems is the hydrostatic test. Usually this involves water at ambient temperature as the test medium. B31.1 requires that the system be pressurized to 1.5 times the design pressure, ASME III, to 1.25 times the design pressure, and B31.3 requires a test pressure of 1.5 times the design pressure adjusted by the ratio of the allowable stress at test temperature divided by the allowable stress at operating temperature. In each case, however, the test pressure of unisolated equipment or some function of the yield stress of the line material may be a limiting factor. See the applicable code for particulars. The line must be held at test pressure for at least 10 min, but may be reduced as permitted in the applicable code until the examination for leakage is complete.

Depending on the specific situation, alternative test fluids may be employed. As an example, in a liquid sodium system, where water could be very hazardous, or in cases where the possibility of freezing exists, a hydrocarbon or other fluid might be used.

In instances where water or other liquids are unacceptable, or where supports may not be adequate to carry the added weight of water, pneumatic tests may be performed. Pneumatic tests are potentially more dangerous than hydrostatic tests, and extreme care should be exercised. B31.1 and ASME III require the pneumatic test be performed at not less than 1.2 times the design pressure, while B31.3 limits the test to 1.1 times design. In each case, the limits regarding equipment and yield strength previously cited for hydrostatic tests also apply.

Prior to the test a detailed review of the section of the line to be tested should be made with the following in mind:

1. Temporary supports for those sections where the permanent supports were not designed to take the additional weight of the test fluid.

2. Isolation or restraints on expansion joints.

3. Isolation of equipment or valves which may be overstressed at test pressure.

4. Location of test pump and the need for additional test gauges if there is a significant head variation due to elevation differential.

5. Location of vents and drains.

6. Location of a relief valve to preclude excessive overpressure due to possible thermal expansion of the test fluid.

7. Consideration of the probable ambient test temperature relative to the expected brittle fracture toughness of the system materials. Heating the water may be a solution.

8. Alternative test fluid.

9. Accessibility to the weld joints for inspection. Some codes require that the weld joints be left exposed until after the test.

10. Assurance that no part of the system will exceed 90 percent of its yield strength.

It is advisable to prepare a written procedure outlining the scope and boundaries of each test to assure that it is performed in a safe manner. The codes vary a bit on the required test pressures, time at test pressure, pressure during inspection for leakage, and whether alternative tests may be performed. It is advisable to look at each one specifically. For more details, refer to Chap. B14 of this handbook.

CHAPTER A7
BOLTED JOINTS

Gordon Britton

President, INTEGRA Technologies Limited
Sarnia, Ontario, Canada

INTRODUCTION

While other chapters of the *Piping Handbook* deal with the pressure integrity of the piping system, this chapter deals with managing the leak integrity of bolted flanged systems. It covers the main elements of a bolted joint system to provide an understanding of the bolted joint connection and the science of joint sealing.

This chapter focuses exclusively on bolted joints subjected to internal pressures. While integrity of mechanical (structural) joints are also critical, they are not covered in this book.

Oil, gas, and power plants and other process industries are under constant pressure to work their plants at maximum design limitations and for longer periods. The bolted joint is often regarded as the weak link in the plant's pressure envelope. Whether a pipe flange, heat exchanger, reactor manway, or valve bonnet, the joint integrity relies not only on the mechanical design of the flange and its components, but also on its condition, maintenance, and assembly. Plant personnel are looking for equipment to achieve leak-free joints with reduced shutdown periods while increasing the time between shutdowns. Similarly, flanged joints in other piping and distribution systems found throughout industrial, commercial, and residential facilities are required to maintain their structural integrity and leak tightness.

Several standards have been written to enable designers to design bolted joints. Compliance to the requirements of these standards ensures mechanical integrity of bolted joints. However, these standards do not provide adequate and effective requirements or guidelines to assure leak integrity of flanged joints.

To achieve leak integrity, a broader view of the bolted flange joint as a system must be adopted. Ideally, a process is to be followed that manages the key elements of the bolted system, which allows the design potential of the bolted joint to be realized and helps in achieving continued leak-free operation.

This chapter reviews the process required to achieve flange-joint integrity.

COST OF A LEAK

Some believe leaking flanges are normal and leaks cannot be prevented. Some also hold similar views about health and safety. Safety professionals now know that accidents can be prevented and that the goal of zero accidents is achievable. The goal of zero leaks is also achievable. Leaks are still very commonplace. A thorough survey throughout North American industry, performed by Pressure Vessel Research Council (PVRC), concluded that the average plant experiences 180 leaks per year. A breakdown of the severity of these leaks is shown in Fig. A7.1.

The average plant experiences 180 leaks per year

Ratio of Leaks   **Severity of Leaks**

1   → Major - Shutdown

4   → Serious - High repair cost

9-17   → Minor - Some damage

158-167   → Near misses - Nuisance
                   Leaks
FIGURE A7.1   Industry leak study (PVRC Study, July 1985).

In a manner similar to accident ratio statistics, there is a relationship between minor, serious, and other dangerous events. All events represent failure in control. Failures in control that result in leaks cost industry millions of dollars yearly due to:

- Emission
- Pollution, spills
- Rework
- Leak sealing
- Fires
- Lost product
- Late schedules
- Forced shut downs—production losses

Control is the issue. Leaks are controllable. Control is achieved by implementation of a Flange Joint Integrity program. Joint Integrity is a control program that becomes an integral part of a plant's safety and reliability.

THE PROCESS OF JOINT INTEGRITY

To assist in managing a process, ask yourself the following questions: why, what, who, and how?

Why do we need a Flange Joint Integrity program? This was addressed in the previous section, "Cost of a Leak." The stakes are enormous. A Flange Joint Integrity program will help improve plant safety and reliability while reducing its environmental impact.

What do we need to control? The operating environment, the components, and assembly all need to be controlled.

Who do we need to control? The designers, field operatives, and supervisors.

How do we control? Train personnel to required competency. Design components using latest engineering standards. Develop best practices for assembly and maintenance. Implement a quality assurance program that provides traceability and ensures compliance to specifications.

There are over 120 variables that affect flange joint integrity. These can be controlled through the following categories:

- Environment (internal and external)
- Components
- Assembly

The internal environment outlines the design and operating conditions of temperature, pressure, and fluid. With the external environment, consideration is given to location of the flange, whether it is operating in air or sub-sea, and externally applied piping loads. An understanding of the environment is crucial to the design and selection of the appropriate components with the correct assembly methods.

The components include the most appropriately designed and selected flange, gasket, and bolting, commensurate with the risk dictated by the environment.

Assembly includes checking the condition of the components and proceeding according to established procedures. Proper assembly requires that

- Flange faces meet the standards
- Gasket-seating stress is achieved
- Bolts, nuts, and gaskets are free of defects
- Appropriate lubrication is used

Execution requires trained, competent people using the correct tools and following procedures.

The steps in the joint integrity process are shown in Fig. A7.2.

FLANGE JOINT COMPONENTS

Flanges

There are numerous types of flanges available. The type and material of flanges is dependent on the service environment. The service environment is specified in the Piping and Instrumentation Drawing (P&ID) and other design documents. Refer

FIGURE A7.2   Steps in joint integrity process.

to Chap. B1 of this handbook. Selection of flange materials is done in conjunction with piping specification.

Flange Standards

There are a variety of standards used in the design and selection of flanges. The following codes and standards relate to pipe flanges:

ASME Codes and Standards:

B16.1	Cast Iron Flanges and Flanged Fittings
B16.5	Pipe Flanges and Flanged Fittings
B16.24	Bronze Flanges and Fittings–150 and 300 Classes
B16.42	Ductile Iron Pipe Flanges and Flanged Fittings–150 and 300 Classes
B16.47	Large Diameter Steel Flanges

Section VIII

Division 1	Pressure Vessels
Appendix 3	Mandatory Rules for Bolted Flange Connections

ANSI/AWWA Standards

C-111/A21.15	Flanged C.I. Pipe with Threaded Flanges
C-207	Steel Pipe Flanges

API Specifications

Spec 6A-96	Specification for Wellhead and Christmas Tree Equipment

The two most commonly used flange standards for process and utilities pipework are ASME B16.5 and BS 1560 (British Standards). API 6A (American Petroleum Institute) specifies flanges for wellhead and Christmas tree equipment. Less common flange standards which may be encountered are flanges for metric or DIN standards.

Refer to Chap. A4 for other codes and standards.

Flange-End Connection

The flange-end connection defines the way in which it is attached to the pipe. The following are commonly available standard flange end types:

Weld-Neck (WN) Flange. Weld-neck flanges are distinguished from other types by their long, tapered hub and gentle transition to the region where the WN flange is butt-welded to the pipe. The long, tapered hub provides an important reinforcement of the flange, increasing its strength and resistance to dishing. WN flanges are typically used on arduous duties involving high pressures or hazardous fluids.

The butt-weld may be examined by radiography or ultrasonic inspection. Usually, the butt-welds are subject to visual, surface, or volumetric examinations, or a combination thereof, depending on the requirements of the code of construction for piping or a component. There is, therefore, a high degree of reliability in the integrity of the weld. A butt-weld also has good fatigue performance, and its presence does not induce high local stresses in the pipework.

Socket-Weld (SW) Flange. Socket-weld flanges are often used on hazardous duties involving high pressure but are limited to a nominal pipe size NPS 2 (DN 50) and smaller. The pipe is fillet-welded to the hub of the SW flange. Radiography is not practical on the fillet weld; therefore correct fitting and welding is crucial. The fillet weld may be inspected by surface examination, magnetic particle (MP), or liquid penetrant (PT) examination methods.

Slip-on Flanges. Slip-on flanges are preferred to weld-neck flanges by many users because of their initial low cost and ease of installation. Their calculated strength under internal pressure is about two-thirds of that of weld-neck flanges. They are typically used on low-pressure, low-hazard services such as fire water, cooling water, and other services. The pipe is ''double-welded'' to both the hub and the bore of the flange, but, again, radiography is not practical. MP, PT, or visual examination is used to check the integrity of the weld. When specified, the slip-on flanges are used on pipe sizes greater than NPS 2½ (DN 65).

Composite Lap-Joint Flange. This type of flanged joint is typically found on high alloy pipe work. It is composed of a hub, or ''stub end,'' welded to the pipe and a

backing flange, or lapped flange, which is used to bolt the joint together. An alloy hub with a galvanized steel backing flange is cheaper than a complete alloy flange. The flange has a raised face, and sealing is achieved with a flat ring gasket.

Swivel-Ring Flange.   As with the composite lap-joint flange, a hub will be butt-welded to the pipe. A swivel ring sits over the hub and allows the joint to be bolted together. Swivel-ring flanges are normally found on sub–sea services where the swivel ring facilitates flange alignment. The flange is then sealed using a ring-type joint (RTJ) metal gasket.

Blind Flange.   Blind flanges are used to blank off the ends of piping, valves, and pressure vessel openings. From the standpoint of internal pressure and bolt loading, blind flanges, particularly in the larger sizes, are the most highly stressed of all the standard flanges. However, since the maximum stresses in a blind flange are bending stresses at the center, they can be safely permitted to be stressed more than other types of flanges.

These common flange types are shown in Fig. A7.3.

Flange Faces

There are five types of flange faces commonly found. The surface finish of the faces are specified in the flange standards quoted above.

Raised Face (RF).   The raised face is the most common facing employed with bronze, ductile iron, and steel flanges. The RF is ¹⁄₁₆-in high for Class 150 and Class 300 flanges and ¼-in high for all pressure classes, higher than Class 300. The facing on a RF flange has a concentric or phonographic groove with a controlled surface finish. Sealing is achieved by compressing a flat, soft, or semimetallic gasket between mating flanges in contact with the raised face portion of the flange.

Ring-Type Joint (RTJ).   This type is typically used in the most severe duties, for example, in high-pressure-gas pipe work. Ring-type metal gaskets must be used on this type of flange facing.

RTJ for API 6A Type 6B, BS 1560 and ASME B16.5 Flanges
The seal is made by plastic deformation of the RTJ gasket into the groove in the flange, resulting in intimate metal-to-metal contact between the gasket and the flange groove. The faces of the two opposing flange faces do not come into contact because a gap is maintained by the presence of the gasket. Such RTJ flanges will normally have raised faces, but flat faces may also be used or specified.

RTJ for API 6A Type 6BX Flanges
API 6A Type 6BX flanges have raised faces. These flanges incorporate special metal ring joint gaskets. The pitch diameter of the ring is slightly greater than the pitch diameter of the flange groove. This factor preloads the gasket and creates a pressure-energized seal. A Type 6BX flange joint that does not achieve face-to-face contact will not seal and, therefore, must not be put into service.

Flat Face (FF).   Flat-face flanges are a variant of raised face flanges. Sealing is achieved by compression of a flat nonmetallic gasket (very rarely a flat metallic

c) Raised Face Slip-On Weld Flange   d) Composite Lap Joint Flange
FIGURE A7.3   Common flange types.

gasket) between the grooved surfaces of the mating FF flanges. The gasket fits over the entire face of the flange. FF flanges are normally used on the least arduous of duties, such as low pressure water piping having Class 125 and Class 250 flanges and flanged valves and fittings. In this case the large gasket contact area spreads the flange loading and reduces flange stresses.

Note: Both ASME B16.5 and BS 1560 specify flat face flanges and raised face flanges as well as RTJ flanges. API 6A is specific to RTJ flanges only.

Male and Female Facings.   The female face is ³⁄₁₆-in deep, the male face is ¼-in high, and both are smooth finished. The outer diameter of the female face acts to locate and retain the gasket. Custom male and female facings are commonly found on the heat exchanger shell to channel and cover flanges.

Tongue-and-Groove Facings.   Tongue-and-groove facings are standardized in both large and small types. They differ from male-and-female in that the inside diameters of the tongue-and-groove do not extend into the flange base, thus retaining the gasket on its inner and outer diameter. These are commonly found on pump covers and valve bonnets.

Flange Specification and Identification

A flange is specified by the following information:

Type and Facing.   The flange is specified according to whether it is, for example, "weld-neck RTJ" or "socket-weld RF." Ring joint facing and RTJ gasket dimensions for ASME B16.5 are shown in Table A7.1.

Nominal Pipe Size (NPS).   This is a dimensionless designation to define the nominal pipe size (NPS) of the connecting pipe, fitting, or nozzle. Examples include NPS 4 and NPS 6.

Flange Pressure Class.   This designates the pressure temperature rating of the flange, which is required for all flanges. Examples include Classes 150, 300, 900, and 1500.

Standard.   Basic flange dimensions for ASME B16.5 are shown in Table A7.2. Examples include ASME B16.5, BS 1560, DIN or API 6A.

Material.   A material specification for flanges must be specified and be compatible to the piping material specifications.

Pipe Schedule.   This is only for WN, composite lap-joint and swivel-ring flanges where the flange bore must match that of the pipe, such as schedule 40, 80, 120, and 160.

Gaskets

A gasket is a material or combination of materials designed to clamp between the mating faces of a flange joint. The primary function of gaskets is to seal the irregulari-

ties of each face of the flange, preventing leakage of the service fluid from inside the flange to the outside. The gasket must be capable of maintaining a seal during the operating life of the flange, provide resistance to the fluid being sealed, and meet the temperatures and pressure requirements.

Gasket Standards

There are a variety of standards that govern dimensions, tolerances, and fabrication of gaskets. The more common international standards are

ASME B16.20-1997	Metallic Gaskets for Pipe Flanges, Ring-Joint, Spiral Wound and Jacketed
ASME B16.21-1990	Nonmetallic Flat Gaskets for Pipe Flanges
BS 4865 Part 1	Flat Ring Gaskets to Suit BS4504 and DIN Flange
BS 3381	Spiral Wound Gaskets to Suit BS 1560 Flanges
API 6A	Specification for Wellhead and Christmas Tree Equipment

Types of Gaskets

Gaskets can be defined into three main categories: nonmetallic, semimetallic, and metallic types.

Nonmetallic Gaskets. Usually composite sheet materials are used with flat-face flanges and low pressure class applications. Nonmetallic gaskets are manufactured with nonasbestos material or compressed asbestos fiber (CAF). Nonasbestos types include arimid fiber, glass fiber, elastomer, Teflon (PTFE), and flexible graphite gaskets. Full-face gasket types are suitable for use with flat-face (FF) flanges. Flat-ring gasket types are suitable for use with raised faced (RF) flanges.

Gasket dimensions for ASME B16.5 flanges are shown in Table A7.3. Gasket dimensions for ASME B16.47 Series A large diameter steel flanges are shown in Table A7.4a. Gasket dimensions for ASME B16.47 Series B large diameter steel flanges are shown in Table A7.4b.

Semimetallic Gaskets. Semimetallic gaskets are composites of metal and nonmetallic materials. The metal is intended to offer strength and resiliency, while the nonmetallic portion of a gasket provides conformability and sealability. Commonly used semimetallic gaskets are spiral wound, metal jacketed, camprofile, and a variety of metal-reinforced graphite gaskets. Semimetallic gaskets are designed for the widest range of operating conditions of temperature and pressure. Semimetallic gaskets are used on raised face, male-and-female, and tongue-and-groove flanges.

Spiral Wound Gaskets. Spiral wound gaskets are the most common gaskets used on raised face flanges. They are used in all pressure classes from Class 150 to Class 2500. The part of the gasket that creates the seal between the flange faces is the spiral wound section. It is manufactured by winding a preformed metal strip and a soft filler material around a metal mandrel. The inside and outside diameters are reinforced by several additional metal windings with no filler.

24	24.00	30.50	30.25	31.12	33.00

General note: Dimensions are in inches.

For applications involving raised face flanges, the spiral wound gasket is supplied with an outer ring; for critical applications it is supplied with both outer and inner rings. The outer ring provides the centering capability of the gasket as well as the blow-out resistance of the windings and acts as a compression stop. The inner ring provides additional load-bearing capability from high-bolt loading. This is particularly advantageous in high-pressure applications. The inner ring also acts as a barrier to the internal fluids and provides resistance against buckling of the windings.

Spiral wound–ring gaskets are also used in tongue-and-groove flanges. Inner rings should be used with spiral wound gaskets on male-and-female flanges, such as those found in heat-exchanger, shell, channel, and cover-flange joints.

Spiral wound gaskets are designed to suit ASME B16.5 and DIN flanges. See Table A7.5 for dimensions for spiral wound gaskets used with ASME B16.5 flanges.

See Table A7.6a and A7.6b for dimensions for spiral wound gaskets used with ASME B16.47 large diameter steel flanges.

See Table A7.7 for inner-ring inner diameters for spiral wound gaskets.

Camprofile Gaskets. Camprofile gaskets are made from a solid serrated metal core faced on each side with a soft nonmetallic material.

The term camprofile (or kammprofile) comes from the groove profile found on each face of the metal core. Two profiles are commonly used: the DIN 2697 profile and the shallow profile. The shallow profile is similar to the DIN 2697 profile except

that the groove depth is 0.5 mm (versus 0.75 mm for DIN 2697). This allows for a cost advantage for the shallow profile. The profile can be made from sheet metal or strip with a thickness of 3 mm instead of a thickness of 4 mm for DIN profile. For the original German Standard see Fig. A7.4, DIN 2697, Profile for Camprofile Gasket.

The most common facing for camprofile gaskets is flexible graphite. Other facings such as expanded or sintered PTFE and CAF are also used. The camprofile gasket combines the strength, blowout, and creep resistance of a metal core with a soft sealing material that conforms to the flange faces providing a seal. Standard camprofile gaskets are available to suit ASME B16.5, BS1560, and DIN 2697. These dimensions are shown in Table A7.8, Camprofile Dimensions to Suit Standard Flanges.
FIGURE A7.4 DIN 2697 Profile for camprofile gasket.

Camprofile gaskets are used on all pressure classes from Class 150 to Class 2500 in a wide variety of service fluids and operating temperatures.

Jacketed Gaskets. Jacketed gaskets are made from a nonmetallic gasket material enveloped in a metallic sheath. This inexpensive gasket arrangement is used occasionally on standard flange assemblies, valves, and pumps. Jacketed gaskets are easily fabricated in a variety of sizes and shapes and are an inexpensive gasket for heat exchangers, shell, channel, and cover flange joints. Their metal seal makes them unforgiving to irregular flange finishes and cyclic operating conditions.

Jacketed gaskets come in a variety of metal envelope styles. The most common style is double jacketed, shown in Fig. A7.5.

Metallic Gaskets. Metallic gaskets are fabricated from one or a combination of metals to the desired shape and size. Common metallic gaskets are ring-joint gaskets and lens rings. They are suitable for high-temperature and pressure applications and require high-bolt loads to seal.

Ring-Joint Gaskets. Standard ring-joint gaskets can be categorized into three groups: Style R, RX, and BX.

They are manufactured to API 6A and ASME B16.20 standards.

Dimensions of Style R gaskets are shown in Table A7.1.

Style R gaskets are either oval or octagonal. Style RX is a pressure-energized adaptation of the standard Style R ring-joint gasket. The RX is designed to fit the same groove design as the Standard Style R. These gasket styles are shown in Fig. A7.6. Dimensions of RX gaskets are shown in Table A7.9.

Style BX pressure-energized ring joints are designed for use on pressurized systems up to 20,000 psi (138 MPa). Flange faces using BX-style gaskets will come in contact with each other when the gasket is correctly fitted and bolted up. The BX gasket incorporates a pressure-balance hole to ensure equalization of pressure which may be trapped in the grooves. Dimensions of BX gaskets are shown in Table A7.10.

FIGURE A7.5 Double-jacketed gaskets.

Lens Rings Gaskets. Lens rings gaskets have a spherical surface and are suited for use with conical flange faces manufactured to DIN 2696. They are used in specialized high-pressure and high-temperature applications. Standard lens rings gaskets in accordance with DIN-2696 are shown in Table A7.11.

Other specialty metallic seals are available, including welded-membrane gaskets and weld-ring gaskets. These gaskets come in pairs and are seal-welded to their mating flanges and to each other to provide a zero-leakage high-integrity seal.

Bolts and Nuts

Bolts and nuts provide for clamping of the flange and gasket components. Bolting is a term that includes studbolts, nuts, and washers.

Bolting Standards. The following are international standards that pertain to bolting:

ASME B1.1   Unified Inch Screw Threads
ASME B18.2.1   Square and Hex Bolts and Screws

Oval   **Octagonal**

ASTM F436	Mechanical Properties of Plain Washers
BS 4882	Bolting for Flanges and Pressure Containing Purposes

Bolts.   A bolt is a fastener with a head integral with the shank and threaded at the opposite end. Bolting for flanges and pressure-containing purposes are usually studbolts. Studbolts are fasteners that are threaded at both ends or for the whole length. The general forms of studbolts are shown in Fig. A7.7. Screw threads for studbolts for all materials are shown in Table A7.12. The nominal length of an

inch-series studbolt is the overall length, excluding the point at each end. The ends of the studbolt are finished with a point having an included angle of approximately 90 degrees to a depth slightly exceeding the depth of the thread. Markings indicating the grade of studbolt are applied to one end of the studbolt.

The minimum length of the studbolt should ensure full engagement of the nut such that the point protrudes above the face of the nut. For applications that utilize hydraulic stud-tensioning tools for tightening, one bolt-diameter is added to this minimum length. Hydraulic stud tensioning and other tightening methods are covered later in this chapter. While there is no maximum length of thread, unnecessarily long studs are avoided due to cost and to prevent corrosion and other damage to exposed threads, which would make subsequent removal difficult.

Nuts

Heavy Series.   Heavy-series nuts are generally used with studs on pressure piping. The nonbearing face of a nut has a 30-degree chamfer, while its bearing face is finished with a washer face. Dimensions of heavy-series nuts are shown in Table A7.13.

Avoid nominal pipe sizes in brackets.

Length of point
Nominal length

(a) Studbolt threaded full length

Nominal length

Length of thread = nominal dia. plus 0.375

Dia. of plain portion
(b) Studbolt threaded each end with nominal diameter portion at center

Nominal length

Length of thread = nominal dia. plus 0.375

Min. R = 1/8 † 1
3/16 > 1 † 2
1/4 > 2

Reduced dia. = 0.95 × minor dia.
(c) Studbolt threaded each end with reduced diameter portion at center

Nominal length

Length of thread plus length of reduced dia.

Length of reduced dia. = 0.6 × nominal dia.

Dia. of plain portion

Length of thread = nominal dia. plus 0.375

R 0.375 min.

Reduced dia. = 0.95 × min. minor dia.

Min. R = 1/8 † 1
= 3/16 > 1 † 2
= 1/4 > 2
(d) Studbolt threaded each end with two reduced diameter portions and nominal diameter portion at center

Dimensions are in inches.

NOTE 1. Exclusion of length to points from nominal length is in agreement with USA oil industry practice.
NOTE 2. Dimensions at each end are the same for all designs. Centering holes are permitted in types (c) and (d).

FIGURE A7.7 Dimensions of studbolts—inch series.

TABLE A7.12   Pitch of Screw Threads for Studbolts

a) Metric sizes

Nominal diameter	Pitch
<M27 ≥M30 ≤ M43 ≥M45 ≤ M100	ISO Metric coarse (see BS 3643) 3 mm 4 mm

b) Inch sizes

Nominal diameter	Pitch
≤1 inch ≥ 1⅛ inch	ISO Unified inch coarse (UNC) 8 threads/in UN Series

Lock Nuts.   The primary purpose of a self-locking nut is to resist loosening under service conditions experiencing vibration and shock. The self-locking nut produces an interference fit between the bolt threads and the nut threads. Most common self-locking nuts contain a nylon insert. The degree of interference is controlled during manufacture of the nylon-insert minor diameter. The elastic nature of the nylon provides uniform reaction from nut to nut. Generally, in pressure-piping systems, the primary concern is obtaining and maintaining proper stud preload to affect the gasket seal. Vibration is not normally a concern in these applications, and in situations where vibration is prevalent, adequate preload control will prevent nut rotation and loosening.

Washers

Flat Washers.   Flat washers are used principally to minimize embedment of the nut and to aid torquing. Plain washers are manufactured in accordance with standard ANSI/ASME B18.22.1. Hardened washers are utilized in high-torque applications. Suitable mechanical properties for hardened, stamped, plain washers are covered by ASTM F436. Applicable properties for plain washers rolled from wire shall be AISI 1060 steel or equivalent, heat treated to a hardness of Rockwell C 45–53.

Dimensions of preferred sizes of Type A plain washers are shown in Table A7.14.

Live Loading.   Live loading using belleville springs improves the elasticity of the flange joint. A belleville spring is a washer that is dished in the center to give it a cone shape. The cone shape provides for a very stiff spring, in comparison to coil springs. The cone will deflect and flatten at a specified spring rate (ratio of load to deflection) when subjected to the axial load (Fp) generated in a stud. Figure A7.8 shows a section of a belleville spring. Belleville springs are described by the following dimensions:

OD = outside diameter

ID = inside diameter

t = material thickness

h = deflection to flat

H = overall height

Note: The dimensions are illustrated in figure 6.
Flange assemblies always tend to relax in time, particularly at elevated temperatures. The rate of relaxation is dependent on many factors, including embedment relaxation of studs and nuts, flange rotation, bolt creep, and gasket creep. The relaxation phenomenon is covered more fully in the section "Behavior of the Flanged Joint System." The high load-deflection or spring rate, characteristics of belleville springs, aid in maintaining bolt preload, compensating for some of the joint relaxation.

The spring rate of a belleville spring depends on geometry, material, and loading conditions. The load-deflection characteristics can be varied by stacking springs in combinations of series and parallel stacks. Figure A7.9 shows load-deflection curves

FIGURE A7.9   Load deflection in curves of several Belleville arrangements.

of several different belleville arrangements. The hysteresis between increasing and decreasing load (the upper and lower curves, respectively) is caused by the friction between the spring and the loading surfaces. Two springs stacked in parallel doubles the load to flatten the pair with no further increase in deflection. Two springs stacked in series will produce twice the deflection at the same load.

FUNCTION OF GASKETS

The function of a gasket is to conform to the irregularities of the flange faces to affect a seal, preventing the inside fluid from leaking out. See Fig. A7.10 for a typical flange-gasket arrangement. The leak performance of the gasket is dependent on the stress on the gasket during operation. Each different type of gasket has its own inherent leak-tightness capabilities. The higher the gasket stress, the higher the leak-tightness capability.

The ideal gasket is comprised of a body with good load-bearing and recovery characteristics, with a soft conformable surface layer. Gaskets have a combination of elastic and plastic characteristics. Ideal gaskets should have the following properties:

1. Compressibility—Gaskets that have sufficient compressibility to suit the style and surface finish of the flange, ensuring that all the imperfections will be filled with the gasket material.
2. Resilience—Gaskets that have high resilience will enable the gasket to move with the dynamic loadings of the flange to maintain its seating stress.
3. No change in thickness—Gaskets that will not continue to deform under varying load cycles of temperature and pressure or under a constant load at elevated temperatures (creep).

Unfortunately, most gaskets available on the market are not ideal gaskets. Most gaskets usually just have one or sometimes two of the above properties. For critical

Flange Faces Must Contact
Inner/Outer Ring

Raised Face Flanges
FIGURE A7.10   Typical flange gasket arrangement.

applications, designers are always on the lookout for gaskets that have all three properties.

The most difficult, often critical, property required of a gasket is its ability to resist creep during operation. In high-temperature services, the flanges will heat up at a faster rate than the bolts and under steady-state conditions will continue to be hotter than the bolts as a result of the thermal gradient. This results in a higher thermal expansion of the flanges with respect to the bolts, increasing the boat load and concurrently the gasket stress. The gasket will then deform under the higher applied load during this cycle. Most gaskets will deform permanently and will not rebound when the load cycle goes away with varying conditions. The permanent set or plastic deformation that occurred during operation will cause loss of bolt load and concurrently loss of gasket stress. As gasket stress decreases leak rate increases.

FUNCTION OF BOLTS

The function of a bolt is to provide a clamp load or preload (Fp) to sufficiently compress and stress the gasket and resist the parting forces exerted by the hydrostatic end force and other external loads. The hydrostatic end force is created by the pressure of the internal fluid across the internal area of flange. The internal area is generally the inside diameter of the sealing element.

All bolts behave like a heavy spring. As you turn down the nut against the flange, the bolt stretches and the flange and gasket compress. All bolt-tightening methods result in stretching the bolt. The torque-tightening method uses the thread helix of turning the nut against the reactive forces of the flange to stretch the bolt. The hydraulic bolt-tensioning method utilizes an annular piston threaded on the end of the bolt to provide an axial stretch. Torque tightening and hydraulic bolt

tensioning are discussed in the section "Methods of Bolt Tightening." In its elastic region, bolts stretch according to Hooke's law:

$$\Delta L_b = \frac{Fp \times L_b}{E \times A_s} \tag{A7.1}$$

ΔL_b = Change in length of bolt, in (mm)

F_p = Applied tensile load (Preload),   lb (kN)

L_b = Effective length of bolt Length   of bolt in which tensile stress is applied, in (mm)

E = Young s Modulus of Elasticity, psi (N/mm^2)

A_s = Tensile stress area of bolt, in^2(mm^2)

= $0.7854(D - 0.9743/n)^2$

where D = Nominal diameter of bolt
n = is the number of threads per in

Preload is the applied bolt load generated during tightening.

BEHAVIOR OF THE FLANGED JOINT SYSTEM

It is important to recognize that the individual components of flanges, gaskets, nuts, and bolts operate together as a system. Gasket companies are continually fielding questions from concerned users about their "gasket" leakage. Gasket leakage is symptomatic of a broader problem. To focus exclusively on the gasket as the cause of the leakage fails to recognize that the flange joint operates as a system, and a systems approach should be used to design flange joints and trouble shoot flange problems.

Under actual operating conditions, the confined fluid, under pressure, creates a hydrostatic end force trying to separate the flange faces. The preload developed in the bolts keeps the flanges together while maintaining a residual gasket-seating stress. The internal pressure of the fluid tries to move, go through, or bypass the gasket. This is illustrated in Fig. A7.11, "What Happens under Actual Operating Conditions."

Joint Stiffness

The flange joint consists of a series of springs in a combination of tension and compression. The bolts are springs in tension, while the flange is a spring in compression. The interaction of the two depends on their respective stiffness. The interaction between the stiffness of the bolt and flange can be represented by a joint diagram. See Fig. A7.12, "Joint Diagram of Simple Elastic Joints."
1. END FORCE - *which originates with the pressure of the confined media - trying to separate the flange faces*

2. GASKET LOAD - *or Bolting Load - tries to keep the flange faces together to compress the gasket.*

3. INTERNAL PRESSURE - *which tries to move, go through, or by-pass the gasket.*

FIGURE A7.11 What happens under actual operating conditions.

The stiffness of the bolt is:

$$K_b = \frac{F_p}{\Delta L_b} \qquad \frac{\text{lb}}{\text{in}} \frac{(\text{kN})}{(\text{mm})} \qquad (A7.2)$$

The stiffness of the joint is:

$$K_i = \frac{F_p}{\Delta L_j} \qquad \frac{\text{lb}}{\text{in}} \frac{(\text{kN})}{(\text{mm})} \qquad (A7.3)$$

where F_p = Preload lb(kN)
  ΔL_b = Change in length of bolt, in (mm)
  ΔL_j = Change in compression of joint, in (mm)
FIGURE A7.12 Joint diagram of simple elastic joints.
FIGURE A7.13 Joint diagram with external tensile load (Lx).

At the mating surfaces, the bolt sees the preload (F_p) in tension while the joint sees the same preload in compression. Their deflection under this preload is proportional to their respective stiffness.

If an external tensile load (L_x) is applied (i.e., pressure end force), the bolt load increases and the bolt lengthens, while the joint unloads. The change in deformation of the bolt equals its change in deformation of the joint such that they maintain contact with each other. The external load is shared between the bolts and the joint in proportion to their stiffness. This is illustrated in Fig. A7.13.

In a flange joint containing a gasket, behavior is governed to a great degree by the gasket. Unfortunately, the gasket stiffness is nonlinear and very difficult to predict. Gaskets unload quickly following a steep curve, as shown in Fig. A7.14.
FIGURE A7.14 Joint stiffness diagram for a flanged connection with spiral wound gasket.

Therefore, externally applied loads have a significant effect on reducing the stress of the gasket. A sufficiently high enough bolt preload is required to compensate for gasket unloading in order to maintain sufficient stresses to seal during operation. If the bolt preload is lost due to bolt creep, gasket creep, or flange rotation, the gasket stress drops dramatically and leakage follows.

Elastic Interaction

As one bolt is tightened, the flange and gasket partially compress in relation to their relative stiffness. As subsequent bolts are tightened, the joint compresses further. As each additional bolt is tightened, the compression on the joint will tend to reduce the preload in adjacent bolts. Figure A7.15 shows the elastic behavior of a simplified four-bolt flange. After tightening bolts 1 and 2, bolts 3 and 4 are tightened by compressing the joint further and relaxing the previously tightened bolts 1 and 2. The effect of tightening bolts separately and affecting the loads in adjacent bolts is referred to as elastic interaction, or cross talk. Elastic interaction is one reason why wide scatter in bolt preloads are found in flanged joints. Figure A7.16 shows a typical load scatter of a 28-bolt heat-exchanger channel to shell flange. The top line is the preload for each stud as it was originally tightened with torquing. Notice the wide variation in bolt load with this method of tightening.

Relaxation of the Flange Joint

Flange joint relaxation is one of the most important areas to consider when designing or troubleshooting flange systems. Over and over again, flanges are hydrostatically tested to verify conformance to leak tightness requirements. After successful hydrostatic testing, some flanged joints are found to be leaking during startup, shutdown, or at some time during their operating life. Verification of actual bolt load (using ultrasonic measurement) has revealed that the residual load in the studs after the hydrostatic test is usually lower than the original bolt preload achieved during tightening.

Relaxation of the bolt load observed is due to permanent deformation of the

Elastic Behavior of the Joint

(Channel To Shell)
FIGURE A7.16   Typical load scatter of 28-bolt heat exchanger.

gasket element experienced as a result of the pressure test loads. During the hydrostatic test, high external compressive loads are added to the gasket. The gasket will continue to compress (deform) as a result of the additional hydrostatic end load. Since most gaskets have poor elastic properties, the hydrostatic end force will result in permanent deformation of the gasket. On conclusion of the hydrostatic test, the permanent deformation of the gasket will be seen as loss of bolt load and overall joint relaxation. This is illustrated in Fig. A7.16. The lower curve is the residual bolt load measured after the hydrostatic test.

The wide scatter shown is consistent with uncontrolled tightening techniques. The relaxation effects are typical of gaskets that continue to deform under varying load cycles of temperature and pressure or poor creep resistance at elevated temperatures. This flange would likely leak at any number of points in its operating life. The wide scatter of the bolt loads illustrated in Fig. A7.16 may lead to failure after the hydrostatic test.

With the wide load scatter in combination with relaxation of the joint after hydrotest, the joint may leak during startup. In addition, operating temperatures and pressure cycles will continue to relax the joint until there is insufficient bolt load and gasket stress at a particular position around the flange to maintain a seal, and leakage results.

Operating relaxation of the flanged joint is affected by the creep-resistant material properties of the flange, studbolts, and gaskets. Materials that continue to creep (deform) during operation will lead to leakage.

The solution to relaxation-affected leak problems is to

1. Control the initial bolt preload to eliminate the wide scatter around the flange

and to ensure the bolt loads are sufficient to maintain a seal throughout the operating life. Controlled bolting is described more fully later in this chapter.

2. Design and install components that are resistant to creep by ensuring that they are suitable for the operating temperatures and pressures.

GASKET SELECTION

The proper selection of gasket is critical to the success of achieving long-term leak tightness of flanged joints. Due to their widespread usage, gaskets are often taken for granted. Industry demands for reduced flange leakage in environments of increasing process temperatures and pressures have led gasket manufacturers to develop a wide variety of gasket types and materials, with new gaskets being introduced on an ongoing basis. This rapidly changing environment makes, and will continue to make, gasket selection difficult.

It is highly recommended that the gasket manufacturer be consulted on the proper selection of gaskets for each application. Gasket manufacturers are familiar with the industry codes and standards and conduct extensive testing of their products to ascertain performance under a variety of operating conditions.

Flange design details, service environment, and operating performance guide the gasket selection process. Start with the flange design. Identify the appropriate flange standard, outlining size, type, facing, pressure rating, and materials (i.e., ASME B16.5, NPS 4, Class 1500, RF, carbon steel). Identify the service environment of temperature, pressure, and process fluid. It is useful to highlight gasket-operating performance.

Gasket-Operating Performance

New flange and gasket designs are incorporating tightness factors in their calculations to reduce leak rates. Traditional ASME Section VIII code utilizes m and y gasket factors in the design calculations of flanges. These factors are useful to establish the flange design required to help ensure the overall pressure integrity of the system; however, they are not useful parameters to predict flange leak rates.

All flanges leak to a certain degree. Industry requirements are demanding reduction in leak rates along with predictable performance. This has lead to a more rigorous approach to establishing gasket factors and the associated methods for gasketed flanged-joint design.

Significant progress has been made in the last six years in Europe by CEN and in North America by ASME's Pressure Vessel Research Council (PVRC) to establish gasket test procedures and the development of design constants that greatly improve the gasketed flanged-joint design. Maximum allowable leak rates have been established for various classes of equipment. EPA Fugitive Emissions basic limits are shown below.

Component	Allowable leakage level
Flange	500 ppmv
Pump	1,000 ppmv
Valve	500 ppmv
Agitator	10,000 ppmv

PVRC has established a new set of gasket factors, G_b, a, and G_s and a related tightness parameter, T_p, which can be used in place of traditional m and y factors in determining required bolt load.

G_b and a (Part A testing) represent the initial gasket-compression characteristics. G_b is the gasket stress at a tightness parameter (T_p) of 1; a is the slope of the line of gasket stress versus tightness parameter plotted on a log-log curve. This line shows that the tightness parameter (or leak tightness) increases with increasing gasket stress. That is, the higher the gasket stress, the lower the expected leakage. G_s is the unloading (Part B) gasket stress at a $T_p = 1$.

A low value of G_b indicates that the gasket requires low levels of gasket stress for initial seating. Low values of G_s indicate that the gasket requires lower stresses to maintain tightness during operation and can tolerate higher levels of unloading, which maintain sealability. An idealized tightness curve showing the basis for gasket constants G_b, a, and G_s is shown in Fig. A7.17.

The data for many gasket styles and materials have been published in various PVRC-sponsored publications. Typical PVRC gasket factors for a variety of gasket types are shown in Table A7.15.
FIGURE A7.17 PVRC idealized tightness curve.

TABLE A7.15   Typical PVRC Gasket Factors

Type	Material	Gb(psi)	a	Gs(psi)

Note: All data presented in this table is based on currently available published information. The PVRC continues to refine data-reduction techniques, and values are therefore subject to further review and alteration.

PVRC Convenient Method.   The PVRC Convenient Method provides an easy conservative method for determining bolt load (W_{mo}) used in flange and gasket design as an alternate to using m and y values.

Gasket operating stress

$$S_{m1} = G_s[G_b/G_s \times T_{pa}{}^a]^{1/Tr} \tag{A7.4}$$

Seating stress

$$S_{m2} = G_b[e \times 1.5] \, T_{pa}{}^a = Pd[Ai/Ag] \tag{A7.5}$$

Design factor

$$M_o = \text{the greater of } \frac{S_{m1}}{Pd} \text{ or } \frac{S_{m2}}{Pd} \text{ or } 2 \tag{A7.6}$$

Design bolt load

$$W_{mo} = Pd(AgMo + Ai) \tag{A7.7}$$

where a—The slope associated with Part A tightness data

A_g—Area of gasket-seating surface, in^2 (mm^2) = .7854(OD^2 − ID^2)

A_i—Hydrostatic area; the area against which the internal pressure is acting, in^2 (mm^2) = .7854G^2

b_o—Basic gasket seating width, in (mm)
b_o = (OD − ID)/4

b—Effective gasket seating width

$b = b_o$, when $b_o \leq \frac{1}{4}$ in

$b = \sqrt{b_o/2}$, when $b_o > \frac{1}{4}$ in, in (mm)

C—Tightness constant
C = 0.1 for tightness class T1 (economy)
C = 1.0 for tightness class T2 (standard)
C = 10.0 for tightness class T3 (tight)

e—Joint assembly efficiency; recognizes that gasket-operating stress is improved depending on the actual gasket stress achieved during boltup; also recognizes the reliability of more sophisticated bolting methods and equipment in actually achieving desired bolt loads
e = 0.75 for manual boltup
e = 1.0 for "ideal" boltup, e.g., hydraulic stud tensioners, ultrasonics

G—Diameter of location of gasket load reaction, in (mm), from ASME Section 8

$G = \dfrac{(OD + ID)}{2}$ if $b_o \leq \frac{1}{4}$ in, in (mm)

$ = OD − 2b$, if $b_o > \frac{1}{4}$ in, in (mm)

G_b—The stress intercept at $T_p = 1$, associated with Part A tightness data psi (MPa)

G_s—The stress intercept at $T_p = 1$, associated with Part B tightness data psi (MPa)

P_d—Design pressure, psi (MPa)

P_t—Test pressure (generally 1.5 × P_d), psi (MPa)

S_{m1}—Operating gasket stress, psi (MPa)

S_{m2}—Seating gasket stress, psi (MPa)

M_o—Design factor

TC—Tightness class that is acceptable for the application, depending on the severity of the consequences of a leaker
T1 (economy) represents a mass leak rate per unit diameter of 0.2 mg/sec-mm
T2 (standard) represents a mass leak rate per unit diameter of 0.002 mg/sec-mm
T3 (tight) represents a mass leak rate per unit diameter of 0.0002 mg/sec-mm

T_p—Tightness parameter. T_p is a dimensionless parameter used to relate the performance of gaskets with various fluids, based on mass leak rate. Recognizes that leakage is proportional to gasket diameter (leak rate per unit diameter). T_p is the pressure (in atmospheres) required to cause

a helium leak rate of 1 mg/sec for a 150 mm OD gasket in a joint. PVRC researchers have related T_p to other fluids through actual testing as well as use of laminar flow theory.

T_{pa}—Assembly tightness; the tightness actually achieved at assembly $= .1243 \times C \times P_t$

T_{pmin}—Minimum tightness; the minimum acceptable tightness for a particular application $= .1243 \times C \times P_d$

T_r—Tightness ratio; $= \log(T_{pa})/\log(T_{pmin})$

W_{mo}—Design bolt load, lb (kN)

Example A7.1 Example of PVRC Convenient Method

Input data

Application: Heat exchanger. Reboiler channel

Design pressure $(P_d) = 400$ psi

Test pressure $(P_t) = 600$ psi

Operating temperature

Gasket type: camprofile

Gasket dimensions ID $= 37.63$ in

$$OD = 38.88 \text{ in}$$

Tightness class required T3, therefore $C = 10.0$

Assembly efficiency $(e) = 1.0$, using hydraulic stud tensioners

From Table A7.15 $G_b = 387$ psi

$$a = .33$$

$$G_s = 14.0 \text{ psi}$$

Calculations:

$G = 38.32$ in

$A_g = 75.10$ in^2

$A_i = 1,153.8$ in^2

$T_{pmin} = 497.20$

$T_{pa} = 745.80$

$T_p = 1.07$

$S_{m1} = 2,450$ psi

$S_{m2} = (3,852)$ psi

$$M_o = \frac{2,450}{400} = 6.13$$

Design total bolt load to achieve T3 leak tightness

$$W_{mo} = 400 \times (75.10 \times 6.13 + 1{,}153)$$

$$= 645{,}345 \text{ lb}$$

To illustrate the usefullness of PVRC calculations in gasket selection, the following example shows the same calculations using a double-jacketed gasket typically found in the above application instead of the camprofile.

Input data (as above except)

Gasket type: Double jacketed

$G_b = 2900$ psi

$a = .23$

$G_s = 15$

This changes the calculation of S_{m1} and S_{m2} to

$S_{m1} = 8{,}759$ psi

$S_{m2} = 2{,}709$ psi

$M_o = 21.90$

$W_{mo} = 1{,}119{,}255$ lb

TABLE A7.16 Application of Types of Gaskets

	Pressure class			
Gasket type	Low Class 150–300	Medium Class 600–900	High Class 1500–2500	Maximum temperature of materials (°F)
Nonmetallic				
–CAF	x	—	—	650–1000
–Nonasbestos fibre	x	—	—	550
–PTFE	x	—	—	390–550
–Graphite	x	—	—	750
Semimetallic				
–Metal jacketed	x	x	—	750+*
–Metal reinforced graphite	x	x	—	750+*
–Spiral wound	x	x	x	750+*
–Camprofile	x	x	x	750+*
Metallic				
–Ring-joint gaskets	—	x	x	650+*
–Lens ring	—	x	x	650+*
–Machined ring	—	x	x	650+*

x applicable
– not applicable
* depends on material

The total bolt load to achieve the same leak tightness of T3 is 1,119,255 lb.

These examples would indicate that higher leak tightness can be achieved using the camprofile gasket versus the double-jacketed gasket under the design conditions outlined.

Types of Gaskets

As discussed earlier, gaskets can be defined into three main categories: nonmetallic, semimetallic, and metallic. The general applications for each gasket type are shown in Table A7.16.

High Temperature Selection

In high temperature applications, above 650°F (343°C), gasket selection becomes even more critical. Many gaskets may perform well at low temperatures but fail to meet leak-tightness requirements at elevated temperatures.

Many gaskets lose their resiliency at elevated temperatures, with changes in their elastic behavior. The gasket's inherent stiffness will also tend to diminish, resulting in the gasket continuing to deform under the applied flange loads. This deformation (or creep) will result in loss of gasket stress, bolt load, and leak tightness. In elevated temperature applications, search out materials that retain their resiliency and gasket designs that will not change in thickness (retain its stiffness).

Considerable technical information on gasket selection is available from gasket manufacturers and from other technical sources such as the Pressure Vessel Research Council and industry trade associations such as the Fluid Sealing Association (FSA).

BOLT SELECTION

Bolts and nuts should be selected to conform to the design specifications set out with the flange design. Care is taken to ensure that the correct grade of material is selected to suit the recommended bolting temperature and stress ranges. Material specifications for bolts are outlined in BS 4882 and ASME Section VIII.

Common material specifications for bolts and nuts are shown in Table A7.17.

The following information should be specified when ordering bolts and nuts:

1. Quantity
2. Grade of material, identifying symbol of bolt or nut
3. Form
   - Bolts or studbolts
   - Nuts, regular or heavy series
4. Dimensions
   - Nominal diameter, length
   - Diameter of plain and reduced portion, length of thread (if applicable)
5. Identification of tests in addition to those stated in the standard
6. Manufacturer's test certificate (if required). Fully threaded studbolts and heavy series nuts are most common in industrial applications.

TABLE A7.17 Material Specifications for Bolts and Nuts and Recommended Bolting Temperature Range

Material specifications	Alloy types	Mechanical properties						Recommended corresponding nut grades
		Tensile strength		Yield strength .2% proof stress min		Recommended bolting temperature range[1] °C		
B7, L7 BS 1506–621A	1% Chromium molybdenum steel	N/mm²	psi	N/mm²	psi	min	max	2H, 4, 7, or 8 (L4, 7 or 8 with L7 bolts)
		860	123,000	730	103,000	−100	400	
B16 BS 1506–661	1% Chromium molybdenum vanadium steel	860	123,000	730	103,000	0	520	4, 7, or 8
B8, L8 BS 1506–801B	Austenitic chromium nickel 18/8 type steel	540	77,000	210	30,000	−250	575	8, 8F
B8, CX BS 1506–821T:	Stabilized austenitic chromium nickel 18/8 type steel, cold worked after solution treatment	860	123,000	700	99,000	−250	575	8 CX
B17B	Precipitation hardening austenitic nickel chromium steel	900	128,000	590	84,000	−250	650	17B
B80A BS 3076 NA20	Precipitation hardening nickel chromium titanium aluminum alloy	1000	143,000	620	88,000	−250	750	80A

Note: (1) Temperature of bolting refers to actual metal temperatures.
FIGURE A7.18 Stress relaxation behavior of various bolting materials showing percentage of initial stress retained at 1000 hours.

High Temperature Bolting Applications

The relaxation of bolt stress under constant strain conditions is widely recognized and has been measured in research on studbolt assemblies. At temperatures in excess of 300°C, special steels and alloys are required to improve upon the stress relaxation performance of low alloy steels. The relaxation behaviors of different bolting materials are shown in Fig. A7.18.

Different nut materials influence the stress-relaxation behavior of the stud, nut assembly.

The recommended nut for each grade of stud is shown in Table A7.17.

High temperature relaxation is a combined effect of gasket creep, bolt creep, and flange rotation. All three or any combination may occur. The symptoms show up as loose bolts that reduce gasket stress, resulting in increased leakage.

FLANGE STRESS ANALYSIS

The most common design standard for flanges is in ASME Section VIII, Appendix 3—"Mandatory Rules for Bolted Flange Connections." This standard applies in the design of flanges subject to hydrostatic end loads and to establish gasket seating.

The maximum allowable stress values for bolting outlined in the ASME code are design values to be used in determining the *minimum* amount of bolting required under the code. A distinction is made in the code between the design value and

the bolt stress that may actually exist in the field. The ASME code Appendix S further acknowledges that an initial bolt stress higher than design value may (and, in some cases, must) be developed in the tightening operation. This practice to increase bolt stress higher than the design values is permitted by the code, provided that regard is given to ensure against excessive bolt loads, flange distortion, and gross crushing of the gasket.

General Requirements

Bolt Loads. In the design of the bolted flange connection, the bolt loads are calculated based on two design conditions of operating and gasket seating.

Operating Condition. The operating condition determines the minimum load according to

$$W_{m1} = \frac{3.14}{4} G^2 P_t + 2b \, 3.14 \, Gm \, P_t \tag{A7.8}$$

where b, G and P_t are defined previously and m is gasket factor expressed as a multiple of internal pressure

The equation is the sum of the hydrostatic end force plus a residual gasket load equaling a multiple of internal pressure.

Gasket Seating. The second design condition requires a minimum bolt load determined to seat the gasket regardless of internal pressure according to

$$W_{m2} = 3.14 \, bGy \tag{A7.9}$$

where y is the minimum seating stress for the gasket selected

PVRC Method. As discussed earlier the PVRC method can be used as an alternate to W_{m1} or W_{m2} in calculating the bolt loads used in the design of the flange.

Total Required Bolt Areas. These design values on bolt loads are used to establish minimum total cross-sectional areas of the bolts A_m. A_m is determined as follows:

$A_{m1} = \dfrac{W_{m1}}{Sb}$, where Sb is allowable bolt stress at operating temperature

$A_{m2} = \dfrac{W_{m2}}{Sa}$, where Sa is allowable bolt stress at atmospheric temperature

Using PVRC bolt loads:

$$A_{mo} = \frac{W_{mo}}{Sa}$$

A_m is greater of A_{m1} or A_{m2} or A_{mo}. Bolts are then selected so that the actual bolt area, A_b, is equal to or greater than A_m.

Example Calculation.   Using the same application outlined in the "Gasket Selection" section, the following shows the calculation of bolt loads using m and y factors.

Input Data

$$\text{Gasket type: Camprofile}$$

$$m = 2$$

$$y = 2500$$

$$\text{ID} = 37.63 \text{ in}$$

$$\text{OD} = 38.88 \text{ in}$$

$$\text{Design Pressure } (P) = 400 \text{ psi}$$

Operating Conditions

$$W_{m1} = \frac{3.14}{4} \times 38.32^2 \times 400 + 2 \times .28 \times 3.14 \times 38.32 \times 2 \times 400 = 515{,}225 \text{ lb}$$

Gasket Seating

$$W_{m2} = 3.14 \times .28 \times 38.32 \times 2500 = 84{,}227 \text{ lb}$$

$W_{m1} > W_{m2}$, therefore W_{m1} would govern in the flange design. Note that using the PVRC method, the design bolt load was 645,345 lb, higher than both W_{m1} and W_{m2}. This will be a common occurrence, revealing that higher bolt loads than assumed using m and y factors are required to achieve required leak tightness.

Flange Design.   The bolt loads used in the flange design by the code is

$$W = \frac{(A_m + A_b)Sa}{2} \qquad \text{(A7.10)}$$

Alternately, where additional safety is desired, the code recommends that the bolt load for flange design is actual bolt area (A_b) times the allowable bolt stress (Sa).

For critical flanges, it is suggested that a more conservative approach to flange design be adopted, calculating the design bolt load as actual bolt area (A_b) times expected field bolt stress (Se). The expected field-bolt stress (Se) achieved is often $1.5 \times Sa$. By using this approach a higher bolt load is determined. This will increase the flange thickness. The benefits to increased flange thickness are

1. Thicker flanges will rotate less and distribute the applied bolt load more uniformly to the gasket.
2. Thicker flanges require longer bolts. Longer bolts have more strain energy and are more forgiving to joint relaxation.

Finite Element Analysis

Finite Element Analysis (FEA) is being used more frequently to review designs of critical flanges. FEA costs are dropping dramatically while the procedure's effectiveness to model complex structure is increasing.

FEA can be used to predict the behavior of the flange structure subjected to its operating conditions. It is possible to predict the behavior of the flange structure mathematically because the behavior of the materials can be described mathematically. Hooke's law describes the mechanical behavior of the metal materials and their elastic response. Other types of stress-strain relationships have been developed to model the nonlinear, plastic behavior of the gasket.

The key is to determine the actual operating stress on the gasket to predict its leak-tightness performance subjected to thermal effects, pressure, bolt stress, relaxation, and flange rotation.

ASSEMBLY CONDITIONS

The flange components consisting of flange, gaskets, and bolts may have been adequately designed but their performance to specifications will be affected by assembly conditions.

Flange Surface Finish

Flange surface finish is critical to achieve the design-sealing potential of the gasket. Again, gasket-leak tightness is dependent upon its operating gasket stress. Flanges that are warped, pitted, rotated, and have incorrect flange gasket-surface finish will impair the leak tightness of the gasket.

Flanges out of parallelism and flatness should be held within ASME B 16.5 specifications. This will ensure that the uniform bolt loads translate to uniform gasket stress.

The resiliency and compressibility of the gasket are affected by flange surface finish. Recommended flange surface finishes for various gasket types are shown in Table A7.18.

TABLE A7.18 Recommended Flange Surface Finish for Various Gasket Types

Gasket type	Flange surface finish microinch CLA	Flange surface finish micrometer Ra
Soft cut sheet gaskets	Material <1.5 mm thick 125–250	Material <1.5 mm thick 3.2–6.3
	Material ≥1.5 mm thick 125–500	Material ≥1.5 mm thick 3.2–12.5
Camprofile	125–250	3.2–6.3
Metal reinforced graphite	125–250	3.2–6.3
Spiral wound	125–250	3.2–6.3
Metal-jacketed gaskets	100 max	2.5 max
Solid metal gaskets	63 max	1.6 max

Gasket Condition

Never reuse a gasket. A gasket's compressibility and resiliency are severely reduced once it has been used.

Check the gasket for any surface defects along the contact faces that may impair sealing.

Keep the gasket on its storage board until immediately prior to assembly.

Do not use any gasket compounds to install the gasket to the flange, as it affects the compressibility, resiliency, and creep behavior of the gasket. Consult the gasket manufacturer when installing large diameter gaskets for a recommendation on how to secure them to the flange during installation.

Bolt Condition

Bolts and nuts may be reused providing they are in new condition. Ensure bolts and nuts are clean, free of rust, and that the nut runs freely on the bolt threads. Install bolts and nuts well lubricated by using a high quality anti-seize lubricant to the stud threads and the nut face.

Methods of Bolt Tightening

Once the total bolt loads (W) are calculated for the flanges, specifications, and procedures should be adopted outlining how to achieve the design bolt load.

The total bolt load (W) for the flange is divided by the number of bolts to determine the individual bolt preload (F_p).

To achieve improved leak tightness sufficient and uniform gasket stress must be realized in the field. This obviously requires uniform and correct applied bolt load. The higher the requirement to reduce leakage, the more controlled the method bolt tightening.

The common methods of bolt tightening are:

- hammer, impact wrenches
- torque wrenches
- hydraulic tensioning systems

Each method has its own assembly efficiency. Bolt tightening methods and their assembly efficiencies are shown in Table A7.19.

Hammer, Impact Wrenches Method

This method remains the most common form of bolt tightening. The advantages are speed and ease of use. Disadvantages include a lack of preload control and the inability to generate sufficient preload on large bolts.

Torque Method

Torque wrenches are often regarded as a means to improve control over bolt preload in comparison with hammer-tightening methods. However, as indicated in Table A7.19, significant variation in stud-to-stud load control is still evident.

TABLE A7.19 Tightening Methods and Assembly Efficiencies

Method to control bolt preload	Tightening method	Stud-to-stud load variation from the mean (%)	Assembly efficiency (e)
No torque/stretch control	Power impact, lever or hammer wrench	$> \pm 50\%$	0.75
Torque control	Calibrated torque wrench or hydraulic wrench	± 30 to $\pm 50\%$	0.85
Tensioner load control	Multiple stud tensioners	± 10 to $\pm 15\%$	0.95
Direct measurement of stress or strain	Ultrasonic extensometer, calipers, strain gages	$\pm 10\%$ or less	1

Much attention is given to the level of torque that should be applied to a specific application. However, it is not the torque that is important but the end result of the torque-bolt preload. Control over bolt preload is the factor for ensuring proper gasket-seating stresses are achieved.

Torque is the measure of the torsion required to turn a nut up the inclined plane of a thread. The efficiency of the nut's turn along the bolt thread to generate preload is dependent upon many factors, including thread pitch, friction between the threads, and friction between the nut face and the flange face.

In general, only about 10 percent of the applied torque goes toward providing bolt preload. The rest is lost in overcoming friction: 50 percent in overcoming the friction between the nut and flange faces, and 40 percent in overcoming friction between the threads of the nut and the bolt.

Another variable to overcome is the elastic behavior of the joint as illustrated in Fig. A7.15.

As the bolts are tightened creating the desired preload, the flange will partially compress. As additional bolts are tightened, the flange joint will compress a little further. The continuous deflection of the flanged joint reduces the stretch (or preload) of previously tightened joints. This phenomenon is referred to as cross talk and is a result of tightening a multistud flange one bolt at a time.

A typical wide variation in bolt and bolt preload is experienced using torquing because of the uncontrolled effects of friction and cross talk, as illustrated in Fig. A7.16, "Typical Load Scatter of 28 Bolt Heat Exchanger Flange."

Torque Calculations. The amount of torque that is required to generate a specific bolt preload is calculated by

$$T = \frac{KDF_p}{12} \text{ ft-lb} \tag{A7.11}$$

where K = nut factor, experimentally determined (see Table A7.20)
D = nominal diameter of stud, in
F_p = desired bolt preload, calculated by dividing total design bolt load (W) by number of bolts

TABLE A7.20   Torque Nut Factors (K)

Bolt and lubricant	Nut factor (K) reported range
As received alloy bolt	0.158–0.267
As received stainless studbolt	0.3
Copper-based antiseize	0.08–0.23
Nickel-based antiseize	0.13–0.27
Moly paste or grease	0.10–0.18

Note: It is important to remember that the K value is an experimentally derived constant. The K value should be verified in the field for each new application.

Example: Torque Calculation.   Application: Heat exchanger–Reboiler channel (see Section "Gasket Selection")

Input data:

> Type of stud bolt: ASTM A193, Gr. B7
>
> Number of bolts: 56
>
> Size of bolt: $(d) = .875$ in
>
> Design bolt load: $(W_{mo}) = 645,345$ lb
>
> Nut factor $(K) = .18$ copper based antiseize lubricant

Calculations:

$$F_p = 645,345/56 = 11,524 \text{ lb/bolt}$$

$$T = .18 \times .875 \times 11,524/12 = 150 \text{ ft-lb}$$

Torque Procedure.   Torquing should be applied in multipasses following a cross pattern to reduce warping of flange, crushing the gasket, and to minimize cross talk in achieving bolt preload.

Pass	Torque
1	⅓ of final torque (T). Start at bolt no. 1 and follow cross pattern
2	⅔ of final torque (T) following cross pattern
3	At final torque (T) following cross pattern
4	At final torque (T), start at highest bolt number and tighten in a counterclockwise sequence

The cross pattern is easily followed once the bolts are numbered in the flange. Randomly select a bolt and designate it as bolt number 1. Proceed in a clockwise motion to the next bolt and add four to the previous bolt number. Moving clockwise, the next bolt number would be 1, 5, 9, and so on.

This system of adding four to the previous bolt number continues until adding four to the previous number exceeds the total number of bolts in a flange. At this

point, start again at bolt number 3. Continue in the same clockwise direction, numbering bolts 3, 5, 11, and so on until again this number is larger than the total number of bolts in a flange. At this point the next number is 2; continue as previously described: 2, 6, 10, and so on. The last series of bolt numbers start with bolt number 4 and continue 8, 12, 16, and so on.

A sample 16-bolt flange showing a typical cross pattern is shown in Fig. A7.19.
FIGURE A7.19   Typical torquing cross pattern of a 16-bolt flange.

Tensioning Systems

Many of the variables that reduce the control of bolt preload using the torque process are eliminated using hydraulic tensioning systems.

Hydraulic tensioners are hollow hydraulic compact cylinders that are threaded onto a protruding section of the studbolt generally using a pulling device. A bridge supports the hydraulic head straddling the nut and reacting against the flange while hydraulic pressure is applied to the hydraulic head. Under the applied hydraulic load, the bolt stretches at the same time as it compresses the flange and gasket. Residual bolt load equivalent to the desired preload (F_p) is achieved by manually turning down the nut under the tensioner bridge during the applied hydraulic load. Applied bolt load is directly proportional to the hydraulic pressure and the area of the hydraulic cylinder. There are no frictional losses associated with tensioning, as compared to torquing. A cross section of a hydraulic stud tensioner is illustrated in Fig. A7.20. The residual load (preload F_p) = Applied Load − Load Loss Factor.

The load loss factor is dependent upon the stud stress realized, bolt diameter, and effective length of the bolt. For each application its load loss factor can be precisely calculated to determine the necessary applied load to generate the residual preload. Development of thorough procedures is essential to maintain the accuracy of hydraulic stud-tensioning process.

Cross talk is significantly reduced by utilizing multistud tensioning. Generally 50 percent of the studs in a flange are tensioned simultaneously by using multiple
FIGURE A7.20   Hydraulic stud tensioning.

tools interconnected with a high-pressure hose tied into a common pump source. Many flange configurations allow for 100 percent of the studs to be tensioned simultaneously. This completely eliminates cross talk.

Hydraulic tensioning provides the most controlled tightening method for achieving specified bolt preload.

Controlled Bolting

Controlled bolting is the method where the loading-stress of the flange bolts is measured using ultrasonic equipment to ensure that the correctly specified bolt preload is achieved.

The application of torque alone to the flange is not controlled bolting, as there remain many uncertainties about the actual bolt load.

Torquing in combination with ultrasonic measure provides necessary controls to achieve the required bolt preload.

Multistud tensioning following established procedures provides a high degree of control over bolt preload. In critical application, multistud tensioning should also be combined with ultrasonic measurement to verify that all specifications are met.

BOLT LOAD MONITORING

Monitoring of the actual residual bolt load after tightening is essential to ensure that leak-tightness goals are achieved and becomes an important part of the quality assurance process of achieving flange joint integrity.

All tightening methods provide a degree of stud-preload scatter as a function of their process capability. The only way to be sure that specified stud preload is achieved is to measure it.

There are several methods for performing stud-stretch measuring, including strain gauges, bow micrometers, mechanical extensometers, and ultrasonic extensometers. The most common and versatile is the ultrasonic extensometer.

Theory of Operation

The ultrasonic extensometer operates by placing a high-frequency transducer at one end of the stud. Frequencies used for stud measurement range from 1 to 20 megahertz. At these frequencies a liquid couplant (gel) is used to couple the ultrasound from the transducer to the stud.

An ultrasound wave is generated by the transducer and travels down the body length of the stud. The wave reflects off the opposite end of the stud and travels back to the transducer.

The ultrasonic instrument measures the time of flight of the ultrasound in the stud. Many factors, including material density, stud length, temperatures, and stress are used to convert the time-of-flight measurement into an ultrasonic reference length.

Hooke's Law and Stud-Stretch Measurement

All studs elongate in their elastic region following Hooke's law, as outlined in the section ''Function of Bolts''.

In the relaxed state, a reference length is measured using the ultrasonic extensometer. After the stud has been tightened, an additional reading is made to measure stud stretch. Given the known parameters of effective bolt length (L_b), tensile area of bolt (A_s), Young's modulus of elasticity (E), the preload (F_p) can now be directly correlated to stretch. Rearranging equation A7.1 allows the calculation of bolt preload (F_p):

$$F_p = \frac{\Delta L_b}{L_b} \times E \times A_s$$

The measured residual preload can then be compared to design preload to ensure it falls within an acceptable tolerance. Alternately the stretch reading ΔL_b actual is compared to ΔL_b design.

Example A7.2 Example Calculation: Application: Heat exchange–Reboiler channel

Input data:

$$A_s = .7854 \left(.875 - \frac{.9743}{9} \right)^2 = .462 \ \text{in}^2$$

Stud size $(D) = 0.875$ in

Thread pitch$(n) = 9$

Material $=$ A193, Gr. B7

Young's modulus $(E) = 30 \times 10^6$ psi

Effective length $(L_b) =$ Grip length $+ 1 \times D$, where grip length equals measured distance between nut faces

Design bolt load $(F_p) = 11,524$ lb

Calculation:

$$\Delta L_b = \frac{11,524 \times 9.5}{30 \times 10^6 \times .462} = 0.008 \ \text{in}$$

Expected tolerance on critical application is $\pm$ 10%; therefore, actual ΔL_b should fall between 0.0072 in and .0088 in.

MANAGING FLANGE JOINT INTEGRITY

Leaks are a threat to profits, safety, and the environment. Problems resulting from leaks in flanges can range from local in severity to plant-wide catastrophe. Although the range of negative results can vary widely, leaks have one thing in common: all leaks are preventable.

Leaks don't happen by accident, they happen by design. Rather than being symptoms of product failure, leaks are generally evidence of failure in process control. When you fix the process control, you fix the leaks before they happen.

This chapter has reviewed the key elements to achieving flange joint integrity to assure leak-free integrity of the bolted flange joint. An integrated approach must be adopted to ensure success of the process of joint integrity.

This process begins with an understanding of the operating environment, continues with design and selection of the flange components, setting of assembly specifications, establishment of best-practices procedures, assignment of competent personnel, quality assurance, traceability through complete documentation, and finishes with meeting the goal of leak prevention.

The goal of leak prevention is achievable and starts with a mind-set of doing things right the first time.

CHAPTER A8
PRESTRESSED CONCRETE CYLINDER PIPE (PCCP) AND FITTINGS

Richard E. Deremiah, P.E.
Project Manager
Price Brothers Company
Dayton, Ohio

INTRODUCTION

History

Prestressed concrete cylinder pipe (PCCP) has been manufactured in the United States since 1942. An American Water Works Association (AWWA) tentative standard was developed in 1949 and was made a permanent standard in 1952. Since that time, this standard has been reviewed and updated on a regular basis. PCCP offers the specifier and owner numerous advantages, including ease of installation, custom-designed fittings, superior corrosion resistance, high-flow characteristics, low maintenance costs, and product support by the manufacturer. PCCP is used extensively for a wide range of project types both in the United States and around the world.

There are three other types of concrete pressure pipe: reinforced concrete cylinder pipe (referenced in the AWWA Standard C300[1]), reinforced concrete noncylinder pipe (referenced in the AWWA Standard C302[2]), and pretensioned concrete cylinder pipe (referenced in the AWWA Standard C303[3]).

Terminology and Definitions

Spigot ring—   the protruding end of a PCCP joint which contains a shaped groove to retain the O-ring rubber gasket (refer to Fig. A8.1)
FIGURE A8.1   Spigot ring.

Bell ring—	the receiving portion of a PCCP joint (refer to Fig. A8.2)
O-ring gasket—	rubber ring of circular cross-section which, when compressed into the spigot-ring groove by the bell ring, provides a water-tight seal
Laying length—	a measure of a pipe or fitting's length along its axis for purposes of advancing the length of a pipeline
Working pressure—	the long-term, steady-state internal pressure
Transient pressure—	the incremental change in internal pressure in a pipeline, which is usually of short duration, that is caused by a relatively sudden change in flow velocity
FIGURE A8.2   Bell ring.

Field test pressure— an internal pressure applied to a pipeline or portion of a pipeline to test its structural and water-tight performance

External dead load— an applied load to a pipe which is generally constant, such as earth weight, foundation loads, and so on

External live load— an applied load to a pipe which is transient in nature and usually of short duration, such as motor vehicles

Applications for Prestressed Concrete Pressure Pipe

PCCP is the most widely used type of concrete pressure pipe for the transport of water and wastewater in the United States and the world. Uses include raw and potable water transmission lines, water distribution systems, gravity and pressure sewers, power plant cooling systems, industrial process lines, water and wastewater treatment plant process lines, sewer outfalls, raw water intakes, and impoundment-dam spillway conduits. It is a versatile pipe that can be installed in the normal direct-buried condition; as an aerial crossing over canals, rivers, and other obstacles; or subaqueously in both freshwater and seawater.

Reference Standards

Table A8.1 summarizes the standards covering the design and manufacture of PCCP. The AWWA standards in Table A8.1 include reference to other standards published by the American Society for Testing and Materials (ASTM), American Society of Mechanical Engineers (ASME), American Concrete Institute (ACI),

TABLE A8.1 Reference Standards

Title	Purpose
American National Standards Institute/ American Water Works Association C301 Prestressed Concrete Pressure Pipe, Steel-Cylinder Type[4]	Covers the manufacturing process for PCCP, including raw material specifications, manufacturing techniques, and testing procedures.
American National Standards Institute/ American Water Works Association C304 Design of Prestressed Concrete Cylinder Pipe[5]	Covers the design process for PCCP.
American Water Works Association Manual of Water Supply Practices "M9—Concrete Pressure Pipe" [6]	Provides general information regarding the design, manufacturing, and use of PCCP. Also includes information on the other types of concrete pressure pipe: reinforced cylinder pipe, reinforced noncylinder pipe, and pretensioned concrete cylinder pipe.

American Iron and Steel Institute (AISI), American Welding Society (AWS), and American Association of State Highway and Transportation Officials (AASHTO).

DESCRIPTION

Pipe Types

Prestressed concrete cylinder pipe consists of a structural, high-strength concrete core, a steel cylinder with steel joint rings welded at each end providing water-tightness, steel prestressing wire, and a portland cement-rich mortar coating. Two
FIGURE A8.3 (a) Lined cylinder pipe (LCP) and (b) embedded cylinder pipe (ECP) profiles.

Standard Elbow
FIGURE A8.4   Typical elbow fitting.

types of PCCP are manufactured: lined cylinder pipe (LCP), which is detailed in Fig. A8.3a and embedded cylinder pipe (ECP), which is detailed in Fig. A8.3b. Lined cylinder pipe has the entire concrete core placed inside the steel cylinder. The cured concrete core and steel cylinder are then helically wrapped with prestressing wire, which is subsequently coated with cement mortar. Embedded cylinder pipe has the concrete core placed both outside and inside the steel cylinder by a vertical casting operation. The cured concrete core and steel cylinder are then helically wrapped with prestressing wire and, as LCP, is coated with cement mortar.

Available Size Ranges

LCP is normally manufactured with inside diameters ranging from NPS 16 (DN 400) through NPS 48 (DN 1200), although larger sizes have been made. ECP is normally manufactured with inside diameters ranging from NPS 54 (DN 1350) through NPS 144 (DN 3600), but diameters smaller and larger than this range are possible. The nominal laying length for pipe up to and including NPS 114 (DN 2850) is usually 20 ft (6 m), and 16 ft (4.9 m) for larger sizes. These diameter ranges and laying lengths can sometimes vary by manufacturer, so the user should check with suppliers on specific sizes. In larger sizes, the laying length can be controlled

Tee With Crotch Plates
FIGURE A8.5   Typical tee fitting.

by the weight of the piece and the manufacturer's and installing contractor's ability to handle it.

Fittings and Special Pipe

A wide range of fittings and special pipe lengths are available for all types of project requirements. Fittings are manufactured from steel plate which is cut, rolled, and welded to form the required shape. The completed steel shell is lined and coated with portland cement mortar for corrosion protection. Each fitting is designed for the same external load and internal pressure as the adjoining pipe. Common fittings are elbows, tees, wyes, reducers, wall pieces, and adapters. Adapters are needed for connections to other types of joints such as flanges, mechanical joints, and couplings. Figures A8.4 through A8.7 show the general configurations of elbows, tees, concentric reducers, and flange adapters.

Special pipe consists of prestressed pipe lengths with additional features such as outlets or beveled ends. Prestressed pieces with a laying length shorter than the standard constitute a special pipe that can be supplied to match specific job requirements.
FIGURE A8.6 Typical concentric reducer fitting.
FIGURE A8.7 Typical flange adapters.

DESIGN

Design Parameters

PCCP is designed as a rigid structure to resist the simultaneous application of external loads and internal pressures. External dead loads normally encountered are earth loads, foundation loads, or surcharges applied at the ground surface. External live loads are caused by vehicular traffic, railroads, or construction equipment. The weight of the pipe and the weight of water inside the pipe are also considered in the design procedure. Internal pressures used for design are the working pressure, transient pressure, and the field hydrostatic test pressure. The working pressure should be the expected steady-state internal pressure for the system. The transient pressure is the expected internal pressure over and above the working pressure that can occur during surge (water hammer) conditions. If the purchaser does not include a transient pressure in the specifications, the AWWA C304[5] design standard requires that, as a minimum, the transient pressure allowance be 40 percent of the working pressure, or 40 psi (0.27 MPa), whichever is greater. A postconstruction hydrostatic pressure test is usually conducted to confirm the structural integrity and watertightness of the completed system. In the absence of a field hydrostatic test pressure specified by the purchaser, the AWWA C304 design standard requires the use of a test pressure of 1.2 times the working pressure. Support under the pipe provided by the bedding material must also be used in the design procedure. Various suggested bedding types are shown in the AWWA C304 design standard.

The pipe purchaser's plans and specifications should contain as a minimum the following design parameters for PCCP:

Earth cover over the top of the pipe

Expected live load (normally AASHTO HS20 truck loading configuration)

Internal working pressure

Internal transient pressure allowance

Field hydrostatic test pressure

Bedding type

The pipe and fittings manufacturer will design and manufacture the pipe and fittings to comply with the pressures and loadings specified.

Hydraulics

Energy use in pipeline operation can be greatly reduced during the design stage. Head losses due to pipe wall friction are among the most manageable causes of energy consumption for pipelines which use pumps. These losses can be minimized with the use of pipe which has excellent long-term hydraulic characteristics and by selecting a large enough pipe diameter to avoid high-flow velocities which accelerate energy costs. Energy savings resulting from these design decisions will help reduce operating costs each year throughout the life of the pipeline.

Flow Formulas

Over the years, many empirical flow formulas have been proposed. The Hazen-Williams formula, shown below, was first published by Allen Hazen and Gardner S. Williams in 1905, and continues to be the most widely used for pressure pipe systems.

$$V = 0.550C_h \left(\frac{h_L}{L} \right)^{0.54} d^{0.632} \quad \text{(A8.1)} \qquad V = 0.3549C_h \left(\frac{h_L}{L} \right)^{0.54} d^{0.632} \quad \text{(A8.1M)}$$

where V = mean velocity, ft/s
$\quad$ C_h = Hazen-Williams flow
$\quad\quad$ coefficient
$\quad$ d = inside pipe diameter, ft
$\quad$ h_L = head loss, ft
$\quad$ L = pipe length, ft

where V = mean velocity, m/s
$\quad$ C_h = Hazen-Williams flow
$\quad\quad$ coefficient
$\quad$ d = inside pipe diameter, m
$\quad$ h_L = head loss, m
$\quad$ L = pipe length, m

A statistical analysis of 67 flow tests of concrete pressure lines was made by Swanson and Reed and published in the January 1963 AWWA Journal.[7] Some of this pipe was manufactured as early as 1895. This report presented a "best fit" mean deviation comparison with the well-known formulas by Hazen-Williams, Morris, Moody, and Scobey. The authors concluded that the Hazen-Williams expression for head loss most closely matched the test results for the range of velocities normally encountered in water transmission. The average mean deviation between calculated and observed losses was lowest for the Hazen-Williams formula. A regression analysis least-squares method was used to develop a correlation equation for the Hazen-Williams "C_h" term for concrete pipe, as follows:

$$C_h = 139.3 + 2.028d \qquad \text{(A8.2)} \qquad C_h = 139.3 + 6.654d \qquad \text{(A8.2M)}$$

where d = inside pipe diameter, ft $\qquad\qquad$ where d = inside pipe diameter, m

The Hazen-Williams flow formula can be rewritten in a more convenient form where head loss is expressed in terms of flow velocity.

Head loss in ft: $\qquad\qquad\qquad\qquad$ Head loss in m:

$$h_L = 3.021 \frac{L}{d^{1.167}} \left(\frac{V}{C_h} \right)^{1.852} \quad \text{(A8.3)} \qquad h_L = 6.8102 \frac{L}{d^{1.167}} \left(\frac{V}{C_h} \right)^{1.852} \quad \text{(A8.3M)}$$

Head Losses Due to Fittings

While head losses due to fittings are generally a minor portion of the overall head loss in a pipeline, they can be important in certain applications such as treatment plants when the length of a line is short and the number of fittings is high. These head losses occur in elbows, reducers, enlargements, valves, and other fittings in the pipeline. The rational method of calculating these losses assumes full turbulence and expresses the loss in terms of velocity head. This expression is

$$h_L = C_L \frac{V^2}{2g} \tag{A8.4}$$

where h_L = head loss, ft (m)
    V = velocity, ft/s (m/s)
    C_L = a dimensionless coefficient
    g = acceleration due to gravity, 32.2 ft/s^2 (9.81 m/s^2)

Values of "C_L" commonly used for design purposes for a variety of fittings and appurtenances, along with a more comprehensive treatment of hydraulics, are included in the AWWA manual "M9—Concrete Pressure Pipe."[6]

MANUFACTURE

Figure A8.8 illustrates the various steps in the manufacturing process for PCCP.

Figure A8.9 shows the various steps in the manufacturing process for fittings. The AWWA standard C301[4] provides a comprehensive description of the manufacturing requirements for pipe and fittings. The purchaser should require, in the specifications, that all pipe and fittings be manufactured per the AWWA C301 standard.

Quality Assurance

All PCCP manufacturers should establish quality assurance departments within the pipe plant to provide step-by-step attention to all production procedures and assure that all machinery and equipment is operating properly. Incoming raw materials must be carefully inspected and tested for compliance with the governing standards. The AWWA C301 standard contains the testing methods to be used and acceptance criteria for all raw materials to be incorporated into the pipe and fittings.

JOINTS

Rubber O-ring Bell and Spigot Joint

Figures A8.3a and A8.3b show a cross-section of the typical LCP and ECP bell and spigot joint. As can be seen, an O-ring rubber gasket is compressed into the spigot groove by the bell ring when assembled to form a water-tight seal. Portland
FIGURE A8.10   Snap Ring® restrained joint.

cement grout is poured into a fabric band (diaper) by the installer to provide corrosion protection.

Restrained Joints

Figure A8.10 depicts a Snap Ring® type restrained joint and Fig. A8.11 a harness clamp type restrained joint. These joints can be used to resist axial tensile forces on the pipe due to unbalanced thrusts caused by internal pressure at fittings such as elbows, tees, and bulkheads. The Snap Ring joint incorporates a split ring which is preassembled in the manufacturing plant so that it is recessed into a groove in the bell ring. After the spigot is pushed home into the bell, the installer tightens a single bolt which draws the split ring down around the shank of the spigot ring. This effectively locks the joint together. The harness clamp joint utilizes a two-part clamp which engages bars on the bell and spigot rings. After the spigot is pushed home into the bell, the installer places the clamp halves over the harness bars, securing them with bolts and nuts. The clamp installed in this manner locks the joint together.

FIGURE A8.14   Bonded joint. Exothermic fusion welded copper cable method.

Testable Joints

Figure A8.12 shows a joint configuration which allows for testing the joint seal without the need to fill the pipeline with water. These joints are normally used when pipe is installed in a manner that necessitates immediate verification of the gasket seal. This feature is sometimes necessary for certain pipelines in power, industrial, water, and wastewater plants; for pipe in tunnel casings; and for subaqueous pipelines. This can be an effective tool for finding a problem with a joint seal at the time it can most easily be corrected. Testable joints are normally available

in diameters NPS 54 (DN 1350) and larger. However, some manufacturers may be able to supply them in smaller diameters. Testable joints should not be considered a replacement for postconstruction hydrostatic pressure tests since they do not confirm the overall system integrity (restrained joints or concrete thrust blocks) and watertightness of connecting appurtenances such as valves and access manholes.

Other types of special joints available for PCCP include subaqueous joints and bonded joints. Subaqueous joints, depicted in Figs. A8.13a and A8.13b, are designed to facilitate jointing underwater by divers. They normally incorporate external lug and drawbolt assemblies. Bonded joints, shown in Figs. A8.14a, A8.14b, and A8.14c, are designed to provide electrical continuity across the joint for the future monitoring of electrical activity on the pipeline or for the application of cathodic protection.

INSTALLATION

Pipe Handling and Storage

A crane or backhoe outfitted with a steel cable sling may be used to unload pipe unless the pipe has a special exterior coating that could be damaged by a steel cable sling. In such cases, a fabric sling should be used. Multiple slings are often used in handling large pipe and fittings. Pipe can be stored directly on the ground in nonfreezing conditions. If freezing conditions are expected, the pipe should be set on wooden timbers off the ground to prevent the pipe from becoming frozen to the ground. Rubber gaskets should be stored in a cool place, out of the sun, away from fuel oil, gasoline, electric motors, and any other environment that can damage rubber.

Excavation and Bedding Preparation

In most cases, the trench is excavated to be long enough for one section of pipe. The trench should be wide enough to allow installing personnel adequate room to work at the sides of the pipe. Pipe should not be laid directly on rocks or other unyielding foundation. Refer to the AWWA C304 standard for the bedding and backfill requirements for PCCP.

Jointing

Just prior to jointing, the steel joint rings should be carefully cleaned and the rubber gasket and contact surfaces of the joint rings lubricated. Only lubricant recommended by the pipe manufacturer should be used. Once the joint ends are properly prepared and the rubber gasket is in place on the spigot, the ends are aligned so the spigot will enter the bell squarely. Then the spigot is pushed home with a smooth, continuous motion. The position of the gasket is then checked in the manner recommended by the pipe manufacturer. A fabric band is secured around the exterior joint recess to receive the portland cement grout for corrosion protection.

Backfilling

After the joint has been assembled and the exterior joint recess has been grouted, the pipe can be backfilled to grade. In general, the requirements for backfilling rigid PCCP will not be as critical as for flexible types of pipe such as steel, plastic, and ductile iron. The backfill in contact with the pipe should not contain large rocks, clods, or excessive organic material.

Field Hydrostatic Testing

In most situations, a post-construction hydrostatic pressure test of the completed pipeline is required before final acceptance by the owner. For very long lines, it may be convenient to test shorter sections as they are completed rather than wait and test the entire project at one time. This test can verify the overall system integrity such as the restrained joints or thrust blocks and the watertightness of the connecting appurtenances such as valves, access manholes, and outlets.

Repair

Occasionally, damage may occur in the field due to impacts from construction equipment or other objects. Minor damage can usually be repaired in the field by qualified personnel. Major damage may require shipment of the piece back to the manufacturing plant for repair or replacement. Before attempting any repairs in the field, the pipe manufacturer should be consulted for specific recommendations and assistance.

Special Installation Situations

During the design phase of some projects, areas of unstable soil conditions and crossings of small rivers, streams, or canals should be identified. In these cases, a pier support arrangement for the pipe may be needed. The pipe for this application must be designed and manufactured to span the supports and to resist the concentrated load applied to the pipe at the support.

PCCP to be placed underwater such as for intakes, outfalls, or lake and river crossings may require special consideration for joining pipe underwater by divers. PCCP to be used for subaqueous lines may have modifications made to the joints to allow for joint engaging assemblies such as drawbolts, or special devices may be used which create a vacuum force to pull the joint home while the pipe's weight is supported by a barge-mounted crane. In either case, it may be advantageous to use longer pipe lengths in order to minimize the number of underwater joint assemblies.

The concrete and mortar linings and coatings specified in the AWWA C301 standard provide ample corrosion protection in most buried environments. There are, however, certain conditions where the ability of the concrete and mortar to provide a passivating environment around the embedded steel may need to be supplemented. Additional protective measures may be needed in these instances. These conditions include

- High chloride environment
- Stray current interference

- High sulfate environments
- Severe acid conditions
- Aggressive carbon dioxide
- Atmospheric exposure
- Connections to other pipelines

Refer to the AWWA manual "M9—Concrete Pressure Pipe"[6] for further information on the identification and evaluation of these conditions. The pipe manufacturer should also be consulted for specific recommendations and availability of supplemental protective measures.

Tapping Prestressed Concrete Cylinder Pipe

Outlets, tees, and wyes can be built into the pipe when their need is identified at the time the project is designed. When unforeseen circumstances occur that require outlets, connections, or branch lines on already installed pipe, tapping of PCCP can be done.

Tapping PCCP for connecting outlets after a pipeline is installed is a common occurrence on most public works projects. Taps can easily be made on PCCP. In
After the tap is installed, all metal parts must be encased in a 1:3 concrete or mortar mix with a minimum cover of 1 inch.

most cases, the tap can be done under pressure without interrupting service to customers. Tap diameters commonly range from NPS ¾ (DN 20) up to one size smaller than the pipe being tapped. For full size branch connections, a cut-in tee arrangement or a line stopping process may be feasible. The tapping saddle assembly used must be properly designed to work with PCCP. Figure A8.15 shows a strap-type tapping saddle assembly, and Fig. A8.16 shows a larger flange-type tapping saddle assembly. The strap-type saddle is normally used for tap diameters NPS ¾ (DN 20) to NPS 2 (DN 50). The flange-type saddle is used for tap diameters NPS 3 (DN 80) and larger. Consult the pipe manufacturer for additional information on tapping saddle assemblies and services provided.

CHAPTER A9
GROOVED AND PRESSFIT PIPING SYSTEMS

Louis E. Hayden, Jr.
Divisional Operations Manager
Victaulic Company of America
Easton, Pennsylvania

The use of mechanical joints in the design and construction of piping systems is rapidly becoming a general practice. This chapter discusses two types of mechanical pipe joints. The first is a mechanically pressed joint called Pressfit®* that is designed to join light-wall carbon steel and stainless steel pipe. The second joint is generically termed a grooved joint. This type of joint is designed for joining any type of pipe, metallic or nonmetallic, that is capable of being cut or roll grooved.

Both types of joints rely on a mechanical interlock with the pipe end for pressure and structural integrity and an elastomeric gasket for the pressure boundary seal.

PRESSFIT®

Introduction

The Pressfit piping system is an innovative, rigid, self-restrained mechanical joining method for schedule 5 or lighter weight lightweight stainless steel and carbon steel pipe. This proprietary mechanical pipe joint is designed for use in small-bore piping systems, NPS ½ (DN15) to NPS 2 (DN50). The Pressfit system may be applied to any service that is compatible with the piping materials, the gasket material, and the temperature range of the system, unless prohibited by the manufacturer's instructions. Typical applications would include building-services piping, potable water, fire protection, heating and cooling, industrial processes, process cooling and heating systems, plant utilities, and vacuum systems.

Joint Concept

The Pressfit joining system concept is illustrated in Fig. A9.1 The left side of Fig. A9.1 shows the pipe fully inserted into the Pressfit fitting in the ''unpressed'' condi-

tion. The right side of Fig. A9.1 shows a cross-sectional view of the Pressfit joint in the "pressed" condition. Note that the pressing operation indents the Pressfit fitting and pipe, thus providing the mechanical restraint required to resist pressure and external loads that try to separate the pipe. The O-ring seal has also been compressed to provide the pressure-boundary seal of the joint. Additionally, the final pressed shape of the Pressfit joint provides resistance to torsional movement.

Industry Specification, Codes and Product Testing

Pressfit fittings and pipe meet the requirements of the following specifications, codes, and standards:

- Pressfit carbon steel products meet the requirements of ASTM A53 Grade A and A135 Grade A. Pressfit stainless steel products meet the requirements of ASTM A312 Grade 316/316L and ASTM A269 Grade 304/304L.

- Pressfit products meet the requirements for use in piping systems designed to comply with ASME B31.1, B31.3 and B31.9 piping codes. Pressfit products are qualified for use in these systems by the following paragraphs:

  ASME B31.1, Power Piping, Paragraphs 104.1.2, 104.7(c), and 118

  ASME B31.3, Process Piping, Paragraphs 304.1, 304.7.2(a), and 304.7.2

  ASME B31.9, Building Services Piping, Paragraphs 904.7, 904.7.2, and 913

- Codes and standards that have approved or listed Pressfit products are

System Pressure and Temperature Rating

The Pressfit pipe joining system, when installed in accordance with the manufacturer's instructions, is rated as follows:

- Pressfit joints are rated for 300 psi (2065 kPa) when used in general service or process systems.
- Pressfit joints are rated for 175 psi (1200 kPa) for all fire protection services.
- The maximum and minimum continuous service temperatures for Pressfit joints are defined by the selection of the O-ring seal which is compatible with the system fluid. Thermal service conditions are shown in Table A9.1 A comparison of the maximum allowable design pressure of the Pressfit joint to an ASME Class 150 joint over the temperature range from ambient to the maximum continuous service temperature of the Pressfit joint is shown in Figs. A9.2, A9.3 and A9.4.

Joint Installation

Pressfit pipe fittings are designed to be installed on square cut, plain-end pipe. No special pipe-end preparations are needed. Pressfit joints are made using generally accepted pipe fitting techniques with the addition of the following requirements:

- Each pipe end must be marked by measuring back from the end to establish an insertion or witness mark. This mark should be highly visible and extend for at least 180° of the pipe circumference. The insertion depth should be measured and marked as shown in Table A9.2.
- The marked pipe end should be fully inserted into the Pressfit fitting completely to the pipe stop. The insertion or witness mark should be adjacent to the end of

TABLE A9.1

the Pressfit fitting. The Pressfit pipe fitting should be squared to the pipe and pressed onto the pipe using the proper pressing jaw and Pressfit tool.

System Installation

As with all piping systems, a Pressfit system must be properly installed to provide the system performance envisioned by the piping designer. At minimum, the following installation requirements should be considered:

- *System Support:* Like all other piping systems, pipe joined with Pressfit joints requires support to carry the weight of the piping system, system fluid, and other system equipment. As in other methods of joining pipes, the support or hanging method must be adequate to eliminate undue stresses on joints, piping, and other

* Carbon steel only

system components. The suggested maximum span between supports for Pressfit piping systems is shown in Table A9.3.

- *Thermal Expansion and Contraction:* As with all rigid piping systems, piping installed utilizing Pressfit joints must be reviewed by the piping designer to assure proper allowances are incorporated into the piping system design to eliminate undue stresses from thermal expansion or contraction. The use of flexible mechanical coupling-type expansion joints is highly recommended for this service. If installation of flexible mechanical joints is not possible or desired, the designer is encouraged to use single-leg (Z-shaped) or dual-leg (U-shaped) expansion compensation loops as shown in Figs. A9.5 and A9.6 For calculated piping movement, Δl, the minimum expansion compensate leg length L may be determined by using Figs. A9.7 and A9.8 As a result of thermal expansion

FIGURE A9.5 Z-shaped expansion compensator.

and contraction of pipe, Pressfit joints may be subjected to torsional or rotational movement. Rotational angles must be limited to a maximum of 5°.

Advantages of Pressfit

The Pressfit pipe joint was conceived to provide a fast, clean, and cool method of installing lightweight carbon and stainless steel piping systems. Advantages provided by using Pressfit are listed as follows:
FIGURE A9.6 U-shaped expansion compensator pipe with fittings.

- The Pressfit piping system, with its lower weight, lack of required pipe-end preparation, along with ease and speed of pressing joints, will provide a lower final cost installation to the contractor and owner than the same size carbon or stainless steel system installed by threading, flanging, or welding.
- Due to the design of the Pressfit fitting, piping designers can take advantage of the full-rated pressure capability of the Pressfit fitting across the allowed temperature range of the selected O-ring material. Pressure derating with an increase in metal temperature is not a factor in Pressfit systems as compared to a flanged system. Refer to Figs. A9.2, A9.3, and A9.4 for comparison.
- Pipe used in piping systems utilizing Pressfit joints has thinner nominal wall thickness than Schedule 40 pipe used in most applications where Pressfit should

FIGURE A9.7

U-Shaped Expansion Compensator
FIGURE A9.8

be considered. This difference results in significant increases of flow area and less pressure drop in Pressfit piping systems, compared to systems designed utilizing Schedule 40 pipe. A tabulation of these factors is shown in Tables A9.4 and A9.5.

• When considering carbon steel Pressfit and Schedule 40 piping from an internal corrosion perspective, the Pressfit system provides adequate performance when used in closed-loop service where water treatment is maintained or introduction of oxygen into the system is limited to periodic testing or system makeup. In Table A9.6 and Fig. A9.9, the corrosion resistance ratio (CRR) of Schedule 5 and Schedule 40 carbon-steel Pressfit pipe are compared. The corrosion resistance ratio (CRR) is a method, established by Underwriters' Laboratories in 1970, by which to compare the effective wall thicknesses for various pipes. The effective

TABLE A9.4 Friction Loss

NPS (DN)	Flow rate (GPM)	Schedule 5	Schedule 10		Schedule 40	
			psi	Higher	psi	Higher
½ (15)	15	0.500	0.643	22%	0.951	90%
¾ (20)	25	0.3713	0.4510	21%	0.6351	71%

1¼ (32)	1.839	1.633	11%	1.496	19%
1½ (40)	2.461	2.222	10%	2.036	17%
2 (50)	3.960	3.650	8%	3.360	15%

wall thickness is the minimum thickness remaining at any point within a system which has exposure to both internal and external corrosion. For Schedule 5 pipe, the effective wall thickness is the minimum allowed by the applicable ASTM standard and for threaded Schedule 40, it is the minimum remaining thickness under the first exposed thread. Threaded Schedule 40 is used as the baseline and has a CRR of 1. Piping with a CRR greater than 1 will have an effective wall thickness greater than threaded Schedule 40. As can be seen in the table above, Schedule 5 Pressfit pipe has an effective wall thickness greater than threaded Schedule 40 in sizes up through NPS 1½ (DN 40). This is normally adequate to assure long system life.

GROOVED MECHANICAL PIPE JOINTS

Introduction

The grooved piping method for mechanically joining pipe is recognized as the fast, easy, economical, and reliable method of joining pipe for many services. With over 70 years of service experience, the grooved piping method is now accepted along with the pipe joining methods, such as welding, flanging, and threading.

The grooved system provides a self-restrained pipe connection which can withstand the full-pressure thrust loads at the maximum-rated working pressure of the coupling. Easy assembly also allows easy disassembly. This, in combination with a union at every joint, permits easy system access for maintenance, repair, component replacement, and retrofits. Also, fittings can be loosely assembled and rotated to line up with mating components before the couplings are tightened. This eases work in tight places and around existing pipe, structures, or equipment. Features such as easy assembly, system access, and installation in confined spaces are not available with other joining methods.

Reference Codes, Standards, and Specifications

Grooved joints consist of grooved pipe ends and grooved pipe couplings. The pipes themselves may meet many various industry specifications. The pipe ends and couplings meet the requirements of the following:

Pipe Grooves—ANSI/AWWA C606–87 Grooved and Shouldered Joints

Pipe Couplings—ASTM F1476–93 Standard Specification for Performance of Gasketed Mechanical Couplings for use in Piping Applications

Grooved couplings may meet the requirements or be listed by the following codes or agencies. The designer should check with the coupling manufacturer to verify compliance or listing:

American Bureau of Shipping (ABS)

American National Standards Institute (ANSI)

American Petroleum Institute (API)—API Std. 5L Sect. 7.5

American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE)

American Society of Mechanical Engineers (ASME) Pressure Piping Code, B31; B31.1, Power Piping; B31.3, Process Piping; B31.5, Refrigeration Piping; B31.9, Building Services Piping; B31.11, Slurry Pipelines

Building Officials and Code Administrators (BOCA)

Canadian Standards Association—B242 (CSA)

Factory Mutual Research Corp. (FM)—Approved for fire protection services

International Association of Plumbing & Mechanical Officials (IAPMO)

National Fire Protection Association (NFPA)

New York Materials and Equipment Acceptance (NY-MEA)

Southern Building Code Congress International (SBCCI)—Standard Plumbing and Mechanical Code

Underwriters' Laboratories, Inc. (UL)—Listed for fire protection services

Underwriters' Laboratories of Canada (ULC)—Listed for fire protection services

Underwriters' Laboratories Inc. Listed (ANSI/NSF-61)

Joint Concept

The grooved pipe-joining method is simple and reliable. The coupling housing performs several functions as an integral part of the pipe joint. It contains the fully enclosed gasket and reinforces and secures it in position for a proper seal. The housing also engages the pipe grooves around the full pipe circumference and creates a unified joint while it provides the advantages of mechanical joining. The leak-tight joint is created without exposing workers and property to the fire, smoke, and health hazards associated with welded joints or with welding flanges onto pipe.

Types of Grooves

Cut Groove.   Grooved piping systems normally use two types of grooves. The first type, cut groove, is achieved by machining a groove in the pipe end. This type of groove may be used for standard weight and heavier pipe walls, cast ductile iron pipe, and other pipe materials that do not lend themselves to mechanical deformation, such as fiberglass reinforced plastic. Cut grooving removes material from the pipe wall and therefore should not be used for grooves in pipes with walls thinner than standard weight.

Rolled Groove.   The second type, roll groove, is achieved by placing the pipe end in a roll grooving machine and rolling (mechanically deforming) a groove into the pipe. This grooving is accomplished by pressing a grooving roll into the pipe wall as the pipe is rotated by the machine. The resultant groove does not remove any pipe material. Fig. A9.10 shows the roll grooving process.
Roll grooving tools cold form groove into pipe – maintains dimensions
Roll grooving removes no metal from pipe

FIGURE A9.10   Roll grooving process.

Types of Couplings

Flexible Couplings.   As with grooves, there are two basic types of pipe couplings. The first type is defined as a flexible coupling. Flexible couplings allow for controlled pipe movement within the coupling while maintaining a positive seal and a self-restrained joint. Such performance is achieved through the combination of the elastomeric gasket, which seals the joint, with the housing, which engages the groove without clamping rigidly onto the pipe. The design allows for expansion, contraction, and deflection generated by thermal changes, building or ground settlement, and seismic activity. Pipe movement accommodation with flexible couplings will minimize the stresses that can be generated by this movement. Figure A9.11 is an exaggerated illustration of a flexible coupling. A welded system requires additional components such as expansion loops and expansion joints, since it consists solely

Possible Movement
FIGURE A9.11   Flexible coupling.

of rigid connections and has no inherent characteristics to prevent the buildup of thermal and mechanical stresses.

In order to ensure that the flexible behavior is available when required, it is necessary to support a flexible system in such a manner as to direct all motion to the preferred location. For example, to accommodate piping expansion in a long piping run, pipe lengths should be in axial alignment joined by properly gapped pipe couplings between two opposing anchors. When used in mechanical equipment rooms and on pump connections, flexible couplings will characteristically provide greater piping deflections than those generated by traditional piping methods when adequate additional support is provided.

Flexible couplings do not clamp rigidly onto the pipe. Therefore, every joint minimizes noise and vibration transmission to the piping system generated by pumps or other equipment (in contrast to other joining methods). Independent laboratory tests have confirmed that three flexible couplings connected in a series reduce more vibration than do elastomeric-arch or corrugated flexible-metal hose-type vibration isolators. Welded, flanged, or threaded joints offer no vibration attenuation, so additional costly vibration control devices are required.

Rigid Coupling.   The second type of coupling is defined as rigid coupling. Rigid couplings positively clamp the pipe to create a rigid joint, so axial movement and deflection are eliminated. They are particularly useful on risers, mechanical rooms, horizontal runs with numerous branches, and other areas where flexibility is not desired. Proper rigid coupling installation provides system behavior characteristics similar to those of other rigid systems, so that all piping remains in strict alignment and is not subject to axial or angular movement during operation. Figure A9.12 is an exaggerated illustration of a rigid coupling. For this reason, systems installed with rigid couplings utilize support techniques similar to those used in traditional flanged and welded systems and do not require additional support as in a flexible system. ASME Pressure Piping Code Section B31.1, Power Piping, and B31.9, Building Services Piping, may be used as guidelines for supporting rigid systems. Risers consisting entirely of rigid couplings can be treated similarly to welded piping systems, and where thermal movement is required, expansion joints or offsets will be necessary to prevent piping system movement and damage to components. The piping systems using rigid couplings are obviously advantageous where rigidity is
No Movement

FIGURE A9.12   Rigid coupling.

desired, as in mechanical equipment rooms, long straight runs, and similar applications.

Using Flexible and Rigid Couplings in a Piping System.   When both flexible and rigid couplings are utilized, the system designer can optimize hanger spacing, eliminate expansion loops and flex connectors, and incorporate rigidity and flexibiltiy where desired. An example of such a system would be a pumping system which bridges two buildings via an underground line. At the pump end, rigidity may be desirable in the mechanical room to control piping motion, whereas within the straight piping run between buildings, flexible couplings are the most desirable to accommodate anticipated settlements or thermal movements. In the adjoining building for the distribution system, it may be advantageous to use a rigid system, as a high-joint intensity may require an extensive support system when flexible couplings are used. By designing risers and long straight runs with rigid and flexible couplings, the designer can make use of the rigidity of rigid couplings to reduce guiding requirements and the flexibility of flexible couplings to accommodate thermal movement as required.

The use of flexible and rigid couplings provides a variety of benefits to the system designer, installer, and owner, which results in the most reliable system for most applications and makes the grooved method an excellent choice for joining pipe.

Grooved Joint Gaskets

Many factors must be considered in determining the optimum gasket for a specific service. The foremost consideration is temperature, along with concentration of product, duration of service, and continuity of service. Temperatures beyond the recommended limits have a degrading effect on the polymer. Therefore, there is a direct relationship between temperature, continuity of service, and gasket life.

The piping system designer should also consider the gasket style that will provide the desired system performance. Three basic styles are shown in Fig. A9.13 The standard gasket style is suitable for most piping system applications. The FlushSeal® style is designed with a centrally located lip that seals the internal gasket cavity and minimizes the entrapment of system fluids or debris. The EndSeal® seals the pipe ends to virtually eliminate entrapment of system fluids and debris. The piping system designer should review the grooved joint manufacturer's gasket styles and select the style most suited to his system design.

Gasket Selection

A variety of synthetic rubber gaskets are available to provide the option of grooved piping products for the widest range of applications. To assure the maximum life for the service intended, proper gasket selection and specification is essential.

The compounding of synthetic rubbers is both a science and an art form. There are many gasket materials available from the various manufacturers of grooved pipe joints. The piping system designer should consult the manufacturer for gasket material recommendations about the grooved joint he has specified. The designer is further cautioned that in instances where a gasket is not affected by several substances used alone, their combination could adversely affect the gasket. Where possible, these materials should be subjected to simulated service conditions to determine their suitability.

FlushSeal® and EndSeal® are registered trademarks of Victaulic Company of America.

TABLE A9.8   Gasket Temperature Rating

Gasket grade*	Temperature range*	Compound
E	−30°F to +230°F −34°C to +110°C	EPDM
T	−20°F to +180°F −29°C to +82°C	Nitrile
E (Type A)	Ambient	EPDM
M-2	−40°F to +160°F −40°C to +71°C	Epichlorohydrin
V	+30°F to +180°F −1°C to +82°C	Neoprene
O	+20°F to +300°F −7°C to 149°C	Fluoro- elastomer
L	−30°F to +350°F −34°C to +177°C	Silicone #
A	+20°F to +180°F −7°C to +82°C	White nitrile
T (EndSeal)	−20°F to +150°F −29°C to +66°C	High modulus nitrile

* The gasket grades and temperature ranges shown in this table are for gaskets as manufactured by Victaulic Company of America. Other manufacturers' products may not be rated as shown here. Consult the gasket manufacturer for exact temperature range.

Pressure-Temperature Ratings.   Couplings used in grooved mechanical pipe joints are proprietary designs offered by their various manufacturers. The piping system designer should review the manufacturer's literature to determine pressure and temperature ratings. Pressure ratings for flexible and rigid coupling are shown in Table A9.7, and temperature ratings of gasket materials are shown in Table A9.8, courtesy of Victaulic Company of America.

Piping System Design Considerations.   Grooved mechanical-joint piping systems have some specific characteristics that are different from conventional threaded, welded, and flanged systems. When understood and properly utilized, the piping system designer can achieve well-designed, economical piping systems. As always, professional piping design practice must prevail. The following considerations should be reviewed during the piping system design.

In all piping systems designs, piping system thermal growth must be considered. Common methods of accommodating grooved piping system movement are 1) to allow the system to free float. This design method allows the pipe to move in a desired direction through the use of anchoring or guidance; or 2) utilize the linear movement-deflection capabilities of flexible grooved couplings.

The selection of either of these methods is dependent on the type of piping system and the designer's preference. Since it is difficult to predict all system designs,

it is the intent here to call attention to the mechanical advantages of the grooved piping method and how it can be used to the piping system designer's benefit. These examples are presented to stimulate thought and should not be considered as recommendations for a specific system.
FIGURE A9.14

Free-Floating System

Free-floating systems are piping systems which are allowed to thermally expand or contract without the use of expansion joints, provided that this movement does not cause bending-moment stresses at branch connections or is not harmful to joints and changes in direction or to parts of structures or other equipment. This can be accomplished by randomly installing joints or, if desired, by installing guides to control the direction of movement. The effects of pressure thrusts must be taken into account when utilizing flexible grooved couplings, as the pipe may move to the full extent of the available pipe end gaps when allowed to float. See Fig. A9.14 for pressure-thrust example.

$$\text{PT} = \frac{\pi}{4}D^2 P \qquad (A9.1)$$

PT = Pressure thrust (lb) (newtons)

D = Outside diameter of pipe (in) (mm)

P = Internal pressure (psi) (kPa)

The system designer should ensure that branch connections and offsets are sufficiently long so that the maximum angular deflection of the coupling is never exceeded and that it can accommodate the anticipated total movement of the pipes. Otherwise, the designer must anchor the system and direct movements. See Table A9.9 for recommended pipe alignment guide spacing.

Flexible Grooved Couplings Utilizing Their Linear Movement and Deflection Capabilities

When designing piping joined with flexible mechanical grooved type couplings, it is necessary to give consideration to certain characteristics of these couplings. These characteristics distinguish flexible groove-type couplings from other types and methods of pipe joining. When this is understood, the designer can utilize the many advantages that these couplings provide.

Linear and angular movement available at flexible grooved pipe joints is published for each coupling manufacturer. These values are theoretical maximums. For design purposes, these figures should be reduced by the following factors to allow for coupling and pipe groove tolerances.

Linear and Angular Movement Tolerance

NPS ¾–3½ (DN20-90)—Reduce published figures by 50 percent

NPS 4 (DN100) and larger—Reduce published figures by 25 percent

Standard roll grooved pipe will provide ½ the expansion-contraction or deflection capabilities of the same size standard cut grooved pipe

The angular deflection available at a flexible grooved pipe joint is useful in simplifying and speeding system design and installation.

Angular deflection or misalignment is calculated

$$Y = L \, \text{SIN} \blacklozenge$$
$$\Theta = \text{SIN}^{-1} G$$
$$D \qquad\qquad\qquad (A9.2)$$
$$Y = \frac{G \times L}{D}$$

Y = deflection of misalignment (in) (mm)
G = allowable pipe end movement (in) (mm)
$\blacklozenge$ = allowable deflection (degrees) from centerline of pipe reduced by angular movement tolerance
D = pipe outside diameter (in) (mm)
L = pipe length (in) (mm)

Reference Fig. A9.15 for sample diagram.

Flexible grooved-type couplings allow angular flexibility and rotational movement to take place at joints. These features provide advantages in installing and

of system runs. Offsets at the ends
stem runs as illustrated in Fig. A9.17
to be capable of deflecting suffi-
ly to prevent harmful bending mo-
ts which would be induced at the
s of the offset. It should be noted
if the pipes were to expand due to
mal changes, then further growth of
pipes would also take place at the
FIGURE A9.16   Support requirement.

Angular deflection at butted or fully spaced joints is not possible unless the ends
he pipes can shorten and grow as required. Unrestrained deflected joints will
ghten up under the action of axial pressure thrusts or other forces acting to
FIGURE A9.17 Pressure thrust movement.

pull pipes apart. If joints are to be maintained deflected, then lines must be anchored to restrain pressure thrusts and end pull forces, otherwise sufficient lateral force must be exerted to keep joint deflected. Lateral forces will always act on deflected joints due to internal pressure. A fully deflected joint will no longer be capable of providing the full linear movement normally available at the joint.

The grooved piping method will not allow maximum linear and angular movement simultaneously at the same joint. If linear and angular movement are expected simultaneously, systems should be designed with sufficient joints to accommodate both, including allowance for recommended tolerances. Figure A9.18 shows a typical arrangement used to accommodate simultaneous linear and angular movement.

For anchored systems, where pressure thrusts do not act to hold the joints in tension, or in systems where the joints have been intentionally deflected (e.g., curves), lateral restraint should be provided to prevent movement of the pipes due to pressure thrusts acting at deflections. Lightweight hangers are not adequate in preventing sideways movement of pipes. It should be anticipated that small deflections will occur in all straight lines, and side thrusts will be exerted on the joints. An example of inadequate lateral restraint is shown in Fig. A9.19.

FIGURE A9.18 Accommodating piping expansion and deflection.

Flexible couplings do not automatically provide for expansion or contraction of piping. In anchored systems, gaps must be set to handle combinations of expansion and contraction. In free-floating systems, offsets of sufficient length must be used to accommodate movement without overdeflecting joints. Design anchors to direct movement away from or to protect critical changes in direction, branch connections, and structure. Spacing and suitable types of supports should be considered in accommodating anticipated pipe movements. Refer to Table A9.10 for suggested support spacing for flexible and rigid coupled systems.

Movement in piping systems due to thermal changes can be accommodated with the grooved piping method. Sufficient flexible joints must be available to accommodate anticipated movement, including movement tolerance. If anticipated movement will be greater than provided by the total number of joints in the system, additional expansion in the form of an expansion joint should be considered. The

FIGURE A9.19 Inadequate lateral restraint.

first step in accommodating thermal movement is to compute the exact change in the linear length of the piping system over the distance of interest. The actual expansion of 100 ft and 100 m pipe lengths has been computed at different temperatures for the most common piping materials (carbon steel, stainless steel, and copper tubing) and are shown in Table A9.11. These values should not be applied to pipe of other materials, as they will vary. Expansion coefficients may vary 5 percent or more when obtained from different sources. This variation should be taken into account. Example A9.1 illustrating the use of Table A9.11 follows:

Example A9.1

   Given: 240-ft (75-m)–long carbon-steel pipe

   Maximum operating temperature = 220°F (104°C)
   Minimum operating temperature = 40°F (4°C)
   Temperature at time of installation = 80°F (26°C)

   Calculation: From Table A9.11, carbon-steel pipe expansion

   220°F (104°C)   1.680 in per 100 ft of carbon-steel pipe
   40°F (4°C)   0.300 in per 100 ft of carbon-steel pipe
   Difference: 1.380 in per 100 ft of carbon-steel pipe for
                   temperature 40°F (4°C) to 220°F (104°C)

   Therefore, 240-ft of pipe $= \dfrac{240(1.380)}{100} = 3.312$ in (8.41 cm)

Example A9.2   A Simplified Calculation for a Long Straight Piping System.
400-ft (122-m)-long, straight piping system; NPS 6 (DN 150); 20-ft (6-m) random lengths; installed at 60°F (+16°C) (also lowest operating temperature; maximum

FIGURE A9.20 Example piping systems.

Expansion Loops Utilizing Flexible Couplings and Fittings

Grooved piping offers the designer the advantage of using flexible couplings and fittings in expansion loops without inducing stresses in the pipes, elbows, or joints. The deflection capability of flexible couplings allows for thermal growth-contraction to be absorbed within the couplings at the elbows as the thermal forces induce deflection. It is important that rigid couplings are not used on expansion loops, as these couplings are not designed to accommodate angular deflection.

As shown in Fig. A9.21a, a total of eight flexible couplings, four grooved 90° elbows, and three pipe spools are required to complete each expansion loop. As system temperature decreases and the pipe run contracts (see Fig. A9.21b), the loop expands, and the deflection capability of the couplings accommodates this movement. As system temperature increases (see Fig. A9.21c), the opposite effect occurs as the pipe run expands and the loop contracts with the couplings accommodating the deflection in the opposite direction.

The amount of thermal expansion and contraction, ΔX, should be determined by the system designer based on the length of pipe run between anchors and the anticipated temperature changes from the installation temperature (see Table A9.11 for details). The angular deflection available at each coupling is a design characteristic inherent to the coupling size, style, and the type of groove—cut or roll grooved. The length of the perpendicular branches of the loop dimension A (see Figure A9.21a) is determined by the amount of expected pipeline expansion or contraction, ΔX, and the deflection available per joint. Dimension A should be the same on both sides of the loop. The length of the parallel branch of the expansion loop, Dimension B, is determined by ΔX, and it must be sufficiently long enough to prevent the elbows at the pipe run from butting during thermal expansion. It is recommended that Dimension B be at least 2 in (50.8 mm) larger than ΔX.

The designer can use Fig. A9.22, Expansion Loop Design, to aid in the design of expansion. These loops incorporate all the design information for each size of Victaulic Flexible Coupling, including the angular movement tolerance. The nominal pipe size and either the design thermal expansion, ΔX, or the length of perpendicular branches, dimension A, must be known, and the other can be determined. It is essential for a properly functioning expansion loop that it be installed without any coupling deflection and that the pipeline be properly anchored and guided. Whenever possible, the expansion loop should be located adjacent to an anchor within four pipe diameters. The first and second alignment guides on the opposite side of the expansion loop should be located a maximum distance of 4 and 14 pipe diameters, respectively. Additional intermediate guides may be required throughout the system for pipe alignment. Refer to Table A9.9 for recommended spacing. If the expansion loop cannot be located adjacent to an anchor, guides should be installed on both sides of the unit, as mentioned.

Example A9.3   Expansion Loop Calculation.   Using the parameters established in Example A9.2, NPS 6 (DN 150) nominal pipe size and 3.75 in (95.2 mm) of total anticipated movement, refer to Fig. A9.22 to determine the length of perpendicular loop branches for both cut and roll groove pipe. Reference Fig. A9.20 for a sketch of Example 2 piping system.

FIGURE A9.22 (*Continued*)　Expansion loop design.

For cut groove pipe (Fig. A9.22)

$A = 2.7$ ft (0.82 m) minimum

For roll groove pipe (Fig. A9.22)

$A = 5.4$ ft (1.65 m) minimum

To provide an expansion loop for the described system, the two branches must be a minimum of 2.7 ft (0.82 m) and 5.4 ft (1.65 m) long for cut and roll groove pipe, respectively. The parallel branch of the expansion loop must be at least 2 in (50.8 mm) larger than ΔX.

$B = \Delta X + 2$

$B = 3.75$ in $+ 2$ in $= 5.75$ in minimum (95.25 mm $+ 50.8 = 146.05$ mm)

The simple system described in Example A9.2 and above accommodated thermal expansion through the use of flexible couplings and an expansion loop. We must also discuss the application of flexible couplings and rigid couplings with the use of main anchors, intermediate anchors, and guides to accommodate thermal movement and pressure thrust.

Anchors

Anchors can be used to prevent movement due to pressure thrust and thermal growth. There are two types of anchors which are commonly used:

A. Main anchors
B. Intermediate anchors

Main anchors are installed at or near terminal points and changes of direction of a pipe line. The forces acting on a main anchor will result from internal pressure thrust and thermal growth. These forces can generate substantial loads which may require structural analysis. Intermediate anchors divide a long pipe run, with main anchors at each end, into individual expanding sections. The pressure thrust on the intermediate anchors cancel each other out. Where there is a change in pipe diameter, there will be a differential pressure thrust acting on an intermediate anchor. Typical examples of main and intermediate anchors are shown in Fig. A9.23.

The following examples illustrate the mechanical advantages of the grooved piping method and how they can be utilized to the piping systems designer's benefit. These are presented to stimulate thought and should not be considered as recommendations for a specific system. The grooved piping method, when used in a piping system, should always be utilized in designs consistent with good piping practice.

Example A9.4 Anchor Locations. To properly restrain this system, reference Fig. A9.20 for Example 3 piping system sketch. It would be necessary to provide a pressure thrust anchor at "A" to prevent the piping outside the structure from being forced inside by the pressure thrust acting at the elbow "B." Inside, it would be necessary to provide a hanger at point C1, or a base support at point C2. No

PT = Pressure Thrust (Pounds/kg)
D = Outside Diameter of Pipe (Inches/mm)
p = Internal Pressure (PSI/kPa)

$$PT = \frac{\pi}{4} D^2 p$$

$$PT_r = 2\ PT \sin \frac{\Theta}{2}$$

PT_r = Pressure Thrust Resultant

$$PT_r = 2\ PT \sin \frac{\Theta}{2}$$
FIGURE A9.23

anchoring would be required, and the self-restraining feature of the joints would hold the piping securely together. Outside, it would be necessary to ensure that the maximum end load of the joints was not exceeded due to thermal movement of the pipes. Intermediate anchors may be required. The pipe must be properly supported and guided. Refer to Tables A9.9 and A9.10. Where flexible couplings are not required to accommodate thermal movement, rigid couplings can reduce supports and offsets.

Example A9.5   Anchor and Guide Locations.   Anchor at location D to support weight of pipe. Use hangers to support weight of piping. Anchors as well as guides may be required at B and C if flexible couplings are used as expansion joints. Refer to Fig. A9.20 for Example 4 piping system sketch.

Example A9.6   Treatment of Risers with Branch Connections.   Free-moving risers can cause shear forces at branch connections due to pressure thrusts or thermal movement. The pipe should be anchored at or near the base with a main pressure thrust anchor, A, capable of supporting the full pressure thrust and local weight of pipe and fluids. Any movement of horizontal pipe at the bottom of the riser must

be considered independently, with adequate provision for movement. Refer to Fig. A9.20 for Example 5 piping system sketch.

When flexible couplings are used, the system can be anchored at the top, B, with an anchor capable of withstanding full pressure thrust at the top of the riser plus local weight of pipe. The use of this upper anchor prevents any possibility of closed flexible joints opening under pressure and causing movement at the riser top. This method is often used for fire standpipe or similar systems where movement would cause shearing of intermediate components or branches.

Piping between upper, B, and lower, A, anchors should be supported by intermediate anchors, C, capable of supporting local pipe weight and preventing lateral movement. Intermediate anchors should be placed a minimum of every other random length of pipe.

The system can be anchored at A also, and intermediate anchors at C can be used to support local pipe weight. Allowance for thermal movement should be considered, depending on application.

Example A9.7 Treatment of Risers Without Branch Connection for Flexible Couplings.   Reference Fig. A9.20 for Example 6 piping system sketch. With this method, a main thrust anchor is again needed at the bottom of the riser, A, which supports the total weight of pipe and fluids. Guidance is necessary at suitable intervals to prevent buckling of the riser. It is necessary that the pipe length, S, at the top of the stack be long enough to accommodate the total vertical movement. This movement is the result of the combined effect of pipe being moved to the full extent of the available pipe linear movement due to pressure thrusts and thermal growth.

Rigid couplings also could be used to prevent linear movement due to pressure thrust. For offset S at the top of the riser to accommodate thermal growth, it would be necessary to use the proper number of flexible couplings to provide the angular deflection.

Example A9.8 Treatment of Risers to Eliminate Concentrated Anchor Loads.
Refer to Fig. A9.20 for Example 7 piping system sketch. When structural requirements dictate that base anchor load or upper anchor load must be minimized, then the use of a *looped* system should be considered. In the system illustrated, each anchor carries the local weight of pipe. This method is often considered in tall buildings where high anchor loads would be generated. The offsets must be long enough to accommodate movement in the pipes due to flexible-coupling linear movement due to pressure thrust plus any thermal or other movements of pipes or supports. The use of rigid couplings could be considered to prevent linear movement due to pressure thrust.

Offsets and Differential Settlement

In many piping system designs, offsets or differential settlement must be considered. This is particularly important, as pipes pass from one structure to another. Flexible couplings offer the designer a method to accommodate offsets of pipe runs due to misalignment or building settlement. The offset transition can be achieved only with flexible couplings, as they allow for angular deflection at each joint.
FIGURE A9.24   Pipe displacement.

Offsets are determined by the amount of lateral misalignment on the particular pipe run and the length along the pipe run that is required for the parallel shift of the run. In Fig. A9.24, these two parameters are shown as the Y-Displacement, lateral misalignment, and the X-Displacement, offset length, respectively.

The pipe spools are first deflected in the direction of the misalignment until the midpoint of a particular pipe spool is more than half the required Y-Displacement. This spool then becomes a transition spool, as an equal number of couplings and pipe spools are required on either side of the transition spool to deflect the pipeline back to its original direction.

A major objective in designing for a misalignment is to achieve the required Y-Displacement, using the minimum number of couplings. To this end, because of symmetry around a transition point, as explained earlier, the point of inflection is a pipe spool and not a coupling. Therefore, for all calculations and results in this section, an even number of couplings and an odd number of pipe spools have been used. Also, to maximize the deflection at each joint, cut-groove pipe should be considered. Should roll-grooved joints be used, then the deflection available will be one-half that of a cut-grooved joint.

The number of couplings and the length of the pipe spools are the two variables that can be altered to obtain the desired misalignment. Other factors, such as the maximum angle of deflection at each coupling and the maximum pipe-end separation are a function of the size and style coupling being used.

The following is a technical explanation of the formulas derived to calculate the number of couplings, spool length, X- and Y-Displacements.

The geometric derivation to accommodate offsets starts with the deflection on one pipe spool from the pipe run at the angle, Θ (see Fig. A9.24). The Y-Displacement from the pipe-run centerline after the first deflected spool is shown as $\Delta Y_1 = (L + a) \sin \Theta$, where L is the length of the pipe spool and a is one-half the maximum pipe-end separation for the particular coupling to be used. As the second spool is connected and deflected, also at the angle, Θ, the total angle of deflection from the pipe run is $\Theta + \Theta$, or 2Θ (see Fig. A9.25). The Y-Displacement due to the second coupling and pipe spool is $\Theta Y_2 = (L + a) \sin 2\Theta$.
FIGURE A9.25   Deflection of pipe.

Since the length of each pipe spool is equal, then the total Y-Displacement to the end of the second pipe spool from the pipe run is the sum of each spool or

$$\Delta Y_{\text{TOTAL}} = \Delta Y_1 + \Delta Y_2 = (L + a)\,(\sin \Theta) + \sin 2\Theta). \tag{A9.3}$$

When the value of ΔY_{TOTAL} is at least half of the required Y-Displacement, then the last calculated pipe length up to that point becomes the point of transition. Geometrical symmetry about this point allows that the actual Y-Displacement of the completed misalignment will be equal to two times the ΔY_{TOTAL} up to the transition spool piece plus the Y-Displacement of the spool piece itself, or

$$\text{Y-Displacement} = (L + a)[2(\sin \Theta) + 2(\sin \Theta) + \ldots$$
$$2(\sin(P - 1)\Theta) + (L + a)[\sin P\Theta] \tag{A9.4}$$

where P is the number of spool pieces to achieve the transition and is equal to one-half of the number of couplings involved in the total misalignment.

This expression is mathematically simplified to:

$$P - 1$$
$$\text{Y-Displacement} = (L + a)[\sin P\Theta + 2 \sin n\Theta]$$
$$n = 1$$

When n = the total number of couplings in the misalignment, and

$P = n/2.$

By using the same geometric and trigonomic relations, the distance in the X direction required for the misalignment is as follows:

$$X\text{-Displacement} = (L + a)\left[\sum_{n=1}^{P-1} \cos P\Theta + 2e\tau \cos n\Theta\right] \qquad \text{(A9.5)}$$

Example A9.9 Pipe Misalignment. A designer wants to connect a NPS 6 (DN150) feed main from an existing building to a new structure. There is 66 in (1676 mm) of pipe run between the connection points, and it is expected that a settlement of 3 in (76.2 mm) will occur. To utilize the maximum deflection available from flexible coupling, cut grooved-pipe nipples will be used.

Requirements

Y-Displacement $= 3$ in (76.2 mm)

X-Displacement $=$ less than 66 in (1676 mm)

Maximum pipe-end separation $= 0.25$ in (6.4 mm) (from coupling manufacturer performance data for flexible coupling)

Design pipe-end separation* $= 0.188$ in (4.8 mm)

$1/2$ pipe-end separation, $a = 0.094$ in (2.4 mm)

Maximum angle of deflection $= 2° \, 10' = 2.167°$ (from coupling manufacturer performance data for flexible coupling)

Design angle of deflection,* $\Theta = 1° \, 38' = 1.625°$

*Maximum values reduced by 25% for design and installation purposes. The published maximum pipe-end separation and angular deflection figures should be reduced by 50% for NPS $3/4$–NPS $3\frac{1}{2}$ (DN 20–DN 90) sizes, and 25% for NPS 4 and larger sizes.

Try: 4 couplings $(n = 4) \, P = n/2 = 2$

Spool lengths, $L = 12$ in

$a = 0.094$ in

$\Theta = 1.625°$

$$Y\text{-Displacement} = (L + a)\left[\sum_{n=1}^{P-1} \sin P\Theta + 2 \sin n\Theta\right]$$

$$= (12 + 0.094)\{\sin(2 \times 1.625) + 2$$

$$[\sin(1 \times 1.625)]\}$$

$$= 12.094 \, \{0.057 + 2(0.028)\} = 1.37 \text{ in}$$

Not enough; Y-Displacement of 3 in (76.2 mm) is required, so try 6 couplings:

$n = 6$

$P = n/2 = 3$

$L = 12$ in

$a = 0.094$ in

$\Theta = 1.625°$

Y-Displacement $= (12 + 0.094)\{\sin(3 \times 1.625) + 2$
$$[\sin(1 \times 1.625) + \sin(2 \times 1.625)]\}$$
$$= 12.094\,\{0.085 + 2[0.028 + 0.057]\} = 3.08\,\text{in}$$

Y-Displacement is sufficient (exceeds 3 in requirement).

Check: X-Displacement

$$P - 1$$

X-Displacement $= (L + a)[\cos P\Theta + 2e\tau\cos n\Theta]$

$$n = 1$$

$n = 6$

$P = n/2 = 3$

$L = 12$ in

$a = 0.094$ in

$\Theta = 1.625°$

$$= 12.094\,\{\cos(3 \times 1.625) + 2[\cos(1 \times 1.625) + \cos(2 \times 1.625)]\}$$

X-Displacement $= 60.38$ in (1533.7 mm)

X-Displacement is sufficient [less than 66 in (1676 mm) requirement]

With six NPS 6 (DN150) flexible couplings and five 12 in (300 mm) cut-groove pipe spools, the misalignment can be accommodated, attaining the required Y-Displacement in the limited X-Displacement.

Earthquake Design Considerations

Piping systems designed for earthquake prone areas must be analyzed for the movements and loads associated with these events. The grooved system provides many mechanical design features useful in systems subject to earthquake conditions. The inherent flexibility of flexible couplings acts to reduce the transmission of stresses throughout the piping system, and the resilient gasket aids to further reduce

the transmission of vibration. Where flexibility is not desired, rigid couplings can be used.

As a general practice, seismic bracing and piping supports are utilized in piping systems to prevent excessive movement by controlling and directing system movement during a seismic occurrence which would result in overstressing the piping system. In a similar manner, piping supports for a grooved piping system must limit pipe movements such that they do not exceed the recommended allowable deflections and end loads. An excellent reference source, which covers these piping systems, is NFPA 13 Installation of Sprinkler Systems. This standard requires sprinkler systems to be protected to minimize or prevent pipe breakage where subject to earthquakes.

This is accomplished by using two techniques:

- Making the piping flexible where necessary by use of flexible couplings
- Affixing the piping to the building structure for minimum relative movement by using sway bracing

Flexibility is provided by using flexible couplings joining grooved end pipe and swing joints. ''Rigid-Type'' mechanical couplings, which do not permit movement at the grooved connection, are not considered flexible couplings. Rigid couplings are used in horizontal piping for purposes other than the requirements of earthquake protection. Where large pipe movements are anticipated, seismic swing joints are made up using flexible grooved couplings, pipe nipples and grooved elbows, as shown in Fig. A9.26.

Product Applications

The use of grooved piping systems has become widespread throughout the world. Applications of these joints come from all commercial, industrial, and municipal areas. Grooved joints are being used from NPS ¾ (DN 20) to NPS 100 (DN 2500). Applications are limited by the pressure, temperature, and system media. Each manufacturer of grooved piping joints has published pressure and temperature ratings of their various style couplings and gaskets. The piping system designer should consult this information to assure proper systems design.

The piping system designer can expect to find joints and gaskets available to accommodate temperatures from $-30°F$ ($-34°C$) to $300°F$ ($140°C$) and pressures of up to 1000 psi (6900 kPa) and above. Materials of construction are normally ductile cast iron; however, couplings are also available in stainless steel, aluminum, and other castable materials, as special applications may require. Grooved systems can utilize pipe made of steel, stainless steel, aluminum, PVC, fiberglass, ductile iron and lined ductile iron, and steel, or any metallic or nonmetallic material that can be grooved.

Benefits of Grooved Piping Systems

Grooved piping systems offer a number of benefits when designed and installed properly.

- Grooved systems provide the designer the choice of flexible and rigid joints. The system can be designed to be flexible, allowing for expansion, contraction, and
FIGURE A9.26 Seismic swing joint.

structure settlement. Rigid couplings can be included in the system design to provide rigidity to minimize pipe supports.

- Grooved piping systems provide dampening of system vibration. The prevention of the transmission of objectionable vibration induced by piping systems to the building structure has become increasingly crucial, as vibration induced noise is a major complaint by building occupants.

- A properly designed grooved piping system will normally result in a lower installation cost to the facility owner. Piping is prepared rapidly through roll grooving. Installation is accomplished with simple hand tools and standard pipe-fitting techniques. Takeout dimensions for fittings and valves are consistent, thus pipes can be roll grooved at ground level and then lifted into place and coupled into the system. Where the designer chooses, piping can be prefabricated off site. In either case, installation is much more rapid when compared to welding or threading. In most cases, this speed of installation will result in a more cost-effective system.

- Where piping must be removed for replacement or maintenance, the grooved system should be the system of choice. With each joint becoming a *union*, a grooved system is the easiest and quickest piping system to service. Flanges for the same size pipe have many more bolts to remove and replace, and a new gasket is always needed. A grooved coupling is removed more rapidly because it has fewer bolts. The bolts and gasket are readily reusable unless they have been damaged.

CHAPTER A10
PART 1 SELECTION AND APPLICATION OF VALVES

Mohinder L. Nayyar, P.E.
ASME Fellow

INTRODUCTION

Valves are an essential part of any piping system that conveys liquids, gases, vapors, slurries and mixtures of liquid, and gaseous phases of various flow media. Starting with primitive means for stopping, allowing, or diverting water-flow from a source through shallow or deep channels, such as wooden or stone wedges stuck between the edges of a water passage, man has developed several different types of simple and sophisticated valve designs. Different types of valves include: gate, globe, check, ball, plug, butterfly, diaphragm, pinch, pressure relief, and control valves. Each of these types has several categories and designs, each offering different features and functional capabilities. Some valves are self-actuated while others are manually operated or have actuators that are powered with electric motors, are pneumatic or hydraulic, or a combination to operate the valve. Valves are manufactured with metals and nonmetals. Valves are used in industrial piping systems, transportation and distribution pipelines, building services piping, civic facilities, and irrigation piping systems. The piping systems of industrial, commercial, residential, and other civic facilities carry the lifeblood of modern civilization, like arteries and veins. And the valves in those piping systems serve the functions of allowing, stopping, regulating, and controlling the flow, to fulfill the intended objectives of the system. When fluid pressure builds up beyond a set limit, the valves relieve the overpressure to safeguard the integrity of the piping system or a component. Valves help in maintaining or breaking a vacuum. Valves also assist in maintaining the pressure or temperature of the flow medium within the desired range or limit. In order to select a suitable valve for a particular application, the user must evaluate the valve characteristics, including the design features, materials of construction, and performance, in light of specific application requirements: flow medium, process design requirements, piping design criteria, and economic factors. This chapter provides a brief discussion of topics considered in the selection and application of commonly used valves.

VALVE TERMINOLOGY

Actuator: A device that operates a valve by utilizing electricity, pneumatics, hydraulics, or a combination of one or more of these energies. Sometimes actuators are referred to as *operators*. In this chapter, the word operator will be used for a person who operates any equipment, machine, plant, or system.

Ambient conditions: The pressure and temperature of the environment surrounding a valve.

Backflow: The flow that occurs in the opposite direction of the normal or expected fluid flow.

Back pressure: The static pressure existing at the outlet of a pressure-relief device due to pressure in the discharge system.

Backseat: A seat on the bonnet or bonnet bushing which contacts a corresponding seating surface of the stem or disc holder when the stem is fully retracted. It provides a seal between the stem and the inside of the bonnet. It prevents leakage of flow medium and allows replacement of valve packing while the valve is open and under pressure.

Block-and-bleed valve: A valve with two seating surfaces which provide simultaneous blockage of flow from both valve ends, and means for draining or venting the cavity between the seating surfaces. When the valve is closed (blocked) the drain is opened, allowing the trapped fluid between the seats to drain (bleed).

Block valve: A valve that is used to start or stop the flow. It is also referred to as an *on-off valve*.

Blowdown: The difference between the set pressure and the disc-reseating pressure of a pressure-relief valve, which is expressed as a percentage of the set pressure.

Blowdown valve: A valve used to release the pressurized contents of a pressure vessel or piping.

Bonnet: A valve body closure component that contains an opening for the stem.

Bore: The diameter of the smallest opening through a valve. It is also called *port*.

Bubble tight: A valve is termed *bubble tight* when the upstream side of the valve is pressurized with air and the downstream side is filled with water and no air bubbles are detected on the downstream side with the valve in fully closed position.

Bypass: A piping loop provided to permit flow around the flow control element (disc, plug, etc.) of a valve in its closed position. A stop valve installed in the bypass loop is called the *bypass valve*.

Cavitation: This occurs when the fluid pressure at the *vena contracta* falls below the vapor pressure, followed by pressure recovery above the vapor pressure. The pressure below vapor pressure causes vapor bubbles to form, which then collapse as the pressure recovers. Collapsing bubbles can cause erosion of valve and downstream pipe metal surfaces. The phenomena of fluid pressure falling below and recovering above vapor pressure, combined with forming and collapsing of bubbles, is termed *cavitation*.

Chatter: Abnormal rapid reciprocating motion of the movable parts of a pressure-relief valve in which the disc contacts the seat.

Choked flow: When the flow rate cannot be increased even if the downstream pressure is decreased. In liquid applications, it is caused by vapor bubbles, formed by cavitation or flashing, choking the flow passage. In the case of gases, choked

flow is caused when the flow velocity reaches sonic proportions and a reduction in downstream pressure cannot increase the gas flow.

Closing pressure: The pressure equal to the valve of decreasing inlet static pressure at which the valve disc reestablishes contact with the seat or at which lift becomes zero.

Coefficient of discharge: The ratio of the measured relieving capacity to the theoretical relieving capacity of a pressure-relief valve.

Coefficient of flow: The flow rate that passes through the fully open valve at unit pressure differential. It is measured in gal (3.8 liters) per minute of 60°F (16°C) water with 1 psi (6.9 kPa) pressure differential. It is also referred to as *flow coefficient* or *valve coefficient.*

Cold working pressure (CWP): This is the maximum flow-medium pressure at the ambient temperature to which the valve may be subjected during normal service. This is also referred to as *water-oil-gas* (WOG) rating.

Control valve: A valve serving as a control element in a system, providing means for varying the rate of flow of the fluid passing through the valve.

Cracking pressure: The upstream fluid pressure at which a closed check valve starts to open and allow the flow through the valve.

Cryogenic valve: A valve used in applications with fluid temperatures below −50°F (−45°C). A cryogenic valve is provided with an extended stem contained in an extension tube so that the valve packing and operator remain at ambient temperature when the cryogenic fluid is in the valve body. The valve is oriented so that the packing is at a higher elevation than the valve body. It allows a vapor-gas pocket to form inside the extension tube, thereby making the extension tube more effective at insulating the packing from cryogenic fluid cold temperature.

Disc: The part of the valve which is positioned in the flow stream to permit or to obstruct flow, depending on closure position. In specific designs, it may also be called a wedge, plug, ball, gate, or other functionally similar expression. In international standards it is referred to as obturator.

Double-disc: A two-piece disc or two separate discs that mate with two seating surfaces. Double discs are used in some designs of gate valves.

Double-seated valve: A valve with two separate seating surfaces that come in contact with two separate seating surfaces of a disc or a double disc.

Flow characteristic: Defines the relationship between the Flow Coefficient and the valve *stroke.*

Flow coefficient: See *Coefficient of flow.*

Flow control element: The part of the valve that allows, stops, obstructs, and controls the fluid flow through the valve. See *Disc.*

Fugitive emission: The amount of leakage of hazardous and toxic flow medium (fluids) from a valve to the environment.

Full bore: When valve *bore (port)* is approximately of the same size as the inside diameter of the connecting pipe, it is called *full bore (full port).*

Fully stellited: A valve is termed fully stellited when seating surfaces of the valve seat(s) and the disc(s) are hard faced with wear and corrosion-resistant material (*Stellite* or other such material).

Half stellited: A valve is termed half stellited when only the seating surfaces of the valve seat(s) are hard faced with wear and corrosion-resistant material (Stellite or other such material).

Hard facing: Application or deposit of hard, wear, and corrosion-resistant material on soft surfaces subject to wear.

Inside screw–nonrising stem (ISNRS): Threads on the stem are inside the valve body. The valve disc travels up and down the stem threads when the stem is rotated. Stem does not rise.

Inside screw–rising stem (ISRS): Threads on the stem are inside the valve body and exposed to the flow medium. The stem rises when it is rotated, thus opening the valve. Position of the stem indicates the position of the valve disc.

Iron body–bronze mounted (IBBM): A valve having cast iron body and bronze trim.

Lantern ring: A spacer ring used in the *lantern ring* type of packing chamber to permit lubrication of the packing, purging of the shaft or stem, or a leak-off system.

Leak-off connection: A pipe or tube connected to a hole in the stuffing box at the level of lantern ring. It is used to collect leakage past a lower set of lantern ring–type of packing or to inject lubricant into the stuffing box.

Linear-flow characteristics: A flow characteristic of the valve when the flow is directly proportional to the position of the flow control element.

Liner: Lining of protective materials applied on the inside surfaces of valve body (or valve trim) to enhance resistance to corrosion, erosion, or contamination.

Nonreturn valve: Stop-check valve, a check valve in which the closure member can be mechanically closed.

Nonrising stem: Refer to *Inside screw, nonrising stem (ISNRS)*.

Outside-screw-and-yoke (OS&Y): A valve design in which the threaded portion of the stem is outside the pressure boundary of the valve. The valve bonnet has a yoke, which holds a nut through which the rotating stem rises as the valve is opened. The stem part inside the valve is smooth and is sealed so that stem threads are isolated from the flow medium.

Pilot operated pressure relief valve: A pressure-relief valve in which the major relieving device is combined with and controlled by a self-actuated auxiliary pressure-relief valve.

Port: See *bore*.

Power actuated pressure-relief valve: A pressure-relief valve in which the major relieving device is combined and controlled by a device requiring an external source of energy.

Quarter-turn valve: A valve whose closure member rotates approximately a quarter turn (90°) to move from full-open to full-closed position.

Reduced port: Valve port smaller than the inside diameter of the end-connecting pipe. It is approximately equal to the inside diameter of the one pipe size smaller than the end size for gate valves, and 60 percent of full bore on ball valves.

Regular port: A valve port smaller than the full bore, approximately 75 to 90 percent of full bore on ball valves and 60 to 70 percent on plug valves.

Relief valve: A pressure-relief valve actuated by inlet static pressure and having a gradual lift generally proportional to the increase in pressure over the opening pressure (set pressure).

Rotary motion valve: A valve that involves a quarter-turn motion to open or close the valve closure element.

Rupture disc: A nonclosing pressure-relief device actuated by inlet static pressure and designed to function by the bursting of a pressure-containing disc.

Safety-relief valve: A pressure-relief valve characterized by rapid opening pop action, or by opening generally proportional to the increase in pressure over the opening pressure.

Safety valve: A pressure-relief valve actuated by inlet static pressure and characterized by rapid opening or pop action.

Seat: The portion of the valve against which the closure member presses to effect shutoff.

Seat ring: A separate piece inserted in the valve body to form a seat against which the valve-closure member engages to effect shut-off.

Set pressure: The inlet static pressure of the system at which a relief valve starts to open, or safety valve pops open.

Short pattern valve: A valve that has face-to-face or end-to-end dimension for a short pattern design according to standard ASME B16.10.

Steam working pressure (SWP): The maximum rated or working pressure corresponding to the steam temperature that must not be exceeded when valve is used in steam service. It is marked with S, SP, or SWP on the valve.

Stroke: The amount of travel the valve-closure member is capable of from a fully closed position to a fully open position or vice versa. In linear-motion valves it is expressed in in (mm) and in degrees, 0 to 90, for rotary motion valves.

Throttling: The process of regulating the fluid flow rate or pressure by controlling the position of the closure member between the full-open and full-closed positions.

Trim: Functional parts of a valve which are exposed to the line fluid. Usually refers to the stem, closure member and, seating surfaces. The removable or replaceable valve metal internal parts that come in contact with the flow medium are collectively known as valve trim. Valve parts such as body, bonnet, yoke, and similar items are not considered trim.

Venturi port: A valve bore or port that is substantially smaller than the full port, approximately 40 to 50 percent of full port. It is normally found in plug valves.

Wafer body: A valve body that has a short face-to-face dimension in relation to pipeline diameter and is designed to be installed between two flanges using special length studs and nuts.

Wedge: A gate valve–closure member with inclined sealing surfaces which come in contact with valve-seating surfaces that are inclined to the stem centerline. Wedge is available in solid, split, and flex designs.

Yoke: That part of the valve assembly used to position the stem nut or to mount the valve actuator.

Yoke bushing, yoke nut: Yoke nut, yoke bushing, or *stem nut* is the valve part that is held in a recess at the top of the yoke through which the stem passes. It converts rotary-actuating effort into thrust on the valve stem.

REFERENCE CODES AND STANDARDS

The following is a list of commonly used valve standards in the United States. Based upon the scope, each of these standards contains rules and requirements for design, pressure-temperature ratings, dimensions, tolerances, materials, nondestructive examinations, testing, and inspection and quality assurance. Compliance to these

and other standards is invoked by reference to codes of construction, specifications, contracts, or regulations.

ASME Standards

B16.10	Face-to-Face and End-to-End Dimensions of Valves
B16.33	Manually Operated Metallic Gas Valves for Use in Gas Piping Systems Up to 125 psig (Sizes ½ Through 2)
B16.34	Valves—Flanged, Threaded, and Welding End
B16.38	Large Metallic Valves for Gas Distribution (Manually Operated, NPS 2½ to 12, 125 psig Maximum)
B16.40	Manually Operated Thermoplastic Gas Shutoffs and Valves in Gas Distribution Systems
B16.44	Manually Operated Metallic Gas Valves for Use in House Piping Systems
N278.1	Self-Operated and Power-Operated Safety-Related Functional Specification Standard

CLASSIFICATION OF VALVES

The following are some of the commonly used valve classifications:

Classification Based on Mechanical Motion

Based on the mechanical or cyclical motion of the valve closure member, valves are classified as follows:

Linear Motion Valves. The valves in which the closure member, as in gate, globe, diaphragm, pinch, and lift check valves, moves in a straight line to allow, stop, or throttle the flow. Table A10.1 lists the valves based on motion of valve-closure member.

Rotary Motion Valves. When the valve-closure member travels along an angular or circular path, as in butterfly, ball, plug, eccentric- and swing check valves, the valves are called rotary motion valves. See Table A10.1.

TABLE A10.1 Classification of Valves Based on Motion

Valve type	Linear motion	Rotary motion	Quarter turn
Gate valve	X		
Globe valve	X		
Swing check valve		X	
Lift check valve	X		
Tilting-disc check valve		X	
Folding-disc check valve		X	
In-line check valve	X		
Stop check valve	X	X	
Ball valve		X	X
Pinch valve	X		
Butterfly valve		X	X
Plug valve		X	X
Diaphragm valve	X		
Safety valve	X		
Relief valve	X		

Notes: Tilting-disc check valves are in the same category as swing check valves in regard to motion of the disc.

When a swing check valve is provided with the external means to close and maintain the valve disc in a closed position, it can be used as a stop check valve.

Quarter Turn Valves. Some rotary motion valves require approximately a quarter turn, 0 through 90°, motion of the stem to go to fully open from a fully closed position or vice versa. Refer to Table A10.1.

Classification Based on Valve Size

Valve Size. Valve size is denoted by the nominal pipe size (NPS), which is equal to the size of valve-connecting ends or the flange-end size. In the metric system, valve size is designated by the nominal diameter (DN) of connecting pipe or the connecting flange ends. When a valve is installed with reducers on each end, the size of the valve will be equal to the size of the reducer-connecting ends attached to the valve. The valve size is not necessarily equal to the inside diameter of the valve.

It is a normal industry practice to categorize valves, based upon size, in two classification: small and large.

Small Valves. NPS 2 (DN 50) and smaller valves are called small valves. At times, NPS 2½ (DN 65) and smaller valves are referred to as small valves. As such, the size classification can vary and, therefore, it should not be considered a uniform industry practice.

Large Valves. NPS 2½ (DN 65) and larger valves are classified as large valves. As indicated earlier, NPS 2½ (DN 65) valves may be designated as small valves, depending on the criteria used in classifying small valves.

Classification Based on Pressure-Temperature Rating

Class Ratings. Pressure-temperature ratings of valves are designated by class numbers. Based on the material(s) of construction, the pressure-temperature ratings for each class are tabulated to provide the maximum allowable working pressures, expressed as gauge pressures, at the temperature shown. The temperature shown

TABLE A10.2 ASME B16.34 Classification of Valves and Limitations

Class	150	300	400	600	900	1500	2500	4500[1]
Standard[2]	X	X	X	X	X	X	X	X
Special[3]	X	X	X	X	X	X	X	X
Limited[4,5]	X	X	X	X	X	X	X	X
Intermediate[6]	X	X	X	X	X	X	X	X
Butt welding	X	X	X	X	X	X	X	X
Socket welding[4,7]	X	X	X	X	X	X	X	X
Flanged[8]	Std	Std	Std	Std	Std	Std	Std	
Threaded[4,7,9]	X	X	X	X	X	X	X	

[1] Class 4500 applies only to welding end valves.

[2] Valves conforming to the requirements of ASME B16.34, for standard class valves. Ratings shall not exceed the values shown in those Tables 2 having an identifying suffix "A." (ASME B16.34).

[3] Threaded or welding-end valves which have successfully passed the examination required by Section 8 (of ASME B16.34) may be designated Special Class valves. Ratings shall not exceed the values shown in those Tables 2 having an identifying Suffix "B." (ASME B16.34). Special Class ratings shall not be used for flanged-end valves.

[4] Welding- or threaded-end valves in sizes NPS 2-1/2 and smaller that conform to the requirements of Annex G (ASME B16.34) may be designated Limited Class valves. Limited Class ratings shall not be used for flanged-end valves.

[5] Threaded-end valves rated above Class 2500 and socket-end valves rated above Class 4500 are not within the scope of ASME B16.34.

[6] A welding- or threaded-end valve may be assigned an intermediate pressure and temperature rating or Class, either Standard or Special, in accordance with paragraph 6.1.4 of ASME B16.34, provided all applicable requirements of this standard are met.

[7] Threaded and socket-welding-end valves larger than NPS 2-1/2 are beyond the scope of ASME B16.34.

[8] Flanged-end valves shall be rated as Standard Class.

[9] A class designation greater than Class 2500 or a rating temperature greater than 1000°F applied to threaded-end valves is beyond the scope of ASME B16.34.

TABLE A10.3 Valves Covered by MSS Standards

MSS Standard	Rating/class	Valve types	Size (NPS)	Material
MSS SP–42 Class 150 Corrosion Resistant Gate, Globe, Angle, and Check Valves with Flanged and Butt-Weld Ends	Class 150	a. Gates, (OS&Y)[1]	a. NPS ¼–24	A351; CF8, CF8M, CF8C, CF3, CF3M Alloy 20, CN7M A182 A240 A276 A479

[1] Outside screw and yoke.
[2] Valve ends shall conform to ANSI/AWWA C-606.
[3] Refer to figures in MSS SP–71.
[4] For equivalent metric (DN) sizes, refer to App. E2, E2M, and Table A1.1 (Chapter A1).
[5] Tables and annexes referenced are the ones in the standard.
[6] The application of valve type, size, rating, material of construction, and suitability for service are the responsibility of the purchaser and are outside the scope of this standard.
[7] Cold working pressure.

for a corresponding pressure rating is the temperature of the pressure-containing shell of the component. Items such as a piping system or a portion thereof, a pump, tank, heat exchanger, pressure vessel, valves, et cetera are considered components.

ASME B16.34, Valves—Flanged, Threaded, and Welding End is one of the most widely used valve standards. It defines three types of classes: standard, special, and limited. ASME B16.34 covers Class 150, 300, 400, 600, 900, 1500, 2500, and 4500 valves. It also allows valves to be classified as intermediate whose pressure-temperature ratings may fall within those listed for the standard and special class valves. See Table A10.2 for valve classifications and their limitations covered by ASME B16.34. Refer to Table A1.2 in Chapter A1 for metric equivalent (PN) of valve classifications.

Tables A10.3 and A10.4 provide a listing of valve classes covered by various commonly used valve standards published by the Manufacturers Standardization Society (MSS) and the American Petroleum Institute (API). Table A10.5 provides a brief summary of valves covered by AWWA standards.

Cold Working Pressure (CWP) Rating. Valves are also rated by the CWP rating. This rating represents the maximum allowable working pressure at the ambient temperature to which the valve may be subjected in normal service. Sometimes it is referred to as cold rating. The pressure rating of a valve at −20 to 100°F (−29 to 38°C), as listed in ASME B16.34 and other valve standards, is considered cold working pressure (CWP) or cold rating. CWP is also designated as the water-oil-gas (WOG) rating. Valves marked with CWP or WOG rating are primarily intended for applications in which the flow medium is maintained at ambient temperature, such as, but not limited to, water, oil, and gas distribution and transmission systems.

NFPA Rating. Valves to be used in fire protection systems in the United States are required to be rated for fire service. These valves are rated for 175 and 250 psi (1210 and 1725 kPa), and they are designated as UL (Underwriters Laboratories) listed and FM (Factory Mutual) approved. A valve rated for 175 psi (1210 kPa) for fire protection service may also be rated for higher pressure marked as CWP or Water Working Pressure (WWP) for general service. As such, a fire-rated valve may be used at pressures higher than fire service rating in applications termed as general service.

General Service Rating. The general service rating may be considered to be the equivalent of the CWP rating. Some valve manufacturers assign two ratings, fire rating and general service rating, to a valve. A UL-listed and FM-approved valve rated for 175 psig (1210 kPa) may have a general service rating of 400 psig (2760 kPa) at ambient temperature. It means that this valve can be used in a fire protection system having a maximum allowable working pressure of 175 psi (1210 kPa) or less, whereas it can be used in other services termed as general services and be subjected to a maximum allowable working pressure of 400 psig (2760 kPa). One must classify the service in accordance with the code of construction, as required. If the service does not fall within the jurisdiction of a code, then prudent engineering judgment may be followed in selecting the valve.

Steam Working Pressure (SWP) Rating. The SWP rating of a valve is intended to define the maximum working pressure corresponding to the steam temperature. A valve assigned a SWP rating must not be used in steam service at pressures and temperatures exceeding the rating.

Dual or Multiple Ratings. A valve may be assigned one or more ratings by the valve manufacturer. Ratings assigned must be marked on the valve. The marking

TABLE A10.4 Valves Covered by API Standards

API Standard	Rating/class	Valve types	Size	Materials
API Standard 526 Flanged Steel–Pressure Relief Valves	150, 300, 600, 900, 2500	a. Spring loaded	a. Table 2–15 for spring-loaded Valves	SA 216, Gr. WCB SA 217, Gr. WC SA 351, Gr. CF8M

1. For detail scope, refer to applicable AWWA Standard.
2. Valves for operating pressure outside these limits are beyond the scope of this standard.
3. Gate valves with either double-disc gates having parallel or inclined seats, or solid-wedge gates. Flanges and mechanical joints per section 3.5 of this standard.
4. Valves 14 in (350 mm) NPS and 18 in (450 mm) are not covered by this standard.
5. Standard cover valves suitable for a maximum steady state fluid–working pressure of 150 psig (1034 kPa), a maximum steady state ΔP of 150 psi (1034 kPa) and maximum velocity 16 ft/sec (4.9 m/sec).
6. For classification A and B, reference section for definition of classification.
7. Reference Table 1 of the standard for complete details.

on the valve must be in accordance with the applicable valve standard or standards. A valve may comply with one or more valve standards. For example, a Class 600, NPS 4 (DN 100), butt-welding end, steel gate valve complying with ASME B16.34 may be marked as Class 800 valve in accordance with API Standard 603, provided the valve complies with the design and construction requirements of both ASME B16.34 and API 603. Some valve manufacturers may have proprietary design valves that are rated for specialty applications.

Dual- or multiple-rated valves may be used within the pressure-temperature rating(s) conforming to the valve standard referenced in the code of jurisdiction under which the system is designed and constructed. Dual- or multiple-rated valves have increased utility and broad market. The manufacturer benefits from reduced design and production costs.

MAJOR VALVE PARTS

Pressure Retaining Parts

Valve body, bonnet or cover, disc, and body-bonnet bolting are classified as pressure-retaining parts of a valve. The following provides a brief description of these parts:

Body.   The valve body houses the internal valve parts and provides the passage for fluid flow. The valve body may be cast, forged, fabricated, or made by a combination of cast, forged, or fabricated portions. Valve bodies can be and are made from a variety of metals and alloys. Also, valve bodies can be and are made of nonmetals; however, these must be within certain size and pressure-rating limits.

The valve-body ends are designed to connect the valve to the piping or equipment nozzle by different types of end connections, such as butt or socket-welded, threaded, flanged or bolted, soldered, brazed, solvent cement joint, mechanical joint, or coupling. Refer to Table A10.6.

Bonnet or Cover.   The bonnet or cover is fastened to the valve body to complete the pressure-retaining shell. In case of gate, globe, stop check, and diaphragm valves, it contains an opening for the valve stem to pass through. Usually, it contains a stuffing box. It provides access to valve internals, especially when the valve is installed. The top works of valves include bonnet, yoke, and operating mechanism. The bonnet is the base that supports the valve top works.

The valve bonnet is attached to the valve body by many different types of joints: bolted, pressure-seal joints—breach lock and standard pressure seal joints—threaded, welded, union joint, and clamp seal. Some valves have a bonnetless design in which valve body and bonnet are combined into one. This is also known as an integral bonnet.

The bolted bonnet design is commonly used with cast or ductile iron, cast or forged steel, and alloy valves, which are rated NPS 2½ (DN 65) and larger, and Class 600 and below. Valves with a pressure seal–bonnet design are usually manufactured in Class 600 and higher rating classifications and are considered superior in regard to the leaktightness of the body bonnet joint. Bolted bonnet designs are also produced in valves rated Class 900 and higher. The user needs to consider the potential consequences of flow-medium leakage through body bonnet joints and take the necessary measures to prevent or contain the leakage.

[1] Flanged-end valves include flanged, wafer-and-lug–style valves, which are installed between flanges.

Bonnet or Cover Bolting.   Bolting includes bolts, nuts, and washers. The bolting to be used must be made from materials acceptable for the application in accordance with the applicable code, standard, specification, or the governing regulation. Refer to the applicable valve standard for acceptable bolting materials.

Disc.   The disc is the part which allows, throttles, or stops flow, depending on its position. In the case of a plug or a ball valve, the disc is called plug or a ball. A valve disc could be cast, forged, or fabricated. A disc is seated against the stationary valve seat or seats when the valve is in the closed position. It can be moved away from the valve seat(s) by motion of the valve stem, with the exception of check and safety-relief valves, in which the disc is moved away from its seat(s) by fluid flow and pressure.

   At times some users do not consider the valve disc to be a pressure-retaining or -containing part. The reasoning advanced is that when the valve is in an open position, the disc does not perform a pressure-retaining or -containing functions. However, when the same valve is closed, the disc performs pressure-retaining functions. Refer to Table A10.7 for disc materials.

Valve Trim.   The removable and replaceable valve internal parts that come in contact with the flow medium are collectively termed as valve trim. These parts include valve seat(s), disc, glands, spacers, guides, bushings, and internal springs. The valve body, bonnet, packing, et cetera that also come in contact with the flow medium are not considered valve trim.

Valve trim parts may be constructed of assorted materials because of the different properties needed to withstand different forces and conditions. Bushings and packing glands do not experience the same forces and conditions as do the valve disc and seat(s). Flow-medium properties, chemical composition, pressure, temperature, flow rate, velocity and viscosity are some of the important considerations in selecting suitable trim materials. Trim materials may or may not be the same material as the valve body or bonnet.

API has standardized trim materials by assigning a unique number to each set of trim materials. Refer to Table A10.8 for API trim materials.

Nonpressure Retaining Parts. Valve seat(s), stem, yoke, packing, gland bolting, bushings, handwheel, and valve actuators are some of the major nonpressure-retaining parts of a valve.

Valve Seat(s). A valve may have one or more seats. In the case of a globe or a swing-check valve, there is usually one seat, which forms a seal with the disc to stop the flow. In the case of a gate valve, there are two seats; one on the upstream side and the other on the downstream side. The gate-valve disc or wedge has two seating surfaces that come in contact with the valve seats to form a seal for stopping the flow. Multiport plug and ball valves may have several seats, depending upon the number of ports in the plug or ball.

The valve leakage rate is directly proportional to the effectiveness of the seal between the valve disc and its seat(s). The valve standards MSS SP 61, API 598, and ASME B16.34 specify acceptable leak rates. A user may specify more or less restrictive leak rates to satisfy the application requirements.

Valve manufacturers have developed several designs of combination valve seats involving elastomer and metal seats that are effective in achieving the desired leaktightness, which is not readily accomplished with metal seats.

Valve seats may be integral, replaceable, or renewable seat rings. Small valves generally are provided with screwed-in, swaged-in, welded, or brazed-in valve seats. Large valves may have any of the seat designs listed for small valves, or have seats integrally cast or forged with the valve body and hardened by heat treatment or surfaced with hard material such as Stellite. Stellite is a trade name of the Deloro Company. There are other metals that can be used for hardening the seating surfaces.

Galling Prevention. In order to prevent or minimize galling of the valve disc and valve seats, it is common industry practice to maintain a hardness differential between the stationary seating surfaces of valve seats and the moving seating surfaces of the valve disc. The stationary valve seats are hardened slightly more than the disc-seating surfaces. When both the valve seats and the disc are hardened by use of Stellite, the valve is termed fully stellited. When only the seats are hardened by use of Stellite, the valve is called half stellited. Heat treatment is another method of hardening.

Valve Stem. The valve stem imparts the required motion to the disc, plug, or the ball for opening or closing the valve. It is connected to the valve handwheel, actuator, or the lever at one end and the valve disc on the other. In gate or globe valves, linear motion of the disc is needed to open or close the valve, while in plug, ball, and butterfly valves, the valve disc is rotated to open or close the valve. With the exception of stop-check valves, check valves do not have valve stems.

Rising Stem with Outside Screw and Yoke. The outermost part of the stem is threaded, while the portion of stem inside the valve is smooth. The stem threads are isolated from the flow medium by the stem packing. Two different styles of this design are available: one having the handwheel fixed to the stem so that they rise together, and the other having a threaded sleeve that causes the stem to rise through the handwheel. The rising stem with outside screw and yoke (O. S. & Y.) is a common design for NPS 2 (DN 50) and larger valves. Some codes, such as ASME B31.1, Power Piping, require that an outside screw-and-yoke design be used

FIGURE A10.2   Nonrising stem gate valve for 250-psig steam service.

for NPS 3 (DN 80) and larger valves in pressures above 600 psi (4140 kPa). See Fig. A10.1.

Rising Stem with Inside Screw.   The threaded part of the stem is inside the valve body, and the stem packing is along the smooth part that is exposed to the atmosphere outside. In this case the stem threads are in contact with the flow medium. When rotated, the stem and the handwheel rise together to open the valve. This design is commonly used in the smaller-sized low-to-moderate pressure gate, globe, and angle valves.

Nonrising Stem with Inside Screw.   The threaded part of the stem is inside the valve and does not rise. The valve disc travels along the stem like a nut when the stem is rotated. Stem threads are exposed to the flow medium and, as such, are subjected to its impact. Therefore, this design is used where space is limited to allow linear stem movement, and the flow medium does not cause erosion, corrosion, or wear and tear of stem material. See Fig. A10.2.

Sliding Stem.   This stem does not rotate or turn. It slides in and out of the valve to close or open the valve. This design is used in hand-lever–operated quick-opening valves. It is also used in control valves that are operated by hydraulic or pneumatic cylinders.

Rotary Stem.   This is a commonly used design in ball, plug, and butterfly valves. A quarter-turn motion of the stem opens or closes the valve.

Stem Packing.   Stem packing performs one or both of the following two functions, depending on the application:

• Prevent leakage of flow medium to the environment
• Prevent outside air from entering the valve in vacuum applications

Stem packing is contained in a part called the stuffing box. Packing rings are packed and compressed by tightening a packing nut or packing gland bolts. Compression must be adequate to achieve a good seal. Sometimes it requires regular inspection and tightening of packing rings, if required, to stop leakage. If this does not stop the leakage, the packing may need to be replaced. Belleville washers are used to maintain *live loading,* or the required compression of packing to achieve an effective seal against leakage.

A stuffing box may be provided with some or all of the following features as dictated by the valve application:

- Two sets of packing rings separated by an intermediate lantern ring
- A bottom junk ring
- A leak-off connection which detects leakage past the lower set of packing rings and is piped off to a leakage collection tank
- A blow-off connection for removal of packing rings using compressed air
- Belleville washer, live loading
- A steam-seal connection, where an external steam supply is used to prevent leakage from the packing chamber
- As an alternate to steam-seal connection, a grease or sealant-seal connection used to prevent loss of vacuum within the valve
- Inverted-V packing for vacuum service

Figure A10.3a shows a standard graphite packing arrangement; Figure A10.3b depicts the inverted Teflon packing arrangement for vacuum service; Figure A10.3c reflects a lantern-ring packing arrangement; and Figure A10.3d shows a live-loading packing system.

Stem Protector.   In the case of outside-screw-and yoke rising-stem gate and globe valves, a portion of the threaded valve stem is exposed to the outside environment when the valve is in the open position. Airborne dirt and other substances may be deposited on the exposed portion of the threaded stem and impair its smooth operation or shorten its stem-bushing life. A stem protector in the form of a clear plastic sleeve, tubing, or a pipe with a cap at the end is installed to protect the stem. The length of the stem protector must be adequate to allow full stem travel.

Back Seat.   Back seat is comprised of a shoulder on the stem and a mating surface on the underside of the bonnet. It forms a seal when the stem is in the fully open position. It prevents leakage of flow medium from the valve shell into the packing chamber and consequently to the environment. Back seat enables dismantling of the valve beyond the bonnet, without disrupting the fluid flow through the valve. In addition, it allows the replacing of the stuffing box while the valve is in service.

Yoke.   Yoke is also called yoke arms. It connects the valve body or bonnet with the actuating mechanism. In some cases, it provides support for the gland-pull-down bolts. On many valves, the yoke and bonnet are designed as one-piece construction. The top of the yoke holds a yoke nut, stem nut, or yoke bushing and the valve stem passes through it. See Fig. A10.1.

For power-actuated valves, the yoke arms are of a heavier construction to provide adequate support to the actuator. The yoke usually has openings or windows to allow access to the stuffing box, position-switch dogs, actuator couplings, et cetera.

Structurally, a yoke must be sturdy enough to withstand forces, moments, and torque developed by the actuator.

Yoke Bushings.   An internally threaded nut held in the top of a yoke through which the valve stem passes. In gate and diaphragm valves, the yoke nut is turned and the stem travels up or down depending upon the direction of rotation of the nut. In the case of globe valves, the nut is held fixed and the stem is rotated through it. Usually, the yoke nut or yoke bushing is made of softer material than the stem for valves requiring medium effort to actuate. Valves which require greater effort to open or close are provided with anti-freeze yoke-sleeve bearings that minimize the friction between the hardened stem and the yoke bushing.

MATERIALS

Each of the valve standards listed in the beginning of this chapter lists material specifications which are acceptable for construction of valves covered by the standard. At times, a valve standard may make reference to other standard(s) which list the acceptable materials. One of the most widely used valve standards is ASME B16.34. It lists three groups of acceptable materials that are further subdivided into several subgroups.

Valve bodies, discs, and bonnets may be made from forgings, castings, or fabricated from combination of plate materials and others. Stems are usually produced from bar stock. Stems may be heat treated to provide needed hardness. Tubular materials are also used to make valve parts.

Valve bodies and trim materials may be totally different. For example, cast iron body valve may have stainless steel or bronze trim. Sometimes, the discs may be electroplated or lined to provide protection against corrosion.

Refer to Tables A10.3, A10.4, A10.5, A10.7, and A10.8 for lists of valve materials. For additional listing of acceptable valve materials, refer to valve standards and the code of jurisdiction.

VALVE CATEGORIES

Stop (Isolation) Valves

As the name implies, stop valves are used to stop flow or isolate a portion of the system until it is desirable to achieve flow downstream of the valve. The basic design requirement of stop valves is to offer minimum resistance to flow in the fully open position and to exhibit tight shut-off characteristics when fully closed. Gate, globe, ball, butterfly, plug, and diaphragm valves satisfy the above requirements in varying degrees and, therefore, are widely used in shut-off service. The actual type of valve selected is dictated by several parameters, including:

- Pressure drop
- Seat leakage
- Fluid properties

- System leakage
- Actuation requirements
- Initial cost
- Maintenance

Regulating Valves

Regulating valves are used extensively in piping systems to regulate the flow of fluid. Whether the desired effect is to control flow, pressure, or temperature, the task is accomplished by increasing or decreasing the flow through the valve in response to a signal from a pressure, flow, or temperature controller.

The primary requirement of a flow-control valve is to predictably regulate the flow with respect to its open position and impart the required pressure drop without sustaining damage. Specially designed globe, needle, butterfly, ball, plug, and diaphragm valves are capable of satisfying these requirements in varying degrees. The manufacturer's literature should be consulted for the limitations placed on a particular valve.

Backflow Prevention

Valves are generally used for the prevention of backflow. The valves are self-actuating and the valve disc is kept open by the forward flow of fluid. The valve disc is quickly closed by reverse flow. In certain applications, pneumatic actuators may be used to assist in the rapid closure of the valves on reversal of flow.

Pressure-Relief Devices

Pressure-relief devices are used to protect piping and equipment from being subjected to pressures that exceed their design pressures. Generally, the seating of relief valves is accomplished by a compressed spring, which exerts a force on the valve disc, pressing it against the valve seat. When the force exerted by the fluid on the valve disc exceeds the spring force, the valve automatically opens to release the excess pressure. Other designs incorporate a pilot valve, which uses system pressure to control the movement of the disc. Another type of pressure-relieving device, although not a valve, is a rupture disc. See Fig. A10.4. The rupture disc is designed to burst open at a predetermined pressure.

FIGURE A10.4   The rupture disc, a type of relief device.

A rupture disc cannot be reseated and, therefore, must be replaced once it has performed its relieving function. Rupture discs have the advantage of being leak tight up to the rupture pressure and of being capable of relieving large rates of flow. The set pressure of rupture discs cannot be adjusted.

VALVE TYPES

Gate Valves

Gate valves are primarily designed to serve as isolation valves. In service, these valves generally are either fully open or fully closed. When fully open, the fluid or gas flows through the valve in a straight line with very little resistance. Gate valves should not be used in the regulation or throttling of flow because accurate control is not possible. Furthermore, high-flow velocity in partially opened valves may cause erosion of the discs and seating surfaces. Vibration may also result in chattering of the partially opened valve disc. An exception to the above are specially designed gate valves that are used for low-velocity throttling; for example, guillotine gate valves for pulp stock.

Advantages of Gate Valves

1. They have good shutoff characteristics.
2. They are bidirectional.
3. The pressure loss through the valve is minimal.

Disadvantages of Gate Valves

The following are some of the disadvantages of gate valves that must be considered when selecting a gate valve for an application:

1. Gate valves are not quick opening or closing valves. Full-stem travel to open or close a gate valve requires many turns of its handwheel or an actuator.
2. Gate valves require large space envelope for installation, operation, and maintenance.
3. The slow movement of the disc near the full-closed position results in high-fluid velocities, causing scoring of seating surfaces, referred to as wire drawing. It also causes galling of sliding parts.
4. Some designs of gate valves are susceptible to thermal or pressure binding, depending upon the application.
5. In systems experiencing high-temperature fluctuations, wedge-gate valves may have excessive leakage past the seats due to changes in the angular relationship between the wedge and the valve seats caused by piping loads on the valve ends.
6. Repair or machining of valve seats in place is difficult.

Construction of a Gate Valve

Gate valves consist of three major components: body, bonnet, and trim. The body is generally connected to the piping by means of flanged, screwed, or welded connections. The bonnet, containing the moving parts, is joined to the body, generally with bolts, to permit cleaning and maintenance. The valve trim consists of the stem, the gate, the wedge, or disc, and the seat rings.

Two basic types of gate valves are the manufactured-wedge type and the double-disc type, and there are several variations within each of these types. A third type of gate valve, called conduit valve, is shown in Fig. A10.5.

Wedge Type

There are four types of wedges: *solid, hollow, split, and flexible wedge.* The solid wedge is a single-piece solid construction. It does not compensate for changes in seat alignment due to pipe-end loads or thermal fluctuations. As such it is most susceptible to leakage. Except for NPS 2 (DN 50) and smaller, solid-wedge discs are generally not recommended for use in applications having temperatures in excess of 250°F (121°C). Solid-wedge gate valves are considered the most economical. Almost all small, NPS 2 (DN 50) and smaller,

FIGURE A10.5   Conduit valve.

gate valves are solid-wedge gate valves. Solid-wedge gate valves are generally used in moderate to lower pressure-temperature applications. It is common practice to use cast iron or ductile iron solid-wedge gate valves in cold or ambient water lines.

A hollow wedge is a variation of solid wedge with the exception of a hole in the center. The hollow wedge travels along the stem when the threaded stem is rotated, thus opening or closing the valve port.

The flexible wedge is also one-piece construction like a solid wedge, but areas behind the seating surfaces are hollowed out to provide flexibility. This construction compensates for changes in seat alignment for improved seating while maintaining the strength of a solid wedge in the middle. This design offers better leaktightness and improved performance in situations with potential for thermal binding.

The split wedge consists of two-piece construction which seats between the tapered seats in the valve body. The two pieces of split wedge seat flat against the valve seats as the stem is moved downward, and they move away from the valve seats when the stem is pulled upward.

In the wedge or disc-wedge types either a tapered solid or tapered split wedge is used. In the rising stem valves (Fig. A10.1), the operating threads are out of direct contact with the fluid or gas. The nonrising stem type (Fig. A10.2) is preferred where space is limited and where the fluid passing through the valve will not corrode or erode the threads or leave deposits on the threads. Also, the nonrising stem valve is preferred for buried service. When the valve is closed, the gate disc is wedged on both sides against the seat. In split-wedge gate valves (Fig. A10.6), the two-piece wedge disc is seated between matching tapered seats in the body. This type is preferred where the body seats might be distorted due to pipeline strain.

In the rising-stem type of valve, the upper part of the stem is threaded and a nut is fastened solidly to the handwheel and held in the yoke by thrust collars. As the handwheel is turned, the stem moves up or down. In the nonrising stem valve, the lower end of the stem is threaded and screws into the disc, vertical motion of
FIGURE A10.6 Split-wedge gate valve.
FIGURE A10.7a Double-disc rising-stem flanged-end gate valve for 150-psig service.
FIGURE A10.7b Double-disc nonrising-stem gate valve.

the stem being restrained by a thrust collar. The rising-stem valve requires a greater amount of space when opened. However, it is generally preferred because the position of the stem indicates at once whether the valve is open or closed. Nonrising stem valves are sometimes provided with an indicator for this purpose.

Double-Disc Type

In the double-disc parallel-seat valves (Figs. A10.7a, A10.7b, and A10.7c), the discs are forced against the valve seats by a wedging mechanism as the stem is tightened. Some double-disc parallel-seat valves employ a design which depends mainly upon the fluid pressure exerted against one side of the disc or the other for its tightness. The major advantage of this type is that the disc cannot be jammed into the body, an action that might make it difficult to open the valve. This is particularly important where motors are used for opening and closing the valve.

Unlike the wedge in a wedge-gate valve, which only comes into contact with the seat rings when the valve is nearly closed, each disc in the parallel-seat valve slides against its seat while the

FIGURE A10.7c Parallel-seat gate valve showing welded construction for high-temperature service with welded-in seat ring.

valve is being opened or closed. Consequently, these components must be made of metals, which do not gall or tear when in sliding contact with each other. The double-disc parallel-seat gate valve is often favored for high-temperature steam service because it is less likely to stick in the closed position as a result of change in temperature.

Conduit Gate Valve

It is also referred to as a slide valve or parallel slide. The disc surfaces are always in contact with the body seats. Like the double-disc or parallel-seated gate valve, its disc seats against the downstream seat, depending on the flow direction. The inside diameter of a conduit gate valve is equal to the inside diameter of the connecting pipe. These valves are used in pipelines where pigs are run through the piping to perform cleaning of builtup deposits or debris. The typical applications of conduit valves include dirty river water with suspended solids or water with sludge or debris.

Conduit gate valves require a large-space envelope because of their longer disc proportions to accommodate both the blank and the spacer halves of the disc assembly. The valve is closed by moving the blank half downward to block the

valve port. The spacer is accommodated in the sump part of the valve body. Refer to Fig. A10.5.

Conduit valves with Teflon (PTFE) seats can be used for low to intermediate temperatures (to 450°F or 232°C). Metal-seated valves may be used for temperatures up to 1000°F (538°C).

Thermal Binding

Thermal binding occurs when a valve is tightly shut off while the high temperature system is in operation. Later when the system is shut down and allowed to cool, thermal contraction of the valve seats move inward more than the wedge shrinkage. This can bind the wedge and seats tight enough to not allow the wedge to unseat or move when the handwheel or the valve actuator is activated to open the valve.

Parallel seated gate valves are most suitable for applications having potential for thermal binding. Split-wedge or flexible-wedge type gate valves are expected to perform better than solid-wedge gate valves when thermal binding is a concern.

Pressure Binding

Sometimes in high-temperature applications, the flow medium, such as water or steam, is trapped in the valve bonnet area when the valve is closed for system shutdown. The valves that do not permit this trapped liquid or the condensate to
FIGURE A10.8a Pressure binding caused by built-up pressure in bonnet cavity.

reenter the piping either upstream or downstream may experience excessive pressures in the bonnet cavity when the system returns to operating temperature. This built-up pressure in the bonnet cavity can prevent the valve from opening and may cause damage to valve parts. See Fig. A10.8a.

Pressure binding may not occur if the leakage past the upstream seat is adequate to prevent overpressurization of the valve bonnet cavity. The following options offer solutions to this problem:

- Drill a small hole on the upstream side of the disc. See Fig. A10.8b.

- Install a small manual stop valve between the valve bonnet-neck and the upstream end of the valve. This valve shall be opened during startup.

- Install a small relief valve in the bonnet.

- Edward valves offer a new valve called ACEVE to solve this problem.
FIGURE A10.8b   A hole on the upstream side of wedge to release built-up pressure in bonnet cavity.
FIGURE A10.9 Large wye-pattern globe valve (with gear actuator).

Typical Gate Valve Applications

Socket or butt-welding end-gate valves in air, fuel gas, feedwater, steam, lube oil, and other systems are typical applications. Threaded-end gate valves may be used in air, gaseous, or liquid systems. Concern for leakage from threaded connection can be addressed by seal welding the threaded connection or by using thread sealants, as appropriate. In low-pressure and low-temperature systems such as fire protection systems' water piping or water distribution pipelines, flanged gate valves are commonly used.

Globe Valves

Conventional globe valves may be used for isolation and throttling services. Although these valves exhibit slightly higher pressure drops than straight-through valves (e.g., gate, plug, ball, etc.), they may be used where the pressure drop through the valve is not a controlling factor. Also, wye-pattern (Fig. A10.9) and angle-pattern (Fig. A10.10) globe valves exhibit improved flow characteristics over the tee-pattern (Fig. A10.11) globe valve. Because the entire system pressure exerted on the disc is
FIGURE A10.10 Angle globe valve with screwed ends.

transferred to the valve stem, the practical size limit for these valves is NPS 12 (DN 300). Globe valves larger than NPS 12 (DN 300) are an exception rather than the rule. Larger valves would require that enormous forces be exerted on the stem to open or close the valve under pressure. Globe valves in sizes up to NPS 48 (DN 1200) have been manufactured and used.

Globe valves are extensively employed to control flow. The range of flow control, pressure drop, and duty must be considered in the design of the valve to avert premature failure and to assure satisfactory service. Valves subjected to high-differential pressure-throttling service require specially designed valve trim. Generally the maximum differential pressure across the valve disc should not exceed 20 percent of the maximum upstream pressure or 200 psi (1380 kPa), whichever is less. Valves with special trim may be designed for applications exceeding these differential pressure limits.

Iron body globe valve
rising stem
FIGURE A10.11   A typical large globe valve with flanged ends.

Types of Globe Valves

Tee Pattern globe valves have the lowest coefficient of flow and higher pressure drop. They are used in severe throttling services, such as in bypass lines around a control valve. Tee-pattern globe valves may also be used in applications where pressure drop is not a concern and throttling is required. Refer to Fig. A10.11.

Wye Pattern globe valves, among globe valves, offer the least resistance to flow. They can be cracked open for long periods without severe erosion. They are extensively used for throttling during seasonal or startup operations. They can be *rod through* to remove debris when used in drain lines that are normally closed. Refer to Fig. A10.9.

Angle Pattern globe valves turns the flow direction by 90 degrees without the use of an elbow and one extra weld. They have a slightly lower coefficient of flow than wye-pattern globe valves. They are used in applications that have periods of pulsating flow because of their capability to handle the slugging effect of this type of flow. Refer to Fig. A10.10.

Construction of a Globe Valve

A typical large globe valve with flanged ends is illustrated in Fig. A10.11, and a large wye-pattern globe is illustrated in Fig. A10.9. Globe valves usually have rising stems, and the larger sizes are of the outside screw-and-yoke construction. Components of the globe valve are similar to those of the gate valve. This type of valve has seats in a plane parallel or inclined to the line of flow.

Maintenance of globe valves is relatively easy, as the discs and seats are readily refurbished or replaced. This makes globe valves particularly suitable for services which require frequent valve maintenance. Where valves are operated manually, the shorter disc travel offers advantages in saving operator time, especially if the valves are adjusted frequently.

The principal variation in globe-valve design is in the types of discs employed. Plug-type discs have a long, tapered configuration with a wide bearing surface. This type of seat provides maximum resistance to the erosive action of the fluid stream. In the composition disc, the disc has a flat face that is pressed against the seat opening like a cap. This type of seat arrangement is not as suitable for high differential pressure throttling.

The conventional disc, in contrast to the plug type, provides a thin contact between the taper of the conventional seat and the face of the disc. This narrow contact area tends to break down hard deposits that may form on the seats and facilitates pressure-tight closure. This arrangement allows for good seating and moderate throttling.

In cast-iron globe valves, disc and seat rings are usually made of bronze. In steel-globe valves for temperature up to 750°F (399°C), the trim is generally made of stainless steel and so provides resistance to seizing and galling. The mating faces are normally heat-treated to obtain differential hardness values. Other trim materials, including cobalt-based alloys, are also used.

The seating surface is ground to ensure full-bearing surface contact when the valve is closed. For lower pressure classes, alignment is maintained by a long disc locknut. For higher pressures, disc guides are cast into the valve body. The disc turns freely on the stem to prevent galling of the disc face and seat ring. The stem bears against a hardened thrust plate, eliminating galling of the stem and disc at the point of contact.

Advantages of a Globe Valve

The following summarizes the advantages of globe valves:

1. Good shutoff capability
2. Moderate to good throttling capability
3. Shorter stroke (compared to a gate valve)
4. Available in tee, wye, and angle patterns, each offering unique capabilities
5. Easy to machine or resurface the seats
6. With disc not attached to the stem, valve can be used as a stop-check valve.

Disadvantages of a Globe Valve

The following are some shortcomings inherent in globe valves:

1. Higher pressure drop (compared to a gate valve)
2. Requires greater force or a larger actuator to seat the valve (with pressure under the seat)
3. Throttling flow under the seat and shutoff flow over the seat

Typical Applications of Globe Valves

The following are some of the typical applications of globe valves:

1. Cooling water systems where flow needs to be regulated
2. Fuel oil system where flow is regulated and leaktightness is of importance.

3. High-point vents and low-point drains when leaktightness and safety are major considerations.
4. Feedwater, chemical feed, condenser air extraction, and extraction drain systems.
5. Boiler vents and drains, main steam vents and drains, and heater drains.
6. Turbine seals and drains.
7. Turbine lube oil system and others.

Needle Valves

Needle valves generally are used for instrument, gauge, and meter line service. Very accurate throttling is possible with needle valves and, therefore, they are extensively used in applications that involve high pressures and/or high temperatures. In needle valves (Fig. A10.12), the end of the stem is needle point.
FIGURE A10.12 Needle valve for accurate throttling of flow.

Check Valves

Check valves are designed to pass flow in one direction with minimum resistance and to prevent reverse or backflow with minimal leakage. The principal types of check valves used are the tee-pattern lift check, the swing check, the tilting-disc check, the wye-pattern lift check, and the ball check, illustrated in Figs. A10.13 to A10.17, respectively.
FIGURE A10.13 Lift check valve.
FIGURE A10.14 Swing check valve.

Construction of a Check Valve

A basic check valve consists of a valve body, bonnet or cover, and a disc which is attached to a hinge and swings away from the valve seat to allow fluid to flow in the forward direction, as in a swing- or tilting-disc check valve, and returns to valve seat when upstream flow is stopped. Thus, reverse flow is prevented. In folding-disc check valves, the disc consists of two halves attached in the middle. The two halves fold backward when upstream flow is initiated. Activated by a spring, the two halves quickly close the flow path when upstream flow ceases. In the case of lift-check valves, the disc is in the form of a piston which is moved out of the flow path by upstream flow and returns to the valve seat by gravity to stop back flow. Ball-check valves have a disc in the form of a ball.

FIGURE A10.15 Tilting-disc check valve. (*Courtesy BTR Inc./Edward Valve*)

Check valves are available in sizes from NPS ¼ (DN 6) through NPS 72 (DN 1800). Other sizes may be made available to meet specific size requirements. Depending upon the design requirements of a piping system, a check valve may have butt welding, socket welding, threaded, or flanged ends.

Advantages of Check Valves

They are self-actuated and require no external means to actuate the valve either to open or close. They are fast acting.

Disadvantages of Check Valves

The following are some of the disadvantages that are attributed to check valves:

1. Since all moving parts are enclosed, it is difficult to determine whether the valve is open or closed. Furthermore, the condition of internal parts cannot be assessed.
FIGURE A10.16   Wye-pattern lift check valve. (*Courtesy, BTR Inc./ Edward Valve*)

2. Each type of check valve has limitations on its installation configurations.

3. Valve disc can stick in open position.

Types of Check Valves

There are several types of check valves having varying body configurations. The following are some commonly used types of check valves:

Swing Check Valve.   In swing check valves, the disc is unguided when it moves to fully open position or to fully closed position. Many different disc and seat designs are available to satisfy requirements of varying applications. Soft-seated–swing check valves provide improved leaktightness compared to metal-to-metal seating surfaces. Combination seats consisting of a metal seat ring with resilient insert also offer better leaktight characteristics. The seating angle, the angle between the seat and the vertical plane, may vary from 0 to 45 degrees. Vertical seats have a 0° angle. Larger seat angles reduce the disc travel, resulting in quick closing, thus minimizing the possibility of water hammer. Usually the seat angles are in the range of 5 to 7 degrees.

Lift Check Valve.   Lift check valves are particularly adapted for high-pressure service where velocity of flow is high. In lift check valves, the piston disc is
FIGURE A10.17   Ball check valve.

accurately guided by long contact and a close sliding fit with the perfectly centered dash pot. The walls of the piston and dash pot are of approximately equal thickness. Large steam jackets are located outside of the dash pot and inside the piston to eliminate sticking because of differential expansion. The seat ring is of a barrel-type design of heavy uniform cross-section. It is normally screwed in and seal welded. The flow opening is full port size. Refer to Figs. A10.13 and A10.16.

The seat design of a lift-check valve is similar to a globe valve. The disc is usually in the form of a piston or a ball. The ball-lift check valves are used in highly viscous fluid service. These valves have superior leaktight characteristics to those of swing-check valves.

The piston type lift check valves have a tendency to stick in the open position when service fluid has sediment trapped above the piston. Large lift check valves are furnished with an equalizer line between the chamber above the disc and the downstream side of the valve.

Tilting Disc Check Valve. The tilting-disc check valve is designed to overcome some of the weaknesses inherent in conventional swing check valves. A combination of design features enables the valve to open fully and remain steady at lower flow velocities and to close quickly upon cessation of forward flow. The dome-shaped disc floats in the flow with fluid on both bottom and top of its surfaces, thus it has minimum dashpot effect. It performs well in pulsating, turbulent, and high-velocity flows. These attributes prolong the valve's lift and reduce flow-induced dynamic loads on the piping system. Refer to Fig. A10.15.

Folding Disc Check Valves. This valve is also referred to as *double-disc* or *split-disc* check valve. Refer to Fig. A10.18. It is manufactured in wafer-body pattern and is available with soft or hard seats. It is very popular in low-pressure liquid and gaseous services. Its lightweight compact construction makes it a preferable check valve when space and convenience are important.

Vertical or In-Line Check Valve. These valves are available in two configurations: in-line ball check and fully guided disc with soft or hard seats. In-line ball check valves can be used in both vertical and horizontal lines. The fully guided disc in-line check valves must be provided with a spring-assist closure when used in horizontal lines. In vertical lines, the guided disc in-line check valves may or may not be provided with spring-assist closure. The spring-assist closure not only assists in closing the valve quickly, it minimizes the possibility of water hammer by preventing flow reversal.

They can be used in applications having pulsating flows, such as in a discharge line of a reciprocating compressor. Because they are compact in size, they are ideal for application in tight spaces.

Stop Check Valve. A stop check valve can either be used as a unidirectional check valve or as an isolation (stop) valve like a gate or globe valve. During normal operation of a system, these valves are used as a regular check valve; however, when needed, these valves can be closed with the help of a screw-down stem which is not fastened to the valve disc. The stem, when fully screwed down, holds the free-floating disc against the valve seat, just as in a gate or a globe valve. These valves are available in tee-pattern, wye-pattern, angle-pattern, and inclined pattern. The swing-and-piston lift-disc design check valves are commonly used as stop check valves. Refer to Figs. A10.19a and A10.19b.

Application Considerations

The force of gravity plays an important role in the functioning of a check valve and, therefore, the location and orientation of the check valve must always be given consideration. Lift and ball check valves must always be placed so that the direction of lift is vertical. Swing checks must be located to ensure that the disc will always be closed freely and positively by gravity.

The flow velocity of the fluid through the valve has a significant effect on the life of the check valve. The valve should be sized such that the fluid velocity under normal conditions is sufficient to keep the disc fully open and pressed against the stop. This minimizes disc fluttering, which is the primary cause of valve failure.

Also, a check valve should not be located immediately downstream of a source of turbulence, such as a pump, elbow, control valve, or a tee-branch connection. It is recommended that manufacturer's recommendations be followed to provide the required straight run of pipe upstream of the check valve. Some manufacturers recommend 8-to-10 pipe-diameter length of straight run of pipe upstream of the valve. Sometimes, the layout and the space available may not allow compliance to manufacturer's recommendations. Alternatives must be evaluated and the most reasonable and feasible approach be implemented.

A swing check valve may be used in the vertical run of a pipe only when the

TABLE A10.9 Application of Check Valves

Type flow	Media type	Velocity range FPS (m/s)	Recommended check valve type
Uniform with insignificant reversal	Water or oil	1 to 6 (0.3 to 2)	Swing check w/ lever and ctr wt.
	Steam, water, gas	7 to 100 (2 to 30)	Simple swing
Uniform	Water or oil	5 to 10 max (1.5 to 3)	In-line guided disc
Pulsating	Air or gas	5 to 10 max (1.5 to 3)	In-line guided disc with cushion chamber
Uniform with normal reversal	Water or oil	7 to 10 (2 to 3)	Swing with spring assist to close
Uniform with severe reversal	Water or oil	7 to 10 (2 to 3)	Swing with dashpot
Uniform or pulsating	Steam, water or gas	8 to 160 (2.5 to 50)	Tee- or inclined-pattern lift
Uniform or pulsating (severe reversal)	Steam, water or gas	10 to 160 (3 to 50)	Tee-pattern lift with dashpot
Uniform	Steam, water or gas	12 to 250 (4 to 75)	Tilting disc
Uniform or pulsating	Steam, water, gas, oil	20 to 250 (6 to 75)	Wye-pattern lift
Uniform or pulsating (severe reversal)			Wye-pattern lift with dashpot

flow is upward. In addition, the flow velocity and the fluid pressure must be adequate to overcome the disc weight and swing it to the fully open position. In-line ball check valves are suitable for application in horizontal or vertical lines.

When the flow is suspected to be pulsating and low, use of a swing check valve is not recommended. Due to the continuous flapping of the swing disc against the seat, valves suffer considerable damage, and at times the swing discs can come loose.

Table A10.9 summarizes preliminary application guidelines for selection of a suitable type of check valve. The user must evaluate specific application features to determine the right valve for the application.

Typical Applications of Check Valves. Table A10.9 provides a brief summary of different types of check valves and their typical applications. The preliminary

guidelines of this table may be used to determine the suitable check valve for an application, considering the specifics of the application.

Ball Valves

The ball valve (Fig. A10.20) is a quarter-turn valve suitable for clean gas, compressed air, and liquid service. They also can be used for slurry service, but provisions for
FIGURE A10.20   Ball valve in closed position.

prevention of *crud* buildup must be made. The use of soft-seat materials such as nylon, delrin, synthetic rubbers, and fluorinated polymers imparts excellent sealing ability. With fluorinated polymer seats, ball valves can be used for service temperatures ranging from -450 to $500°F$ ($-270°$ to $260°C$); with graphite seats, service temperatures to $1000°F$ ($538°C$) or even higher are possible. Also, with metal-backing seats, the valves can be used in fire-safe services. Ball valves are similar to plug valves in operation. They are nonbinding and provide leak-tight closure. The valves exhibit negligible resistance to flow because of their smooth body and port.

Construction of a Ball Valve

Major components of the ball valve are the body, spherical plug, and seats. Ball valves are made in three general patterns: *venturi port*, *full port*, and *reduced port.* The full-port valve has an inside diameter equal to the inside diameter of the pipe. In the venturi and reduced-port styles, the port is generally one pipe size smaller than the line size. Stem sealing is accomplished by bolted packing glands and O-ring seals. Valves are also available with a lubricant-seal system that is similar to that available for plug valves. A typical lubrication system is illustrated in Fig. A10.21.

A ball valve may be unidirectional, bidirectional, or multidirectional, depending on the number of valve ports and the number of valve seats. Therefore, ball valves are referred to as 2-way, 3-way, 4-way, or 5-way multiport valves. A 2-way ball valve with a single seat will be unidirectional with the flow direction indicated. Even a 3-way, 4-way, or 5-way ball valve can be unidirectional when flow must
FIGURE A10.21   Lubricant-seal system in a ball valve.

enter through a designated port. A 2-way ball valve provided with two seats, one on the upstream side and the other on the downstream side of the ball, is termed a bidirectional valve. Multiple-port ball valves permit flows in more than one direction, thus eliminating the need for several valves.

Ball valves are manufactured in several different body configurations: *top entry, side entry, split body,* and *three-piece body.* The valve ends are available as butt-welding, socket welding, flanged, threaded, soldering, or brazing ends.

Ball valves are manufactured in high- and low-pressure classifications. The advances in ball valve designs have made it possible to use these valves in high-pressure and high-temperature applications.

Types of Ball Valves

The following provides a brief description of types of ball valves:

Split-Body Ball Valve.   The split body design consists of a two-part body, a cover, ball, seat rings, stem, and other internals. The two-part body is held together by a flange connection. One body part is smaller than the other. The ball is inserted in the larger body part, and the smaller body part is assembled by a bolted connection. The stuffing box is constructed integral with the larger body part. On smaller size split-body ball valves, the two-part body is joined by threaded connection. The flanged or threaded joint between the two-part body is an added source of potential leakage.

Flanged end connections are commonly available on all sizes; however, they are standard for large size valves. NPS 2 (DN 50) and smaller split-body ball valves are furnished with screwed ends. The split-body ball valves are manufactured in sizes ranging from NPS ½ (DN 15) through NPS 36 (DN 900). Refer to Fig. A10.22.

Top-Entry Ball Valve.   Top-entry ball valves allow access to valve internals for assembly, disassembly, repair, or maintenance by removal of the valve bonnet-cover. The valve is not required to be removed from the pipeline. Refer to Fig. A10.23.

End-Entry Ball Valve.   End-entry ball valves have a single-piece body. The ball is inserted from one end and is retained by an insert. These valves have flange- or

screwed-end connections. This design is commonly used for inexpensive small valves. They are also available in larger sizes up to NPS 6 (DN 150).

Three-Piece—Body Ball Valve. The middle part of the valve is the major part that holds all valve internals, and the stem passes through a hole in the top. Two end caps are held together with the middle body by bolts or studs and nuts. The end connections are part of the end caps, and they may be butt-welding, socket-welding, threaded, or flanged. This design is available in sizes ranging from NPS ½ (DN 15) through NPS 36 (DN 900). The two end cap joints are two additional sources of potential leakage.

Double Trunnion Ball Valves. In this ball-valve design, the ball is provided with two integral short-shaft extensions called the top and the bottom trunnions. These trunnions are fitted in bearings and rotate freely when the shaft installed in the top trunnion is turned to open or close the valve. The ball is held firmly in place, unlike the ball in other designs where the ball is supported by the two seat rings and is allowed to float in the direction of the slot on top of the ball. A shaft installed in the top slot is turned to open or close the valve.

The trunnion-mounted ball-valve design is used with split-body large size valves, whereas the floating-ball design is the most common design for all other types of ball valves. The torque required to actuate a trunnion-mounted ball valve is substantially smaller than the torque required for a floating-ball design.

Lubricated or Nonlubricated Ball Valves. Like other valves, the stem sealing is usually accomplished by bolted packing glands and O-ring seals. Some valve designs are available with a lubricant-seal system similar to the one used in plug valves. Such a design is shown in Fig. A10.21. The valves with lubrication seal systems are termed lubricated ball valves, while others are called nonlubricated.

Advantages of Ball Valves

The following are the advantages of ball valves:

1. Provides bubble-tight service.
2. Quick to open and close.
3. Smaller in size than a gate valve.
4. Lighter in weight than a gate valve.
5. Multiport design offers versatility not available with gate or globe valves. It reduces the number of valves required.
6. Several designs of ball valves offer flexibility of selection.
7. Can be used in clean and slurry applications.
8. High-quality ball valves provide reliable service in high-pressure and high-temperature applications.
9. Force required to actuate the valve is smaller than that required for a gate or a globe valve.

Disadvantages of Ball Valves

1. They are not suitable for sustained throttling applications.

2. In slurry or other applications, the suspended particles can settle and become trapped in body cavities causing wear, leakage, or valve failure.

Typical Applications of Ball Valves

The following are some typical applications of ball valves:

1. Air, gaseous, and liquid applications requiring bubble-tight service

2. Low-point drains and high-point vents in liquid, gaseous, and other fluid services

3. Instrument root valves

4. Cooling water and feedwater systems

5. Steam service

Plug Valves

Plug valves, also called *cocks,* generally are used for the same full-flow service as gate valves, where quick shutoff is required. They are used for steam, water, oil, gas, and chemical liquid service. Plug valves are not generally designed for the regulation of flow. Nevertheless, in some applications, specially designed plugs are used for this purpose, particularly for gas-flow throttling.

Plug valves generally can be readily repaired or cleaned without necessitating removal of the body from the piping system. They are available for pressure service from vacuum to 10000 psi (69000 kPa) and temperatures from -50 to $1500°F$ (-46 to $816°C$). Also, plug valves are available with a wide variety of linings suitable for many chemical service applications.

Construction of a Plug Valve

The basic design of plug valves is illustrated in Fig. A10.24. Full flow is obtained when the opening in the tapered plug is aligned in the direction of flow. When the plug is rotated a quarter turn, flow is terminated. The body and tapered plug represent the essential features in plug valves. Careful design of the internal contours of the valve produces maximum flow efficiency. The port in the tapered plug is generally rectangular. However, valves are also available with round ports. Major valve patterns or types are identified as *regular, venturi, short, round-port,* and *multiport.*

Plugs are usually tapered downward, while in some cases they are tapered upward. Most of the plug valves are top entry. In top-entry plug valves, the tapered plug is installed from the top of the valve. In some cases the plug is tapered upwards and is installed from the bottom opening in the valve body. Such a plug is called bottom entry or *inverted* plug valve.

Plug valves are also available with cylindrical plugs. The cylindrical plugs provide for larger port openings equal to or greater than the pipe flow area.

The regular pattern employs the tapered form of port openings, the area of which is from 70 to 100 percent of the internal pipe area. In some cases, the face-
FIGURE A10.24   Plug valve with lubricant system, as specified in API Standard 600.

to-face lengths are greater than those of standard gate valves. The venturi pattern provides streamlined flow and thus permits reduction in the port size. The port opening area is approximately 40 to 50 percent of the internal pipe area. In most of the plug valves, the port opening varies from 60 to 70 percent of the pipe area. The round-port full-bore pattern has a circular port through the plug and body equal to or greater than the inside diameter of the pipe or fitting. Operating efficiency is equal to or greater than that of gate valves of the same size.

Use of multiport valves is advantageous in many installations because it provides simplification of piping and convenience in operation. One three-way or four-way multiport valve may be used in place of two, three, or four straightway valves. Refer to Fig. A10.25.
FIGURE A10.25   Multiport valves: (*a*) three-way, two-port; (*b*) three-way, three-port; (*c*) four-way, four-port.

Types of Plug Valves

The following describes salient features of different types of plug valves:

Lubricated Plug Valves.   The plug in a lubricated plug valve is provided with a cavity in the middle along its axis. This cavity is closed at the bottom and fitted with a sealant-injection fitting at the top. The sealant is injected into the cavity, and a check valve below the injection fitting prevents the sealant from flowing in the reverse direction. The sealant oozes out from the center cavity through radial holes into lubricant grooves that extend along the length of the seating surface of the plug. The sealant or the lubricant performs the following functions:

1. Establishes a renewable seal between the plug and the body. As a result, internal leakage is prevented or minimized.
2. Protects the seating surfaces against corrosion.
3. Acts as a lubricant, thus reducing the force required to open or close the valve.

The lubricant pressure developed by a turn of the lubricant screw or injection of lubricant with a pressure gun exerts a powerful hydraulic jacking action on the plug, momentarily lifting it from the seat and making it easy to turn. Since the lubricant pressure is greater than the line pressure, it is virtually impossible for solids to lodge between the valve body and plug.

The type of sealant to be used must be compatible with the flow medium in the pipe. The sealant must not dissolve or be washed away by the flow medium. The washed-away or dissolved sealant could contaminate the fluid, and the seal between the plug and the body would be destroyed, resulting in leakage. In addition, the sealant used must be able to withstand the flow-medium temperature.

Lubricated plug valves are normally manufactured in sizes ranging from NPS ½ through 36 (DN 15 through 900). They can be used in applications with pressures over 2500 psi (17250 kPa). They have been used in services involving air, gases, acids, alkalis, water, steam, oils, fuels, among others. Lubricated plug valves are less subject to seizing or wear and may exhibit somewhat greater resistance to corrosion in some service environments.

Nonlubricated Plug Valves.   Nonlubricated plug valves contain an elastomeric body liner or a sleeve, which is installed in the body cavity. The tapered and polished plug acts like a wedge and presses the sleeve against the body. Thus, the nonmetallic sleeve reduces the friction between the plug and the body.

Nonlubricating plug valves are used where maintenance must be kept to a minimum. Like lubricating plug valves, these valves also provide a bubble-tight closure and are of compact size.

Lubricants

The word *lubricant* does not precisely define the part this material plays in the efficient functioning of lubricated plug valves. More properly such valves might be called *plastic sealed valves,* and the lubricant could better be designated *plastic sealant.* The use of an effective lubricant is important, as, in operation, the valve structure and plastic scaling film are an integral unit, and each component is dependent on the other for ultimate performance.

The lubricant in effect becomes a structural part of the valve, as it provides a

flexible and renewable seat. This eliminates the necessity of *force fits* and metal-to-metal *distortable-seat* contacts to effect a seal. For this purpose, the lubricant must exhibit proper elasticity as well as resistance to solvents and chemicals to avoid the destructive action of the line fluid and to form an impervious seal around each body port, even under pressure. The film of lubricant also protects the metal surfaces between the plug and body from corrosion. The seal formed by the lubricant transmitted in a system of lubricant grooves circuiting each port aids in maintaining the essential film on the metal, closure surfaces.

Advantages of Plug Valves

The following summarizes the advantages of plug valves:

1. Simple design with few parts.
2. Quick to open or close.
3. Can be serviced in place.
4. Offers minimal resistance to flow.
5. Provides reliable leaktight service. Seal can be maintained by injection of sealant or by replacement of sleeve, in addition to utilizing the wedging action of a tapered plug.
6. Multiple port design helps reduce number of valves needed and permits change in flow direction.

Disadvantages of Plug Valves

The disadvantages include:

1. Requires greater force to actuate, due to high friction.
2. NPS 4 (DN 100) and larger valves require use of actuators.
3. Reduced port, due to tapered plug.
4. Typically, plug valves may cost more than ball valves.

Typical Applications of Plug Valves

As indicated earlier, the plug valves can be and have been used in many different fluid services. They perform well in slurry applications. They are primarily used in bubble-tight services as on-off stop valves. The wiping-off action of a plug does not permit suspended particles to accumulate and form crud. The following are some typical applications of plug valves:

1. Air, gaseous, and vapor services
2. Natural gas piping systems
3. Coal slurries, mineral ores, mud, and sewage applications
4. Oil piping systems
5. Vacuum to high-pressure applications

Diaphragm Valves

All diaphragm valves are bidirectional. They can be used as on-off and throttling valves. Diaphragm valves offer advantages in certain low-pressure applications not possible with other types of valves. Their fluid passages are smooth and streamlined, minimizing pressure drop. They are suitable for moderate throttling applications, and they exhibit excellent leak-tight characteristics, even when conveying liquids containing suspended solids. The fluid stream is isolated from the working parts of the valve, preventing contamination of the fluid and corrosion of the operating mechanism. Since there is no leak path around the valve stem, the valve is virtually leak tight. This feature makes the valve indispensable where leakage into or out of the system cannot be tolerated.

The maximum pressure that these valves can be subjected to is a function of the diaphragm material and the service temperature. Also, the rated design life of the valve is influenced by the service conditions. Furthermore, the system hydrostatic test pressure must not exceed the maximum pressure rating of the diaphragm.

Construction of a Diaphragm Valve

Diaphragm valves (Fig. A10.26) consist of a rigid body formed with a weir placed in the flow path, a flexible diaphragm which forms the upper pressure boundary
FIGURE A10.26 Sketch of a weir-type of diaphragm valve in open and closed positions.

of the valve, a compressor which is used to force the diaphragm against the weir, and the bonnet and handwheel which secure the diaphragm to the body and actuate the compressor.

Diaphragm valves are manufactured in a variety of end connections: welding-end socket or butt welding; flanged, screwed, or threaded; clamp ends or grooved ends; solvent cement joint ends for thermoplastic valves; and male sanitary threaded ends.

The valve body is available in two patterns: tee-pattern and angle pattern.

Diaphragm valves are available in a wide choice of body, diaphragm, and lining materials that are suitable for service with a wide variety of chemicals. For severe corrosive applications, diaphragm valves are made of stainless steel or PVC plastics,

TABLE A10.10 Typical Materials Used for Diaphragms

Valve type	Service	Material	Temp, °F (°C) Min	Max
Conventional weir	Abrasive	Soft natural rubber	−30 (−34)	180 (82)

	Cold beer	Pure gum rubber	−30 (−34)	160 (71)
Straightway	Water	Natural rubber	−30 (−34)	180 (82)
	Chemical, air, oil	Neoprene	0 (−18)	180 (82)
	Oils and gasoline	Hycar (gen. purpose)	10 (−23)	180 (82)
	Fatty acids	Black chlorinated butyl	0 (−18)	225 (107)
	Oxidizing services	Hypalon	0 (−18)	200 (93)
	Food and beverage	White chlorinated butyl	−10 (−23)	200 (93)

or they are lined with glass, rubber, lead, plastics, titanium, or still other materials. Some of the common materials used for diaphragms are listed in Table A10.10.

Adjustable travel stops are used to prevent excessive compression of the diaphragm. The adjustable travel stop can be enclosed in a temper-proof housing. The temper-proof housing prevents inadvertent mishandling after the travel length is set. It requires a special tool to open the housing and to make an adjustment in the travel length.

When an actuator is required, it should be sized and tested by the valve manufacturer and furnished with the valve as an assembled unit with settings made and verified in the shop.

Types of Diaphragm Valves

Primarily there are two basic designs of diaphragm valves: *weir* and *straight-through* types. The body interior and the end flanges can be lined to make the diaphragm valves suitable for corrosive applications. Various lining materials can be used, depending upon the application.

Weir-Type Diaphragm Valves. As shown in Fig. A10.26, a weir is provided as an integral part of the valve body. The weir acts as the valve seat against which the diaphragm is compressed to stop the flow. This type of diaphragm valve is generally produced in large sizes. The raised weir reduces the amount of diaphragm travel from the fully open to the fully closed position, thus reducing the amount of stress and strain in the diaphragm.

Straight-Through Diaphragm Valves. Variations of the weir diaphragm valve are the *straightway* (Fig. A10.27) and the *full-bore* types (Fig. A10.28). When the straightway valve is open, its diaphragm lifts high for full streamline flow in either direction. When the valve is closed, the diaphragm seals tight for positive closure even with gritty or fibrous materials in the line.

FIGURE A10.27 Straightway-type diaphragm valve.

The full-bore type of valve is most extensively used in the beverage industry. It permits ball-brush cleaning with either steam or caustic soda, without opening or removing the valve from the line.

Advantages of Diaphragm Valves

The following summarizes some distinct advantages of diaphragm valves:

1. Can be used as on-off and throttling service valves.
2. Offer good chemical resistance due to variety of linings available.
3. Stem leakage is eliminated.
4. Provides bubble-tight service.
5. Does not have pockets to trap solids, slurries, and other impurities. It is suitable for slurries and viscous fluids.
6. These valves are particularly suitable for hazardous chemicals and radioactive fluids.
7. These valves do not permit contamination of flow medium, thus they are used extensively in food processing, pharmaceutical, brewing, and other applications which cannot tolerate any contamination.
FIGURE A10.28 Full-bore-type diaphragm valve illustrating passage of ball-brush cleaner through valve.

Disadvantages of Diaphragm Valves

1. The weir may prevent full drainage of piping.

2. Working temperatures and pressures are limited by the diaphragm material. Generally the pressures are limited to 200 psi (1380 kPa) and temperatures up to 400°F (204°C).

3. The diaphragm may also limit the hydrostatic pressure.

4. The diaphragm may experience erosion when used extensively in severe throttling service containing impurities.

5. Diaphragm valves are available in limited sizes, usually NPS ½ to 12 (DN 15 to 300).

Typical Applications of Diaphragm Valves

1. Clean or dirty water and air service applications

2. Demineralized water systems

3. Corrosive applications

4. Radwaste systems in nuclear facilities

5. Vacuum service

6. Food processing, pharmaceutical, and brewing systems

Butterfly Valves

Butterfly valves are used to control and regulate or throttle the flow. They are characterized by fast operation and low-pressure drop. They require only a quarter-turn from closed to full-open position. A typical flanged butterfly valve is illustrated in Fig. A10.29. Butterfly valves are produced in sizes ranging from NPS 1½ (DN 40) to over NPS 200 (DN 5000). They are usually manufactured in flanged, wafer, and lug, or single-flange-type designs. The welding-end style is a specially engineered valve for a specific application. Threaded-end, grooved-end, and shouldered-end butterfly valves are also available to satisfy the joint type selected for the piping system. Butterfly valves are produced with metal-to-metal seats, soft seats, and with fully lined body and disc. The soft seats permit bubble-tight shutoff and the full lining enhances erosion and corrosion resistance.

Butterfly valves are suitable for low-pressure and low-temperature applications as well as high-pressure and high-temperature applications. The term *high-performance butterfly valve* is intended to signify their suitability for moderate- to high-pressure and temperature services.

The butterfly valves have a low-pressure drop and high-pressure recovery factor. They are suitable for low-pressure drop applications. These valves are extensively used in large water transmission, distribution, and cooling water lines.

Construction of a Butterfly Valve

A butterfly valve has a short circular body, a round disc, shaft, metal-to-metal or soft seats, top and bottom shaft bearings, and the stuffing box. The valve body may
FIGURE A10.29 Typical flanged-end butterfly valve.

have flanged ends, lugs, or wafer style (Fig. A10.30) configurations to be installed between pipe flanges. The welding-end (Fig. A10.31) butterfly valves are usually large and have butt-welding ends. Sometimes butterfly valves are manufactured in rectangular or square configurations.

The wafer-style butterfly valves are usually available in sizes NPS 12 (DN 300) or smaller. The limitation on size is essentially imposed by the difficulty of holding the larger weight valve in place between the flanges. The lug and flanged-end butterfly valves are available in all sizes and pose no problem in installation between flanges except for the normal problems associated with warped-flanged surfaces and uneven torquing of bolts.

Types of Butterfly Valves

Low Pressure or Concentric Butterfly Valves. In low pressure and low temperature designs of a butterfly valves, the disc and shaft axes are concentric. In open position, the disc divides the
FIGURE A10.30 Wafer butterfly valve. (*Courtesy, Keystone International, Inc.*)

flow in two equal halves, with the disc in the middle and parallel to the flow. These valves are provided with resilient seats. These valves are available as *lined* or *unlined.* Most commonly used lining and seating materials include: Buna N, Neoprene, Fluorcel, Hypalon, EPDM, TFE, Viton, among others. The application temperature is limited by the temperature capability of the resilient material. These valves are generally produced in Classes 150 and 300.

High-Performance or Eccentric Butterfly Valves. The disc in high performance butterfly valves is offset from the center of the valve, and the shaft is also offset from the center of the disc. The offsets provided allow the disc to move eccentrically uninterrupted away from or toward the valve seat. Thus, the uninterrupted motion of the disc until it seats against the valve seat prevents unwanted wear and tear of the valve seat and disc due to friction and rubbing of the seating surfaces. The high-performance butterfly valves are used for on-off and throttling services. Some butterfly valve manufacturers produce high performance

FIGURE A10.31 Butterfly valve; welding end on one end.

butterfly valves with triple offset, which enhances their actuation and leak-tightness.

Advantages of Butterfly Valves

The following summarizes the advantages of butterfly valves:

1. The compact design requires considerably less space, compared to gate, globe, or other valves.
2. Light in weight.
3. Quick acting; as a quarter-turn valve, it requires less time to open or close.
4. It is available in large sizes, ranging from NPS 1½ (DN 40) to over NPS 200 (DN 5000).
5. They have low-pressure drop and high-pressure recovery.
6. Provide bubble-tight service.

Disadvantages of a Butterfly Valve

1. Throttling service is limited to low differential pressure.
2. Throttling is restricted to a 30- to 80-degree disc opening. Location of valve,

pipe routing, free, and closed discharge are to be considered while using a butterfly valve in a throttling application.

3. Cavitation and choked flow are two potential concerns.

4. The disc movement is unguided and affected by flow turbulence.

Typical Applications of Butterfly Valves

Concentric or low-pressure and low-temperature butterfly valves, the high-performance butterfly valves, cover a wide range of applications. These applications include:

1. Cooling water, air, gases, and other similar applications, such as fire protection, circulating water, et cetera

2. Corrosive services requiring lined valves

3. Food processing, chemical, and pharmaceutical services

4. Slurry and similar services

5. High-pressure and high-temperature water and steam services

6. Throttling service involving low differential pressures, as in cooling water or air supply systems

7. Vacuum service

Application Considerations for Butterfly Valves

1. It is noted that the disc of butterfly valve is unguided; therefore, operability of the valve is affected by the flow characteristics. A butterfly valve should not be located just downstream of a source of flow turbulence, such as pump-discharge nozzle, elbow, control valve, or a tee-branch. To minimize the effects of flow turbulence on the valve, attempts should be made to

   - Locate the valve 4 to 6 diameters downstream of the source of flow turbulence.
   - Orient the valve shaft in the same plane as the elbow or the pump outlet configuration. When there is more than one component on the upstream side of the valve, then the component adjacent to the valve is to be considered in determining the valve-shaft orientation.

2. When used in throttling applications, an attempt must be made to provide an adequate straight length of pipe downstream of the valve to allow the flow turbulence to subsidize prior to diverting the flow.

3. Butterfly valves are essentially bidirectional. In the case of high-performance butterfly valves, and sometimes in the case of low-pressure and low-temperature butterfly valves, the valve design may require more actuating torque to open or close the valve when the flow is reversed. In such cases, the valve manufacturer must be contacted to ensure that the valve is designed and the actuator is sized for flow in both directions.

PRESSURE-RELIEF DEVICES

Safety Valves and Pressure-Relief Devices

Safety valves and pressure-relief valves are automatic pressure-relieving devices used for overpressure protection of piping and equipment. Safety valves (Fig. A10.32) are generally used in gas or vapor service because their opening and reseating characteristics are commensurate with the properties and potential hazards of compressible fluids. The valves protect the system by releasing excess pressure. Under normal pressure, the valve disc is held against the valve seat by a preloaded spring. As the system pressure increases, the force exerted by the fluid on the disc approaches the spring force. As the forces equalize, fluid begins to flow past the seat. The valve disc is designed in such a way that the escaping fluid exerts a lifting pressure over an increased disc surface area, thereby overcoming the spring force and enabling the valve to rapidly attain near-full lift. An added benefit to the safety-valve disc design is that the pressure at which the valve reseats is below the initial set pressure, thereby reducing the system pressure to a safe level prior to resealing. The ratio of the difference between the set pressure and the resealing pressure to the set pressure is referred to as the *blowdown.*

Pressure-relief valves (Fig. A10.33) are used primarily in liquid service. These valves function in a way similar to safety-relief valves, except that as liquids do not
FIGURE A10.32 Safety valve.
FIGURE A10.33 Relief valve opens when line pressure exceeds preset loading on the spring.

expand, there is no additional lifting force on the disc and, therefore, the valve lift is proportional to the system pressure. Also, the valves reseat when the pressure is reduced below the set pressure.

A third type of pressure-relieving valve is a safety-relief valve, which can be used with both compressible and incompressible fluids. It combines the design features of a safety- and a relief-valve into one. Therefore, when it is used with compressible fluids, such as steam or a gas, it pops open to release the overpressure, and when used with incompressible fluids, such as water or other liquids, it opens gradually, proportional to the increase in pressure over the set pressure, to safeguard the vessel, tank, heat exchanger, piping, or other equipment.

ACTUATORS

A brief discussion is provided to assist the user in understanding the considerations affecting the selection of the type of actuators required for an application. Manually actuated valves do not change position due to a change in the mode of system operation or an accident. As such, a manually operated valve remains in the last position it was placed in. Manually operated valves are usually furnished with a handwheel attached to the valve stem or yoke nut which is rotated clockwise or counter-clockwise to close or open a valve such as a gate or globe valve. Manually operated quarter-turn valves, such as a ball, plug, or butterfly valve, is provided with a lever to actuate the valve. There are applications in which the force required to actuate the valve is more than the force manually imparted through a handwheel or a lever. These applications include:

- Large valves and valves required to be operated against high-fluid pressure
- When the time required to open, close, throttle, or regulate the valve manually is longer than that required by system-design criteria
- When the valve is required to be operated from a remote location
- When the valve must attain a position (open or close) in the event of an accident or in a particular mode of system operation

The valves to be furnished with an actuator utilizing external source(s) of energy, such as electricity, pneumatics, hydraulics, mechanical springs, or a combination of one or more of these energies, are called actuated valves. Upon failure of the external source of energy, a valve may not be in the required position for accomplishing the design function. One must be aware of failure modes prior to selecting a valve actuator.

Failure Modes

Fail-As-Is (FAI): The valve remains in its last position following upon an external power failure.

Fail-Closed: The valve is provided with external source(s) of energy to place it in the closed position, regardless of valve position before power failure.

Fail-Open: The valve is provided with external source(s) of energy to place it in the open position, regardless of valve position before power failure.

Fail-Locked: Air or inert gas actuators may be provided with a device or devices to seal in actuator pressure upon the loss of normal pneumatic source control.

Types of Actuators

The following are some of the commonly used valve actuators:

Gear Actuators.   Spur, bevel, or worm-gear actuators are used to reduce the manual force required to operate a valve. Spur gears are used with globe, angle, and nonreturn valves. Bevel-gear actuators are used on gate valves. Worm-gear actuators are usually used on quarter-turn valves. The use of a gear actuator is warranted when the rim pull force required to manually actuate a valve exceeds a given value, which varies from 50 lb (22 kgf) to 250 lb (113 kgf).

Electric Motor Actuators.   An electric motor provides the actuating energy to place the valve in the desired position. Upon loss of power, the failure mode is fail-as-is. The stem speed may vary from 12 in/min (30 cm/min), known as manufacturer's standard, to 60 in/min (150 cm/min). Special features are required to accomplish stem speeds over 45 in/min (112 cm/min).

Pneumatic Actuators.   Pneumatic actuators utilize the motive force provided by a compressed gas such as air, nitrogen, or other inert gas. There are many different types of pneumatic actuators. These include linear, rotary, and linear-to-rotary. Linear-type actuators are used with valves having translating stems. Rotary and linear-to-rotary pneumatic actuators are used on valves having rotating stems.
   Pneumatic actuators can generate very high thrust and an extremely high torque. The length and speed of stroke may vary considerably, depending upon the type of pneumatic actuator. These actuators are capable of providing either fail-open or fail-close failure mode upon loss of air. Piston-type air actuators are furnished with springs to open or close the valve upon air failure. Diaphragm air actuators have limited thrust and torque generation capabilities due to limits on air pressure because of diaphragm strength. In addition, the diaphragm actuators have limited stroke ranging from 1 to 4 in (25 to 100 mm).
   Air-vane pneumatic actuators are used with quarter-turn valves, and they can be directly mounted on the valve stem.

Hydraulic Actuators.   Hydraulic actuators utilize pressurized liquids, usually oils but sometimes water, or the process liquid is used to provide the motive force for actuating the valve. Like pneumatic actuators, these actuators can help achieve fail-open or fail-close failure modes.

Solenoid Actuators.   Solenoid actuators have short-stroke and low-thrust capabilities. Two types of actuating methods are used in solenoid valves: direct acting and pilot operated. In the direct acting solenoid valve, the disc is lifted off the seat to a fully open position by magnetic flux generated by energizing the coil, and the disc is returned to its seat by deenergizing the coil. The pilot-operated solenoid valve utilizes the system pressure to provide the actuating force.
   Solenoid valves can accomplish all failure modes.

SELECTION AND APPLICATION GUIDELINES

The following guidelines are provided to assist in selecting a suitable valve for any application. These guidelines are intended to cover all physical features and capabilities or limitations of different types of valves and which may be suitable for one particular application. The user must fully evaluate the pros and cons of using a particular type of valve and arrive at the most suitable selection, taking into consideration the life span expected and costs involved.

Identify Application Characteristics

1. Identify the system and various modes of system operation: startup, normal operation, accident condition, standby, shutdown, et cetera.

2. Identify the flow medium and its properties, flow rate during all modes of system operation, system design pressure, and design temperature.

3. Identify the pipe size, pipe wall thickness, piping material, piping joint(s) to be used, and any other information which relates to valves in the system.

4. Establish the code of jurisdiction, which governs the construction of the system, component, or equipment. The codes related to piping systems are discussed in Chap. A4. The applicable code (ASME B31.1, B31.3, B31.5, B31.8, B31.9, B31.11, ASME Sec. I, Sec. III, Sec. VIII, etc.) does contain requirements for valves. Become familiar with the code requirements for valves in general and for the system under consideration in particular.

5. Identify the valve standards referenced in the code of jurisdiction. Each code lists the valve standards that are acceptable for construction of valves to be used in piping within the jurisdiction of the code. Use valves complying with the valve standards listed in the code of jurisdiction. The most commonly used valve standards are listed in the beginning of this chapter.

6. Establish the pressure drop through the valve that can be critical on overall system performance. For example, the pressure drop through the stop valve(s) in the main steam system of a power facility is critical to achieve the guaranteed performance of the plant.

Select Type of Valve Required

1. In reference to the various modes of system operation, determine the function(s) a valve has to perform.

2. Based upon the valve functions, the valve type(s) can be selected. The valve needed may be an isolation valve or a stop valve. What are the choices available?

3. Similarly, the valve required may be a check valve or the valve required to stop the flow in reverse direction. There are many different types of check valve. Which is the most suitable?

4. Does flow need to be throttled? Based upon the amount of throttling required, one may select a globe valve, butterfly valve, or a needle valve. Size limitations also play a role in the availability of these valves.

5. If flow has to be regulated and controlled based on variation in pressure, temperature, fluid level, or the design limitations of a component or equipment,

TABLE A10.11   Valve Types and Typical Applications

Valve type	Isolation or stop	Throttling	Pressure relief	Directional change
	Service/Function			
Gate	yes	no	no	no
Globe	yes	yes	no	yes (note 1)
Check	note 2	no	no	no
Stop check	yes	no	no	no
Butterfly	yes	yes	no	no
Ball	yes	note 3	no	yes (note 4)
Plug	yes	note 3	no	yes (note 4)
Diaphragm	yes	no	no	no
Safety/relief	no	no	yes	no

Notes:
1. Only angle-globe valves can be used for a 90-degree change in direction of flow.
2. Check valves (other than the stop-check valves) stop flow only in one (reverse) direction. Stop-check valves can be and are used as stop, block, or isolation valves, in addition to being used as a check valve.
3. Some designs of ball-and-plug valves (contact the valve manufacturer) are suitable for throttling service.
4. Multiport ball-and-plug valves are used for changing the direction of flow and mixing flows.

the valve required would be a control valve. Refer to selection and application of control valves section at the end of this chapter.

6. The first step is to determine the valve type: *isolation, check*, or a *control valve.* If the component or the piping system is required to be protected against overpressure built up, then one of the pressure-relief devices ought to be selected.

7. To begin the selection process, Table A10.11 provides a good starting point.

8. The next step is to narrow down the choices of valves to be used. As discussed earlier, there are several different designs available in different categories of valves. For example, large-size butterfly valves are preferred to large-size gate valves as stop valves in low-pressure and low-temperature cooling water systems, due to space, weight, actuator, and cost considerations.

Select Valve Size

1. Pipe size will indicate the valve size unless there are other requirements that may make it necessary to install a smaller- or larger-than-pipe-size valve.

2. The valve availability is one of those factors. In addition, some valves are not manufactured in certain small or large sizes. Refer to valve vendor catalogs

and evaluate application requirements and valve features in addition to space, cost and, operational concerns.

Select Valve-End Connection

1. Types of piping joints to be used depend upon several considerations, such as ease of removal and replacement of components in the piping system, frequency of repairs and replacements, life span of valves, and trim items. For example, the power plants utilize welded joints, whereas the petroleum refineries and chemical plants use flanged joints predominantly. Use of threaded, soldering, and brazing joints is common in plumbing piping systems.

2. Check code requirements concerning piping joints. At times codes prohibit or restrict the use of different types of joints based upon size, pressure, temperature, materials of construction, flow medium, and other criteria. When leakage through joints is a concern, use of a threaded joint may be prohibited or limited by the code or by prudent engineering.

3. When valve-body material is different from the pipe material, transition pieces may be needed to attach the valve to piping.

4. To prevent galvanic corrosion between valve and pipe flanges, insulating flanges may be needed.

Select Valve-Body, Bonnet, and Trim Materials

1. Flow medium and its characteristics will help in selecting the valve-body and valve-trim materials. The flow-medium characteristics include: liquid, gaseous, vapor or two-phase flow, viscosity, clean fluid, dirty fluid, suspended impurities, pH-value (0 to 14), and pressure, and temperatures during different modes of system operation. Nonmetallic, stainless steel, or high-alloy piping may be utilized. Accordingly, valve materials should be selected keeping in mind the manufacturing limitations and availability of valve types and sizes required.

2. Flow rate will dictate requirements for the valve-flow coefficient. Should the valve be full port, standard port, reduced port, et cetera?

3. Valve materials for pressure-retaining parts must be in accordance with the applicable code and acceptable valve standard.

4. Materials for valve parts other than pressure retaining parts must be suitable for withstanding all conditions of loading and assist the valve in performing its design functions.

Identify Seat-Leakage Criteria

1. Determine the minimum and maximum acceptable seat leakage across the valve seat when the valve is in closed position during various modes of system operation. In some cases the seat leakage may not be of concern, while in other applications, such as in piping handling cryogenic fluids, radioactive materials (liquids, gases, and mixtures) or toxic and hazardous waste materials may be a serious concern and must be limited to an acceptable level.

2. The applicable valve standard may specify the acceptable seat leakage when

the valve is tested in the shop. Alternatively, more stringent criteria may be specified. Refer to the valve standard, such as MSS SP-61 and API 598.

Identify Requirements for Valve-Stem Packing Arrangement

1. If the valve is to be connected to a piping system or to equipment which is continuously maintained at vacuum, the stem packing must be suitable to prevent inward air leakage. Inverted–V Teflon packing is used to temperatures up to 400°F. Graphite packing may be specified at temperatures above 400°F. Contact the valve manufacturer to ensure effectiveness of the packing.

2. When fugitive emission is a concern, specify the requirements for a suitable packing arrangement.

3. In cryogenic applications the leakage of fluid across the valve seat must not come in contact with the stem packing. Refer to Chap. C8.

Be Aware of Piping Layout and Valve Orientation

1. If a valve is located near or close to an elbow, tee-branch connection, or another source of turbulence, precautions must be taken to select the valve that can withstand flow conditions or modify the layout. It is particularly true for swing check and butterfly valves.

2. If a gate valve is installed with its stem in a horizontal plane, the bonnet cavity may not fully drain after hydrostatic testing, be filled with condensed vapor when the system is shut down, or contain chemicals if the system was cleaned using chemicals. Such situations may result in damage to the valve due to pressure binding or chemical reaction. A drain or vent in the bonnet may be needed to alleviate potential problems.

Take into Consideration Maintenance Requirements

1. Maintenance considerations are important for the selection of valves. The plant designer must provide for access, assembly, and disassembly of valves.

2. Space limitations may impose restrictions on the use of a particular type of valve even though it may be the most suitable valve for the application. Select an alternative valve.

3. When plants are designed for long life, the valves selected must not require frequent maintenance, with the exception of items such as the replacement of packing or lubrication.

Initial Cost

1. A low-initial-cost valve may necessitate frequent repairs or replacements of the valve or valve parts. Be aware of future costs involved.

2. High initial costs may be prohibitive. Therefore, a compromise may be made to choose the right valve for the application.

Actuation Requirements

1. Does the valve require an actuator? If needed, select the proper actuator, keeping in mind the facilities and utilities available at the location.

2. Failure mode desired will dictate the type of power actuator.

3. Gear-actuated valves require special attention with regard to the size of the actuator. The actuator size would depend on the maximum rim pull that can be applied without use of crowbars, rods, or hammers. The rim pull may vary from as low as 50 lb (22 kgf) to 250 lb (113 kgf). Consideration must be given to the plant-operating individuals and their safety and health. A high rim pull may result in injury to an operator.

The above-stated guidelines are provided to assist the user in arriving at a reasonable solution for selecting and applying valves. They are not to be considered the only guidelines. They are for initiating the thought process and offering users critical information for making a final decision.

CHAPTER A10
PART 2 SELECTION AND APPLICATION OF CONTROL VALVES

Dr. Hans D. Baumann, P.E.
Fisher Controls International, Inc.

DEFINITION OF CONTROL VALVES

Unlike valves in a piping system that primarily serve to shut off, drain, fill, or divert, control valves are a part of an automated control system. They are considered the "final control element" in an automated and usually very sophisticated "control loop." Aside from the control valve, the "loop" consists of a transmitter that measures the variable to be controlled (usually pressure, flow, level, or temperature) and a controller (nowadays a computer of sorts). Following an error in the variable to be controlled (such an error being sensed by the transmitter), the controller sends a signal change to the control valve which, in turn, responds by altering the flow rate through the valve sufficiently to restore the desired variable (such as pressure, for example).

Control valves have basically three interactive components: (1) a valve body subassembly (either with a reciprocating or rotating stem), (2) an actuating device (usually a spring diaphragm type), (3) a valve positioner (an instrument that converts an electronic control signal from a controller, or computer, into an air signal to control the position of the control valve stem), and (4) an airset or regulator to supply air pressure to the positioner (see Figure A10.34).

HOW TO SPECIFY CONTROL VALVES

The first step in specifying a control valve is to define its function in the given application. In some, it will operate as an on-off valve that opens or closes following the commands of a programmable controller on, say, a batch process. In others, it will be used to remotely set a flow rate in a process—that is, it will be used as a manually controlled variable orifice in a pipe (an open-loop application). Finally, in more sophisticated applications, the control valve will serve as the final control
FIGURE A10.34   Typical globe-style control-valve assembly with various components. *(Courtesy of H.D. Baumann, Inc.).*

element in a process control loop and respond to the sometimes infinitely small variations of a signal coming from a controller (typically a computer). The signal will be generated in response to a deviation in the desired temperature, pressure, or level of a process fluid as measured by a transmitter.

Application Classes

In the first type of application, any on-off valve with a pneumatic or electrical actuator (say, for example, a ball valve) may suffice. The requirements are to provide tight shutoff (perhaps with a Teflon® seat) to withstand the pressure, temperature, and corrosiveness of the fluid, and, finally, to have sufficient flow capacity. No valve positioner is required (see Figure A10.35).

Open-loop control requires a higher level of sophistication, such as a characterized valve plug and good repeatability. The latter calls for a valve/actuator combination with low dead band (low friction). A valve positioner, a device that is essentially a stem position controller with an accuracy between 0.5 and 1.0 percent of stem position, may be required. Controlling the stem position may not always assure that the valve plug or ball moves the required amount unless the stem or shaft is pinned or welded to the ball, vane, or plug (unless fluid pressure assures constant contact). See Figure A10.36.

The modulating control valve that is part of a control loop is the most sophisticated device. Typical features are plug or ball with either linear or equal percentage flow characteristic, low-friction packing and actuating devices, and, if required, low-

FIGURE A10.35   Typical automated ball valve *(Courtesy of XOMOX Corp).*

noise or anticavitation features. These are in addition to the previously stated requirements.

Figure A10.37 shows an eccentric rotary plug valve with a low noise restrictor in the valve outlet port. Part of the pressure drop at moderate to high flow rates occurs across this slotted device. The smaller jets created by the slots produce about 10 to 15 dBA less noise than the valve itself.

Flow control is only possible if the control valve can reduce some of the fluid pressure. Such pressure reduction (also used for valve sizing) typically amounts to 5 to 10 percent of the maximum pump pressure. This makes a streamlined valve trim (highly desirable for on-off valves) actually less desirable for control purposes. It takes much higher velocities with a streamlined trim or valve (hence, more noise or cavitation) to achieve a certain pressure drop than with a nonstreamlined valve.

Signals from controllers to control valves are 3 to 15 psi (0.2 to 1.0 bar) if pneumatic or 4 to 20 mA if electronic. Digital signals will be used in the future once the question of fieldbus standardization has been resolved.

Control Valve Styles.   Let's take a look at the characteristics of some of the most commonly used control valve types:

- *Globe valve*   The globe valve (see Figure A10.34), which is the most widely used type of control valve, has a screwed-on, integrally attached, or cage-supported seat ring, and typically a lathe-turned, single-seated valve plug. Larger valves or
FIGURE A10.36 Section of V-ball showing pinned stem to ball. *(Courtesy of Fisher Controls International, Inc.).*

high-pressure valves may have designs such that the valve plug is cage-guided and pressure-balanced to reduce actuator force requirements. Globe valves are cost effective in sizes NPS 2 (DN 50) and below and are available in sizes as small as NPS ¼ (DN 6) for research applications. End connections are flanged or threaded. High-pressure or high-temperature valves can be welded to the piping. NPS 2 (DN 50) and smaller can be provided with socket-welding or threaded ends. NPS 2½ (DN 65) and larger are generally butt-welded or flanged.

- *Angle valves* Angle valves are a special variety of globe valves typically having an inlet port at a right angle to the valve stem and a discharge port in line with the valve orifice. Typical applications include flashing and erosive fluids.

- *Three-way valves* As the name implies, three-way valves are globe valves (or some rotary valves) that have three access ports and two plugs and orifices opposed to each other. Depending on the flow direction, three-way valves may serve as either mixing valves (where two different fluids enter the valve through two of the ports, and discharge as a mixture through the third), or diverting valves around heat exchangers (for example, where a fluid enters at one port and discharges through either the second or the third port).

- *Eccentric rotary plug valves* Eccentric rotary plug valves are designed especially for modulating control (i.e., they have solid stem connections, low or constant operating torque, a good flow characteristic, and tight shutoff). They feature a
FIGURE A10.37   Eccentric rotary plug valve with low noise restrictor built into the valve outlet port. *(Courtesy of H.D. Baumann Inc.).*

lower weight than globe valves and, therefore, have a cost advantage in sizes NPS 3 (DN 80) and above. They are either flanged or wafer-style for installation between flanges (Figure A10.37).

- *Characterized semispherical ball valves*   The characterized semispherical ball valve is another form of "designed for modulation" rotary control valve with a backlash-free stem connection. Here, the seal is a thin metal or plastic ring that engages a segmented rotating ball. A V-notch in the ball surface gives a good repeatable flow characteristic. This valve type is popular in the paper industry and is available in either flanged or wafer-style (Figure A10.36).

- *Ball valves*   Ball valves have a good shutoff characteristic and high flow capacity. As a result, they are a good choice for on-off or sequencing control. End connections are flanged or wafer-style. Metal-seated ball valves are designed for high temperature applications and can be provided with welded connections. Soft-seated ball valves are used for normal liquid or gaseous fluids up to 482°F (250°C) and where tight shutoff is required (Figure A10.35).

- *Butterfly valves*   Except for some special designs with low-torque and low-noise features, butterfly valves for modulating control have to be selected with care. This is because their high-torque (both seating and dynamic) and high-pressure recovery tend to encourage noise and cavitation. A lower-cost valve choice in sizes NPS 6 (DN 150) and above, butterfly valves are typically wafer-style due to their narrow profile.

Actuators.   More than 90 percent of all control valves use pneumatic actuating devices—either spring-opposed diaphragm types or piston actuated.

The *spring/diaphragm actuator* is by far the most popular due to its simplicity and ability to fail-safe (that is, the spring force will drive the valve either to close [fail-close] or in the open position [fail-open], depending on process safety requirements, should the air pressure be lost).

Piston actuators provide more dynamic stiffness. In addition, because they use higher air pressures, they are more compact than spring-opposed diaphragm actuators. Other forms of actuation are electric or hydraulic. They are used more for special applications and their use is limited due to higher cost and limited reliability.

Materials of Construction.   For noncorrosive use, the material of choice is carbon steel (ASTM A216 Grade WCB, if cast; and A105 when forged). Valve plugs and seat rings are typically ASTM A 351, CF8M (316 stainless steel).

For mild, corrosive applications, valve housings are made from type CF8M (316 stainless steel). However, Teflon®-lined housings and exotic alloys, such as Hastelloy®, monel, or titanium are available for highly corrosive fluids.

For additional information, refer to: Hans D. Baumann, *Control Valve Primer, A User's Guide*, ISA, Research Triangle Park, 1998.

How to Size Control Valves

The flow capacity of control valves is expressed by the coefficient C_v. This is a combination of valve flow area and the valve's headloss coefficient K. It is expressed as

$$C_v = \frac{A \times N_1}{\sqrt{K}} \tag{A10.1}$$

where A is the "vena contracta" area of the valve's orifice, typically 70 percent of the orifice area. C_v is expressed in the flow of U.S. gallons per minute of water when the pressure drop is one psi. N_1 is a numerical constant $= 0.059$ if A is in mm², or 38.1 if A is in inch². For example, if $K = 1$ and $A = 25$ mm², then the $C_v = 25 \times 0.059/\sqrt{1} = 1.475$.

While C_v was initially a liquid flow coefficient, this term can also be used for gases or steam with the proper conversion coefficients as shown below.

We have to distinguish two modes of flow in a control valve which, in turn, governs the use of the correct equation.

1. *Normal Flow*   This occurs when the pressure drop across the valve lies below the following limits:

   For liquids: $\Delta p_{\lim} = F_L{}^2(p_1 - p_v)$ $\qquad$ (A10.2)

   For gases: $\Delta p_{\lim} = F_L{}^2(0.5 \times p_1)$ $\qquad$ (A10.3)

   where $\Delta p_{\lim}$ is the limited pressure drop across the valve (see equations), p_1 is the valve's inlet pressure, and p_v is the vapor pressure of the respective fluid and at the flowing temperature (all pressures absolute).

2. *Choked Flow*   This occurs if the actual pressure drop exceeds $\Delta p_{\lim}$. CAUTION: Such conditions could cause cavitation in valves handling liquids, or high sound levels with gas or steam. Consult your control valve supplier.

FOR LIQUID SERVICE

Normal Flow	**Choked Flow**	**Remarks**
When Δp is less than $F_L^2(\Delta p_s)$, use equations in this column.	When Δp is more than $F_L^2(\Delta p_s)$, use equations in this column.	Δp_s = Maximum Δp for sizing. Use $p_1 - p_v$ when outlet pressure is higher than vapor pressure, or use

$$P_1 - \left(0.96 - 0.28\sqrt{\frac{P_v}{P_c}}\right)P_v \quad \text{(A10.4)}$$

Volumetric Flow

$$C_v = N_2 q \sqrt{\frac{G_f}{\Delta p}} \quad \text{(A10.5)} \qquad C_v = N_2 \frac{q}{F_L}\sqrt{\frac{G_f}{\Delta p_s}} \quad \text{(A10.6)}$$

when outlet pressure is equal to or lower than vapor pressure.

Flow by Weight

$$C_v = N_3 \frac{W}{500\sqrt{G_f \Delta p}} \quad \text{(A10.7)} \qquad C_v = N_3 \frac{W}{500 F_L \sqrt{G_f \Delta p_s}} \quad \text{(A10.8)}$$

where F_L = pressure recovery factor (dimensionless)
  G_f = specific gravity @ flowing temperature (water = 1 @ 16°C)
  $\Delta p = p_1 - p_2$, psia (kPa)
  N_2 = 11.7 if q is in m³/h and p in kPa; N_2 = 1 is q is in gpm and p is in psia.
  N_3 = 5.32 if W is kg/h and p in kPa; N_3 = 1 if W is lb/h and p is in psia.
  P_c = pressure at thermodynamic critical point, water is 3206 psia (21,370 kPa)
  P_v = vapor pressure of liquid at flowing temperature, psia (kPa)
  q = liquid flow rate, m³/h (U.S. gpm)
  W = flow in kg/h (lb/h)

FOR GAS AND STEAM SERVICE

Surprising as it may sound, the basic C_v equation can also be applied to gases and steam. The difference here is that the density of the gas changes with Δp, and, since this is a gradual process, the relationship $\sqrt{\Delta p}$ to flow is no longer linear but curved. However, the following simplified equations give reasonable accuracy.

Normal Flow	**Choked Flow**
When Δp is less than $F_L^2(p_1/2)$, use equations in this column.	When Δp is more than $F_L^2(p_1/2)$, use equations in this column.

Volumetric Flow

$$C_v = \frac{N_4 q}{963}\sqrt{\frac{G_g T}{\Delta p(p_1 + p_2)}} \quad \text{(A10.9)} \qquad C_v = \frac{N_4 q \sqrt{G_g T}}{834 F_L p_1} \quad \text{(A10.10)}$$

Flow by Weight

$$C_v = \frac{N_5 W}{3.22\sqrt{\Delta p(p_1 + p_2)G_g}} \quad \text{(A10.11)} \qquad C_v = \frac{N_5 W}{2.8 F_L p_1 \sqrt{G_g}} \quad \text{(A10.12)}$$

TABLE A10.12 Application Guide for Modulating Control Valves (d = mm)

Valve Type	Pipe size		Relative cost[4]	Typical flow capacities, C_v/d^2		Flow chara.	Max. temp. °C	Min. temp. °C	Max. press. ratings	Special service conditions

3-Way Valve (Globe)	15–150	½–6	1.3	0.016	N	A	200	-30	Class 300	N	N	N	N
Eccentric Rotary Plug Valve	25–300	1–12	0.7	0.021	0.018	G	250	-200	Class 600	N[6]	N	Y	Y[7]
Charac. Segmented Ball Valve	25–300	1–12	0.8	0.04	0.024	G	250	-110	Class 300	N	Y	Y	N
Full Ball Valve	15–600	½–24	0.7	0.05	0.026	A	250	$-268^{(5)}$	Class 2500	N	Y	Y	Y[7]
Butterfly Valve at 70° open	50–900	2–36	0.6	0.04	0.028	A	250	-30	Class 300	N	N	Y	N

Notes:
[1] Low pressure drops are typically less than 20% of the inlet pressure.
[2] High Δp's are defined as those higher than 40% of the inlet pressure. The valve's flow capacity is restricted due to the onset of vaporization of liquids and sonic flow for gases.
[3] Flow to close.
[4] Relative to Globe valve price (DN 150).
[5] With special bonnets.
[6] Except anticavitation trim.
[7] With ceramic trim.
G = good, N = not recommended, A = acceptable, Y = recommended.

Note:
C_v is a standardized (ISA-S75.01) term to denote the flow capacity of a valve expressed in gallons per minute of water at 60°F when the pressure drop (Δp) is 1 psi. Thus, the flow in gpm = $C_v\sqrt{\Delta p/G_f}$ where G_f is the specific gravity (water @ 16°C (60°F) = 1) and d is the valve diameter in mm. For example, a typical DN 150 globe valve will have a C_v of $0.018 \times 150^2 = 405$ at low Δp. **Caution: Do not select a valve size less than half of the pipe diameter.**

For Saturated Steam

$$C_v = \frac{N_5 W}{2.1\sqrt{\Delta p(p_1 + p_2)}} \quad \text{(A10.13)} \quad \bigg| \quad C_v = \frac{N_5 W}{1.83 F_L p_1} \quad \text{(A10.14)}$$

For Superheated Steam

$$C_v = \frac{N_5 W(1 + 0.0007 T_{sh})}{2.1\sqrt{\Delta p(p_1 + p_2)}} \quad \text{(A10.15)} \quad \bigg| \quad C_v = \frac{N_5 W(1 + 0.0007 T_{sh})}{1.83 F_L p_1} \quad \text{(A10.16)}$$

where C_v = valve coefficient
F_L = pressure recovery factor
G_g = gas specific gravity (air = 1.0)
N_4 = 323 if q is in m^3/h, p is in kPa, and T is °K; N_4 = 1 if q is in scfh, p is in psia, and T is in °R.
N_5 = 14.8 if q is in m^3/h, p is in kPa; N_5 = 1 if q is in scfh, and p is in psia
p_1 = upstream pressure, psia (kPa)
p_2 = downstream pressure, psia (kPa)
Δp = pressure drop $p_1 - p_2$, psi (kPa)
q = gas flow rate at 100 kPa and 16°C, m^3/h (scfh)
T = flow temperature [°R = (460 + °F)], (°K = 273 + °C)
T_{sh} = steam superheat, °F (°C)
W = flow rate, pounds per h (kg/h)

Application Guide. Table A10.12 summarizes application guidelines for modulating control valves.

GENERIC DESIGN CONSIDERATIONS

CHAPTER B1
HIERARCHY OF DESIGN DOCUMENTS

Sabin Crocker, Jr., P.E.
Formerly Project Engineer, Bechtel Power Corporation
Gaithersburg, MD

In today's atmosphere of complex projects, extended liabilities, tight cost controls, and strict quality standards, it is essential that all phases of a project, from inception to operation, be effectively communicated and correctly executed. To this end, contract documents, design documents, fabrication details, procedures, and specifications are developed to communicate, monitor, and document the design, fabrication, and erection of piping systems precisely. The number and variety of documents to be prepared for a particular piping system are determined not so much by the importance of the piping system as by the complexity of the system and by the interface requirements of the owner, the design organization, the contractor, the material suppliers, and the regulatory agencies. In the following sections, the documentation requirements of a complex project are illustrated to provide a broad overview of the hierarchy of documents. However, since the specific requirements of a project are driven by many variables, such as the owner's requirements, budgets, market conditions, company practice, and licensing requirements, the discussion here should be considered as a guideline only.

In this chapter all the principal design documents normally prepared for a complex piping system are identified, and their roles in the overall project are described. Note, however, that future developments in engineering tools might dictate variations from the documents described here. With the ongoing development of sophisticated computer software, several related design documents may be developed from one database with the capability to extract information as required. For example, pressure drop and pipe stress analysis calculations may be executed from a physical piping drawings database.

The production and management of design documents may be influenced by outside parties. There are many industry and national standards that provide guidance in the preparation and control of design documents. Conformance to certain international standards is often mandatory. The references listed below contain standards for the preparation and control of design documents. The list is based on current practices in the United States. Where need for clarity exists, the reference is accompanied by a statement of field of applicability. The list is not all-inclusive;

engineers responsible for the preparation of design documents must, from time to time, review the current codes and standards in order to comply with and take advantage of the changes in the industry which are expected to continue as computerized drafting and preparation of text and record keeping improve. Additionally, where unique requirements exist, as in shipbuilding, the system design evolution process is governed by specialized methods. One reference is provided below for ship system design practice.

The military (MIL) and Department of Defense (DOD) standards and specifications referenced below provide a number of generally useful concepts and procedures for producing and maintaining design documents. Not all the information may be directly applicable to the field of interest of this handbook; however, the referenced documents should not be ignored by anyone setting up a system of design document production and control because the information is of fundamental importance to an organized approach to the task.

1. ASME Boiler and Pressure Vessel Code, Section III, NCA-3252: Contents of Design Specifications. (The American Society of Mechanical Engineers, Three Park Avenue, New York, NY 10016–5990, USA.)

2. ANSI/ASME N626.3: Qualifications and Duties of Personnel Engaged in ASME Boiler and Pressure Vessel Code Section III, Division 1 and 2 Certifying Activities. (The American National Standards Institute, 11 West 42nd St., New York, NY 10036.)

3. U.S. Department of Defense Index of Specifications and Standards (DOD ISS). Naval Publication and Form Center ATT: NPODS, 5801 Tabor Avenue, Philadelphia, PA 19120–5099:

   - MIL-STD-481A Configuration Control; Engineering Changes, Deviation and Waivers, Short Form
   - DOD-STD-480A Configuration Control; Engineering Changes, Deviations and Waivers
   - MIL-STD-483A Configuration Management Practices for Systems, Equipment, and Computer Programs
   - DOD-D-1000B Drawing, Engineering and Associated List
   - MIL-D-8501B Drawing, Undimensioned, Reproducibles, Photographic and Contact, Preparation of
   - ANSI Y14.1, to be ordered from ASME unless the requestor is in the Navy

4. ANSI Y14.1, Drawing Sheet Size and Format (For ANSI ''Y,'' use ASME address.)

5. ANSI Y14.2, Line Conventions and Lettering. Drawings prepared under this standard usually are adequate for micrographic reproduction. (For ANSI ''Y,'' use ASME address.)

6. ANSI Y14.5M, Dimensioning and Tolerancing (For ANSI ''Y,'' use ASME address.)

7. ISA-S5.1: Instrument Symbols and Identification. This reference includes a standard for the amount of instrumentation detail that the piping designer would show on the piping and instrumentation diagram. The U.S. Nuclear Regulatory Commission has adopted a fairly current edition; users should verify that subsequent editions remain acceptable for U.S. nuclear work. (Instrument Society of America, 67 Alexander Drive, P.O. Box 12277, Research Triangle Park, NC 27709.)

8. NMA MS102, National Micrographics Association Drafting Guide for Microfilm has been superseded by ANSI Y14.2, Line Conventions and Lettering, and by MS23. Contact the Association for Information and Image Management International, 1100 Wayne Ave., Silver Spring, MD 20910, for current information. Also, government regulations may dictate certain documentation requirements.

9. ISO 9000 Series Standards relating to quality control and quality assurance.

10. Harrington, Roy L., ed., *Marine Engineering,* Society of Naval Architects and Marine Engineers, Pavonia, NJ, 1992; ISBN 0-939773–10–4.

11. For additional standards applicable to piping design see Chap. B3, Piping Layout, in this handbook.

References 1 and 2 cover the ASME Code requirements for the Design Specification and the certifying activities incidental to completion of the manufactured and erected work. References 3–8 have been required for some projects or they have been used as sources of guidance in the physical aspects of design and drafting. Reference 9 provides quality assurance and control requirements, which are being specified increasingly for piping and other equipment, including services. References 10 and 11 contain information on piping design and the design process itself.

In the United States, federal, state, and local laws apply to various piping systems; in other countries, similar laws may prevail. For example, the U.S. Code of Federal Regulations (CFR), Title 10, Part 50 mandates strict requirements for the design, construction, and operation of piping systems in a nuclear production or utilization facility. State and local governments generally invoke the ASME B31, Pressure Piping Code (Section B31.1 for Power Piping; B31.3 for Process Piping; etc.); and the ASME Boiler and Pressure Vessel Code (Section I, Power Boilers; Section II, Materials; etc.). Laws aimed at protecting the environment may also impact the design of some systems. Parts of the International Standards Organization (ISO) requirements, Ref. 9, are often imposed on piping design projects worldwide. Chapter A4 provides additional information on codes and standards in general. Other chapters provide more detailed information as necessary. The designer becomes familiar with the regulations prevailing at the location of the project by independent research and conference with the owner and local authorities.

PROJECT EVOLUTION

The typical project evolution can generally be divided into three principal stages. The first stage comprises inception, assignment of responsibilities, preliminary design, and estimating. The second stage comprises detailed design, procurement, and definitive cost estimating. (Depending on the project schedule, production of hardware, site preparations, and construction may also be initiated at this stage.) The third stage comprises completion of engineering, production of equipment, erection, start-up, and commercial operation of the systems. Although the demarcation between the various stages may vary with the organization performing the work, the concept remains unchanged. The following discussion describes the various documents that are normally prepared in each phase of the project.

For another sequence, see Ref. 10, pages 5–10, where the *design spiral* is discussed. And, see pages 35 and 36 for a discussion of the *computer product model* now finding use in ship design and production practice. The art is evolving rapidly, and future models may offer even better results than those discussed here. For a

detailed discussion of the major effects of computerized methods on the way that piping design is done today, see Chap. B3 of this handbook.

FIRST STAGE

Contract Specifications

Contract specifications are normally prepared under the sponsorship of the owner to define the owner's basic requirements of the piping system(s). The contract specification establishes the applicable codes and standards, the owner's requirements, and the obligations of the parties involved in the project. It is expected that the organization charged with the development of the design will develop all design data (to the satisfaction of the owner) not expressly provided by the owner in the contract specification.

Codes and Standards

Although codes and standards are not prepared by any of the parties involved in a project, they are discussed here because of their importance.

New or retrofit construction of almost every type of facility is usually regulated by a government agency at the federal, state, and/or local level. Regulators establish safety standards for the purpose of protecting workers and the general public. The regulators may directly issue these regulations or they may invoke industry standards by reference. Furthermore, in locales where no laws exist to regulate safety standards, the owner (as advised by the underwriter) may mandate compliance with certain national construction codes or standards. Also, the piping industry regulates the safety of its projects by establishing minimum design requirements. Therefore, prior to proceeding with the design, the design engineer must establish what the regulatory requirements are. For a detailed discussion of codes and standards, refer to Sec. A, Chap. A4 of this handbook.

Because codes and standards have a significant impact on the project, it is paramount that the codes and standard to which the project must conform be established in the early stages of the project, preferably in the contract specification.

Design Criteria

Before the detailed design is begun, it is usually advantageous for the project to prepare a comprehensive set of documents defining the system design criteria. This criterion may be part of overall project design criteria or may be a separate document prepared solely for the piping design. In either case, the design criteria should reiterate the design requirements delineated in the contract specification and should define the applicable codes and standards, environmental conditions, design parameters, and other pertinent design bases that will govern the work. The design criteria can be updated as the design progresses to reflect any change in the design basis.

Calculations

Calculations are documents prepared to support the establishment of flow rates, system pressures, temperatures, pipe and vessel wall thickness, heat transfer rates,

and other design parameters. Calculations are also prepared for the pipe stress and flexibility analysis and pipe support design.

Because calculations form the foundations for the piping system design, their quality is paramount. The documents used for procurement, construction, and licensing must be supported by suitable calculations. Because the design process is an iterative process, it is usual practice to issue calculations at various stages of completeness, based on firmness of the design input. The intended use of the calculation must be commensurate with the reliability of the results. Calculations may be issued as ''preliminary status'' for in-house review, estimating, and bidding. Unless project conditions dictate otherwise, award of contracts, fabrication, and erection should be based only on final calculations derived from firm data. If calculations are not firm, precautions must be taken to minimize the impact of any changes resulting from changes in the calculation results.

System Descriptions

The many organizations engaged in piping system design may vary the format and content of *system descriptions (SDs)* from that described here based on their needs. Systems whose operation may have public safety implications (e.g., nuclear power plant systems and chemical plant systems) may require very detailed system descriptions.

The purpose of the system description is to set forth, specifically in writing, the functions, intent of the design, and major features of the system. Since some systems need mechanical, electrical, and control system discipline inputs, each discipline may prepare its own system description, or alternatively, one document containing all discipline criteria may be prepared. Customarily, the mechanical discipline assumes the lead for preparing system descriptions for piping systems. The four major topics covered in a typical SD are (1) system design bases, (2) operating modes (start-up, normal, shutdown, emergency, or as appropriate), (3) descriptions and performance ratings of major equipment, and (4) control concepts.

The design basis stated in the SD is used to develop the system flow diagram (which shows the features necessary to accomplish the design basis) and the piping and instrumentation diagram (which shows the basic controls, interlocks, pipes, valves, vessels, pumps, and miscellaneous equipment comprising the system). Therefore, the system description is important in the development of the documents used in procurement, manufacturing, fabrication, and erection.

Table B1.1 presents topics to be covered in a system description applicable to fossil fuel and nuclear power plants. Systems for other uses may not require all the topics listed or may require topics not covered in the table. In any event, the SD should include no more and no less than what is required to fulfill the purpose stated above. In this example, no more information is presented than is necessary to obtain the construction and operating permits from the government authorities and to provide direction to the users of the document (designers, engineers, operators, vendors, etc.).

System Flow Diagram

The *system flow diagram (SFD)* serves to illustrate the system description. To realize full benefit from the SFD, it should be issued with the SD. The SFD extends the purpose stated for the system description by schematically showing the operational relationships among the major system components and by stating the design and

    * Applicable if code and/or law prescribes safety design bases. Another area subject to law is the environment; for some systems Environmental Design Bases would have to be identified.
    † Power plant practice names this section Power Generation Design Bases. Other industries use titles appropriate to their conditions.
    ‡ This section is used to track unresolved matters during design development, and it is closed out with ''None'' in the final issue of the system description.

expected process variables for selected modes of operation. Table B1.2 presents a list of topics to be included and excluded from the SFD. Figure B1.1 is a portion of a typical system flow diagram based on the concepts described above.

Piping and Instrumentation Diagram

The *piping and instrument diagram (P&ID)* provides a schematic representation of the piping, process control, and instrumentation which shows the functional relationships among the system components. The P&ID also provides important information needed by the constructor and manufacturer to develop the other construction input documents (the isometric drawings or orthographic physical layout drawings). The P&ID provides direct input to the field for the physical design and installation of field-run piping. For clarity, it is usual practice to use the same general layout of flow paths on the P&ID as used on the system flow diagram.

The P&ID ties together the system description, the system flow diagram, the electric control schematic, and the control logic diagram (beyond the scope of this handbook). It accomplishes this by showing all the piping, equipment, principal instruments, instrument loops, and control interlocks. The P&ID contains a minimum amount of text in the form of notes (the system descriptions minimize the need for text on the P&ID). The first P&ID in the set for the job should contain a legend defining all symbols used; if certain symbols are defined elsewhere, it may be appropriate to only reference their source. The P&IDs are also used by the start-up organizations for preparing flushing, testing, and blowout procedures for the piping system and by the plant operators to operate the system. The correctness and completeness of the SD, SFD, and P&ID drawings are crucial to the success of the start-up program.

TABLE B1.2   Topics Covered: System Flow Diagram*

Flow Diagrams should show the following:
   All major equipment
   Equipment names
   Equipment identification numbers
   Major bypass and recirculation lines
   Control valves
   Valves required to demonstrate routing for all modes
   Pipe sizes if required by office practice
   Interconnections to other systems
   Equipment ratings or capacities

Flow Diagrams should *not* show the following:
   Pipe class
   Pipe line numbers, unless required by office practice
   Minor bypass lines
   Isolation and shutoff valves
   Maintenance vents and drains
   Relief and safety valves, unless they serve in a mode
   Instruments
   Code class information
   Seismic class information

---

* It is impossible to generalize about system flow diagrams. The foregoing ''do and don't'' list is subject to as many variations as there are design agents and vendors of packaged systems. For example, piping system line numbers, code class, seismic class, and other information may be found on a flow diagram intended for presentation to another organization having responsibility for the preparation of piping and instrumentation diagrams and other construction documents. In such instances, that flow diagram and that system description convey most of the information required by others to develop the system, and the rest of the information is defined in the contract or attachments to it.

Table B1.3 presents statements of what is included and what is not included in the P&ID. Figure B1.2 depicts a portion of a typical P&ID that complies with the intent of ISA-S5.1, Instrument Symbols and Identification, and with recent electric utility standard practice.

Piping Physical Sketches and Composite Drawings

Isometric or orthographic piping sketches are made, initially of the large-bore piping and later of the small-bore piping, as determined by project requirements. Portions of other piping systems, and structural, electrical, control, and HVAC information may be included in these sketches (in which case they are called composite drawings). These piping drawings form the basis for the working physical drawings such as the system isometrics. The sketches and composites are not used for construction or manufacture; they represent the precomputer version of the present database in a computer-aided design (CAD) system, or one of its several derivative systems, which can provide the design study more efficiently than manual methods in many instances today. Computer-aided design and drafting (CADD) software packages are available from a number of commercial sources.

FIGURE B1.1 Typical system flow diagram.

TABLE B1.3   Topics Covered: Piping and Instrumentation Diagram

---

The P&ID should show the following:
   Mechanical equipment
   All valves associated with the process piping
   Instruments significant to the process piping, including:
      Process pipes
      Vents and drains
      Special fittings
      Sampling lines
      Permanent start-up and flushing lines
   Specific information as applicable to job:
      Instrument designations
      Equipment names and numbers
      Pipeline identification
      Valve identification
   All size transitions in line:
      Reducers and increasers, swages, etc.
   Direction of flow
   Interfaces for class changes
   Seismic category
   Quality level
   Interconnection references
   Annunciation inputs
   Plant computer inputs
   Vendor and contractor interfaces
   Identification of components and subsystems by others
   Reference to a vendor drawing for details not shown
   Intended physical sequence of equipment:
      Including branch lines, reducers, etc.

The P&ID should *not* show the following unless there is a
   compelling need to do so for clarity. Items identified by an
   asterisk may be shown, if necessary.
   Instrument root valves
   Equipment rating or capacity
   Control relays*
   Manual switches*
   Indicating lights*
   Primary instrument tubing and valves
   Pressure, temperature, and flow data
   Vendor package piping which has no interface with engineering or
      construction*
   Elbows, tees, and similar standard fittings
   Extensive explanatory notes

Remarks: The P&ID for a defined system should be limited to coverage of that system to the maximum practical extent. Other systems that interface with the subject system are shown in phantom if such portions are detailed elsewhere.

Whenever a line is broken off as a matter of drafting convenience, both the break and the continuation are labeled so that one can readily trace the line from both sides of the break. This applies whether the break and continuation are on the same sheet or on different sheets of the drawing.

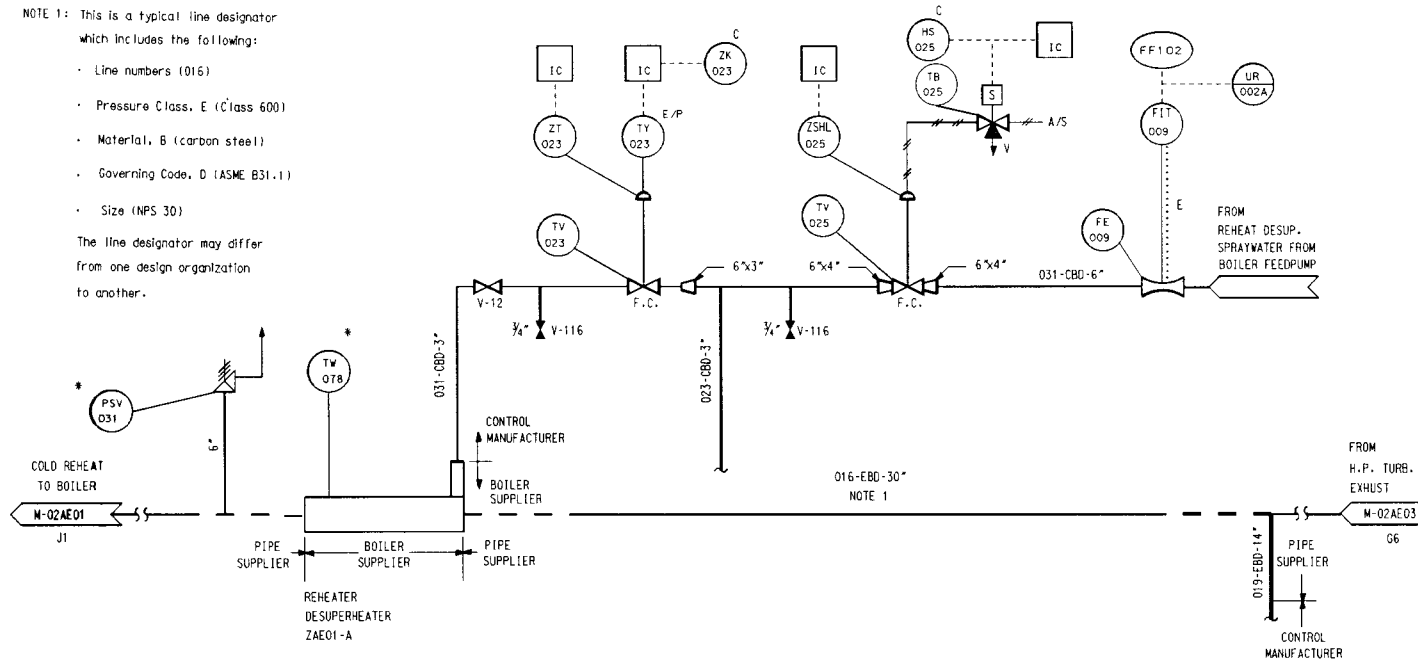
Except for very simple P&ID, the drawing should have the horizontal and vertical borders marked to permit reference to any small area of the drawing, such as by ''Continued at G-7.'' Care should be taken to ensure that these markings are within the sized field of the drawing so that they will always be reproduced with the drawing regardless of the process used.


FIGURE B1.2 Typical system piping and instrumentation diagram.

Composite drawings are used to clarify functional relationships among significant elements of various systems. Figure C10.1 is typical of a composite that might be found in an operating manual or hazards study.

SECOND STAGE

With the completion of the initial draft of the calculations and P&ID, the piping design progresses to the second stage, which consists of the detailed physical design of the piping system, piping stress analysis, and procurement of materials. The types of documents typically issued during this phase are purchase specifications, design specifications, piping erection specifications, piping orthographic drawings, piping isometric drawings, fabrication details, and equipment lists.

Design Specifications

Design specifications are prepared to define the performance requirements for services and materials. The design specifications may be prepared for in-house design work to control the quality of work performed, or the specification may be issued to govern contracted products and services.

For nuclear power plant systems and components required to meet ASME Section III Code requirements, the design specification takes on added importance. A requirement of the ASME Section III Code is that a Design Specification be prepared to provide a complete basis for ASME Section III Division 1 Construction. As a minimum, the ASME Design Specification must define the boundaries of the item covered, the design requirements, environmental conditions, ASME Code Classification, material requirements, operating requirements, effective Edition, Addenda, and Code cases used for construction. Design specifications can stand by themselves, or they can consist of a cover specification incorporating, by reference, all the design documents required to perform the work.

Procurement Specifications

The procurement specification for piping fabrication should define the scope of work, applicable codes and standards, environmental conditions, material requirements, fabrication and examination requirements, testing requirements, and documentation requirements. The specification should reference the applicable design documents (e.g., piping isometric drawings) which govern the work. These documents should be made available to the supplier.

Erection Specification

The specification for piping erection should specify the applicable codes and standards governing the work. The specification should also delineate any fabrication, quality, examination, testing, and documentation requirements imposed beyond those required by the code. Also, all design and fabrication documents should be incorporated into the erection specification.

Physical Design Drawings

General practice among engineering organizations is to prepare orthographic piping drawings. With the development of three-dimensional computer-aided design (3D CAD) software, the designer can check for interference and can generate different views. Once the orthographic drawings are completed, they may be issued for piping fabrication and construction. However, for complex piping systems, it is common practice to develop separate piping isometric drawings for each pipe run. For pipe stress analysis, fabrication, and installation, the piping isometric drawings are easier to use than the orthographic drawings because all the information on the isometric drawing pertains to the piping of interest—the drawing is not cluttered with extraneous information. Also, the isometric drawing is more easily visualized. Figure B1.3 depicts a typical isometric drawing.

Whether the scope of the project dictates that piping spools be shop-fabricated or field-fabricated, isometric drawings are indispensable in relaying the pipe fabrication requirements of the craft.

Stress Analyses

Piping stress analyses is a term applied to calculations which address the static and dynamic loading resulting from the effects of gravity, temperature changes, internal and external pressures, changes in fluid flow rate, seismic activity, fire, and other environmental conditions. Codes and standards establish the minimum scope of stress analyses. Some codes prescribe loading combinations with not-to-exceed stress limits. For specific code requirements, refer to other chapters in this handbook where code requirements relevant to the type of piping system involved are discussed. Chapter B4 of this handbook deals with stress analysis of piping.

Piping Spool Drawings

The piping spool drawing (also referred to as a spool sheet) is the shop detail drawing developed by the pipe fabricator from the piping isometric, or the piping orthographic, for each prefabricated section of piping. Generally, a spool sheet covers only one spool, whether the spool consists of only one fitting or of many piping elements (limited in size only by shipping or handling capabilities). The spool sheet should specify all dimensions, materials, fabrication procedures, examination and testing requirements, and code stamping requirements, as applicable. The spool sheet may also be used to document the performance of the required operations. Figure B1.4 is an illustration of a typical spool sheet.

It is customary for the engineering organization to review the spool sheets to ensure that the fabricator properly interprets the code, specification, and design documents.

Equipment Drawings

The equipment supplier generally submits certified equipment drawings to the engineer. These drawings may be subject to approval by the engineer to ensure that the specification requirements are met. Also, the drawings are used to finalize

the facility design; i.e., the physical and operating characteristics of the actual procured equipment are incorporated into the design.

The supplier document should, as a minimum, contain the following information:

1. Component outline dimensions
2. Location and size of service connections
3. Bill of materials
4. Service requirements
5. Maintenance procedures
6. Instruction manual and list of recommended spare parts
7. Diagrams for piping, logic, electrical wiring, and instrumentation

Pipe Support Drawings

The design and procurement of pipe supports are usually accomplished in one of the following ways. The supports can be preengineered by the engineer, or the design can be contracted to a pipe support manufacturer. In the first case, the engineer prepares a detailed pipe support drawing containing the necessary fabrication details and bill of materials. The pipe support fabricator needs only to fabricate the support in accordance with the drawing. In the second case, the engineer specifies the direction of restraint, the type of support (e.g., variable, constant, rigid), and the support load. The support manufacturer prepares detailed shop fabrication drawings for shop use. The support drawings should contain the same level of detail as described for spool sheets. As with spool sheets, the engineer reviews the pipe support drawings for compliance with the purchase specification.

THIRD STAGE

As the piping system design reaches completion and materials begin to arrive at the job site, the project enters the third stage. It begins with the installation of the piping system.

During installation of the piping system, it is imperative that deviations from the design precipitated by variations in field conditions be controlled and reconciled by engineering. For this purpose, engineers and constructors have developed several vehicles by which deviations are identified and resolved. The following sections describe some of these vehicles. The titles of these documents may vary from organization to organization; however, their purpose remains the same.

Supplier's Deviation Disposition Request

If a supplier cannot furnish material conforming to the purchase specifications, the supplier may request a design change by completing a *Supplier's Deviation Disposition Request (SDDR)* form. The request should identify the existing condition, the reason for the change, the technical justification, and the proposed alternative. Engineering can expeditiously evaluate the condition and prepare a reply on the same form if no review of supplier stress analysis calculations, new laboratory

test results, or any other significant procedure is required. In some cases the SDDR would be resolved after a reiteration of design and testing submittals, and approvals, as for an original design.

Field Change Request

If a contractor cannot install an item as shown on the design documents (or if the contractor identifies an advantageous alternative to the design), the contractor may request a design change by completing a *Field Change Request (FCR)* form. The request should identify the existing condition, the reason for the change, and the proposed alternative. Engineering can expeditiously evaluate the condition and prepare a reply, often on the same form. For an FCR that involves significant technical problems, the closeout might be conditioned on test results, etc., as described for the SDDR.

Nonconformance Report

When an installation does not conform to the design document, a nonconformance report should be generated to document the discrepancy. The report is submitted to the engineer for evaluation and disposition. The engineer determines whether the condition still satisfies the functional requirements of the original design and either approves the FCR or initiates further action. If the deviation cannot be accepted, the engineer will require that the nonconforming item be repaired or replaced to meet the original design requirement.

Start-up Field Report

As each system installation is completed, the contractor turns the system over to the start-up group for system checkout and performance testing. Any deficiencies encountered by start-up are documented on Start-up Field Reports that are submitted to the engineer for resolution. The report should describe the deficiency and should, if possible, offer a recommendation for corrective action.

Conclusion

The careful and timely preparation of design documents is crucial to the economical and successful installation of a piping system. When prepared in the proper sequence, the engineering documents build on the information developed in the foregoing documents, allowing for an organized and methodical development of the project. Thus the number of iterations in the design process is minimized, and schedule and costs are controlled.

For additional information on some of the topics in this chapter, see Chap. B3, App. E9 and the Index under these headings: CAD, computer-aided design, computer-aided drafting, and computer programs.

CHAPTER B2
DESIGN BASES

Joseph H. Casiglia, P.E.
Consulting Engineer—Piping
The Detroit Edison Company
Detroit, Michigan

The design of a piping system is a straightforward process. The technology is extensive and diverse. Piping design requires the application of theory from a number of engineering disciplines, including fluid mechanics, statics, dynamics, strength of materials, and physical metallurgy. It also requires the knowledge and application of a number of codes and standards.

This chapter identifies and explores the various facets of piping design and highlights parameters that must be considered in completing the design process. The design bases discussed here are generic and should be considered during the course of design of any piping system, regardless of its function. In some cases, a number of the parameters discussed may not be applicable; however, they all should be considered when the initial design concept for the system is formulated and developed.

DEFINITION OF THE TERM DESIGN BASES

Design bases are the physical attributes, loading and service conditions, environmental factors, and materials-related factors which must be considered in the detailed design of a piping system, to ensure its pressure integrity over its design life.

Physical Attributes

Physical attributes are those parameters that govern the size, layout, and dimensional limits or proportions of the piping system. Dimensional standards have been established for most piping components such as fittings, flanges, and valves, as well as for the diameter and wall thickness of standard manufactured pipe. Those standards are identified in the section "Use of Codes and Standards in Piping System Design." Certain types of piping systems require special design practices for configuration control, to ensure constructibility, or in-service performance. For example, high-temperature, high-pressure piping systems are usually designed with weld joints spaced a minimum of one pipe diameter apart to facilitate radiographic examination

of the joints. Steam and wet-gas systems are designed to maintain the pipe runs at some minimum pitch to ensure adequate drainage of condensate or other liquids that may separate from the gas stream. Pipelines that are subject to frequent plugging should be designed with adequate clearance, and mechanically joined, to allow for ready disassembly and maintenance.

Loading and Service Conditions

Loading conditions, or *loads,* are forces, moments, pressure changes, temperature changes, thermal gradients, or any other parameters that affect the state of stress of the piping system. Typical examples of loading conditions include internal pressure, piping system deadweight, steady-state or transient temperatures, wind loads, or snow and ice loads. Loads may be external to the piping system, such as environmental temperature changes or wind loads; or they may be internal to the system, such as internal fluid pressure or temperature changes.

Service conditions are combinations of loads or load sets that occur simultaneously, therefore the piping system must be designed to withstand their combined effects. Occasionally, the service conditions will be specified by the piping design code. Examples are found in the American Society of Mechanical Engineers' (ASME) Boiler and Pressure Vessel Code, Section III, *Nuclear Power Plants Components,* Paragraph NCA-2142, where service conditions are defined directly, and the ASME Code for Pressure Piping, ASME B31.1, *Power Piping,* Paragraph 104.8, where service conditions are specified under the topic of analysis of piping components due to the effects of sustained and occasional loads.

Where service conditions are not specified by a particular code, the designer should review the various loading conditions that the piping system is exposed to and formulate the combinations that must be considered in design. Reference to the most commonly used piping design codes listed in the section ''Use of Codes and Standards in Piping System Design'' will provide the designer with guidance in setting appropriate design stress limits.

Environmental Factors

When used within the context of this chapter, the term *environmental factors* refers to operating conditions that result in progressive physical or chemically induced deterioration of the piping system which can ultimately lead to a breach of the pressure boundary or a gross structural failure. Failures that are the result of environmental factors are usually slow to progress and frequently involve localized areas of the piping system. The most common examples of environmental factors include *corrosion, erosion,* and *physical damage.* While corrosion and erosion mechanisms can act independently, a combined reaction known as *erosion/corrosion,* or *flow-assisted corrosion,* frequently occurs in wet-steam and water piping systems constructed of plain-carbon steels.

Materials-Related Considerations

Materials-related considerations are the specific chemical, metallurgical, and physical properties of a piping system's material constituents that can ultimately determine its suitability for a particular service. Proper materials selection can be a crucial

design consideration that will determine the adequacy of performance of a piping system where extremes of temperature, chemical attack, or erosion are significant factors in its operation.

Pressure Integrity

Pressure integrity is the maintenance of a leak-tight condition in piping systems' pressure-containing boundaries coincident with the control of the level of stress or strain within predefined criteria limits. Pressure integrity is not synonymous with leakage integrity; the latter is only an assurance of a leak-tight condition without regard for the state of stress or structural stability of the pressure boundary. Maintenance of the pressure integrity of a piping system, within predefined criteria limits, is a major objective of the design process.

USE OF CODES AND STANDARDS IN PIPING SYSTEM DESIGN

In practice, the assurance that the design and construction of a piping system will meet prescribed pressure-integrity requirements is achieved through the use of published codes and standards. Numerous codes and standards have been formulated and published by major interest groups of the piping and pressure vessel industry. The most widely used codes and standards for piping system design are published by the American Society of Mechanical Engineers. The *American National Standards Institute* (*ANSI*) accredits many of these codes and standards.

Differentiation between Codes and Standards

Codes and standards both provide criteria through which pressure integrity can be ensured and simplified design rules to ensure adherence to the criteria. Many designers and engineers think the terms *code* and *standard* are synonymous, or at least somewhat interchangeable, but this understanding is incorrect.

Codes. Piping *codes* provide specific design criteria such as permissible materials of construction, allowable working stresses, and load sets that must be considered in design. In addition, rules are provided to determine the minimum wall thickness and structural behavior due to the effects of internal pressure, deadweight, seismic loads, live loads, thermal expansion, and other imposed internal or external loads. Piping codes provide design rules for nonstandard components and for the reinforcement of openings in the pipe wall. They do not provide design rules for standard in-line components such as valves, flanges, and standard fittings; rather, they define the design requirements for these classes of components by reference to industry standards.

The use of specific codes for the design and construction of piping systems is frequently mandated by statute or regulations imposed by regulatory and enforcement agencies.

Typically codes are structured around technology or industry user lines. For

example, ASME B31.1, *Power Piping,* covers piping systems in power plants, district heating plants, district distribution piping systems, and general industrial piping systems while ASME B31.3, *Process Piping,* is structured around the chemical, petroleum, and petrochemical industries. Any one of the above-named industrial facilities might have a pipeline with similar service requirements such as a high-pressure steam main, a boiler feedwater line, or a cooling water line. However, the requirements of the specific code, as influenced by the needs and experience of the user industry, will dictate the pipeline's design and construction requirements.

Many piping design and construction codes are listed in the section ''Reference Codes and Standards.'' The systems and subsystems covered by these codes are defined in their scope sections. The scope sections of all potentially applicable codes should be reviewed early in the design phase of a piping project to determine which code, or codes, should be applied to the piping design and construction.

In some cases, multiple codes may be required for the design and construction of the same piping system, depending upon its location. For example, a steam main serving a petrochemical plant from a major utility's district heating system would be designed and constructed to ASME B31.1, up to the petrochemical plant property line. The balance of the piping on the petrochemical plant's property would be designed to ASME B31.3. In the case of a natural gas main serving a utility powerhouse, the outdoor piping is designed and constructed to ASME B31.8 up to and including the meter set, and the in-plant piping is designed and constructed to ASME B31.1. For more details, refer to Chap. A4.

Sometimes, different piping systems within the same building or facility will be designed and constructed to different codes. For example, most of the piping systems in a utility power plant are designed and constructed to ASME B31.l. However, the building heating and air conditioning piping systems are designed and constructed to ASME B31.9, *Building Services Piping.*

Standards.   *Standards* provide specific design criteria and rules for individual components or classes of components such as valves, flanges, and fittings. There are two general types of standards: dimensional and pressure integrity.

Dimensional standards provide configuration control parameters for components. The main purpose of dimensional standards is to ensure that similar components manufactured by different suppliers will be physically interchangeable. Conformity to a particular dimensional standard during the manufacture of a product does not imply that all such similarly configured products will provide equal performance. For example, two different styles of NPS 10 (DN 250) Class 150 flanged-end gate valves could be manufactured, in part, to ASME B16.10, *Face-to-Face and End-to-End Dimensions of Valves.* The valves would be physically interchangeable between mating flanges in a particular piping system. However, because of completely different seat and disk design, one valve might be capable of meeting far more stringent seat leakage criteria than the other.

Pressure-integrity standards provide uniform minimum-performance criteria. Components designed and manufactured to the same standards will function in an equivalent manner. For example, all NPS 10 (DN 250) Class 150 ASTM A105 flanges, which are constructed in accordance with ASME B16.5, *Pipe Flanges and Flanged Fittings,* have a pressure-temperature rating of 230 psig (1590 kPa gage) at 300°F (149°C).

Statute or regulation does not normally mandate standards; rather they are usually invoked by a construction code or purchaser's specification.

The ASME Pressure Classification System

The ASME pressure classification system meets the needs of industry by providing quantitative performance standards for a wide range of piping components, based upon a manageable number of operational variables. This system defines predetermined pressure-temperature ratings that components are designed to meet.

A number of different ASME standards for piping components provide pressure-temperature ratings. The standards in current use in the piping industry are listed in the section "Reference Codes and Standards." In this section the pressure classification system in ASME B16.5, *Pipe Flanges and Flanged Fittings,*[1] will be used for illustration. However, the concepts covered are generally applicable to all the ASME pressure-integrity standards.

Flanges manufactured in accordance with ASME B16.5 are made from materials categorized into 34 material or material alloy groups. There are 8 carbon and low-alloy steel material groups, 10 high-alloy steel material groups, and 16 nonferrous metal groups. Within each of the 34 material groups is a subgroup listing of ASTM materials specifications for forgings, castings, and plates. In addition, acceptable bolting materials and bolting dimensional recommendations are specified. Partial listings of the various material groups, subgroups, and bolting materials are shown in Tables B2.1, B2.2a, and B2.2b. For the complete list, see ASME B16.5.

For any single material group, all flanges made from any material in the group, which carry the same ASME flange pressure class, have the same pressure-temperature rating.

ASME B16.5 provides seven pressure classes for flanges. They are Classes 150, 300, 400, 600, 900, 1500, and 2500. The pressure-temperature ratings for flanges representing all material groups are organized within 34 tables, one for each material group. Table B2.3 is adapted from ASME Standard B16.5 and is typical of the 34 flange rating tables. It provides the pressure-temperature ratings for flanges in material group 1.1. The table is organized with the pressure classes listed across the top and the maximum working temperatures along the left-hand border. The body of the table provides the pressure ratings for flanges from each pressure class, at the given temperature.

In practice, the use of ASME B16.5 to determine a flange rating is quite simple. The procedure is outlined below:

1. Determine the maximum operating pressure and temperature for the required flange.

2. Select a flange material and therefore a material group from one of the 34 listed material groups. Be aware that some of the qualifying notes concerning maximum operating temperatures for various materials may influence the final material selection.

3. Enter the appropriate material group table at the increment of temperature listed which is higher than the desired maximum operating temperature. Start with the Class 150 column and proceed to the right until a pressure rating for the desired temperature is found which equals or exceeds the required operating pressure. The column in which this condition is satisfied dictates the required pressure class and specifies the actual pressure-temperature rating of the flange.

Example B2.1. Assume that an ASTM A105 carbon-steel flange is required to satisfy a pressure rating of 1060 psig (7310 kPa gage) at 650°F (343°C). ASTM A105 is a material group 1.1 material. Entering Table B2.3 at a temperature of 650°F

TABLE B2.3 Pressure-Temperature Ratings for ASME B16.5 Flanges Made from Material Group 1.1 Materials

Class temps., °F	Working pressure by classes, psig†						
	150	300	400	600	900	1500	2500
−20 to 100	285	740	990	1480	2220	3705	6170
200	260	675	900	1350	2025	3375	5625
300	230	655	875	1315	1970	3280	5470
400	200	635	845	1270	1900	3170	5280
500	170	600	800	1200	1795	2995	4990
600	140	550	730	1095	1640	2735	4560
650	125	535	715	1075	1610	2685	4475
700*	110	535	710	1065	1600	2665	4440
750*	95	505	670	1010	1510	2520	4200
800*	80	410	550	825	1235	2060	3430
850*	65	270	355	535	805	1340	2230
900*	50	170	230	345	515	860	1430
950*	35	105	140	205	310	515	860
1000*	20	50	70	105	155	260	430

* For notes concerning the use of carbon-steel materials covered by this table at temperatures over 700°F (371°C), see ASME B16.5, Table 2-1.1.

† To convert pressures to kPa gage, multiply tabular value by 6.9.

Source: Adapted from ASME B16.5, *Pipe Flanges and Flanged Fittings,* American Society of Mechanical Engineers, New York, 1996, Table 2-1.1, p. 15.

(343°C), a Class 600 flange is found to have a rating of 1075 psig (7420 kPa gage) at 650°F (343°C). Therefore, a Class 600 ASTM A105 flange is suitable for the stated conditions.

When using the tables, linear interpolation between listed temperatures and pressures may be employed to determine intermediate pressure ratings.

Reference Codes and Standards

The following listing identifies the codes and standards used for most design work done for modern power and industrial piping systems. It has been prepared as a ready reference.

The ASME Boiler and Pressure Vessel Code.   This Code covers a wide variety of pressure-integrity-related design and construction applications. Certain sections of the Code provide rules for the design of piping systems:

  Section I: *Rules for Construction of Power Boilers*

  Section III: *Rules for Construction of Nuclear Plant Components*

  Section IV: *Rules for Construction of Heating Boilers*

  Section VIII: *Rules for Construction of Pressure Vessels*

The ASME Pressure Piping Codes. These codes are commonly used for the design of commercial power and industrial piping systems:

B31.1, *Power Piping*

B31.2, *Fuel Gas Piping*

B31.3, *Process Piping*

B31.4, *Liquid Transportation Systems for Hydrocarbons, Liquid Petroleum Gas, Anhydrous Ammonia and Alcohols*

B31.5, *Refrigeration Piping*

B31.8, *Gas Transmission and Distribution Piping Systems*

B31.9, *Building Services Piping*

B31.11, *Slurry Transportation Piping Systems*

B31G, *Manual for Determining the Remaining Strength of Corroded Pipelines* ASME Guide for Transmission and Distribution Piping Systems**

The ASME Pressure-Integrity Standards. The standards listed below provide design and manufacturing criteria for many commonly used piping components:

B16.1, *Cast Iron Pipe Flanges and Flanged Fittings*

B16.3, *Malleable Iron Threaded Fittings*

B16.4, *Gray Iron Threaded Fittings*

B16.5, *Pipe Flanges and Flanged Fittings (NPS ½ Through NPS 24)*

B16.9, *Factory Made Wrought Steel Buttwelding Fittings*

B16.11, *Forged Fittings, Socket-Welding and Threaded*

B16.15, *Cast Bronze Threaded Fittings (Class 125 and 250)*

B16.18, *Cast Copper Alloy Solder Joint Pressure Fittings*

B16.22, *Wrought Copper and Copper Alloy Solder Joint Pressure Fittings*

B16.24, *Cast Copper Alloy Pipe Flanges and Flanged Fittings (Class 150, 300, 400, 600, 900, 1500, and 2500)*

B16.26, *Cast Copper Alloy Fittings for Flared Copper Tubes*

B16.28, *Wrought Steel Buttwelding Short Radius Elbows and Returns*

B16.33, *Manually Operated Metallic Gas Valves for Use in Gas Piping Systems up to 125 psig (Sizes ½ Through 2)*

B16.34, *Valves—Flanged, Threaded and Welding End*

B16.36, *Orifice Flanges*

B16.38, *Large Metallic Valves for Gas Distribution (Manually Operated, NPS 2½ to 12, 125 psig Maximum)*

B16.39, *Malleable Iron Threaded Pipe Unions, Classes 150, 250, and 300*

B16.42, *Ductile Iron Pipe Flanges and Flanged Fittings, Classes 150 and 300*

B16.47, *Large Diameter Steel Flanges (NPS 26 Through NPS 60)*

---

* Not an ASME code but listed here for the reader's convenience.

The ASME Dimensional Standards.   Listed below are the most commonly used piping-related dimensional standards:

B1.20.1, *Pipe Threads, General Purpose (Inch)*

B1.20.3, *Dryseal Pipe Threads (Inch)*

B16.10, *Face-to-Face and End-to-End Dimensions of Valves*

B16.20, *Metallic Gaskets for Pipe Flanges—Ring Joint, Spiral Wound, and Jacketed*

B16.21, *Non-Metallic Flat Gaskets for Pipe Flanges*

B16.25, *Buttwelding Ends*

B36.10M, *Welded and Seamless Wrought Steel Pipe*

B36.19M, *Stainless Steel Pipe*

PIPING JOINTS

Joint design and selection can have a major impact on the initial installed cost, the long-range operating and maintenance cost, and the performance of the piping system. Factors that must be considered in the joint selection phase of the project design include material cost, installation labor cost, degree of leakage integrity required, periodic maintenance requirements, and specific performance requirements. In addition, since codes do impose some limitations on joint applications, joint selection must meet the applicable code requirements. In the paragraphs that follow, the above-mentioned considerations will be briefly discussed for a number of common pipe joint configurations. Figures illustrating many common piping system joints are shown in Chap. A2.

Butt-welded Joints

Butt-welding is the most common method of joining piping used in large commercial, institutional, and industrial piping systems. Material costs are low, but labor costs are moderate to high due to the need for specialized welders and fitters. Long-term leakage integrity is extremely good, as is structural and mechanical strength. The interior surface of a butt-welded piping system is smooth and continuous which results in low pressure drop. The system can be assembled with internal weld backing rings to reduce fit-up and welding costs, but backing rings create internal crevices, which can trap corrosion products. In the case of nuclear piping systems, these crevices can cause a concentration of radioactive solids at the joints, which can lead to operating and maintenance problems. Backing rings can also lead to stress concentration effects, which may promote fatigue cracks under vibratory or other cyclic loading conditions. Butt-welded joints made up without backing rings are more expensive to construct, but the absence of interior crevices will effectively minimize ''crud'' buildup and will also enhance the piping system's resistance to fatigue failures. Most butt-welded piping installations are limited to NPS 2½ (DN 65) or larger. There is no practical upper size limit in butt-welded construction. Butt-welding fittings and pipe system accessories are available down to NPS ½ (DN 15). However, economic penalties associated with pipe end preparation and fit-up, and special weld procedure qualifications normally preclude the use of butt-welded

construction in sizes NPS 2 (DN 50) and under, except for those special cases where interior surface smoothness and the elimination of internal crevices are of paramount importance. Smooth external surfaces give butt-welded construction high aesthetic appeal.

Socket-welded Joints

Socket-welded construction is a good choice wherever the benefits of high leakage integrity and great structural strength are important design considerations. Construction costs are somewhat lower than with butt-welded joints due to the lack of exacting fit-up requirements and elimination of special machining for butt weld end preparation. The internal crevices left in socket-welded systems make them less suitable for corrosive or radioactive applications where solids buildup at the joints may cause operating or maintenance problems. Fatigue resistance is lower than that in butt-welded construction due to the use of fillet welds and abrupt fitting geometry, but it is still better than that of most mechanical joining methods. Aesthetic appeal is good.

Brazed and Soldered Joints

Brazing and soldering are most often used to join copper and copper-alloy piping systems, although brazing of steel and aluminum pipe and tubing is possible. Brazing and soldering both involve the addition of molten filler metal to a close-fitting annular joint. The molten metal is drawn into the joint by capillary action and solidifies to fuse the parts together. The parent metal does not melt in brazed or soldered construction. The advantages of these joining methods are high leakage integrity and installation productivity. Brazed and soldered joints can be made up with a minimum of internal deposits. Pipe and tubing used for brazed and soldered construction can be purchased with the interior surfaces cleaned and the ends capped, making this joining method popular for medical gases and high-purity pneumatic control installations.

Soldered joints are normally limited to near-ambient temperature systems and domestic water supply. Brazed joints can be used at moderately elevated temperatures. Most brazed and soldered installations are constructed using light-wall tubing; consequently the mechanical strength of these systems is low.

Threaded or Screwed Joints

Threaded or screwed piping is commonly used in low-cost, noncritical applications such as domestic water, fire protection, and industrial cooling water systems. Installation productivity is moderately high, and specialized installation skill requirements are not extensive. Leakage integrity is good for low-pressure, low-temperature installations where vibration is not encountered. Rapid temperature changes may lead to leaks due to differential thermal expansion between the pipe and fittings. Vibration can result in fatigue failures of screwed pipe joints due to the high stress intensification effects caused by the sharp notches at the base of the threads. Screwed fittings are normally made of cast gray or malleable iron, cast brass or bronze, or forged alloy and carbon steel. Screwed construction is commonly used with galvanized pipe and fittings for domestic water and drainage applications. While certain

types of screwed fittings are available in up to NPS 12 (DN 300), economic considerations normally limit industrial applications to NPS 3 (DN 80). Screwed piping systems are useful where disassembly and reassembly are necessary to accommodate maintenance needs or process changes. Threaded or screwed joints must be used within the limitations imposed by the rules and requirements of the applicable code.

Grooved Joints

The main advantages of the grooved joints are their ease of assembly, which results in low labor cost, and generally good leakage integrity. They allow a moderate amount of axial movement due to thermal expansion, and they can accommodate some axial misalignment. The grooved construction prevents the joint from separating under pressure. Among their disadvantages are the use of an elastomer seal, which limits their high-temperature service, and their lack of resistance to torsional loading. While typical applications involve machining the groove in standard wall pipe, light wall pipe with rolled-in grooves may also be used. Grooved joints are used extensively for fire protection, ambient temperature service water, and low-pressure drainage applications such as floor and equipment drain systems and roof drainage conductors. They are a good choice where the piping system must be disassembled and reassembled frequently for maintenance or process changes.

Flanged Joints

Flanged connections are used extensively in modern piping systems due to their ease of assembly and disassembly; however, they are costly. Contributing to the high cost are the material costs of the flanges themselves and the labor costs for attaching the flanges to the pipe and then bolting the flanges to each other. Flanges are normally attached to the pipe by threading or welding, although in some special cases a flange-type joint known as a *lap joint* may be made by forging and machining the pipe end. Flanged joints are prone to leakage in services that experience rapid temperature fluctuations. These fluctuations cause high-temperature differentials between the flange body and bolting, which eventually causes the bolt stress to relax, allowing the joint to open up. Leakage is also a concern in high-temperature installations where bolt stress relaxation due to creep is experienced. Periodic retorquing of the bolted connections to reestablish the required seating pressure on the gasket face can minimize these problems. Creep-damaged bolts in high-temperature installations must be periodically replaced to reestablish the required gasket seating pressure. Flanged joints are commonly used to join dissimilar materials, e.g., steel pipe to cast-iron valves and in systems that require frequent maintenance disassembly and reassembly. Flanged construction is also used extensively in lined piping systems.

Compression Joints

Compression sleeve-type joints are used to join plain end pipe without special end preparations. These joints require very little installation labor and as such result in an economical overall installation. Advantages include the ability to absorb a limited amount of thermal expansion and angular misalignment and the ability to join dissimilar piping materials, even if their outside diameters are slightly different.

Disadvantages include the use of rubber or other elastomer seals, which limits their high-temperature application, and the need for a separate external thrust-resisting system at all turns and deadends to keep the line from separating under pressure. Compression joints are frequently used for temporary piping systems or systems that must be dismantled frequently for maintenance. When equipped with the proper gaskets and seals, they may be used for piping systems containing air, other gases, water, and oil; in both aboveground and underground service. Small-diameter compression fittings with all-metal sleeves may be used at elevated temperatures and pressures, when permitted by the rules and requirements of the applicable code. They are common in instrument and control tubing installations and other applications where high seal integrity and easy assembly and disassembly are desirable attributes.

LOADING CONDITIONS

In an earlier section, "Definition of the Term *Design Bases*," loading conditions were identified as one of the five principal elements in the definition of the term *design bases*. This section will identify some of the more common loading conditions and discuss the way in which they are considered in design.

Loading conditions may be classified as either sustained or occasional. *Sustained loads* act on the piping system during all or at least the great majority of its operating time. These loads are time-invariant. Examples of sustained loads include the deadweight of the pipe plus its contents or the pressure load, including the effects of static head. *Occasional loads* are transient and act during relatively small percentages of the system's total operation time. Examples of occasional loads include surges due to pump start-up and shutdown or pressure depressions and/or peaks due to sudden valve actuations.

Design Pressure

The *design pressure* is the maximum sustained pressure that a piping system must contain without exceeding its code-defined allowable stress limits. In single-compartment systems the design pressure is the maximum differential pressure between the interior and exterior portions of the system. In multicompartment systems the design pressure is the maximum differential pressure between any two adjacent compartments. The design pressure is the pressure that results in the heaviest piping wall thickness and/or the highest component pressure rating. The design pressure is not to be exceeded during any normal steady-state operating mode of the piping system.

In formulating the design pressure, the designer must consider all potential pressure sources. Among the more common sources to be considered are

- The hydrostatic head due to differences in elevation between the high and low points in the system
- Back-pressure effects
- Friction losses
- The shutoff head of in-line pumps
- Frequently occurring pressure surges
- Variations in control system performance

Variations in System Pressure.   As previously indicated, the system design pressure is the steady-state or sustained maximum pressure. Sustained conditions are those that remain constant over the majority of the total operating time. It is reasonable to expect that short-duration transient system pressure excursions in excess of the steady-state design pressure will occur during normal system operation. These transients, or *occasional pressure* excursions, may be tolerated without increasing the basic system design pressure, provided that the pressure increase does not exceed predefined limits and provided that the amount of time that the transients act does not exceed a specified percentage of the total system operating time.

A number of, but not all, piping design codes provide rules to account for overpressure transients. Among the codes that provide design criteria or guidance are

- The ASME Boiler and Pressure Vessel Code, Section III, *Rules for Construction of Nuclear Power Plant Components*
- Various sections of the ASME Code for Pressure Piping, including

    B31.1, *Power Piping*

    B31.3, *Process Piping*

    B31.4, *Liquid Transportation Systems for Hydrocarbons, Liquid Petroleum Gas, Anhydrous Ammonia and Alcohols*

    B31.11, *Slurry Transportation Piping Systems*

The methods used to qualify overpressure conditions for service vary from code to code. The ASME Code, Section III, uses a rather complex approach in which the range of acceptable overpressure transients is related to the nature of the loading combinations being investigated. The loading combinations are known as *service conditions,* and depending upon their severity and frequency of occurrence, pressure transients of up to 2 times the design pressure may be tolerated. The interested reader is referred to Subsubarticles NB, NC, ND-3600 of Section III for the details. In contrast to the complex methods adopted by Section III, ASME B31.4 and ASME B31.11 allow pressure transients of up to 10 percent over the system design pressure without restricting the amount of time that the transients may act.

ASME B31.1 and ASME B31.3 provide rules that are about midway in relative complexity from the extremes indicated above. As an example, the acceptance criteria for occasional loads specified in Paragraph 102.2.4 of the ASME B31.1 Code for Power Piping are reproduced below:

> **Ratings: Allowance for Variation from Normal Operation**. The maximum internal pressure and temperature allowed shall include considerations for occasional loads and transients of pressure and temperature.
>
> It is recognized that variations in pressure and temperature inevitably occur, and therefore the piping system except as limited by component standards referred to in Para. 102.2.1 or by manufacturers of components referred to in Para. 102.2.2, shall be considered safe for occasional short operating periods at higher than design pressure or temperature. For such variations, either pressure or temperature, or both, may exceed the design values if the computed circumferential pressure stress does not exceed the maximum allowable stress from Appendix A for the coincident temperature by:
>
> **A.**   15% if the event duration occurs less than 10% of any 24 hour operating period;
>
> or
>
> **B.**   20% if the event duration occurs less than 1% of any 24 hour operating period.[2]

Referring to Paragraph 104.1.2 of the ASME B31.1 code, one finds Eq. (4) for the maximum allowable pressure in a straight pipe[3]

$$P = \frac{2SE(t_m - A)}{D_o - 2y(t_m - A)} \tag{B2.1}$$

It can be seen from Eq. (B2.1) that the maximum allowable pressure P varies directly with the allowable stress S. Therefore, the net effect of Paragraph 102.2.4 is to allow short-term pressure excursions of from 15 to 20 percent in excess of the design pressure, as long as the respective time criteria are met.

As indicated above, not all piping codes provide rules for accepting transient pressure excursions in excess of the design pressure. Sections of the ASME Code for Pressure Piping which have no such rules include

- B31.5, *Refrigeration Piping*
- B31.8, *Gas Transmission and Distribution Piping Systems*
- B31.9, *Building Services Piping*

When designing to a code which has no rules for acceptance of overpressure transients, the designer must increase the design pressure to envelop the transient condition. If, however, no specific design code is being used as a basis for design of a project, the designer may make a reasonable engineering judgment concerning the handling of transient overpressure events. In the absence of any other governing criteria, the following may be considered:

> For transient pressure conditions that exceed the design pressure by 10 percent or less and act for no more than 10 percent of the total operating time, the transient may be neglected and the design pressure need not be increased. For transients whose magnitude or duration is greater than 10 percent of the design pressure or operating time, the design pressure should be increased to envelop the transient.

Determination of the Piping Wall Thickness. The determination of the piping wall thickness is one of the most important calculations of the piping system design process. In arriving at the final specification of the piping wall thickness, the designer must consider a number of important factors:

- Pressure integrity
- Allowances for mechanical strength, corrosion, erosion, wear, threading, grooving, or other joining processes
- Manufacturing variations (tolerance) in the wall thickness of commercial pipe
- Wall thickness reduction due to butt-welding of end preparation (counterboring)

While a number of different pipe wall thickness design formulas have been proposed over the years,[4] the ASME piping codes have adopted one or the other of the following formulas for pressure-integrity design:

$$t = \frac{PD}{2(SE + Py)} \qquad \text{(Ref. 5)} \tag{B2.2}$$

or

$$t = \frac{PD}{2SE} \qquad \text{(Ref. 6)} \tag{B2.3}$$

where t = design minimum wall thickness required to ensure pressure integrity, in
P = design pressure, psig
D = outside diameter of pipe, in
S = allowable stress, psi
E = weld joint efficiency factor (some codes also specify a casting quality factor F for cast piping materials)
y = dimensionless factor which varies with temperature

For the precise definition of the method by which either equation is used by the codes, the particular code of interest should be consulted.

Most construction codes require the provision of additional wall thickness, over and above that intended to ensure pressure integrity. This additional material allowance is provided in accordance with Eq. (B2.4):

$$t_m = t + c \qquad \text{(Ref. 7)} \qquad\qquad\qquad \text{(B2.4)}$$

where t_m = minimum wall thickness required to satisfy the design rules of the code, in
t = wall thickness required to provide pressure integrity [see Eqs. (B2.2) and (B2.3)]
c = additional material allowance,† in

The additional material allowance c is made up of a number of individual allowances that are provided to address different loads or conditions the piping system will see during fabrication, installation, and operation. Each allowance is figured separately, and their sum is added to the pressure-integrity wall thickness to arrive at the final design minimum wall thickness. The major constituents of c include

• Wall thickness added to account for progressive deterioration or thinning of the pipe wall in service due to the effects of corrosion, erosion, and wear.

• Wall thickness added to account for material removed to facilitate joining of the various segments of the piping system. Typical joining methods include threading, grooving, and swagging. If a machining tolerance is required as a part of the joint manufacture, this tolerance must be accounted for in the most conservative manner.

• Wall thickness added to provide mechanical strength. This additional strength might be required to resist external operating loads or loads associated with shipping and handling

The effects of pressure result in pipe wall stresses in both the longitudinal and circumferential (*hoop stress*) directions. Typically, the circumferential stress is twice the longitudinal stress. Piping wall thickness selections made using hoop stress-type formulas, such as (B2.2) and (B2.3), result in excess-material availability in the longitudinal direction. In most cases, this excess material is adequate to resist bending stresses associated with the deadweight of the pipe, its contents, and in-line components such as valves, flanges, and piping specialties. In some cases, such as extremely long spans between pipe hangers and piping which is required to support unusually large concentrated loads, it may be necessary to increase the wall thickness to control bending stresses. Refer to Chap. B4.

---

† In some codes, the term A is used in lieu of c, but the intent is the same.

Once the design minimum wall thickness t_m is determined, the only remaining step is to specify the actual or purchase wall thickness.

Pipe is manufactured to one of two wall thickness dimensioning procedures: minimum wall thickness and nominal wall thickness.

Pipe purchased to a minimum wall thickness specification will be manufactured using special processes to control the wall thickness. These processes may include custommade dies, extra rolling passes, or final boring of the inside diameter. Most minimum wall pipe is custom-manufactured. The use of minimum wall pipe is normally limited to high-pressure, high-temperature applications where the savings in material weight is sufficient to offset the additional manufacturing cost.

Pipe purchased to a nominal wall thickness specification is manufactured in accordance with the dimensional criteria specified in ASME Standards B36.10M and B36.19M. These standards provide predetermined nominal wall thicknesses, or *schedules,* for various standard outside diameters of commercially manufactured pipe.

The tolerance on the wall thickness of pipe varies with the particular manufacturing process employed and with the relevant manufacturing specification. Rolled seamless and seam-welded (without filler metal) pipe has a normal wall thickness tolerance of +0, −12½ percent. Forged and bored pipe has a wall thickness tolerance of +⅛ in (3.2 mm), −0. Piping manufactured from rolled and welded plate has a wall thickness tolerance of −0.01 in (0.25 mm). There is no plus tolerance for this type of pipe. The ASTM (or ASME) specification for the particular piping material should be consulted to determine the wall thickness tolerance. Refer to App. E5.

When piping is to be joined by butt-welding, the pipe ends are frequently counterbored to facilitate fit-up. Counterbore dimensions for standard pipe wall thicknesses are given in ASME B16.25. It is important that the net minimum wall thickness resulting from the counterboring process be compared with the code minimum wall thickness t_m to be sure that an under-thickness condition does not occur at the joints.

Example B2.1 demonstrates how the previously discussed concepts associated with the design pressure may be applied to a typical problem.

Example B2.2—Problem Statement. Two motor-driven boiler feed pumps installed on the ground floor of a powerhouse supply 3000 gal/min (11,360 L/min) of water at 350°F (177°C) to a boiler drum which is 260 ft (79.3 m) above the pump discharge. Each pump discharge is NPS 8 (DN 200) pipe, and the common discharge header running up to the boiler drum is NPS 12 (DN 300) pipe. Each pump discharge pipe has a manual valve that can isolate it from the main header. A relief valve is installed upstream of each pump discharge valve to relieve the excess pressure which the pump will develop if the discharge valve is closed while the pump is operating. The normal working pressure at the boiler drum is 2520 psig (17,390 kPa gage). The set pressure of the drum safety valve is 2600 psig (17,940 kPa gage) (MAWP of the drum) and the shutoff head of the pumps is 8700 ft (2652 m). The piping material is ASTM A106, Grade C with an allowable working stress of 17,500 psi (121 MPa) over the temperature range of −20°F (−29°C) to 650°F (343°C). The corrosion allowance is 0.08 in (2.0 mm), and the design code is ASME B31.1. A simplified system diagram is shown in Fig. B2.1.

Find the required nominal pipe wall thickness for the NPS 12 header (DN 300) (zone 1) and the NPS 8 (DN 200) pump discharge lines upstream of the isolation valve (zone 2). Also check the adequacy of the pipe wall thickness in zone 2, assuming the relief valve on one pump does not operate when the associated discharge valve is closed.
FIGURE B2.1   Simplified powerhouse boiler feed system.

Solution.   Note that the piping material used in this example is A106, Grade C. A106, Grade C material has a higher allowable stress than A106, Grade B. The use of Grade C material results in thinner pipe when compared to Grade B. However, A106, Grade B is an acceptable material for this application.

The specific volume of 350°F (177°C) saturated water is 0.01799 ft³/lbm (1.123 cm³/g). Correcting the specific volume for the effects of compression to 2500 psig (17,250 kPa gage) results in a revised specific volume of 0.01778 ft³/lbm (1.109 cm³/g), or a density of 56.24 lb/ft³ (901 kg/m³). The static head P_{st} above the pumps due to the elevation of the boiler drum is

$$P_{st} = 260 \, \text{ft} \times 56.24 \, \frac{\text{lb}}{\text{ft}^3} \times \frac{1 \, \text{ft}^2}{144 \, \text{in}^2}$$

$$= 102 \, \frac{\text{lb}}{\text{in}^2} \, (704 \, \text{kPa gage})$$

Paragraph PG 61.1 of ASME Section I, *Power Boilers,* requires the piping in Zones 1 and 2 be designed for a pressure equal to the highest setting of any safety valve plus 3 percent. In this case the safety valve is set at 2600 psig (17,490 kPa gage). Considering the static head of 102 psi (704 kPa gage) and the 3 percent margin above the set pressure of 2600 psig (17,940 kPa gage), the minimum design pressure for piping is

$$2600 + 0.03(2600) + 102 = 2780 \, \text{psig} \, (19,180 \, \text{kPa gage})$$

ASME B31.1, Paragraph 122.1.3 (A.1), requires the design pressure of the feed-water piping from the boiler, up to and including the required stop valve and check valve, to exceed the maximum allowable working pressure by either 25 percent or 225 psi (1,553 kPa gage), whichever is less. In compliance with this requirement the design pressure for the piping must be greater than $2520 + 225 + 102 = 2847$ psig.

Considering the two code issues discussed above, a design pressure of 2850 psig (19,670 kPa gage) will be used for this piping.

ASME B31.1 uses the approach provided by Eqs. (B2.2) and (B2.4) to yield a combined minimum wall thickness function represented by Eq. (B2.5):

$$t = \frac{PD_o}{2(SE + Py)} \tag{B2.2}$$

$$t_m = t + A \tag{B2.4}$$

$$t_m = \frac{PD_o}{2(SE + Py)} + A \tag{B2.5}$$

The values of the variables are

$$P = 2850\,\text{psig} \ (19{,}670\,\text{kPa gage})$$

$$D_o = 12.75\,\text{in} \ (324\,\text{mm})$$

$$S = 17{,}500\,\text{psi} \ (121\,\text{MPa})$$

$$y = 0.4$$

$$A = 0.08\,\text{in} \ (2.0\,\text{mm})$$

$$E = 1.0$$

Substituting in Eq. (B2.5) yields the following:

$$t_m = \frac{2850(12.75)}{2(17{,}500 + 2850 \times 0.4)} + 0.08$$

$$= 1.055\,\text{in} \ (26.8\,\text{mm})$$

The commercial wall thickness tolerance for seamless rolled pipe is $+0, -12\frac{1}{2}$ percent; therefore, to determine the required nominal wall thickness, t_m must be divided by 0.875:

$$t_{\text{nom}} = \frac{1.055}{0.875} = 1.21\,\text{in} \ (30.7\,\text{mm})$$

Referring to ASME B36.10M, the nearest commercial NPS 12 (DN 300) pipe whose wall thickness exceeds 1.21 in is Schedule 160 with a nominal wall thickness of 1.312 in (33.3 mm). Therefore NPS 12 (DN 300), Schedule 160 pipe meeting the requirements of ASTM A106 Grade C is chosen for this application. Refer to App. E2 and E2M for pipe properties.

This calculation does not consider the effects of bending the pipe during fabrication. If bending during fabrication is planned, the required wall thickness may need

to be increased depending upon the radius of the bend. Refer to the design code for the appropriate bending allowance.

Similarly, the required wall thickness for the NPS 8 (DN 200) pipe upstream of the isolation valves (zone 2) is calculated. The outside diameter of NPS 8 (DN 200) standard pipe is 8.625 in (219 mm). Substituting in Eq. (B2.5) yields:

$$t_m = \frac{2850(8.625)}{2(17,500 + 2850 \times 0.4)} + 0.08$$

$$= 0.739 \, \text{in}$$

$$t_{\text{nom}} = 0.845 \, \text{in} \, (21.5 \, \text{mm})$$

The required nominal wall thickness is 0.845 in (21.5 mm). By referring to ASME B36.10M, or App. E2 or E2M, NPS 8 (DN 200), XXS pipe with a nominal wall thickness of 0.875 in (22.2 mm) is selected.

The only remaining step is to check the pipe in zone 2 to see if the wall thickness is adequate to withstand the pump's shutoff head. It is reasonable to assume that failure of a relief valve to operate is a very low-probability event. The occasional load criteria of ASME B31.1, Paragraph 102.2.4 will be invoked, and it will be assumed that the pump operation at shutoff head due to a failed relief valve occurs less than 1 percent of the time. Therefore, the allowable stress is 20 percent higher than the basic Code allowable stress of 17,500 psi (121 MPa). The higher allowable stress is denoted as S' where

$$S' = 1.20 \times S$$

$$S' = 1.20 \times 17,500 = 21,000 \, \text{psi} \, (145 \, \text{MPa})$$

The maximum pressure rating of the NPS 8 (DN 200), XXS pipe is calculated using Eq. (B2.1):

$$P = \frac{2SE(t_m - A)}{D_o - 2y(t_m - A)} \tag{B2.1}$$

For this evaluation, the value of S is set equal to S', and $E = 1.00$ for seamless pipe; t_m is assumed equal to 87½ percent of the nominal wall thickness of the pipe.

$$t_m = 0.875 \times 0.875 = 0.766 \, \text{in} \, (19.5 \, \text{mm})$$

then

$$P = \frac{2 \times 21,000 \, (0.766 - 0.08)}{8.625 - 2 \times 0.4 \, (0.766 - 0.08)}$$

$$= 3568 \, \text{psig} \, (24,620 \, \text{kPa gage})$$

The shutoff head of the pump was given as 8700 ft. The density of pressurized water at 350°F was previously determined to be 56.24 lb/ft³. The pressure equivalent to the shutoff head may be calculated based upon this density.

$$P = 8700 \, \text{ft} \times 56.24 \frac{\text{lb}}{\text{ft}^3} \times \frac{1 \, \text{ft}^2}{144 \, \text{in}^2}$$

$$= 3398 \, \text{psig} \, (23,450 \, \text{kPa gage})$$

Since the 3568 psig (24,620 kPa gage) occasional pressure rating of the NPS 8 (DN 200), XXS pipe exceeds the 3398 psig (23,450 kPa gage) shutoff head of the pump, the piping is adequate for the intended service.

The design procedures presented in the foregoing problem are valid for steel or other code-approved wrought materials. They are not valid for cast-iron or ductile-iron piping and fittings. For piping design procedures, which are suitable for use with cast iron, or ductile-iron pipe, see ASME B31.1, Paragraph 104.1.2(B).

Design Temperature

The *design temperature* is the temperature at which the allowable stresses for all pressure-retaining parts of the piping system are assigned. The design temperature must be equal to or greater than the maximum sustained temperature that the pressure-retaining components will experience during all normal and expected abnormal modes of operation.

The design temperature of the system's pressure-retaining metal parts is normally assumed equal to the maximum free-stream fluid temperature. The effects of any internal or external heat sources such as heat tracing must be considered, as must any temperature excursions occurring as a result of control system error. The design temperature should be set at or above the peak of these temperature excursions.

While the pressure-integrity design is based upon the design temperature, most other thermally related aspects of the design are based upon the normal operating temperature. The *normal operating temperature* is the temperature achieved by the system fluid while the system is operating in full-load, steady-state, nontransient conditions. It is lower than the design temperature. The normal operating temperature is used as the basis for all thermal design analyses that relate to the structural integrity of the piping system, including the thermal flexibility analysis, the spring hanger sizing and setting calculations, and the thermally induced anchor movement calculations. If a system has more than one "normal" operating mode (i.e., the system runs at different temperatures or has branches that run at different temperatures for different operating modes), then multiple thermal analysis calculations at all normal operating temperatures may be necessary to fully qualify the design.

Deadweight

The *deadweight* (self-weight) of a piping system consists of the sum of the distributed loads from the weight of the pipe itself, its thermal insulation, and/or other uniformly applied covering materials, plus the sum of the weights of any permanently installed concentrated loads such as valves, strainers, or other in-line appurtenances.

External loads on the piping system such as wind loads, snow and ice loads, and the weight of the fluid contents are considered as live loads. They are distinct from deadweight in that live loads may be variable both in magnitude and/or in the percentage of the total system operating time during which they act. An additional distinction is that the effects of live loads may be removed from the piping system while those of deadweight may not (without dismantling the system, of course).

Both the ASME Boiler and Pressure Vessel Code, Section I, *Power Boilers,* and the ASME B31.1 Code, *Power Piping,* require that the effects of deadweight and other sustained loads be considered in verifying the pressure integrity of compo-

nents. Subpart PG-22 of ASME Section I, *Power Boilers,* provides the following generalized rule:

> Stresses due to hydrostatic head shall be taken into account in determining the minimum thickness required unless noted otherwise. Additional stresses imposed by effects other than working pressure or static head, which increase the average stress by more than 10% of the allowable working stress, shall also be taken into account. These effects include the weight of the component and its contents, and the method of support.[8]

ASME B31.1, *Power Piping,* specifies more definitive rules to account for the effects of deadweight. Paragraph 104.8 provides closed-form equations to evaluate the effect of the simultaneous application of the internal pressure, deadweight, and other sustained loads on the design of a piping system. Equation 11 is used to calculate the piping system stress and to compare the calculated stress with code acceptance criteria. Details of this analytical approach are discussed in Chap. B4.

Wind Load

The majority of all piping system installations are indoors where the effects of wind loading can be neglected. However, there are sufficient numbers of outdoor piping installations where wind loading can be a significant design factor. *Wind load*, like deadweight, is a uniformly distributed load that acts along the entire length, or that portion of the piping system that is exposed to the wind. The difference is that while deadweight loads are oriented in the downward vertical direction, wind loads are horizontally oriented and may act in any arbitrary direction. Since wind loads are oriented in the horizontal direction, the regular deadweight support system of hangers and anchors may have little or no ability to resist these loads. Consequently, when wind loading is a factor, a separate structural evaluation and wind load support system design is required.

Determination of the magnitude of the wind loadings is based upon empirical procedures developed for the design of buildings and other outdoor structures. Analysis of piping system stresses and support system loads is accomplished by using techniques that are similar to those applied for deadweight design. Details of these procedures are discussed in Chap. B4.

Snow and Ice Loads

Snow and ice loads, like wind loads, need to be considered in the design of piping systems which are installed outdoors, particularly if the installation is made in the northern latitudes. Since snow and ice loads act in the vertical direction, they are treated the same as deadweight loads. In design, they are simply added as distributed loads in the deadweight analysis, as discussed earlier in the section ''Deadweight'' and in Chap. B4.

Snow Loads. ANSI/ASCE 7–95, *Minimum Design Loads for Buildings and Other Structures,*[9] provides recommendations and data for developing design loadings due to snow. The methods used in this standard are generally applicable to sloping or horizontal flat surfaces such as building roofs or grade slabs. While the methods of ANSI/ASCE 7–95 are completely appropriate for extended flat surfaces, they

may be too conservative for application to a smooth, round, horizontal pipe which will tend to shed most of the snowfall which may land upon it. The data provided in ANSI/ASCE 7–95 can, however, be used as part of a rational method to estimate the maximum probable snow load on an outdoor piping system, and the following procedure may be adopted for piping.

Table B2.4 provides ground snow loading data for 204 locations where those data are measured. The column marked 2% Annual Probability represents the loading associated with the maximum probable snowfall that is likely to occur in a 50-year period. Based upon the data from Table B2.4, the following relationship for the design snow load for outdoor piping systems may be used:

$$W_s = \frac{1}{2} D_o S_{50} \tag{B2.6}$$

where W_s = design snow load to be added to other distributed loads acting on pipe, lb/ft

D_o = outside diameter of pipe or insulation, ft

S_{50} = 2 percent probability snow loading for nearest appropriate location from Table B2.4, lb/ft^2

This formula assumes the snow remaining on the pipe will take the shape of an equilateral triangle whose base equals the outside diameter of the pipe.

Ice Loads. Ice storms are sporadic in the frequency of their occurrence and in their intensity. Weather records dating back to the turn of the 20th century for a typical midwestern state relate instances of ice storm deposits of ⅛ in (3.2 mm) to 4 in (102 mm) in thickness. *The American Weather Book*[10] cites examples of ice accumulations of up to 8 in (203 mm) in northern Idaho (1961) and 6 in (152 mm) in northwest Texas (1940) and New York State (1942).

The paper "Estimated Glaze Ice and Wind Loads at the Earth's Surface for the Contiguous United States"[11] documents the results of a comprehensive study of ice storm records over the 50-winter period from 1919–1920 through 1968–1969. A statistical evaluation of the data indicates that 50-year maximum probable values for ice deposits from a single storm vary over the range of 2 in (51 mm) to 3 in (76 mm), with the larger accumulations occurring in the upper midwest, far west, and northeast and the smaller accumulations occurring in the lower midwest and southeast. Given the relative infrequency of ice storms, this range probably represents a reasonable value for design. It is suggested that the designer contact local weather or agricultural authorities to determine whether any better region-specific data exist.

Once the appropriate design thickness is determined, the following formula may be used to estimate the unit loadings on an exposed pipeline due to ice accumulation:

$$W/L = 1.36t\,(D_o + t) \tag{B2.7}$$

where W/L = unit loading on pipe, lb/ft

D_o = outside diameter of pipe or insulation lagging, in

t = assumed iced covering thickness, in

Table B2.5 provides a tabulation of ice loadings based upon Eq. (B2.7) for piping systems up to 30 in (762 mm) in outside diameter and ice thicknesses up to 3 in (76 mm).

Note: Ice thickness t, in. Loadings are in pounds per foot. To convert loadings to kg/m, multiply tabular loadings by 1.488.

Seismic (Earthquake) Loads

Under certain circumstances it is necessary or desirable to design a piping system to withstand the effects of an earthquake. Although the applications are not extensive, piping system seismic design technology is well developed and readily accessible. Many currently available piping stress analysis computer programs are capable of performing a detailed seismic structural and stress analysis, in addition to the traditional deadweight and thermal flexibility analyses. Most of these programs run on desktop microcomputers.

Because of the higher construction costs and design complexities introduced by the application of seismic design criteria, this type of work is normally done only in response to specific regulatory, code, or contractual requirements. An overview of these applications is outlined in the following paragraphs.

Nuclear Power Plants. Title 10, Part 50, of the Code of Federal Regulations requires that safety-related piping systems* in nuclear power plants be designed to withstand the effects of certain severe natural phenomena, including earthquakes.[12]

In general, seismic analysis of nuclear power plant piping is done to demonstrate that the piping system satisfies one of two specific objectives:

---

* A simplified definition of a safety-related system is one whose failure could result in a reduced capacity to mitigate the effects of an accident or which could ultimately result in the uncontrolled release of radioactivity into the environment. See Refs. 13 and 14.

Operability. Under this objective, the design of the piping system is such that it will retain its pressure-integrity status and remain capable of performing its design function before, during, and after the occurrence of a postulated seismic event at the plant site. Piping systems designed to meet operability criteria must normally comply with code-specified stress limits during the postulated earthquake.

Structural Integrity. Piping designed to this objective is not required to remain functional or to retain its pressure integrity during or after an earthquake. The only requirement is that the piping system retain its gross structural integrity so that it does not deflect excessively or cause the generation of secondary missiles. Either condition could cause impact and subsequent unacceptable damage to adjacent safety-related structures, systems, or components. Piping designed under this classification is normally allowed to attain stress levels, due to seismic excitation, well in excess of normal code limits. Of all modern industrial and commercial applications, nuclear power plant piping systems represent the largest single class of seismically qualified piping systems in service. It is estimated that the typical nuclear power unit contains approximately 100,000 ft of seismically qualified piping.[15] It is safe to say that the nuclear piping industry is the largest single contributor to the technology of seismic design of piping systems.

General Building Codes. Some building codes have rules devoted to the seismic design of buildings and other structures. Two examples of such codes are The Uniform Building Code[16] and The BOCA National Building Code.[17] In addition to these two codes, ANSI/ASCE 7–95, *Minimum Design Loads for Buildings and Other Structures,*[9] provides extensive guidance in the area of seismic design. Note that while both of the above-mentioned codes are intended to be national in scope and applicability, neither is mandatory unless specifically adopted by local statute or ordinance. Both ANSI/ASCE 7–95 and the BOCA code are specifically applicable to all piping systems NPS 2½ (DN 65) and larger in nominal pipe size, with smaller limits of applicability stated for piping systems in boiler rooms [NPS 1¼ (DN 32) and larger] and natural gas piping [NPS 1 (DN25) and larger]. The Uniform Building Code is only applicable to fire protection sprinkler piping systems. Since both the Uniform Building Code and the BOCA code are more specific to the design of buildings and related structures, their application to piping systems requires some interpretation on the part of the designer. It is therefore recommended that the piping designer who intends to apply these codes maintain a close liaison with jurisdictional authorities.

Contractual Arrangements. Under certain specific circumstances, an agreement might be reached to seismically design a piping system; this agreement would be made between the owner-operator of the system and another organization which has a vested financial interest in it, such as an insurance carrier. An example might involve the construction of a pipeline which carries a hazardous fluid through a seismically active region where no statutory design requirement exists. Under such circumstances the insurance carrier might require the owner to seismically design the line to limit the risk of rupture during a seismic event. Should a piping designer become involved in such an arrangement, every effort should be made to ensure that the design criteria are carefully specified, understood, and agreed to by all parties prior to starting design work.

Methods of Analysis. There are three methods of analysis in common use for the seismic design of piping systems: the *static coefficient method,* the *response spectra modal analysis method,* and the *time history analysis method.* The static coefficient

method is the easiest to apply, but due to simplifying assumptions, it provides a very conservative design. The response spectra modal analysis method is about midway in complexity and provides a lesser degree of conservatism. This is the method used for the majority of piping system analysis and design. The time history analysis method is the least conservative and the most difficult to apply. This approach is used only when the most exacting (and least conservative) results are required. All three methods are discussed, in detail, in Chap. B4.

Effects of Seismic Analysis on Overall Design.   The design costs associated with seismic analysis of a piping system go far beyond the simple costs of analyzing the piping system for "just one more load." A piping system is usually a subordinate part of a larger structure, typically a building. Prior to analyzing the piping system to determine its seismic behavior, the analyst must first develop the forcing function. This involves a detailed analysis of the building structure itself to determine its response to the ground motion associated with the postulated earthquake. Development of the postulated ground motion normally requires the consideration of actual earthquake-induced ground motion data taken from geologically similar sites where earthquakes have actually been experienced. It can be seen that the seismic analysis of the piping system is really just the top layer of a multitier design exercise that requires the consideration of the dynamic interaction of a number of complex structures. Such an exercise requires a considerable expenditure of human resources and computer time.

Seismic qualification of a piping system also leads to greatly increased construction costs. Some of the principal contributors to those costs include the following:

Higher Loads.   If the frequency content of the seismic excitation forces is coincident with the natural frequencies of the piping system, resonant amplification of the forcing function loads will occur. The resulting support system loads will be much higher than corresponding loads caused by deadweight effects alone. These higher loads translate to heavier, and consequently more expensive, supporting structures.

Multiple Load Paths.   The multidirectional load characteristics of an earthquake acting on seismically qualified piping systems invariably result in the application of upward and/or lateral reactions on the building structure which would not be present in a typical static design.

Special Supporting Devices.   Seismic design of high-temperature piping systems represents an especially challenging exercise. Thermal expansion effects require that the piping system be flexibly supported to allow for free thermal growth. The dynamic aspects of the design usually require that the piping system be rigidly supported during the earthquake to transfer the seismic loads back into the building structure. The simultaneous consideration of these diametrically opposite requirements results in the need to use a significant number of specialized (and therefore expensive) pipe support devices called *snubbers*. Snubbers lock up and carry load when subjected to the rapidly varying vibratory loads associated with an earthquake, yet remain free to permit thermal movement of the piping system during the relatively slow expansion or contraction caused by temperature changes.

Hydraulic Transient Loads

Of all the loading conditions that a piping system may experience in service, hydraulic transients are among the most damaging. The most common form of damage caused by hydraulic transient loads is the failure of pipe supports and supporting

structures. However, occasional breaches of pressure integrity are also experienced, particularly where large-diameter thin-walled pipe is involved.

Two common types of hydraulic transient loads are waterhammer and relief valve discharge. These two load sets are discussed in detail below.

Waterhammer. If the velocity of water or other liquid flowing in a pipe is suddenly reduced, a pressure wave results which travels up and down the piping system at the speed of sound in the liquid. Depending upon the initial velocity and physical properties of the liquid and the mechanical properties of the piping system, the peak value of the pressure wave may exceed the steady-state pressure.

Waterhammer frequently occurs in systems that are subject to rapid changes in fluid flow rate, including systems with rapidly actuated valves, fast-starting pumps, and check valves. It is most severe in systems which convey fully condensed liquids; however, it is possible to develop waterhammer-type pressure transients in systems containing two-phase fluids and gases, although the magnitude of the pressure rise for these systems will generally be lower. The techniques used to calculate the magnitude of a waterhammer-induced pressure rise are discussed in Chap. B8.

Waterhammer must be considered in the design of those systems where it is likely to occur. For systems designed to codes that provide higher allowable stress criteria for occasional loads, the waterhammer-induced peak pressure should be evaluated under that loading category. For systems designed to codes which do not provide alternative design criteria for occasional loads, the design pressure may be set high enough to envelop the waterhammer-induced peak pressure. The designer is cautioned that this approach can result in an extremely conservative design, which may be prohibitively expensive. Consequently consideration of alternatives may be required.

Relief Valve Discharge Loads. Because of their rapid opening characteristics and generally high flow rates, the actuation of relief valves frequently results in the application of significant loads to the associated piping system. These loads are caused by the differential pressures across the valves, differential pressure between the valve discharge and the downstream discharge piping, and differential pressure between the discharge piping and the receiver or atmosphere. In addition, momentum effects caused by velocity changes at high flow rates result in secondary loads, which act on the attached (or nonattached) piping. These secondary loads must be reacted to by the supporting structures. Actual pipe stress levels in inadequately designed relief valve installations can exceed code-allowable values, and failures of such installations are common. Depending upon the pressure and temperature conditions of the system fluid, such failures can represent a personnel safety hazard as well as a costly economic issue.

To assist the piping designer in developing a safe and functional relief valve installation, Appendix II of ASME B31.1, *Power Piping,* was developed and issued.[18] This nonmandatory appendix to the code provides an extensive treatment of the relevant factors which must be considered to produce a successful design. Relief valve discharge loadings typically occur during a very small percentage of the total system operating time; consequently, they can be treated as occasional loads. The design for load combinations that include these hydraulic transients can therefore be based upon the higher code-defined stress limits.

Acoustically Induced Vibration Loads

When a piping system is exposed to fluctuating pressure disturbances, or pulsations, it frequently responds by vibrating. The magnitude and nature of the piping system

vibration are dependent upon the frequency and energy content of the excitation. Low- to moderate-level periodic excitation, such as the pressure pulsations from positive-displacement or constant-speed centrifugal pumps, will not ordinarily excite significant levels of response in the piping system as long as the excitation frequencies are well removed from the natural vibrating frequencies of the pipe. If the pulsation frequency of the disturbance coincides with the natural frequencies of the piping system, however, resonant vibration can occur. Resonant response normally results in vibratory amplitudes many times that which would occur if the disturbance did not coincide with the natural frequencies of the piping system. Broad-spectrum or random excitation of the type associated with cavitation, bubble collapse, and extreme pressure reductions can also lead to resonant vibration. This type of vibration is known as *self-excited vibration.* The piping system draws energy from the broad-spectrum excitation and responds by vibrating at its own fundamental or harmonic natural frequencies.

Resonant response, whether due to the effects of fixed frequency or random excitation, can lead to unacceptable piping system damage. Cyclical stress reversals associated with resonant vibration can result in short-term fatigue failures, which may occur after only a few hours or days of operation. Reduction in the cyclical stress levels and attendant failures can be accomplished through a number of approaches.

When the excitation is a constant-frequency disturbance, "decoupling" the vibrating piping system from the source of excitation can often be accomplished by changing the frequency of the excitation. If the disturbance comes from a positive-displacement pump, changing the running speed will change the disturbance frequency. If a centrifugal pump is involved, a change in running speed or in the number of vanes on the impeller may have a beneficial effect.

Changing the natural response frequencies of the piping system can also mitigate the effects of fixed-frequency vibration. Again, the objective is to decouple or "detune" the piping system relative to the disturbance. This can often be accomplished by adding supplemental bracing to the pipe or by breaking the system into smaller segments by introducing flexible elements.

When the excitation is broad spectrum or random in nature, detuning by changing the piping system natural frequencies is usually not effective in solving the vibration problem. The modified piping system will continue to draw energy from the broad-spectrum excitation and will vibrate at its new natural frequencies. Mitigation of this class of problems usually requires the reduction of the energy level of the excitation or the "strengthening" of the piping system.

A large number of broad-spectrum vibration problems are the result of high-differential pressure reduction systems.[19] Excitation (noise) reduction for these types of systems can often be accomplished by the use of low-noise cage-type pressure-reducing valves or multiple orifices arranged for staged pressure reduction. In other cases, where the excitation is the result of turbulence, geometric changes to the piping system to smooth out the flow or reduce average and local velocities can have a beneficial effect.

The objective of the strengthening process is the reduction of piping system stresses to a level where fatigue failures are substantially eliminated. Much can be accomplished by the elimination of stress concentrations through the removal of geometric discontinuities. Examples of these discontinuities include hanger lugs, insulation supports, and small pipe (vent, drain, test, etc.) connections. Additionally, where changes in section are required, they should be effected by gradual, smooth changes in contour and generous fillet radii.

Special attention should be paid to all in-line welding done on pipelines that are subject to fluid-induced vibratory loadings. The use of inert-gas root pass welding

with filler metal addition is recommended. This technique reduces the potential for the formation of critical root defects, which can lead to crack initiation and propagation. Radiographic and ultrasonic examinations done in excess of the minimum requirements may prove cost-effective in identifying stress-intensifying volumetric defects. Where such examinations are planned, weld backing rings should not be used since they complicate the job of interpreting the examination results.

Finally, the use of pipe wall thickness in excess of that required for pressure-integrity design alone has been found to be beneficial in mitigating the effects of fluid transient loads.

An experience was encountered which required the replacement of the main turbine bypass piping on a large nuclear unit because of multiple short-term acoustically induced vibration failures. The original system was made up of NPS 30 (DN 750) and NPS 24 (DN 600) × ⅜ in (10-mm) wall pipe. The original design of the piping wall thickness was based upon pressure-integrity considerations alone. Several pressure boundary failures were experienced at pipe support lugs, hanger clamps, and vent and drain connections after only a few hours of operation. The replacement material was NPS 30 (DN 750) × 1-in (25.4-mm) wall and NPS 24 (DN 600) × 1¼-in (31.5-mm) wall. In addition, special attention was paid to the elimination of nonaxisymmetric discontinuities and minor welded attachments. Lugs

BEFORE
AXIAL LOADS RESISTED BY LUGS

AFTER
AXIAL LOADS RESISTED BY RINGS
FIGURE B2.2   Use of shear rings instead of lugs to reduce localized pipe wall stress.

were replaced by rings, as shown in Fig. B2.2, and unnecessary small pipe connections were removed. The upgraded system has been operated extensively without experiencing any further pressure boundary failures.

Since systems subject to flow-induced vibratory loads usually see those loads over much of their service life, their design should be based upon sustained loading criteria with no increase permitted in allowable stress.

Relative Anchor Movements

Every piping system requires some type of support system to function properly. The piping system can be supported from a building or other structure on traditional pipe hangers or from the ground on piers or bents. It even can be supported from another piping system. As long as all the piping system's support points remain motionless relative to the piping system and relative to one another, the system is unaffected. However, if some of the piping system's supports move relative to the

pipe or relative to one another, the piping system will attempt to follow that motion and will experience a change in its state of stress. This condition is called *relative anchor movement.*

Relative movements of a piping system's supports can be caused by a number of phenomena. Some of the more common causes include

- Thermal expansion-related movement of the connection point on a larger piping system, where the subject system is attached
- Earthquake-induced relative movements of the various points on a building's structure where the subject piping system is supported
- Thermal expansion or mechanically induced movements of a piping connection (nozzle) on a machine, pressure vessel, or heat exchanger

The amount of stress, or more properly stated, the change in stress, that a piping system experiences from relative anchor movements is a function of two variables: the magnitude of the anchor movement and the stiffness of the system. As one might expect, larger movements will result in greater changes in stress. Moreover, for a given magnitude of movement, stiffer piping systems will experience greater changes in stress than those that are less stiff. In general, systems that are shorter, have fewer changes in direction, and are made up of larger-diameter pipe are stiffer than those for which the opposite conditions are true.

Certain phenomena result in a loading case in which both the magnitude and direction of the piping system's terminal movements are known, such as movements resulting from the thermal expansion of a pipe. In such a case, the known magnitudes and directions of the anchor movement are input to the piping system stress analysis, and the attendant stress levels are predicted.

There are other cases, however, in which only the magnitude of the anchor movement is known. Examples include earthquake-induced anchor movements or the movements of a building due to wind loading. In this case, the magnitude of the movement is input into analysis as known, but the direction is assumed such that the worst-case change in the state of stress of the piping system under study results. This approach ensures that the piping system stress analysis is conducted in the most conservative manner.

ENVIRONMENTAL FACTORS

The generalized definition of the term *stress,* when used in a structural connotation, is force per unit area. The mathematical equation that relates the stress σ to the load F and the load-resisting area A is

$$\sigma = \frac{F}{A} \tag{B2.8}$$

The loss of a piping system's pressure or structural integrity is invariably the result of its having attained a higher-than-acceptable state of stress. In the preceding section, it was shown that such an increase in the state of stress of a piping system could result from the application of one or more external (or internal) loads. In terms of Eq. (B2.8), it can be said that loading conditions or loads increase the state of stress of the system by increasing the value of the numerator F of the equation. However, there is a second mechanism through which the state of stress

of a piping system may increase, perhaps to the point at which a failure occurs. That mechanism is the loss, or deterioration, of the load-resisting area *A*.

In this chapter the various mechanisms that result in the loss or deterioration of the viable load-resisting base material of a piping system are titled *environmental factors.* An attribute that is common to all environmental factors is that they effectively shorten the useful life of the piping system compared to what it would be if the factors were not present. The following discussion is limited to four specific environmental factors: corrosion, erosion, physical damage, and erosion-corrosion.

Corrosion

Within the context of this chapter, *corrosion* is the loss of load-carrying material in the pipe wall due to an electrochemical reaction between the piping material and the process fluid, or the environment.

Corrosion is normally accounted for in design by the provision of additional material in the pipe wall, the use of a suitable coating or lining, or the specification of a corrosion-resistant material. Frequently, the method used to deal with corrosion depends upon the corrosion rate.

For steel corroding in water, the corrosion rate is strongly influenced by the amount of oxygen present and by the temperature. The effect of these variations
FIGURE B2.3   Effects of oxygen concentration on the corrosion of low-carbon steel in tap water at different temperatures. (*Reprinted by permission from* Corrosion Basics: An Introduction, *National Association of Corrosion Engineers, Houston, 1984, Figure 8.1, p. 149.*)

is shown in Fig. B2.3. Similar data exist in the literature for a wide variety of piping system materials and corrodants. Through the use of these data, the corrosion rate for a given process can often be estimated.

When corrosion is anticipated to occur at a slow, regular rate and this rate can be reliably predicted, it may be accommodated by the provision of excess material in the pipe wall known as the *corrosion allowance.* This excess material will be consumed over the design life of the piping system and therefore cannot be counted upon to serve any other purpose such as pressure integrity, structural strength, or mechanical strength. The relationship of the corrosion allowance to the other components of the total pipe wall thickness was discussed earlier in the section "Design Pressure."

In cases in which the corrosion rate is prohibitively high or would result in

unacceptable contamination of the process fluid, a *pipe lining* or corrosion-resistant piping material may be specified.

Linings tend to be fragile; therefore, their use is limited to applications in which abrasion or other physical injury is not likely to occur. Many linings are temperature-sensitive and cannot be used in extreme-temperature service. Most lined pipe is fabricated from plain-carbon steel, although fiberglass-reinforced plastic pipe with an integral, chemically resistant plastic lining is available. Refer to Chaps. B9–B12 and D2. Joining methods are a significant factor in lined pipe design, and the joints must not allow any corrosion-sensitive material to be exposed to the process stream.

Abrasion or other physical attack may damage a lining and expose the corrosion-sensitive substrate. In such cases, a homogeneous material is frequently warranted. If the original corrosion-resistant surface is physically damaged, the remaining material will continue to resist corrosion. Many corrosion-resistant materials have good high-temperature strength properties and as such are used where linings or plain-carbon steels will not survive. Many near-ambient-temperature, high-corrosion-rate applications can be successfully and economically accommodated by the use of plastic pipe.

Erosion

Erosion is the wearing away of a surface by abrasion. The abrasion may be the result of particles suspended in the fluid stream, or it may be the result of direct action by the fluid itself.

When the erosion rate is small and consistent, and reliable quantitative data concerning that erosion rate are available, an *erosion allowance* may be provided in the design. The erosion allowance is analogous to the corrosion allowance discussed earlier in the sections "Design Pressure" and "Corrosion." Excess material, over and above that required for pressure integrity and structural and mechanical strength, is provided. This excess material is allowed to waste away over the design life of the piping system.

When the erosion process is not readily quantified, a more qualitative approach to design is normally taken. One approach is to specify special erosion-resistant piping system materials. High-hardness materials are generally effective in resisting erosion. An alternative approach is to modify the piping system geometry to mini-mize or eliminate turbulent flow, direct pipe wall impingement, and vortex flow, all of which increase piping system erosion.

Physical Damage

Physical damage or abuse also can be a significant factor in the design of piping systems. This is particularly true of low-pressure, thin-walled piping, which has little resistance to external loadings.

Direct buried pipe is subject to damage from soil pressure and loads from overhead traffic. Uniformly distributed soil pressure loads can normally be estimated with reasonable accuracy and the pipe designed for these loads using methods described in the literature.[20] The effects of heavy concentrated overhead loads cannot be accounted for as easily. Consequently, pipelines which run under heavily trafficked roads or railroad tracks are frequently run through oversized sleeves or conduits which prevent the imposed loads from being directly transmitted to the pipe.

Piping systems of all sizes that carry important services, toxic fluids, or high-pressure, high-temperature fluids should be physically protected from impact from passing motor vehicle traffic, including such vehicles as industrial forklift trucks. The preferred method of protection is to route the piping outside the reach of passing traffic. Where this is not possible, substantial barriers should be erected to protect the piping from impact.

Small-diameter piping takeoffs from large headers such as vents, drains, and instrumentation source connections are particularly prone to damage from unspecified external loads. Common design practice is to make the small piping from the header out to the first isolation valve at least one schedule heavier than called for by the pressure design. Similarly, the first isolation or *root valve* is normally made one or two pressure classes heavier than called for by pressure design considerations. These steps may make the small lines durable enough to resist random impact or other undefined external loadings that can occur during shipping, construction, or operation.

Erosion-Corrosion (Flow-Assisted Corrosion)

When iron or steel corrodes in water, a soluble oxide layer called *magnetite* is formed. During steady-state conditions, the magnetite attains a constant protective thickness which promotes a uniform corrosion rate. If the magnetite layer is "swept" by a water film deposited by wet steam or by a locally high-velocity jet in a liquid stream, the dissolution rate of the magnetite increases. This results in an increase in the localized corrosion rate and an attendant loss of metal from the surface. Since the sweeping away of the oxide layer is an essential part of this corrosion process, it has been named *erosion-corrosion* [also known as *flow-assisted corrosion* (*FAC*)].

A number of factors have been found to affect the rate of erosion-corrosion (FAC) in piping systems. In wet-steam systems, percentage of moisture, material composition, pH and water chemistry, temperature, oxygen level, and flow path geometry have all been found to be significant.[21] In water piping systems, piping material, temperature, pH and oxygen level, and flow path geometry all affect the rate of erosion-corrosion.[22] Among the variables cited above, two that can be readily controlled in design are the piping system materials and the flow path geometry.

Carbon steel is known to be highly susceptible to erosion-corrosion (FAC). Both chromium-molybdenum (Cr-Mo) and austenitic stainless steels are significantly less susceptible. The EPRI publication "Erosion/Corrosion in Nuclear Power Plant Steam Piping: Causes and Inspection Program Guidelines"[21] cites a study that indicates the rate of erosion-corrosion (FAC) in Cr-Mo wet-steam piping is one-tenth that of carbon steel. Low-alloy Cr-Mo materials can usually be substituted for carbon steel without any other significant design changes. The materials are readily welded to each other, and both have similar physical properties such as tensile and yield strength, density, and thermal expansion coefficient.

The substitution of austenitic stainless steels will normally require some additional engineering. These materials have a thermal expansion rate that averages 50 percent greater than that of plain-carbon steel. Accordingly, increases in terminal reactions and predicted pipe support movements can be expected. These may require that the pipe be rerouted or that different pipe support components be provided.

Piping system geometry plays an important role in mitigating the effects of erosion-corrosion (FAC). High, localized velocities, vortex flow, jet, and direct

stream impingement all increase the rate of magnetite dissolution and therefore increase the rate of erosion-corrosion. Gradual transitions in flow section pipe size and geometric changes to smooth out variations in flow velocity and the provision of shallow-angle intersections will all have a beneficial effect. The removal of discontinuities such as weld backing rings and sharp edges at branch connections will also reduce erosion-corrosion (FAC). The areas immediately downstream of valves and flow measurement orifices are frequently prone to erosion-corrosion due to vortex formation. These areas will benefit from the addition of flow liners or the substitution of erosion-corrosion-resistant alloys.

MATERIALS-RELATED CONSIDERATIONS

The variety of piping system materials currently in use is extensive and continually growing. The purpose of this section is to provide a brief overview of the common engineering properties of those materials and to describe how those properties influence the design process. For the most part, discussions of specific material characteristics will be limited to plain-carbon and low-alloy steel piping materials. Many of the concepts discussed, however, are applicable to virtually all piping materials.

Strength

Most piping design codes relate the allowable working stresses for materials to their yield strength or ultimate tensile strength at the working temperature. For example, the *allowable working stresses* for materials used for construction in accordance with ASME B31.1, *Power Piping,* are developed using rules defined in the ASME Boiler and Pressure Vessel Code, Section II, *Materials.* At any temperature below the creep range, those rules require that the allowable working stress be set at a value no greater than the lowest of the following alternatives[23]:

- One-fourth of the specified minimum tensile strength at room temperature
- One-fourth of the tensile strength at operating temperature
- Two-thirds of the specified minimum yield strength at room temperature
- Two-thirds of the yield strength at operating temperature

As the temperature of most common pressure-retaining materials increases from ambient, their tensile and yield strengths decrease. Application of the above rules ensures that the decreasing strength of piping materials, with increasing temperature, is reflected in the allowable stresses used for design.

At temperatures within the creep range, the allowable working stress is set at a value equal to the lowest of the following[23]:

- 100 percent of the average stress for a creep rate of 0.01 percent/1000 h
- 67 percent of the average stress for rupture at the end of 100,000 h
- 80 percent of the minimum stress for rupture at the end of 100,000 h

When carbon steels are exposed to temperatures greater than 775°F (413°C) for long periods, the carbide phase may convert to graphite. *Graphitization* causes

steels to experience brittle fracture at stress levels well below their short-term rupture strength. In recognition of this phenomenon, the ASME B31.1, *Power Piping*, Code provides the following warning statement in the allowable-stress tables:

> Upon prolonged exposure to temperatures above 775°F (413°C), the carbide phase of carbon steel may be converted to graphite.[24]

For temperatures in excess of 775°F (413°C), chromium-molybdenum low-alloy steels or high-alloy stainless steels may be used. These steels offer almost complete freedom from graphitization and enhanced creep-rupture resistance. ASME B31.1 allows the use of these materials at temperatures up to 1200°F (649°C).

Toughness

Toughness, or *ductility*, is the ability of a material to resist impact, to withstand repeated reversals of stress, or to absorb energy when stressed beyond the elastic limit. Steel is normally considered to be a ductile material. Contrary to expectation, however, steels sometimes rupture without prior evidence of distress. Under certain conditions, steel may shatter just as glass. In piping, however, this behavior generally occurs only at low temperatures.

The *transition temperature* for any steel is the temperature above which the steel behaves in a predominantly ductile manner and below which it behaves in a predominantly brittle manner. Steel with a high transition temperature is more likely to behave in a brittle manner during fabrication or in service. It follows that a steel with a low transition temperature is more likely to behave in a ductile manner. Therefore, steels with low transition temperatures are generally preferred for service involving severe stress concentrations, impact loading, low operating temperatures, or a combination of all three.

Table B2.6 indicates the low-temperature limitations of various piping materials.

TABLE B2.6 Low-Temperature Operating Limits for Selected Piping Materials

Low-temp. limit, °F (°C)	Material and suitable ASTM designation	Comments
0 (−18)	Mild steel (A53, A135)	No requirements other than suitable pressure rating
−20 (−29)	Mild steel (A53, A135)	Reduce pressure rating 1% for each 1°F below zero, or Charpy impact test, 15 ft·lb at design temperature
−50 (−46)	Killed or limited carbon steel (A333, Gr. 1)	Charpy impact test, 15 ft·lb at design temperature
−150 (−101)	3½% Ni-steel (A333, Gr. 3)	Charpy impact test, 15 ft·lb at design temperature
−325 (−198)	Austenitic stainless steel (types 304, 316, etc.)	Limited carbon content
No limit	Nonferrous copper, brass, aluminum	Aluminum, copper, brass

Low-alloy steels may be used at low temperatures 0°F (−18°C) when they have a Charpy keyhole impact value of at least 15 ft · lb (2.1 kg · m) at the lowest design temperature. Austenitic stainless steels with limited carbon content, copper and copper alloys, and aluminum do not experience transitions in impact strength from ductile to brittle fracture and, therefore, may be used for low temperatures without pressure-rating penalties.

Low-temperature piping is generally covered with insulation which, in addition to limiting heat transfer, helps provide protection from external impact. This, however, is not sufficient insurance against the type of damage that could result if a pipe should fracture.

Additional perspectives on materials strength and toughness are provided in Chap. A3.

Corrosion Resistance

Considered as a material property, *corrosion resistance* is a measure of a piping system material's relative inertness to chemical attack from a specific process fluid at the system's normal operating temperature, or its environment (see earlier section "Corrosion"). The importance of considering the system's operating temperature cannot be overemphasized. It is well known that many chemical reactions are highly temperature-dependent. A particular piping system material could be virtually immune to chemical attack by a specific corrodant at one temperature, while prone to excessive attack by the same corrodant at a higher temperature.

Within this context, then, it is clear that there is no such thing as a universally corrosion-resistant material. All common piping system materials react with some process fluids (corrodants) at certain temperatures. Therefore, when one is pursuing a "corrosion-resistant" material for a specific application, the objective is to identify a material whose corrosion rate in the presence of a specific corrodant is negligible, or at least acceptable, over the design life of the piping system.

It is important also to consider the effect corrosion may have on the process fluid. Under certain conditions, the dissolution of the base metal or the corrosion products into the process stream may require economic or technical considerations that go beyond the piping system's pressure-containing parts. In some cases, the major consideration in choosing a piping system material may be the preservation of the chemical purity of the process fluid. Such is usually the case in choosing piping system materials that handle food products and piping used in many chemical process operations.

THERMAL INSULATION

Whenever the surface temperature of a piping system differs significantly from that of its surrounding environment, the potential need for an insulation system exists. An insulation system serves three principal purposes:

- The significant reduction in the transfer of thermal (heat) energy to or from the surface of the piping system
- The prevention of moisture formation and collection on the surface of the piping system due to condensation

- The prevention of potentially injurious personnel contact with the surface of the piping system

The reduction in heat transfer to or from the surface of a piping system will minimize the gain or loss in temperature of the process fluid, thus maximizing the capability of the fluid to perform its intended function. Minimizing heat exchange between the piping system and the environment also minimizes the unwanted heating or cooling of the environment. This improves the comfort level for the inhabitants, or improves the operating conditions for equipment.

Most insulating systems used aboveground consist of preformed components that are mechanically attached to the pipe. Low-temperature insulation is frequently made of expanded cellular plastic or foam rubber materials. Moderate-temperature insulations are frequently made from glass-fiber products. High-temperature insulation is usually made of preformed cementations or refractory materials or blankets made from ceramic fibers. Insulation used for buried pipe is frequently in loose granular form, so it can be poured loosely into the trench to surround the pipe and isolate it from the ground environment.

If the surface temperature of a piping system is less than the dew point of the surrounding air, water vapor in the air will condense on the surface of the pipe. This condition can be detrimental. The *condensation* can collect and drip onto surfaces below the pipe, thus doing damage. The condensate can also saturate the piping insulation, thus significantly increasing its thermal conductivity and reducing its insulating capability. To prevent condensation on an insulated pipe, the airborne water vapor must be prevented from reaching the pipe surface. This is normally accomplished by providing a *vapor barrier* at the outer surface of the insulation. An adequate vapor barrier may be constructed from a well-fitted metal jacket, an extruded plastic or rubber coating, or a spiral-wrapped impervious tape coating. Whatever the form, the vapor barrier must prevent the airborne water vapor from entering the pores of the insulation and migrating toward the cool pipe surface, where condensation can occur.

Extremely hot or cold piping systems can pose a contact safety hazard to personnel in the vicinity. Surface temperatures above 135°F (57°C) can cause severe burns to unprotected skin, and temperatures below approximately 20°F (-7°C) can cause freeze damage. Thermal insulation can be designed such that the insulation surface temperature is maintained in a safe range.

Frequently piping systems that are otherwise uninsulated will have insulation installed in accessible areas to provide personnel protection.

For a complete treatment of the engineering principles involved in designing a thermal insulation system for piping, see Chap. B7.

SIZING OF A PIPING SYSTEM

The term *sizing of a piping system* refers to the completion of two independent design functions: the fluid flow design and the pressure-integrity design. The purpose of the fluid flow design is to determine the minimum acceptable inside diameter of the various segments of the piping system. The purpose of the pressure-integrity design is to determine the minimum acceptable pipe wall thickness and the pressure ratings of the in-line components.

System Fluid Flow Design

The objective of the fluid flow design is to determine the minimum acceptable inside diameter of each segment of the piping system that will accommodate the design flow rate while maintaining the pressure drop and flow velocity within reasonable limits.

Most piping systems use pumps to develop the pressure or head required to maintain the system design flow rates. Piping system pressure drops must be maintained within reasonable values to limit the installed size of the system pumps and their prime movers. Pump and prime-mover size limitations are necessary to control initial system construction costs and continuing system operating costs. The optimum pipe size is based on an economic tradeoff between the installed capital cost of the piping system and the sum of the capital plus lifetime operating costs of the pumping system.

System flow velocities are limited by design to avoid a number of potential operating problems. These problems have already been discussed in previous sections of this chapter. In the absence of any other formal or more limiting criteria,

TABLE B2.7 Reasonable Design Velocities for Water Flowing through Pipes

Service condition	Reasonable velocity, ft/s (m/s)
Boiler feed	8–15 (2.5–4.6)
Pump suction and drain lines	4– 7 (1.2–2.1)
General service	4–10 (1.2–3.0)
City water	to 7 (to 2.1)

Source: Crane Technical Paper 410, *Flow of Fluids through Valves, Fittings, and Pipe.* The Crane Company, New York, 1985, pp. 3–6.

the flow velocities given for water in Table B2.7 and for steam in Table B2.8 are considered reasonable for normal industrial applications.

The detailed fluid flow design of a piping system requires the consideration of a number of fluid parameters including flow rate, viscosity, density, and pipe wall frictional drag. Further discussions of this aspect of the pipe sizing process are provided in Chap. B8.

TABLE B2.8 Reasonable Design Velocities for Steam Flowing through Pipes

Condition of steam	Pressure P [psig (kPa)]	Service	Reasonable velocity V	
			ft/min	m/s
Saturated	0–25 (173)	Heating (short lines)	4,000– 6,000	20– 31
Saturated	25 (173) and up	Powerhouse equipment, process piping, etc.	6,000–10,000	31– 51
Superheated	200 (1380) and up	Boiler and turbine leads, etc.	7,000–20,000	36–100

Pressure-Integrity Design

The pressure-integrity design of a piping system normally requires the consideration of at least two issues. The first is the determination of the minimum or nominal pipe wall thickness, and the second is the determination of the pressure rating of the in-line components, such as fittings and valves.

Determination of Pipe Wall Thickness

After the fluid design is complete and the minimum inside diameters of the various segments of the piping system are determined, the piping pressure-integrity design may proceed. The major steps in the process are as follows:

1. Using the minimum inside diameter determined from the fluid flow evaluation, select the next-larger standard nominal or outside diameter (OD) size pipe from the listings provided in ASME B36.10M for standard wrought steel pipe or B36.19M for stainless-steel pipe (see earlier section ''The ASME Pressure Classification System'').
2. Based upon the fluid and service, select a suitable piping material, and if necessary, determine the required corrosion, erosion, joining, or mechanical strength allowances.
3. Using equations provided in the design code, calculate the required minimum wall thickness to provide for pressure integrity and allowances.
4. Refer to ASME B36.10M or B36.19M to select an appropriate nominal wall thickness or schedule. Refer to App. E2 and E2M.
5. Confirm that the standard manufacturing tolerance will not reduce the nominal wall thickness selected in step 4 below the minimum required, as calculated in step 3.
6. Confirm that the inside diameter of the pipe selected, based upon the nominal wall thickness selection of step 4, is compatible with the minimum inside-diameter requirements obtained from the fluid flow evaluation.

The process described above is demonstrated in the following example:

Example B2.3. A carbon-steel pipe having a required minimum inside diameter of 11.2 in (284 mm) is to transport water at 700 psig (4830 kPa gage) and 90°F (32°C). The design code is ASME B31.1, and the design life is 8 years. The water has a nominal oxygen content of 1 ppm. Butt-welded construction is used.

   Evaluation. An economical grade of seam-welded carbon-steel pipe (ASTM A53 Grade A) is selected. From ASME B31.1, Appendix A, Table A-1, the allowable working stress at 90°F (32°C) is 10,200 psi (70.4 MPa). From Fig. B2.3, the corrosion rate is estimated at 0.02 in (0.5 mm) per year. The pressure-integrity design will be based upon ASME B31.1, Paragraph 104.1.2, equation (3)[25]:

$$t_m = \frac{PD_o}{2(SE + Py)} + A \qquad (B2.5)$$

From ASME B36.10M, NPS 12 (DN 300) [12.75-in (324-mm) OD] is tentatively selected.

Using the stated 8-year design life and 0.02 in/yr corrosion rate, the total corrosion allowance of $8 \times 0.02 = 0.16$ in (4 mm) is calculated. Butt-welded construction is specified; therefore, no additional wall thickness allowance for joining (threading, grooving, etc.) is required.

From ASME B31.1, Table 104.1.2(A), $y = 0.4$ is selected for ferritic steels at temperatures at or below 900°F (482°C).

Equation (B2.5) may now be used to calculate the required minimum wall thickness:

$$t_m = \frac{PD_o}{2(SE + Py)} + A \qquad\qquad \text{(B2.5)}$$

$$= \frac{700 \times 12.75}{2(10,200 + 0.4 \times 700)} + 0.16$$

$$= 0.586 \text{ in } (14.9 \text{ mm})$$

From ASME B36.10M, under the listings for NPS 12 (DN 300), Schedule 80 pipe with a nominal wall thickness of 0.688 in (17.5 mm) is tentatively selected.

The wall thickness tolerance for ASTM A53 pipe, which is $+0$, $-12\frac{1}{2}$ percent, is checked next:

$$0.688 \times 0.875 = 0.602 \text{ in}$$

$$0.602 \text{ in } (15.3 \text{ mm}) > 0.586 \text{ in } (14.9 \text{ mm})$$

Finally, the nominal inside diameter is checked against the minimum flow diameter:

$$12.75 - 2(0.688) = 11.374 \text{ in}$$

$$11.374 \text{ in } (289 \text{ mm}) > 11.2 \text{ in } (284 \text{ mm})$$

The problem requirements are satisfied; NPS 12 (DN 300) seam welded Schedule 80 pipe meeting ASTM Specification A53 Grade A is acceptable.

The previous example did not consider the effects of bending on the pipe wall. In most instances the pressure design will dominate in the determination of pipe wall thickness. However, if the pipe span between supports is unusually long or if the pipe has a very heavy in-line component, such as a valve, then the longitudinal bending stress may dominate the design. This facet of the design is considered in the piping stress analysis discussion of Chap. B4.

To complete this chapter, five more example problems are presented. They demonstrate the concepts developed and bring them together to show how the design of a simple piping system might proceed.

Determining the Pressure Class for In-Line Components

The first two examples provided here demonstrate the process used to determine the pressure classification for in-line components. The first demonstrates the selection process for a standard flange; the second demonstrates the selection process for a special-class valve.

Example B2.4. An NPS 16 (DN 400) carbon-steel pipeline operates at 840 psig (5800 kPa gage) and 740°F (393°C). Select a standard weld-neck flange for the service.

Evaluation. Table B2.1 lists various materials of construction for standard pipe flanges. Under Material Group 1.1, ASTM Specification A105, *Forgings, Carbon Steel, for Piping Components*, is listed. Next refer to Table B2.3, which lists ASME pressure-temperature ratings for Material Group 1.1 flanges. Noted that a Class 600 flange has a pressure-temperature rating of 1010 psig (6970 kPa gage) at 750°F (399°C). Since this rating exceeds the requirements of 840 psig (5800 kPa gage) at 740°F (393°C), this flange is acceptable.

Example B2.5. An NPS 12 (DN 300) butt-welding end gate valve is required to operate at 2350 psig (16,220 kPa gage) and 1015°F (546°C). The valve material is ASTM A217 Grade WC9. Determine the appropriate ASME pressure classification.

Evaluation. Tables B2.9a and B2.9b list the pressure-temperature ratings for standard and special class valves of ASTM A217 Grade WC9.

There are two correct answers to this problem. The first and simplest answer is to select a standard Class 4500 valve from Table B2.9a. This valve has a pressure-temperature rating of 2625 psig (18,040 kPa gage) at 1050°F (566°C) and obviously meets the stated requirements. However, this valve may prove to be a very expensive alternative since Class 4500 valves are massively constructed, and valve prices vary according to the weight of the material used in their construction.

The second alternative is to consider the Special Class 2500 valves whose ratings are provided in Table B2.9b. *Special-class valves* undergo mandatory nondestructive examinations and, if necessary, defect repairs to allow them to qualify for higher pressure-temperature ratings. For a more detailed discussion of special-class valves, the reader is referred to Section 8 of ASME B16.34.[26] To determine whether a Special Class 2500 valve will meet the requirements of Example B2.3, a linear interpolation of the ratings in Table B2.9b is required. The process is illustrated below:

Temperature, °F	Pressure, psig
1000	2715
1015	P
1050	1820

$$\frac{1050 - 1015}{1050 - 1000} = \frac{P - 1870}{2715 - 1870}$$

$$\frac{35}{50} = \frac{P - 1870}{845}$$

$$P = 1870 + \frac{35}{50} \times 845$$

$$= 2462 \text{ psig } (16,990 \text{ kPa gage})$$

Since the interpolated pressure rating of 2462 psig (16,990 kPa gage) is greater than the specified requirement of 2350 psig (16,220 kPa gage), a Special Class 2500 valve will satisfy the requirements of Example B2.5.

Determining the Design Conditions and Pressure Class of a Piping System

To minimize procurement complications and storage and handling problems during the construction phase, piping systems are frequently designed for the maximum

TABLE B2.9a Pressure-Temperature Ratings for Standard Class Valves Made of ASTM A217 Grade WC9 Body Material*

Temperature (°F)	Working pressure by classes (psig)†							
	150	300	400	600	900	1500	2500	4500

conditions permitted for each pressure class. This allows conservatism, which can accommodate changes in design conditions as a result of design development and minimizes the need to specify and buy different piping for each individual application. In addition, this approach provides an added allowance in the event of unexpected deterioration of the pipe wall thickness in service.

The following examples provide an illustration of determining the design pressure and design temperature for a piping system. They also provide insight into the method of establishing the pressure-temperature rating or pressure class of an entire piping system.

Example B2.6

Fluid:	Water
Normal conditions:	350 psig (2415 kPa gage) @ 350°F (177°C)
Maximum conditions:	(1) 375 psig (2588 kPa gage) @ 390°F (199°C)
	(2) 435 psig (3002 kPa gage) @ 375°F (191°C)

TABLE B2.9b Pressure-Temperature Ratings for Special Class Valves Made of ASTM A217 Grade WC9 Body Material*

Temperature (°F)	Working pressure by classes (psig)†

* For special limitations placed on the materials covered by this table, see ASME B16.34, Table 2-10B.
† To convert working pressures to kPa gage, multiply tabular values by 6.9.
Source: Adapted from ASME B16.34, *Valves—Flanged, Threaded, and Welding End,* American Society of Mechanical Engineers, New York, 1996, Table 2-1.10B, p. 46.

Condition 1 has a maximum duration of 3 h. Condition 2 has a maximum duration of 10 min in any 24-h operating period.

Pipe sizes: NPS 6 (DN 150), NPS 10 (DN 250), NPS 14 (DN 350)

Evaluation.   The piping system being considered is designed in accordance with ASME B31.1; however, the approach discussed below can be used to design a piping system in accordance with other codes.

The fluid and the temperature dictate the use of carbon-steel piping. Assume the following materials:

Pipe: ASTM A106 GR B

Valve body: ASTM A216, WCB

Flanges: ASTM A105

Determine the pressure-temperature ratings for all conditions. The ratings are determined from the pressure-temperature tables of ASME B16.5[1] and ASME

B16.34.[26] The flange and valve materials are in material group 1.1; refer to ASME B16.5, Table 2-1.1, and ASME, B16.34, Table 2-1.1.

350 psig (2415 kPa gage) @ 350°F (177°C)—Class 300

375 psig (2588 kPa gage) @ 390°F (199°C)—Class 300

435 psig (3002 kPa gage) @ 375°F (191°C)—Class 300

Since Class 300 is required for each condition, the design conditions should be selected so as not to exceed the pressure-temperature ratings of Class 300. Otherwise, the design conditions will be overly conservative.

Determine design conditions from normal and maximum conditions. The design conditions are selected to ensure that the minimum wall thickness requirements of ASME B31.1 are met. This requires consideration of two factors: pressure and temperature.

Pressure.   The greater the pressure, the greater the required wall thickness of the pipe. The design pressure must be selected so that each of the following requirements is satisfied:

• The design pressure shall be not less than the maximum sustained operating pressure (MSOP) within the piping system including the effects of static head (ASME B31.1, Paragraph 101.2.2).

• The design pressure shall be of sufficient magnitude that the stress resulting from a variation in pressure and/or temperature in the piping system does not exceed the allowable stress by more than 15 percent during 10 percent of any 24-h operating period, or by more than 20 percent during 1 percent of any 24-h operating period (see ASME B31.1, Paragraph 102.2.4).

Maximum condition 1 will cause a stress in the pipe wall which is less than 15 percent over the stress caused by the normal condition pressure

$$\frac{375}{350} < 1.15$$

But the duration exceeds 10 percent of a 24-h operating period. Therefore, maximum condition 1 must be considered as a sustained condition, which requires that the design pressure not be less than 375 maximum condition. Condition 2 has a duration of less than 1 percent of a 24-h operating period and will not cause a stress greater than 20 percent over the allowable stress using a design pressure of 375 psig.

$$\frac{435}{375} < 1.2$$

Therefore, maximum condition 2 can be treated as an occasional condition.

The minimum acceptable design conditions are

$$\text{Design pressure} = 375 \text{ psig } (2588 \text{ kPa gage})$$

$$\text{Design temperature} = 390°\text{F } (199°\text{C})$$

Example B2.7

Fluid:	Steam
Normal conditions:	400 psig (2760 kPa gage) @ 600°F (316°C)
Maximum conditions:	575 psig (3970 kPa gage) @ 600°F (316°C)

This condition occurs in less than 1 percent of any 24-h operating period.

Pipe sizes: NPS 12 (DN 300), NPS 18 (DN 450)

Evaluation.   The fluid and the temperatures allow the use of carbon steel. Assume the following materials:

Pipe: ASTM A106, Gr. B
Valve body: ASTM A216 WCB
Flanges: ASTM A105

Determine the pressure-temperature ratings. With the help of ASME B16.5, Table 2-1.1, and ASME B16.34,[26] Table 2-1.1, the suitable classes for the normal and maximum conditions are established as follows:

400 psig (2760 kPa gage) @ 600°F (316°C)—Class 300
575 psig (3970 kPa gage) @ 600°F (316°C)—Class 400

The normal condition requires Class 300 flanges and valves while the maximum condition requires Class 400 flanges and valves. The maximum permissible (sustained) pressure for Class 300 at 600°F (316°C) is 550 psig (3,800 kPa gage). This pressure may be exceeded in the same manner as discussed in Example B2.4 (15 percent for 10 percent of the time; 20 percent for 1 percent of the time). Thus, the peak pressure that the flanges and valves may be exposed to is greater than the system maximum of 575 psig (3,970 kPa gage). Therefore, Class 300 can be used.

Determine the design conditions such that 575 psig exceeds the design pressure by not more than 20 percent.

$$\text{Design pressure} \times 1.2 = 575 \, \text{psig} \, (3970 \, \text{kPa gage})$$

$$\text{Design pressure} = \frac{575}{1.2} = 479 \, \text{psig} \, (3310 \, \text{kPa gage})$$

The minimum design conditions are

$$\text{Design pressure} = 479 \, \text{psig} \, (3310 \, \text{kPa gage})$$

$$\text{Design temperature} = 600°F \, (316°C)$$

This piping can also be designed for the maximum design condition permitted for Class 300 flanges made from material group 1.1 per ASME B16.5. The maximum design conditions, per B16.5, Table 2-1.1, are

$$\text{Design pressure} = 550 \, \text{psig} \, (3800 \, \text{kPa gage})$$

$$\text{Design temperature} = 600°F \, (316°C)$$

The piping may also be designed for the minimum design conditions shown above (479 psig at 600°F). Sometimes this can result in substantial savings in material, fabrication, and installation costs. This is particularly true for high-pressure and high-temperature applications that require the use of low- and high-alloy steels.

Design of Piping for Internal and External Pressure

Example B2.8.   An NPS 24 (DN 600) seamless steel pipeline carries purified water from an onshore water treatment plant to an offshore island-sited nuclear power

plant. The line runs vertically down in an open shaft to a depth of 120 ft (36.6 m) below grade. It then runs horizontally 100 ft (30.5 m) below the surface of a seawater strait that separates the two facilities. The discharge pressure of the pumping system that transfers the water is 350 psig (2415 kPa gage) at ambient temperature. The material is ASTM A106, Grade B, and the internal corrosion allowance is 0.065 in (1.7 mm). The line is coated to prevent external corrosion. At times, the line is shut down and drained for maintenance. Under these conditions it must withstand the external pressure exerted by the seawater, without collapse.

Determine the required wall thickness to safely contain the water at the internal design pressure, and verify that this thickness is adequate to withstand the external pressure. The design code is ASME B31.1.

Solution.   The pipeline design will be developed initially for the internal pressure condition. It will then be checked for the external pressure.

The internal design pressure has two components: the pump discharge pressure and the static head due to the vertical run to 120 ft below grade. The head pressure is

$$P_h = 62.4 \, \frac{\text{lb}}{\text{ft}^3} \times \frac{1 \, \text{ft}^2}{144 \, \text{in}^2} \times 120 \, \text{ft} \, (36.6 \, \text{m})$$

$$= 52 \, \text{psig} \, (360 \, \text{kPa gage})$$

The internal design pressure is therefore $350 + 52 = 402$ psig. The minimum wall thickness based upon this pressure is determined by using Eq. (B2.5):

$$t_m = \frac{PD_o}{2(SE + Py)} + A \qquad \text{(B2.5)}$$

The values of the variables are

$P =$ design pressure $= 402$ psig (2780 kPa gage)

$D_o =$ outside diameter of pipe $= 24$ in (610 mm)

$S =$ allowable stress $= 15,000$ psi (103.4 MPa)
     (ASME B31.1, Table A.1 at $-20°$F $(-29°$C) to $650°$F $(343°$C)

$E = 1.0$ seamless pipe

$y = 0.4$ ASME B31.1, Table 104.1.2(A)

$A = 0.065$ in (1.7 mm)

Substituting these values yields

$$t_m = \frac{402 \times 24}{2(15,000 \times 1 + 402 \times 0.4)} + 0.065$$

$$= 0.318 \, \text{in} + 0.065 \, \text{in}$$

$$= 0.383 \, \text{in}$$

The commercial wall thickness tolerance on ASTM A106 pipe is $+0, -12\frac{1}{2}$ percent; therefore the nominal wall thickness is determined by dividing the minimum wall thickness by 0.875.

$$t_{\text{nom}} = \frac{0.383}{0.875} = 0.438 \, \text{in} \, (11.1 \, \text{mm})$$

The next-larger standard pipe wall thickness for ASTM A106, per ASME B36.10M, is 0.500 in (12.7 mm). This nominal thickness is accepted preliminarily, and will be investigated for its adequacy to withstand the external pressure condition.

ASME B31.1, Paragraph 104.1.3, invokes the ASME Boiler and Pressure Code, Section VIII, Division 1, *Pressure Vessels*, Subsections UG-28 through UG-30,[27] for the external pressure design of straight pipe. This subsection provides a series of empirical procedures for the external pressure design of shells and tubes. They may be stiffened or unstiffened. The procedures rely on equations presented in UG-28 to UG-30, and a series of external pressure design charts given in ASME Section II, Part D, Subpart 3.[28]

This example problem is a basic case involving an unstiffened straight tube under external pressure, and simplifying assumptions have been made. The reader is encouraged to study Subsections UG-28 through UG-30 in their entirety, prior to attempting the solution of this class of design problems.

The nomenclature is

A = a geometric factor determined from ASME Section II, Part D, Subpart 3, Fig. G. It is used to enter the applicable material chart given in subpart 3. A simplified version of Fig. G, which is applicable to this sample problem, is shown in Fig. B2.4.

B = a factor determined from applicable material chart of ASME Section II, Part D, for maximum design metal temperature, psi. A simplified version of the material chart which is applicable to this sample problem is shown in Fig. B2.5.

D_o = outside diameter of cylindrical shell course or tube, in

L = total length of tube between tube sheets, or design length of vessel between lines of support*

P = external design pressure, psi

P_a = calculated value of maximum allowable external working pressure, for assumed value of t, psi

t = minimum required thickness of a cylindrical shell or tube

t_s = nominal thickness of a cylindrical shell or tube, in

Detailed Procedure. The following procedure applies to cylindrical shells or tubes whose diameter-to-thickness ratio D_o/t is greater than 10.

- For this example the minimum required wall thickness t is taken as the commercial minimum wall thickness, less the corrosion allowance.

$$t = t_s \times (\text{tolerance factor}) - A$$

$$= 0.500 \times 0.875 - 0.065$$

$$= 0.3725 \text{ in } (9.5 \text{ mm})$$

---

* See ASME Section VIII, UG-28(b).
FIGURE B2.4   External pressure design factor A versus L/D_o. (*Adapted from ASME Section VIII, Division I,* Rules for the Construction of Pressure Vessels, *American Society of Mechanical Engineers, New York, 1998.*)

- For the assumed thickness t, determine the ratios L/D_o and D_o/t. If L/D_o is greater than 50, assume $L/D_o = 50$.

$$L/D_O = 50 \qquad L = \infty; \text{ no tube supports}$$

$$D_o/t = 24.0/0.3725 = 64.4$$

- Using the values for L/D_o and D_o/t, proceed to Fig. B2.4 and determine the value of A. From Fig. B2.4, at $L/D_o = 50$ and $D_o/t = 64.4$, A equals 0.00025.
- Using the value of A found above, proceed to the material chart shown in Fig. B2.5 to determine the value of B. From Fig. B2.5, at the value of $A = 0.00025$; B equals 3600.
- Use the following formula to calculate the maximum allowable external working pressure which may act on the pipe:
FIGURE B2.5 External pressure design factor A versus factor B. (*Adapted from ASME Section VIII, Division I,* Rules for the Construction of Pressure Vessels, *American Society of Mechanical Engineers, New York, 1998.*)

$$P_a = \frac{4B}{3(D_o/t)}$$

$$= \frac{4(3600)}{3(64.4)}$$

$$= 74.5\,\text{psig}\,(514\,\text{kPa gage})$$

This maximum allowable external working pressure must be compared with the actual external pressure due to the submergence in seawater, to determine whether the design is adequate.

The submergence depth is given as 100 ft, and the density of seawater is taken as 64.0 lb/ft³. The seawater pressure P_{sw} acting on the outside of the pipe is

$$P_{sw} = 64 \frac{\text{lb}}{\text{ft}^3} \times \frac{1 \text{ ft}^2}{144 \text{ in}^2} \times 100 \text{ ft}$$
$$= 44.4 \text{ psig } (306 \text{ kPa gage})$$

Since the maximum allowable external working pressure for the pipe P_a exceeds the seawater pressure acting on the pipe P_{sw}, the design is acceptable.

CHAPTER B3
PIPING LAYOUT

Lawrence D. Lynch

Piping is a major expenditure in the design and construction of industrial, refinery, petrochemical, or power-generating plants when one considers engineering costs, material costs, and fabrication and field labor costs. Proper planning and execution of the design and routing of pipe can have a major impact on controlling the total installed cost (TIC).

Piping design and equipment arrangement are interrelated subjects that cannot be well taught in the classroom. Most good designers throughout history have learned their profession by a combination of academic and practical work. Field and design office plus a little shop experience is good preparation for designing or teaching. This topic is very broad-based and relies on a sound mechanical engineering background and a lot of common sense. The use of previous designs and drawings is a good way to learn and improve on current designs.

The experienced piping designer needs to have a working knowledge of plant layout, equipment arrangement, and system functionality associated with one or more fields of endeavor, such as commercial, industrial, refinery, petrochemical, or power. In addition, the designer must have an understanding of the practical application of piping materials, valves, pumps, tanks, pressure vessels, heat exchangers, power boilers, vendor-supplied skid assemblies, steam turbine drivers, and other machinery and equipment.

CODES AND STANDARDS

The various codes and standards applicable to the engineering, design, and fabrication of piping systems are discussed and summarized in Chap. A4 of this handbook.

These codes and standards were written to establish minimum requirements for safe design and construction with very little reference to the physical routing of piping. However, the piping designer should be familiar with them as they apply to his or her work. There are a few specific references to physical piping design of safety relief valve arrangements:

- The ASME Boiler and Pressure Code, Section I, *Power Boilers,* specifies that there is to be no intervening pipe, valves, or fittings between the safety relief valves and the vessel or piping to which they are attached. This means that they must be fitting-bound.
- The ASME B31.1, *Power Piping Code,* Appendix II, Non-Mandatory Rules for the Design of Safety Valve Installation, provides guidelines for the physical arrangement of safety valve piping, the most significant being that the distance between the centerline of the valve and the centerline of the discharge elbow must not exceed 4 times the nominal pipe size of the relief valve outlet.

The Pipe Fabrication Institute has a series of engineering standards (ES) covering the fabrication, design, cleaning, and inspection of piping. Three of these standards, listed below, specifically relate to the physical piping design:

ES2, *Method of Dimensioning Welded Assemblies*

ES3, *Linear Tolerances, Bending Radii, Minimum Tangents*

ES7, *Minimum Length and Spacing for Welded Nozzles*

For piping and valve drawing symbols, refer to ANSI/ASME Y32.2.3, *Graphical Symbols for Piping Fittings, Valves and Piping.*

It is essential that designers read and understand applicable codes and standards prior to developing fabrication piping designs.

PIPING LAYOUT CONSIDERATIONS

Project Client and Owner Requirements

Most projects have project-specific requirements imposed by the owner. These usually include additional requirements above the codes and standards which may have direct impact on both pipe layout and equipment location. Most of these requirements derive from operations feedback which the owner contractually invokes on future projects. Owners may not have a thorough understanding of all the levels of detail required to produce a piping design, but they know the finished product. It is very important that all project personnel and designers know and understand these requirements.

Hierarchy of Reference Design Information

To commence the routing and design of any piping system, the designer is referred to Chap. B1, Hierarchy of Design Documents. In the ever-expanding electronic engineering environment, the documents identified can and will be replaced with databases, but the flow of required information to design the piping systems will remain the same.

System Piping and Instrumentation Diagrams (P&ID).   These are the schematic single line process diagrams which define the sequence of equipment, valves, in-line components, pipeline sizes, and overall system arrangement required for proper system function. Computer-aided P&IDs that link the schematic diagrams to electronic design data are preferred in order to perform computerized P&ID compliance checks.

P&ID Implementation and Physicalization.   Piping and instrumentation diagrams are the piping designer's roadmap for laying out piping systems. The designer should understand the P&ID and the specific system characteristics. With this knowledge the designer is required to develop the P&ID and arrange connections and branches as required to best suit the process to actual physical design.

Project Piping Specifications.   These documents or databases define the following essential information: the system design and operating pressures and temperatures; piping materials; pipe wall thickness or schedules; types of fittings to be used, e.g., butt weld, socket weld, or screwed; and the valve and flange pressure rating and insulation requirements. In addition, the piping specification defines the fabrication, examination, testing, inspection, and installation requirements, including the requirements for seismic installations, where applicable.

Equipment Outlines.   These documents can be either imported computer-aided design and drafting (CADD) files or prints of the equipment being piped. They include overall dimensions and the pipe size, wall thickness, flange pressure rating, and locating dimensions of all pipe nozzles and other connections.

General Arrangements or Equipment Location Drawings.   These drawings will indicate the location of all major pieces of equipment in the plant which the designer will either verify or relocate, as required, to accommodate the physical pipe routing as designed or redesign the piping to accommodate the particular piece of equipment.

Generally equipment location drawings are developed by senior-level piping designers during the proposal preparation and are taken over by the project team upon award of the contract. From this point on they are revised and updated as part of the normal process of design development. Equipment should be arranged with the piping layout in mind. Equipment locations and relational arrangements should be evaluated during the piping layout design process. Adjustments and occasionally major changes to equipment arrangement are required to solve major piping arrangement problems. Piping system design is dependent on the input from numerous reference sources prior to the start of piping design.

Collection of As-Built Information

CADD and electronic surveying capabilities have changed and are continuously changing. Photogrametry (photographs that are input into three-dimensional CADD models) and laser mapping (laser scanning using a time of flight laser connected to a computer that translates the scanned points to a three-dimensional CADD model) are applications that enable the designer to collect existing conditions which can be imported into the designer's CADD files. Total Station Surveying is the computerized surveying system which engineering should request for the

collection of survey data points with the electronic transfer of information being able to be translated directly into the CADD environment.

Piping Layout Considerations and Planning Studies for Improved Piping Economics

Proper planning is an important activity performed by the piping designer in the early stages of a project. Space conservation and a symmetric piping arrangement are achieved when all the systems are evaluated in the preliminary stages of design. This study will become the final design. It is important to consider the cost of the piping material at this time for the expensive lines. These lines should be kept as short as possible, while maintaining proper piping flexibility even if this requires changing the equipment arrangement.

Detailed design should not start until the planning studies are complete. Expending engineering work hours on details that are subject to change pending the completion of the planning study is not recommended.

Piping layout then becomes a matter of designing dimensioned routings from one point to another point with the branches, valves, piping specialties, and instrumentation as indicated on the P&ID. This statement, however, is an oversimplification of the process, since many other factors must be considered, such as interference, piping flexibility, material costs, pipe supports, operation and maintenance, and safety and construction requirements.

An example would be moving a pump 3 in (75 mm) to avoid a compound elbow offset in order to connect to the top discharge nozzle. Perhaps the equipment was arranged while planning on a side suction and discharge. Refer to Fig. B3.1.

THE PUMP SKID INLET NOZZLE AND THE FILTER SKID OUTLET NOZZLE SHOULD BE LINED UP IN ORDER TO AVOID THIS COMPOUND OFFSET
FIGURE B3.1   Nozzle alignment drawing.

Pipe Bending

Pipe bending has become increasingly widespread due to a desire for a decrease in fabrication costs. If bending is to be used, the designer should consider special requirements imposed by the process (i.e., tail ends and clamp dimensions are required by the bending machine, and increased distances and space are required because bends have a greater center-to-face dimension than conventional fitting dimensions).

Interferences

One of the most important aspects of piping layout is the avoidance of interferences with other facilities in the plant such as other piping systems; structural steel and concrete; heating, ventilating, and air-conditioning (HVAC) ductwork; and electric cable trays and conduit. For engineering firms using 2D CADD (two-dimensional computer-aided design and drafting) or manual drafting and design, the search for interferences is very tedious and time-consuming since the designer must mentally and visually look for interferences between the systems currently being designed and previously designed or the existing system or facilities, not to mention those systems or facilities in design concurrently. This process is extremely complex at best. Traditionally, this has been accomplished by the use of area composite drawings (see Fig. B3.2) and plastic scale models.

The composite drawings and plastic models show all plant facilities designed to date and are used by the designers to select an interference-free route for the system currently under design; however, the designer still must search out those systems or facilities in design concurrently. Once the designer is satisfied that the current system layout is interference-free, it will be added to the area composite drawing and the plastic model.

An alternative to composite piping drawings and plastic models for interference detection is the use of computer-aided design (CAD). Specifically, three-dimensional (3D) computer modeling can provide an efficient, accurate, and cost-effective alternative to the traditional manual methods for interference detection. This and other CAD applications for piping layout are addressed in the section ''Application of Computer-Aided Design to Piping Layout.'' Refer to Fig. B3.3.

Piping Flexibility

The effects of the thermal expansion of pipe and fittings as a result of system operating temperature changes cannot be overlooked during the layout and routing of any piping system. The function of piping flexibility or stress analysis has, for the most part, been delegated to the computer particularly in the case of high-temperature, high-pressure piping systems. The piping stress analyst translates and enters the piping design data into the computer, reviews the output data, and if the system is too rigid, may suggest appropriate corrective redesigns. However, it is the piping designer's responsibility to ensure that the final stress analysis results are incorporated into the final pipe support and pipe routing design.

In the past, a computer stress analysis, including the development of input data and the interpretation of the output, could be expensive and time-consuming if numerous iterations of computer runs were needed to arrive at an acceptable system design. The experienced piping designer, with the knowledge and capability of

FIGURE B3.2 Area piping composite.

FIGURE B3.2 *(Continued)* Area piping composite.
FIGURE B3.3   A 3D CAD model used for interferences, equipment layout, and pipe routing.

designing piping systems that are inherently flexible, was relied on to keep the number of computer iterations to a minimum. Today, this is much less of a problem with the advent of the personal computer and many computer programs for calculating stresses in piping systems due to thermal expansion and other static and dynamic loads. However, the piping designer must integrate piping flexibility considerations into the piping layout.

The piping designer should route piping with flexibility designed into it, using the minimum amount of pipe, fittings, and expansion loops by considering the following:

- Avoid the use of a straight run of pipe between two pieces of equipment or between two anchor points.
- A piping system between two anchor points in a single plane should, as a minimum, be L-shaped, consisting of two runs of pipe and a single elbow. This type of arrangement should be subjected to a ''quick-check'' analysis to determine if a formal computer stress analysis is required. A preferred solution in this case may be a series of two or more L-shaped runs of pipe.

- A piping system between two anchor points with the piping in two planes may consist of two L-shaped runs of pipe, e.g., one L-shaped run in the horizontal plane and another in the vertical plane. This arrangement should also be subjected to a quick-check analysis.

- A three-plane configuration may consist of a series of L-shaped runs and/or U-shaped expansion loops designed into the normal routing of the system.

- When the expected thermal expansion in any given run of pipe is high, consider the use of an anchor at or near the center of the run, thereby distributing the expansion in two directions.

- For systems consisting of a large-diameter main and numerous smaller branch lines, the designer must ascertain that the branches are flexible enough to withstand the expansion in the main header.

- Systems which are to be purged by steam or hot gas must be reviewed to ensure that they will be flexible during the purging operation.

- System or equipment bypass lines may be cold due to lack of flow while the main runs are at operating design temperature, resulting in excessive stresses.

- Temperatures during initial start-up and testing are often greater than those at operating conditions.

- Closed relief valve and hot blowdown systems should be given special attention due to rapid transients in temperature.

In addition, the piping designer may use a variety of single- and multiplane piping arrangements, such as the L-shaped, the U-shaped, and the Z-shaped configurations, in the normal routing of any system, as shown in Figs. B3.4 through B3.9.

Chapter B4, Stress Analysis of Piping Systems, discusses in detail pipe stress analysis including quick-check methods that may be used by the piping designer to determine whether the system is flexible enough and to determine if a more rigorous analysis is required.

FIGURE B3.9

Valves

The piping designer must be familiar with proper application of all types of valves including gate, globe, plug, butterfly, ball, angle, diaphragm, check, pressure relief, and control valves and their methods of operation including manual, chain, gear, air, hydraulic, or motor. The following general guidelines should be applied when locating valves in any piping system:

- Valves should be installed with the stems between the vertically upward and horizontal positions with particular attention given to avoiding head and knee knockers, tripping hazards, and valve stems in the horizontal plane at eye level that may be a safety hazard. Large motor-operated valves should be installed in the vertical upright position where possible to facilitate support and maintenance.
- Valves in acid and caustic services should be located below the plant operator's eye level or in such a manner as to not present a safety hazard.
- The location of valves, with consideration for operating accessibility, should be accomplished in the natural routing of the system from point to point, avoiding the use of vertical loops and pockets.
- Valves in overhead piping with their stems in the horizontal position should be located such that the bottom of the handwheel is not more than 6.5 ft (2 m) above the floor or platform. Only infrequently operated valves should be located above this elevation, and then the designer should consider the use of a chain operator or a platform for access.
- Where chain operators are used, the valves should be located such that the chain does not present a safety hazard to the operating personnel.
- A minimum of 4 in (100 mm) of knuckle clearance should be provided around all valve handwheels.
- Valves should not be installed upside down.
- Space should be provided for the removal of all valve internals.

Improper application and placement of valves in the piping system can be detrimental to system function. This can result in malfunction of the valve and in waterhammer, and this can cause the valves to literally self-destruct. What follows are some specific recommendations and methods of avoiding these problems for some specific types of valves.

Control Valves. All control valve stations should be designed with the valve stem in the vertical upright position and a minimum of three diameters of straight pipe both upstream and downstream of the control valve, in order to reduce the turbulence entering and leaving the valve and to provide space for removal of the flange studs or bolts. Where applicable, this straight pipe will include the usual reduction in pipe size required to match the control valve size. Space must be provided for flange stud bolt removal where control valve bodies are designed for through-bolt installation.

Butterfly Valves. Butterfly valves should be provided with a minimum of five diameters of straight pipe upstream of the valve; and if this requirement has been met, the valve stem and operator may be oriented in the position best suited for operation and maintenance. When a butterfly valve is preceded by an elbow and this straight-pipe requirement cannot be met, the valve stem must be oriented in

the same plane as the elbow. That is, if the elbow is in the vertical plane, the valve stem must also be in the vertical plane. This recommendation is based on the fact that the velocity profile of the discharge of an elbow is not symmetric. The result can be fluid dynamic torque that is twice the magnitude of that found for a valve with a straight run of pipe upstream. The resultant eccentric forces applied to valve disk produces excessive vibration and disk flutter which eventually may completely destroy the valve.

Check Valves.   The preferred installation of any check valve is in a horizontal, continuously flooded run of pipe with cap up; however, swing check valves will function properly in vertical runs of pipe with the flow up. However, the velocity and the rate of flow must be adequate to move the valve disk away from the seat and to maintain the valve in the open position, as required.

Experience has indicated that check valves are highly susceptible to chattering due to upstream turbulence caused by elbows and branches. Therefore the designer should provide upstream straight pipe in accordance with the valve manufacturer's recommendations. However, where this information is not available, the preliminary design should include a minimum of five diameters of straight pipe upstream of all check valves. In addition, the designer should be aware that this requirement can be as much as 10 diameters of straight pipe depending on the type of valve and the manufacturer.

Safety Relief Valves.   The arrangement for installation of safety and relief valves is very critical and involves the actual location of the valve itself, the design of the vent stack, and the design of any associated drain piping. The designer should adhere to the valve manufacturer's recommendations and the following guidelines; however, these guidelines relate to the power industry and may be used elsewhere, as applicable.

Valve Location
- All relief valves must be in the vertical upright position and fitting-bound to the top of a horizontal run of pipe, the pressure source, and must not be located less than one nominal header diameter from any butt weld.

- A safety valve inlet connection in a high-velocity steam line should be located at least 8 to 10 nominal header diameters downstream of any bend in the header, to minimize the possibility of acoustically induced vibrations. In addition, it should be at least 8 to 10 nominal header diameters either upstream or downstream of any diverging or converging T or Y fitting.

- No other header branch penetration, for any purpose, should be made in the same circumferential cross section containing the safety valve inlet nozzle.

- Where more than one safety valve or a service branch is to be installed in the same header run, a minimum distance of 24 in (600 mm) or 3 times the sum of the nozzle inside radii, whichever is greater, shall be provided between the nozzles.

- Where more than two safety valves are located in the same header run, the spacing between valves should be varied such that the distance between two adjacent valves differs by at least an inlet nozzle diameter.

Open Discharge.   Open-discharge safety valve installations (see Fig. B3.10) should be in accordance with the following guidelines:

- Open-vent stack diameters shall be the calculated minimum flow diameter required for discharge venting without blowback, except as required to accommo-

date the movement of the relief valve discharge from the cold to hot position such that the outlet pipe will be centered in the vent stack in the hot position. See Fig. B3.10.

- The vent stack entry diameter shall be maintained throughout the length of the vent stack; enlarged entry spools, later reduced in size to the calculated minimum flow diameter, are not acceptable.
- The relief valve outlet shall consist of the mating flange and a fitting-bound short-radius elbow, in order to minimize the moment and forces imposed on the valve body.

- Vent stacks should be routed, where possible, to provide a straight stack of minimum length. Where offsets or changes in direction are unavoidable, it is desirable to limit the change in direction to 30° or less; however, it could be more. The vent stack should terminate a minimum of 7 ft (2.2 m) or higher above the roof level.

   Closed Discharge.   Closed-discharge piping systems (see Fig. B3.11) are those piped continuously from the valve discharge flange to a closed receiver, such as a
FIGURE B3.11   Closed-discharge safety valve.

condenser or blow-off tank. This type of system is required for feedwater heater shell side relief valves to provide protection against the effects of tube rupture, and may be used in other applications. Other than the normal considerations for designing pipe, there are no specific guidelines for the design of closed systems.

   Drains. Relief valve and open-vent stack drains are important, in varying degrees, as discussed in the following:

- The discharge elbow and above seat body drain points are the most critical for safe valve operation. These drains should be collected into a common, closed drainage system and routed to a point where the drain can safely blow to atmosphere. This system must be sloped continuously downward and stress-analyzed to ensure that no strain is imposed on the valve body.

- Some relief valves now incorporate a relatively large valve top vent connection that is pressurized when the valve blows. This connection may be piped into the combined discharge elbow and valve body drain system and continued, at full-vent pipe size, to the point of the drain discharge.

- The open-discharge vent stack drip pan drain connection is of the least importance and is only intended to carry away any rainfall entering the stack and the residual condensate from the stack following a steam blow.

Piping of Centrifugal Pumps

The piping of centrifugal pumps, particularly the suction piping, can seriously affect the operating efficiency and life expectancy of the pump. Poorly designed suction piping can result in the entrainment of air or vapor into the pump and cause cavitation, which displaces liquid from within the pump casing, results in vibrations, and throws the pump out of balance. The cavitation alone can result in severe erosion of the impeller. The out-of-balance condition may result in a slight eccentric shaft rotation, which will eventually wear out the pump bearings and seals, requiring a pump shutdown for overhaul. When routing piping at pumps, the designer should follow the manufacturer's recommendations, the Hydraulic Institute Standards, and the following guidelines:

- The suction and discharge piping must be supported independently of the pump such that very little load is transmitted to the pump casing. The designer may consider the use of expansion joints on either the suction or discharge, or both, as necessary. However, expansion joints should be used only when it is unavoidable.

- The suction of any centrifugal pump must be continuously flooded, and the suction piping shall contain no vertical loops or air pockets.

- When a reduction in pipe size is required at the pump suction, provide an eccentric reducer flat side up. See Fig. B3.12.

- The suction side elbow in the piping at horizontal double suction pumps may be fitting-bound and in the vertical plane with the flow from either above or below the pump.

- When the suction piping is in the horizontal plane, provide a minimum of three to four diameters of straight pipe between the pump suction connection and the first elbow; the eccentric reducer noted above may be included in this straight section.

- Only long-radius elbows are to be used at or adjacent to any pump suction connection.
FIGURE B3.12   Pump suction reducer.

- All pump suction lines must be designed to accommodate a conical-type temporary strainer.
- A pipe anchor must be provided between any expansion joint or nonrigid coupling and the pump nozzle that it is designed to protect.
- When pump flanges are cast-iron flat-faced, the mating flanges must also be flat-faced and the joint made up with full-face gaskets and common steel bolts (ASTM A 307, Grade B), not high-strength bolts (ASTM A193, Grade B7).
  Refer to the Hydraulic Institute Standards for arrangement of pump piping.

Vents and Drains

During the course of physical routing of any system, the designer should provide high-point vent and low-point drain connections for the following purposes:

- The filling of the piping system with water for hydrostatic testing and operation and the evacuation of entrapped air in the process
- The evacuation of all water used for hydrostatic testing and operation during periods of start-up and maintenance

High-point vents that will be used frequently should be piped down to an area where they can be accessed from the floor. When these vents are left out of reach, they tend not to be used. Systems subject to thermal expansion should be reviewed to ensure that they can be properly drained in both the hot and cold positions.

Buried Piping Systems

The economics of installing piping systems have proved that burying pipe in lieu of installing pipe aboveground provides a significant cost savings in both bulk footage and pipe supports. All system piping should be evaluated for underground

installation if possible to decrease the TIC. Low-pressure and low-temperature systems such as for component cooling and demineralized water are good examples of piping that should be buried. Nonmetallic piping materials can be successfully used for buried applications in lieu of metallic piping, carbon steel, or stainless steel which need to be coated and wrapped to protect against galvanic corrosion, resulting in an expensive installation.

Pipe Racks

Pipe racks are structures designed and built specifically to support multiple pipes where adequate structure is not available. Pipe layout on pipe racks should follow the Pipe Planning Study concepts. Avoid designing one pipe at a time in order to avoid unnecessary overcrowding and fittings for pipes to enter and depart from the rack. Where possible, pipes should rest directly on the rack with the use of an insulation, if required. Steam piping should exit the rack with a vertical up-and-over to avoid condensate collection points, while water piping should exit the rack with a vertical down-and-under to avoid a high-point air pocket collection point.

Pipe Supports

Pipe supports require structural support, which means that piping should be located in close proximity to steel or concrete. Do not locate the pipe too close to the structure, so as to allow adequate space for the pipe support hardware to facilitate installation. Additionally the pipe insulation needs to be considered for clearances and insulation saddles. The most preferred location is either resting directly on structural steel for bottom support or using a single rod to the structure directly above the pipe.

The design and engineering of pipe support systems are covered in detail in Chap. B5; however, it is the responsibility of the piping designer to give serious consideration to the means of support during the piping layout, and in doing so, many pipe support problems may be either minimized or avoided altogether. For this reason, the piping designer should be familiar with the commercially available pipe support components and their application. Piping should be routed such that the support designer can make use of the surrounding structure to provide logical points of support, anchors, guides, or restraints, with ample space for the appropriate hardware. Banks of parallel pipelines at different elevations should be staggered horizontally and spaced sufficiently apart to permit independent pipe supports for each line. Piping on pipe racks should be routed using bottom-of-pipe (BOP) elevations. The piping designer should work closely with the structural engineer in the spacing of the pipe rack supports and the method of intermediate support to prevent pipe sagging.

Insulation

The engineering and selection of thermal insulation materials are covered in Chap. B7, and the piping designer should be familiar with these requirements and specifically with the thickness of insulation for any given system. In the location and spacing of piping systems, there must be clearance space between the insulation of one pipe and any adjacent pipe and/or other possible interference such as structural

steel. The piping designer should also recognize that in some applications insulation may not be required for the prevention of heat loss but will be needed for personnel protection, and the spacing and clearances should be adjusted accordingly.

Heat Tracing

Heat tracing is required when there is concern that the pipe may be damaged due to freezing or that the line needs to maintain a temperature higher than ambient (i.e., caustic piping). The designer must provide the space and clearances for either electric or steam heat tracing and its outer insulation when routing the primary system pipe. The detail design requirements for these systems are covered in Chap. B6.

Operability, Maintenance, Safety, and Accessibility

Operability, maintenance, safety, and accessibility are interdependent, and certainly if any given piping component is accessible, it is also assumed to be operable and maintainable. However, maintenance may require additional space for dismantling the component, as noted elsewhere in this chapter. It is the responsibility of the piping designer to design a piping arrangement that satisfies all these (and other) requirements with the lowest total cost, i.e., resulting in the shortest pipe runs and the fewest fittings and pipe supports.

Operability, from the standpoint of operating personnel, means being able to perform daily functions in an efficient manner. This is done with consideration for the frequency of operation and the degree of physical effort required to perform it. The designer cannot make every valve and instrument ideally accessible, but will concentrate on those requiring the most frequent operation. Safety-related equipment and valves that are required to be operated during an emergency or to perform critical system functions must be accessible without exception. To ensure success, the designer, system engineer, and operating personnel work out the final arrangement. Sometimes input from construction, start-up, and vendor personnel is needed. Formerly in difficult cases, models or even full-size mock-ups have been used as design aids. Today the trend is toward virtual reality. Under today's conditions the whole process can be accelerated and, when done effectively, accomplished at lower cost than formerly. Additional considerations are discussed in other sections of this chapter. In general, an operable valve or instrument is one that can be readily reached when standing at grade or on an elevated floor or platform provided for that purpose. The position of the valve handwheel should be such that the force necessary to operate it can be applied without strain or undue contortions or interference from valves, lines, or other equipment. It is recognized that plant operating personnel will occasionally have to reach for a drain from a kneeling position or a vent valve from a ladder, but these are infrequent operations and as such can be tolerated.

Ease of maintenance actually begins with the development of the plant arrangement and equipment locations by providing sufficient space around each piece of equipment not only for the maintenance of the machinery alone but also for the pipe and the maintenance of the related components. These space allocations should include the pull spaces, laydown spaces, and rotor and tube removal spaces for the dismantling of all pieces of equipment. The engineering of the system P&IDs will indicate the need for maintenance facilities in the form of bypasses and block valves

that would permit certain pieces of equipment or components to be worked on while the system is operating, or at least with a minimum of downtime. However, it is then up to the designer to design these facilities into the system and to provide the accessibility necessary to accomplish that maintenance, including the provision for any lifting gear such as cranes, davits, monorails, and hoists.

There are numerous national, state, and local codes and standards relating to safety, the most notable of which is the Occupational Safety and Health Act of 1970 (OSHA), which became law on April 28, 1971. Several thousand specific safety and health standards are being enforced under OSHA. These standards have been selected from the key safety standards developed by the American National Standards Institute (ANSI); the American Society of Mechanical Engineers (ASME); and the American Society for Testing and Materials (ASTM); and others, such as the American Water Works Association (AWWA), the American Petroleum Institute (API), and the National Fire Protection Association (NFPA).

Stairs, platforms, ladders, aisles, means-of-egress aisleways, and minimum headroom allowances designed in accordance with OSHA will provide a safe place to work. It is the responsibility of the piping designer to place equipment, valves, and other piping components in such positions that they do not create hazards. These hazards could include any piping components that presented themselves as ''head knockers,'' ''knee knockers,'' or trippers. The most common cause of these problems is valve stems, and common sense would say to place a valve in a horizontal run of pipe with the stem vertical, wherever possible. When this cannot be done, the designer should ascertain that the stem does not project into an access area and become a hazard. The designer should make every effort to keep such projections out of heights of 4½ to 6 ft (1.5 to 2 m), or specifically at face level. Steam system valves must not be placed at face level in the horizontal position since a packing gland leak may blow steam into the face of an operator; if this were a superheated steam leak, the vapor would not be visible. This same principle applies to hazardous and toxic fluids. However, this may be too restrictive, and it is not meant to rule out any perfectly safe arrangement of valves at face level if

- They are outside the limit of a platform.
- They are a part of a manifold of valves, all projecting about the same distance and with adequate access space in front of them.
- It is an isolated valve guarded by an adjacent pipe or structural steel.

Accessibility has already been discussed at length in terms of space and the normal platforms and stairways provided in any plant; however, the designer should review the layout and determine if there is a need for any platforms which access a remotely located valve or component.

Interfacing Disciplines and Organizations

Piping design requires coordination and cooperation with all interfacing disciplines including civil, electrical, instrumentation, and construction. Piping arrangements should blend with the layout design of interfacing disciplines. Pipes that require extensive support schemes in lieu of being conveniently located near structural support steel should be avoided. Pipes or electrical trays that twist and turn to avoid one another should be uniformly designed in a coordinated design effort which reduces congestion and reduces TIC. Most piping designs are not completed

by a single designer or company, which makes the coordination between designers and different organizations critical. The best way to address this concern is to agree to specific divisions of responsibility in the planning phase of the project.

Electrical Tray and High-Temperature Piping Interfaces

High-temperature piping must not be located near electrical trays, wherever possible. This piping should cross over trays, not under them. The radiant heat could have an adverse effect on the cables. Electrical equipment maintenance space should be identified and accounted for in all piping passing near this equipment.

SPECIFIC SYSTEM CONSIDERATIONS

The power industry, through its many years of experience, has found that piping arrangements and layout can influence the functionality of a piping system. This section will present specific system guidelines and considerations that will enable the piping designer to minimize that influence.

Main Steam and Hot and Cold Reheat

In any power plant, be it a base-loaded electric power generation station or an industrial facility power plant, the main steam system is the backbone of the installation since it ties together the two most important and most costly pieces of equipment, the steam generator and the turbine, and is also usually the first system designed, giving it the preference in space allocation and routing. The recommendations of the following references should be incorporated in the design of the main steam and reheat steam piping systems.

1. ANSI/ASME TDP-1-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Fossil),* American Society of Mechanical Engineers, New York.
2. ANSI/ASME TDP-2-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Nuclear),* American Society of Mechanical Engineers, New York.

Adherence to the following guidelines will ensure that the system performs its intended function:

- All piping in this service should be sloped down a minimum of ⅛ in/ft (10 mm/m), in the direction of flow. Extensive evaluation and design are required for lines that do not slope in the direction of flow to ensure that condensate is collected and drained adequately.
- The final design of the main steam and hot reheat lines should be reviewed, with consideration for thermal growth, to determine the location of any necessary low-point drains and to ensure that the system can be completely drained in both the hot and cold conditions. When these lines are split into more than one branch into the turbine, each branch should be reviewed for low points. Provide a drain

connection in each branch as close as possible to the turbine stop valve. All drain lines and large valve drain ports should have an inside diameter of not less than 1 in (25 mm), to prevent plugging. Main steam piping drains should not be piped together with any other drains from the boiler. In addition, this review should ensure that no condensate can collect in any undrained portion of the system during shutdown.

- Provide a drain pot at the low point of each cold reheat line, which should be fabricated from NPS 6 (DN 150) or larger pipe and be no longer than required to install the level-sensing devices. Each pot should be provided with a minimum NPS 2 (DN 50) drain line and a full-sized, full-ported automatic power-operated drain valve. Each drain pot should be provided with a minimum of two level-sensing devices.

- Steam lines that are fitted with restricting devices such as orifices or flow nozzles should be adequately drained upstream of the device.

- Valves in all steam services should be installed with the valve stem in the vertical upright position to prevent the entrapment of fluid in the bonnet. Where this is not practical, the stem may be positioned between the vertical and horizontal positions, but in no case below horizontal.

- Main steam safety relief valves should be fitting-bound to the main steam headers.

- Sufficient space should be provided around any steam line to allow for insulation, pipe supports and anchors, thermal growth, machine welding, and maintenance repairs and replacements.

Turbine Extraction Steam

Most steam turbines are provided with one or more low- to intermediate-pressure steam extraction points either for boiler feedwater heating or for industrial process service and heating. These systems are extremely critical, particularly from the standpoint of water damage, and must be designed in accordance with the following standards and guidelines:

> ANSI/ASME TDP-1-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Fossil),* American Society of Mechanical Engineers, New York (Ref. 1).

> ANSI/ASME TDP-2-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Nuclear),* American Society of Mechanical Engineers, New York (Ref. 2).

- The routing should be as short and as direct as possible with consideration for thermal growth and piping flexibility.

- Extraction steam piping should be sloped down a minimum of $\frac{1}{8}$ in/ft (10 mm/m), in the direction of flow. Extensive evaluation and design are required for lines that do not slope in the direction of flow to ensure that condensate is collected and drained adequately.

- Bleeder trip valves must be located as close to the turbine extraction point as possible, while at the same time keeping the total volume of the system within the turbine manufacturer's recommendations.

- When extraction steam piping is routed through the condenser neck, an expansion joint must be provided in each line and located at the turbine nozzle. The bleeder trip valves in these lines must be located just outside the condenser neck.
- A drain should be located at the low point in the extraction pipe between the turbine and block valve and routed separately to the condenser. A power-operated drain valve should be installed in this line that opens automatically upon the closure of the block valve in the extraction pipe.
- There should be no bypasses around the extraction line shutoff or nonreturn valves.
- Unavoidable vertical loops which create low points in the piping downstream of the bleeder trip valves must be provided with continuously drained drip pots.
- Provide a minimum of five diameters of straight pipe downstream of all bleeder trip valves.
- Provide maintenance access to all bleeder trip valves including any miscellaneous platforms, if needed.

Condensate

The condensate collection system from the condenser hotwell presents a unique set of parameters since we are dealing with water at slightly elevated temperatures and at a vacuum pressure. These conditions make the condensate pump suction piping susceptible to flashing and cavitation. The following guidelines apply to the design of condensate pump suction and discharge piping:

- Where two or more condensate pumps are used, the individual runs to each pump must be similar, and if a suction manifold or header is used, the individual pump suction lines from that manifold or header must be similar.
- When the manifold or header is larger than the pump suction size, the manifold or header should be made up of full-sized tees and eccentric reducers, flat side up.
- Each individual pump suction run should be sloped down a minimum of $1/8$ in/ft (10 mm/m) toward the pump and be self-venting back to the condenser.
- Provide a minimum of three to four diameters of straight pipe in the pump suction line; in addition, these lines must be fitted with expansion joints and start-up strainers.
- The condensate pump discharge check valve must be located below the hotwell water level and be continuously flooded.
- The discharge header outlet should not be located between the pump discharge connections to the header, to avoid a counterflow condition.
- The condensate pump recirculation control valve should be located at the condenser nozzle.

Feedwater

The boiler feedwater pumps normally take suction from the deaerator storage tank, discharge to the feedwater heaters, and then supply the boiler. Here, too, the designer has to deal with the possibility of flashing fluid and must ensure that the deaerator storage tank is located at an elevation that will provide sufficient net

positive suction head (NPSH) at the pump. The following guidelines apply to the design of this piping:

- The pump suction piping from the deaerator storage tank should drop vertically, avoiding any long horizontal runs of pipe. If short horizontal runs are unavoidable, they should be angled vertically down.
- A minimum of 3 diameters of straight pipe is required at the pump suction. The pump suction strainer may be located in this run of pipe.
- If a reducer is required at the pump suction, it must be eccentric and installed with the flat side up.
- The feed pump discharge swing check valves should be located in horizontal runs of pipe only.
- The feed pump recirculation line control valve should preferably be located at the deaerator storage tank. Horizontal runs are to be avoided in this line at the tank. If the control valve is located in a branch from the pump discharge, the line downstream of the valve must be continuously flooded.

Turbine Drains

This system consists of the turbine casing drains from the turbine to the condenser, a drain collection manifold at the condenser, or other drain vessel as indicated on the system P&ID. The designer should comply with the following standards and consider the guidelines listed below for the physical design of these drains:

> ANSI/ASME TDP-1-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Fossil),* American Society of Mechanical Engineers, New York (Ref. 1).

> ANSI/ASME TDP-2-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Nuclear),* American Society of Mechanical Engineers, New York (Ref. 2).

- Turbine drain lines and valve ports should be sized for the maximum amount of water to be handled under any operating condition, but in no case may they be less than NPS ¾ (DN 20).
- Drain lines should be designed for both hot and cold conditions and should slope continuously downward in the direction of flow. Flexibility loops, when required, should be in the plane of the slope or in vertical downward runs.
- Continuous drain orifices, when used, should be located and designed so that they may be cleaned frequently and will not be susceptible to plugging by debris.
- Steam traps are not satisfactory as the only means of draining critical lines; however, they may be used in parallel with automatically operated drain valves.
- No part of any drain line may be below its terminal point at the condenser, drain collection header, or other drain vessel.
- Only drain lines from piping systems of similar pressure may be routed to a common manifold.
- All drain and manifold connections to the condenser must be above the maximum hotwell water level.

- Drainage from other vessels, such as feedwater heaters, steam jet ejectors, and gland steam condensers, that drain water continuously must not be routed to turbine cycle drain manifolds.
- Drain lines should be connected at a 45° angle to the manifold axial centerline with the drain line discharge pointing toward the condenser. Drain line connections at the manifold should be arranged in descending order of pressure, with the highest-pressure source farthest from the manifold opening at the condenser.
- Drain connections to flash tanks must be above the maximum water level in the tank.
- Drains from the upstream and downstream sides of shutoff valves must not be interconnected.
- Drain lines in exposed areas should be protected from freezing.
- All turbine drain drawings must be reviewed and approved by the turbine supplier.

Heater Drains

The heater drains system consists of the feedwater heater drains from one heater to another at a lower pressure, to a drain tank, or to the dump line to the condenser. The designer should comply with the following standards and consider the guidelines listed below for the physical design of these drains:

> ANSI/ASME TDP-1-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Fossil),* American Society of Mechanical Engineers, New York (Ref. 1).
>
> ANSI/ASME TDP-2-1985, *Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation (Nuclear),* American Society of Mechanical Engineers, New York (Ref. 2).

- Drain piping from feedwater heaters without an internal drains cooler must immediately drop vertically to provide as much static head as possible upstream of the heater level control valve. Thereafter any horizontal runs must be sloped down a minimum of ¼ in/ft (20 mm/m) in the direction of flow.
- Drain piping from feedwater heaters with an internal drain cooler may be routed horizontally without sloping upon leaving the heater.
- Heater level control valves should be located as close as possible to the receiving vessel, with consideration for ease of access and maintenance.
- The heater drain system arrangements must be coordinated with the system engineer for analysis to ensure that single-phase water flow is maintained upstream of the heater level control valves and to determine where downstream velocities may require tees and target plates in lieu of elbows for minimizing erosion.
- Heater drain dump lines should enter the condenser at approximately the horizontal centerline of the tube bundle. This location should be coordinated with the condenser manufacturer, who will provide the necessary baffle plates to prevent impingement on the condenser tubes.
- Only long-radius elbows should be used in heater drain piping.
- The use of reducers should be avoided, except at the control valves, which are generally smaller than the line size.

Compressed Air

The compressed-air systems provide service air and instrument air throughout the plant. The following guidelines apply to the design and layout of these systems:

- Refer to the compressor manufacturer's instruction manual for the recommended relative lengths of intake and discharge piping versus compressor revolutions per minute (rpm).
- The compressed-air system equipment arrangement and piping design should be such that the air receiver is the lowest point in the system and any condensate in the system will drain to the air receiver, particularly during periods of shutdown when large amounts of condensate can form. The point here is to preclude any possibility of condensates draining back to the air compressor, where it could cause extensive damage. The compressor discharge piping should be as short and direct as possible through the aftercooler and into the air receiver. The compressed-air system distribution lines and risers should originate from a separate outlet connection on the air receiver and should be sloped back to the air receiver.
- Compressed-air line header branches should have vertical risers and be drained at their terminations.
- Individual service branches should be taken off the top of the headers.

Floor and Equipment Drains

Floor and equipment drains in process plants are actually a process system and should be considered in the overall equipment layout design process. All equipment should be carefully evaluated for drain requirements, and a drain hub should be provided for pipes that produce continuous flow. The equipment drain system requires a thorough understanding of the equipment and system function because the drains are designed and issued for construction prior to receipt of finalized vendor information. Drain hubs should not be located more than 6 in (150 mm) away from the equipment pads, to prevent them from becoming tripping hazards.

Sump Locations and Pump Discharge

Piping and plant layout should always consider the sump locations as significant due to their impact on overall construction. Civil structural problems can occur when the sump size and location are not evaluated prior to determining a final sump location. Sump discharges should have a nonreturn valve to prevent the draining of the discharge piping. This is required to keep the discharge line solid and to avoid waterhammer.

Fire Protection

The fire protection system usually consists of two or more fire pumps taking suction from the fire water source with the discharge of each pump independently connected to the underground fire main and as widely separated as possible. The underground fire main loop shall completely encircle the plant and may serve multiple sites if cross-connected between units. The National Fire Protection Association codes and the following guidelines may be used to design and lay out the yard fire main loop:

- Locate the yard fire main such that all fire hydrants will be a minimum of 50 ft (15 m) from any building or structure whenever possible.
- The underground fire main shall be sectionalized in accordance with NFPA code using post indicator valves.
- Post indicator valves shall be provided on each side of any fire pump discharge connection into the fire main loop.
- All fire protection system branches from the yard fire main loop shall be provided with a shutoff valve located not less than 40 ft (12 m) from the building or structure being served.
- Two-way fire hydrants with individual curb boxes should be provided at 250- to 300-ft (75- to 90-m) intervals along the yard fire main loop.

Water fire-extinguishing systems within any building may consist of automatic sprinkler systems, spray systems, deluge systems, and hose stations, as determined by the project engineering group. The following guidelines shall apply to the design of these systems:

- Large areas, such as below the turbine operating floor, should be divided into sectors each served by an individual branch from the yard fire main loop.
- Each sector should be controlled by an exterior post indicator valve and an alarm check valve or automatic valve located inside the building.
- The maximum area served by any one alarm check valve or automatic sprinkler valve shall not exceed 25,000 ft^2 (7620 m^2).
- The maximum number of sprinkler heads in any sector shall not exceed 275.
- Provide automatic wet sprinkler systems in the area of the tube oil system below the turbine operating floor and in the ceiling of the clean and dirty tube oil storage tank room.
- Separate water spray systems should be provided in the area of the tube oil system, in addition to the wet sprinkler system noted above, and in the area of the hydrogen seal system.
- Standpipes and hose stations should be provided in accordance with the NFPA code as a complement to the automatic suppression systems noted above.
- The hose stations on any given floor should be fed from above to avoid creating a series of unvented high points.

Cooling Water Systems

There are several types of cooling water systems utilized today in the engineering and design of power generation, petrochemical, and industrial plants. The most common system in use for many years in power generation was the direct use of the water from the nearby river, bay, or ocean. In this system a water intake structure is located along the shoreline and includes as a minimum circulating water pump(s), piping, both fixed and traveling intake screens, and the necessary crane facilities for the removal, replacement, and maintenance of the pumps and their motors. The intake screens are provided to prevent fish, crabs, and other debris from entering and damaging the pumps. In addition to this main cooling water system, there may be one or more service water systems for other equipment

throughout the plant. The following guidelines apply in the design and routing of these systems:

- Where butterfly valves are used, follow the guidelines provided for valves. Any given heat exchanger inlet and outlet valves should be located close together for balancing the system.
- Avoid unnecessary vertical loops in any closed cooling water system. This type of system will usually include an expansion tank, which should be located at or above the highest point in the system, and the outlet from this tank should be piped directly to the pump suction.
- For piping at centrifugal pumps, follow the guidelines provided for piping of centrifugal pumps.
- Consult the Hydraulic Institute standards and the pump manufacturer's guidelines for layout and arrangement of deep-well type of pumps.

Since the temperature in these systems is not high and does not vary widely, piping offsets to accommodate thermal expansion and/or contraction are not of paramount importance.

APPLICATION OF COMPUTER-AIDED DESIGN TO PIPING LAYOUT

The piping industry today is very diverse in its use of computer-aided design. This diversity is shown by the various levels of sophistication of the CAD applications in use by different segments of the industry. Even within the same company, the sophistication of CAD use can vary widely from discipline to discipline, department to department. This diversity ranges from a surprisingly large portion of the industry in which there is little use of CAD to a few who claim to be approaching a paperless office. Between these two extremes, most of the industry appears to be using CAD as computer-aided drafting. In this sense, CAD becomes an electronic pencil, not necessarily a design tool.

The meaning of the term *CAD* has evolved as quickly as the technology itself. From its original use as an acronym for computer-aided drafting, it has spawned a whole family of related acronyms: CADD (computer-aided drafting and design), CAE (computer-aided engineering), CAM (computer-aided manufacturing), and so on. Many of these terms have been applied when describing the design and layout of piping systems. In the minds of many people, CAD and its related acronyms are still envisioned as simply automated drafting, where CAD is basically the substitution of drawing boards with CAD terminals. While computer-aided drafting represents a significant portion of the application of CAD to piping layout, this is changing rapidly. In this section, applications beyond simple drafting will be discussed. Therefore the acronym *CAD* will mean *computer-aided design* and will refer to both design and drafting activities related to piping layout.

The entire field of design automation, including CAD, is changing so rapidly that it would be of little value to make recommendations regarding specific hardware and software systems. What may be the best or most cost-effective system today may be out of the picture tomorrow. However, there are some fundamental issues associated with the selection and implementation of a CAD system which should be considered, regardless of the specific supplier of hardware and software.

Computer-Aided Drafting

Currently, as indicated previously, the most significant use of CAD for piping layout is for drafting. Many software systems exist which can function on nearly every type of computer hardware available, including mainframe computers, minicomputers, workstations, and personal computers. Today, the use of CAD for two-dimensional drafting is dominated by CAD software for personal computers. In selecting a system for producing piping drawings, there are several issues which must be considered, regardless of the hardware to be used.

User-Definable Symbols and Menus. Any CAD software, if it is to be of long-term benefit, must provide the capability to define its own drafting symbols and menus (e.g., tablet, on-screen) for selecting these symbols. Since piping drawings make extensive use of symbology, defining symbols is of critical importance for significantly increasing drafting productivity. This capability allows the user organization to create and manage libraries of its own symbols, standard details, and standard notes, which can be easily and automatically included in any drawing.

Use of Standard Hardware. Traditionally, many CAD systems were provided by the vendor as a turnkey system that included both hardware and software. In these cases, the CAD software was designed to operate specifically on the hardware provided by the vendor. Today, however, many vendors have decoupled the hardware and software, which allows the software to run on a number of hardware platforms. In fact, most of the major providers of CAD software for drafting provide only software, with the users acquiring the hardware and operating system independently. This is particularly true for the personal-computer-based CAD systems. By selecting software which can function on a number of types of hardware, the user has the flexibility to more fully take advantage of rapid changes in the hardware market, i.e., decreasing prices with improved performance. If the CAD software can function only on the hardware from one specific vendor, then the user must rely on the hardware vendor to keep pace with the rest of the industry.

Availability of Third-Party Software. Certainly not every user can have the luxury of developing dedicated software, particularly beyond the development of symbol libraries and menus. Therefore, before selecting a CAD system, the user should determine how much application software is available from the vendor or from third parties. For piping layout, the most important applications to look for are those intended for generating orthographic piping drawings and piping isometric drawings. Application software, specific to piping layout, can significantly increase the productivity of the application of CAD. If little or no applications software exists for the CAD system under consideration, then the user will likely have to develop his or her own applications software or fail to realize the full value of the CAD system.

Support of User-Developed Software. In cases where no applications software exists, perhaps due to the uniqueness of the user requirements, the user needs to ensure that application software can be developed for the specific CAD system. As a minimum, the system should support developing simple ''macro'' commands which execute a series of commands in response to a single command. Many systems have macro languages which offer much of the functionality of general-purpose programming languages. For more sophisticated applications, the system should

provide interfaces to software written in other programming languages, such as Fortran or C.

Support for Multiple Users.   Piping layout is not done in isolation and must interface design information and drawings from other piping designers as well as other disciplines. Therefore, the CAD system must support this type of activity. The CAD system should provide the capability for a designer to have read-only access to the CAD files of other designers for reference, interference checking, or use as background information for the piping drawings. Systems which have this capability often refer to it as a *reference file* capability. This allows one designer to see the file of another designer, as if it were part of his or her file; however, the data cannot be changed. For personal-computer-based CAD systems, this requires that they be part of some type of local or wide-area network. Without this capability in the CAD software or for personal computers which are not in a network, the data from other designers must be copied and incorporated into the designer's file. This does not allow the designer to see the active data of other designers. In addition, it also greatly increases the storage requirements since many drawings are duplicated, perhaps numerous times. Most importantly, this introduces a more complicated file management problem, making it more difficult to (1) know which file has the most up-to-date information and (2) ensure that everyone references the current data.

Database Capabilities.   To utilize the CAD system for more than just drafting requires that the system have the ability to create drawings which, in addition to the drawing graphics, contain (or reference in database) other information which can be extracted from the drawing, such as valve numbers and/or line numbers. With this type of capability, bills of material can be generated automatically from the piping drawings. It is even possible to generate the input to the piping stress analysis program from a piping isometric. However, note that merely having a basic database capability does not mean that it can be effectively used for extracting data from piping drawings. This is the role of applications software developed specifically for piping which automatically generates and manages this information during the creation of the drawing. In the absence of piping applications software, the designer would be required to key in a significant amount of data while generating the drawing. This not only dramatically decreases the productivity of the drawing production process, but also greatly increases the possibility of errors.

Training and Implementation.   In the past, much of the cost of implementing the traditional turnkey CAD systems was in the hardware and software. Today, as the cost of hardware and software continues to decline, the majority of the cost is shifting from hardware and software toward training and support. Therefore, the costs associated with the training and implementation of a CAD system, even for two-dimensional drafting, should not be underestimated. In fact, experience has shown that the relative effectiveness of a CAD system is directly related to the amount of training and support the individual users receive.

The precise method of implementing a CAD system is dependent on the company's current organization and method of executing work. Centralized CAD groups working multiple shifts were often the norm with the installation of the large turnkey systems. Now, however, as the cost continues to decrease and the piping design industry in general increases its sophistication in the use of CAD, more effective uses of CAD are being made by placing the workstations right in the piping design groups. Many companies started by training their drafting personnel. But again, experience has shown that even more effective use can be made of the CAD system

by training senior-level piping designers. Instead of creating sketches which are then passed on to a drafter, the designer, using the CAD system and piping layout applications software, can create an electronic sketch which is very nearly a finished drawing, leaving very little to do in the way of drafting. This approach can greatly increase the productivity of the whole design and drafting cycle.

Computer-Aided Design

While the use of CAD for two-dimensional drafting in support of piping layout can provide a number of productivity benefits, there are inherent limitations as to overall benefits to the entire design, fabrication, and construction cycle. While providing benefits in producing the piping drawings (e.g., drafting quality, drafting productivity) and possibly in generating bills of materials, it offers little in the way of improving design productivity. Also, the cost and effort required for interference detection are only marginally improved. Thus two-dimensional drafting, while improving drafting quality and productivity, does little for improving design quality and productivity.

The use of three-dimensional (3D) modeling offers a significant step forward in improving piping design productivity and quality. Systems for 3D piping modeling have existed since the 1970s in a variety of forms. The early systems were geared primarily toward interference detection and materials management and really were not used as design tools per se. Today, a number of systems exist which address the entire piping design cycle. In selecting one of these systems, all the issues which applied to computer-aided drafting apply to 3D piping design systems. However, there are a number of other issues which must also be considered.

Interactive Design.   To truly improve piping design productivity, the software should provide the capability to interactively lay out the piping systems directly in the 3D computer model. This allows the piping designer to sit at the graphics workstation, viewing the 3D model, and directly add new piping or modify existing piping. Without this capability, the system can provide other benefits, such as in interference detection, but will not necessarily improve the piping design productivity. In fact, without interactive design capabilities, another step is added to the process for entering the data into the 3D model from the 2D design drawings. Many CAD systems provide interactive 3D modeling capabilities, but these are not usually sufficient for 3D piping design. Applications software, specifically aimed at piping design, is required to realize gains in design productivity. Without this type of applications software, 3D modeling is probably only effective for early conceptual design and perhaps detailed modeling of very specific problem areas.

Interference Detection.   A major advantage of using 3D computer modeling for piping layout is the ability to automatically check for interferences. This alone can provide a significant improvement in design quality by making it possible to issue a "provable" design, i.e., an interference-free design. Many CAD systems, particularly those originally developed for mechanical design, can detect interferences between two 3D objects; but this is not sufficient for checking plant models for interferences in a production environment. As a minimum, the software should provide the following capabilities:

- The software should be able to check interferences for all or part of the plant in a batch mode. This check should include not only piping but all other disciplines

as well. The software should have a method of reporting interferences which is easy to interpret and makes it possible to quickly locate the interferences in a large and complex model. Some systems also offer the capability to check for interferences as the piping is being designed. This is especially useful for designing pipe in very congested areas.

- The software should check for not only "hard" interferences, i.e., metal-to-metal, but also "soft" interferences, such as personnel access areas, equipment removal spaces, insulation, and construction access.

- The software should provide some capability for managing interference resolution over the life of the project. This includes the ability to suppress certain types of interferences and flagging certain specific interferences as acceptable which will not be reported in the future.

Drawing Generation.   To fully realize the benefits of 3D modeling, the system should provide the capability to automatically or semiautomatically produce the piping drawings, both orthographic and isometric, directly from the 3D piping model. These drawings should be generated in the form of 2D CAD drawings so that they can be managed along with the 2D drawings not generated from the 3D model. For orthographic drawings, the system should be able to represent the piping in the format required by the user, e.g., single-line; it should be able to automatically remove hidden lines from the model; and it should have some basic capability to automatically place annotation, such as component callouts, into the drawing. For piping isometrics, it is not unreasonable to expect the software to generate the piping isometric automatically.

Bills of Material.   As a minimum, the software should have the capability to produce a bill of materials for any of the components included in the model. If a user requires stringent control of piping materials, the system should also provide a piping materials control system or an interface to a third-party materials control system.

Interface to Other Systems.   Since many disciplines utilize 3D geometry data, the software should have the ability to interface the 3D geometry data with other computer systems. For piping design, this would include the piping stress analysis systems. This could also include interfaces to fabrication equipment, such as numerically controlled pipe-bending systems.

Design Review.   The use of 3D modeling for piping design impacts the design process in a number of ways. First, the design evolves in the 3D model—not on the drawings, as in the case of 2D design. The drawings are not usually produced until the design is completed. This means that the drawings cannot be used as a means of reviewing the design while the design is in progress. Second, since in some companies the use of 3D design has virtually eliminated the plastic model, the plastic model is also no longer available as a design review tool. Thus the 3D software system should provide, either directly or through an interface, the means of reviewing the 3D computer model on a high-performance graphics terminal. These types of systems provide the capability to "walk through" solid shaded models in real time for the purposes of design review.

Training and Implementation.   Once again, the issues related to computer-aided drafting apply here as well. The primary difference is one of degree. Systems for

3D computer modeling of piping require more training, more support, and a longer learning curve. Also, these types of systems are more pervasive than simple 2D CAD drafting in that they require a higher level of integration between disciplines and departments and thus a higher level of management attention and support. For these systems to be effective, it is imperative that senior-level design personnel are trained in the use of the system and can use it effectively for piping layout.

Conclusion

Computer-aided drafting and computer-aided design have been used effectively and productively for piping design for a number of years. One of the most important lessons learned from the application of CAD to piping layout, particularly the use of 3D modeling, is that design firms are no longer tied to the same design process and design documentation as when the design was performed manually. The use of 3D piping design provides a number of opportunities for improving the way in which plant design is performed, over and above simply the increase in design productivity. In fact, experience has shown that force-fitting 3D piping design into a project organization and design process geared to manual design actually leads to some inefficiencies.

There appear to be several factors which are important to the continued effective application of this technology. Perhaps most important is the fact that being able to effectively apply this type of software requires training—not only for the individual designers and engineers but also for the supervisors, project engineers, and project managers who control the project work. This type of software opens up new possibilities for improving the way project work is performed, but being able to take advantage of these requires that people at all levels of the project understand the software capabilities as well as its limitations.

CHAPTER B4
STRESS ANALYSIS OF PIPING SYSTEMS

C. Basavaraju, P.E.

William Saifung Sun, P.E.
Senior Engineering Specialist
Bechtel Power Corporation
Frederick, Maryland

Piping stress analysis is a discipline which is highly interrelated with piping layout (Chap. B3) and support design (Chap. B5). The layout of the piping system should be performed with the requirements of piping stress and pipe supports in mind (i.e., sufficient flexibility for thermal expansion; proper pipe routing so that simple and economical pipe supports can be constructed; and piping materials and section properties commensurate with the intended service, temperatures, pressures, and anticipated loadings). If necessary, layout solutions should be iterated until a satisfactory balance between stresses and layout efficiency is achieved. Once the piping layout is finalized, the piping support system must be determined. Possible support locations and types must be iterated until all stress requirements are satisfied and other piping allowables (e.g., nozzle loads, valve accelerations, and piping movements) are met. The piping supports are then designed (Chap. B5) based on the selected locations and types and the applied loads.

This chapter discusses several aspects of piping stress analysis. The discussion is heavily weighted to the stress analysis of piping systems in nuclear power plants, since this type of piping has the most stringent requirements. However, the discussion is also applicable to the piping systems in ships, aircraft, commercial buildings, equipment packages, refrigeration systems, fire protection piping, petroleum refin-

eries, and so on. Each of these types of piping must meet the requirements of its applicable code.

FAILURE THEORIES, STRESS CATEGORIES, STRESS LIMITS, AND FATIGUE

Failure Theories

The failure theories most commonly used in describing the strength of piping systems are the *maximum principal stress theory* and the *maximum shear stress theory* (also known as the *Tresca criterion*).

The maximum principal stress theory forms the basis for piping systems governed by ASME B31 and Subsections NC and ND (Classes 2 and 3) of Section III of the ASME Boiler and Pressure Vessel Codes. This theory states that yielding in a piping component occurs when the magnitude of any of the three mutually perpendicular principal stresses exceeds the yield strength of the material.

The maximum shear stress theory is more accurate than the maximum principal stress theory for predicting both yielding and fatigue failure in ductile metals. This maximum shear stress theory forms the basis for piping of Subsection NB (Class 1) of ASME Section III.[1]

The maximum shear stress at a point τ_{max} is defined as one-half of the algebraic difference between the largest and the smallest of the three principal stresses σ_1, σ_2, and σ_3. If $\sigma_1 > \sigma_2 > \sigma_3$ (algebraically), then $\tau_{max} = (\sigma_1 - \sigma_3)/2$. The maximum shear stress theory states that failure of a piping component occurs when the maximum shear stress exceeds the shear stress at the yield point in a tensile test. In the tensile test, at yield, $\sigma_1 = S_y$ (yield stress), $\sigma_2 = \sigma_3 = 0$. So yielding in the component occurs when

$$\tau_{max} = \frac{\sigma_1 - \sigma_3}{2} = \frac{S_y}{2} \tag{B4.1}$$

Equation (B4.1) has an unnecessary operation of dividing both sides by 2 before comparing them. For the sake of simplicity, a stress defined as $2\tau_{max}$ and equal to $\sigma_{max} - \sigma_{min}$ of the three principal stresses has been used for Class 1 piping. This stress is called the *equivalent intensity of combined stresses,* or *stress intensity.* Thus the stress intensity S is directly comparable to the tabulated yield stress values S_y from tensile tests with some factor of safety.

Stress Categories

There are various failure modes which could affect a piping system. The piping engineer can provide protection against some of these failure modes by performing stress analysis according to the piping codes. Protection against other failure modes is provided by methods other than stress analysis. For example, protection against brittle fracture is provided by material selection. The piping codes address the following failure modes: excessive plastic deformation, plastic instability or incremental collapse, and high-strain–low-cycle fatigue. Each of these modes of failure is caused by a different kind of stress and loading. It is necessary to place these stresses into different categories and set limits to them.

The major stress categories are *primary, secondary,* and *peak.* The limits of these stresses are related to the various failure modes as follows:

1. The primary stress limits are intended to prevent plastic deformation and bursting.
2. The primary plus secondary stress limits are intended to prevent excessive plastic deformation leading to incremental collapse.
3. The peak stress limit is intended to prevent fatigue failure resulting from cyclic loadings.

Primary stresses which are developed by the imposed loading are necessary to satisfy the equilibrium between external and internal forces and moments of the piping system. Primary stresses are not self-limiting. Therefore, if a primary stress exceeds the yield strength of the material through the entire cross section of the piping, then failure can be prevented only by strain hardening in the material. Thermal stresses are never classified as primary stresses. They are placed in both the secondary and peak stress categories.

Secondary stresses are developed by the constraint of displacements of a structure. These displacements can be caused either by thermal expansion or by outwardly imposed restraint and anchor point movements. Under this loading condition, the piping system must satisfy an imposed strain pattern rather than be in equilibrium with imposed forces. Local yielding and minor distortions of the piping system tend to relieve these stresses. Therefore, secondary stresses are self-limiting. Unlike the loading condition of secondary stresses which cause distortion, peak stresses cause no significant distortion. Peak stresses are the highest stresses in the region under consideration and are responsible for causing fatigue failure. Common types of peak stresses are stress concentrations at a discontinuity and thermal gradients through a pipe wall.

Primary stresses may be further divided into general primary membrane stress, local primary membrane stress, and primary bending stress. The reason for this division is that, as will be discussed in the following paragraph, the limit of a primary bending stress can be higher than the limit of a primary membrane stress.

Basic Stress Intensity Limits

The basic stress intensity limits for the stress categories just described are determined by the application of limit design theory together with suitable safety factors.

The piping is assumed to be elastic and perfectly plastic with no strain hardening. When this pipe is in tension, an applied load producing a general primary membrane stress equal to the yield stress of the material S_y results in piping failure. Failure of piping under bending requires that the entire cross section be at this yield stress. This will not occur until the load is increased above the yield moment of the pipe multiplied by a factor known as the *shape factor* of the cross section. The shape factor for a simple rectangular section in bending is 1.5.

When a pipe is under a combination of bending and axial tension, the limit load depends on the ratio between bending and tension. In Fig. B4.1, the limit stress at the outer fiber of a rectangular bar under combined bending and tension is plotted against the average tensile stress across the section. When the average tensile stress P_m is zero, the failure bending stress is 1.5 S_y. When P_m alone is applied (no bending stress P_b), failure stress is yield stress S_y.
FIGURE B4.1 Limit stress for combined tension and bending (rectangular section). (*ASME, "Criteria."*[1] Courtesy of ASME.)

It also can be seen in Fig. B4.1 that a design limit of $\frac{2}{3}S_y$ for general primary membrane stress P_m and a design limit of S_y for primary membrane-plus-bending stress $P_m + P_b$ provide adequate safety to prevent yielding failure.

For secondary stresses, the allowable stresses are given in terms of a calculated elastic stress range. This stress range can be as high as twice the yield stress. The reason for this high allowable stress is that a repetitively applied load which initially stresses the pipe into plastic yielding will, after a few cycles, "shake it down" to elastic action.

This statement can be understood by considering a pipe which is strained in tension to a point ε_1 somewhat beyond its yield strain, as shown in Fig. B4.2. The calculated elastic stress at this point would be equal to the product of the modulus of elasticity E and the strain ε_1, or $S_1 = E\varepsilon_1$. The path $OABC$ is considered as cycling the strain from 0 to ε_1 (loading) and back to 0 (unloading). When the pipe is returned to its original position O, it will retain a residual compressive stress of magnitude $S_1 - S_y$. On each subsequent loading cycle, this residual compression must be overcome before the pipe can go into tension; thus the elastic range has been extended by the value $S_1 - S_y$.
FIGURE B4.2   Strain history beyond yield. (*ASME, "Criteria."*[1] *Courtesy of ASME.*)

Therefore, the allowable secondary stress range can be as high as $2S_y$ when $S_1 = 2S_y$. When $S_1 > 2S_y$, the pipe yields in compression and all subsequent cycles generate plastic strain *EF*. For this reason $2S_y$ is the limiting secondary stress which will shake down to purely elastic action.

Fatigue

As mentioned previously, peak stresses are the highest stresses in a local region and are the source of fatigue failure. The fatigue process may be divided into three stages: *crack initiation* resulting from the continued cycling of high stress concentrations, *crack propagation* to critical size, and *unstable rupture* of the remaining section.

Fatigue has long been a major consideration in the design of rotating machinery, where the number of loading cycles is in the millions and can be considered infinite for all practical purposes. This type of fatigue is called *high-cycle fatigue*. High-
FIGURE B4.3 Typical relationship among stress, strain, and cycles to failure. (*ASME, "Criteria."*[1] *Courtesy of ASME.*)

cycle fatigue involves little or no plastic action. Therefore, it is stress-governed. For every material, a fatigue curve, also called the *S–N curve,* can be generated by experimental test[2] which correlates applied stress with the number of cycles to failure, as shown in Fig. B4.3. For high-cycle fatigue, the analysis is to determine the endurance limit, which is the stress level that can be applied an infinite number of times without failure.

In piping design, the loading cycles applied seldom exceed 10^5 and are frequently only a few thousand. This type of fatigue is called *low-cycle fatigue.* For low-cycle fatigue, data resulting from experimental tests with stress as the controlled variable are considerably scattered. These undesirable test results are attributable to the fact that in the low-cycle region the applied stress exceeds the yield strength of the material, thereby causing plastic instability in the test specimen.

However, when strain is used as the controlled variable, the test results in this low-cycle region are consistently reliable and reproducible.

As a matter of convenience, in preparing fatigue curves, the strains in the tests are multiplied by one-half the elastic modulus to give a pseudostress amplitude. This pseudostress is directly comparable to stresses calculated on the assumption of elastic behavior of piping. In piping stress analysis, a stress called the *alternating stress* S_{alt} is defined as one-half of the calculated peak stress. By ensuring that the number of load cycles N associated with a specific alternating stress is less than the number allowed in the *S–N* curve, fatigue failure can be prevented. However, practical service conditions often subject a piping system to alternating stresses of different magnitudes. These changes in magnitude make the direct use of the fatigue curves inapplicable since the curves are based on constant-stress amplitude. Therefore, to make fatigue curves applicable for piping, it is necessary to take some other approach.

One method of appraising the fatigue failure in piping is to assume that the cumulative damage from fatigue will occur when the cumulative usage factor U

equals unity, i.e.,

$$U = \Sigma U_i = \Sigma \frac{n_i}{N_i} = 1 \qquad \text{(B4.2)}$$

where U_i = usage factor at stress level i
    n_i = number of cycles operating at stress level i
    N_i = number of cycles to failure at stress level i per fatigue curve

CLASSIFICATION OF LOADS, SERVICE LIMITS, AND CODE REQUIREMENTS

Classification of Loads

Primary loads can be divided into two categories based on the duration of loading. The first category is *sustained loads.* These loads are expected to be present throughout normal plant operation. Typical sustained loads are pressure and weight loads during normal operating conditions. The second category is *occasional loads.* These loads are present at infrequent intervals during plant operation. Examples of occasional loads are earthquake, wind, and fluid transients such as water hammer and relief valve discharge.

In addition to primary loads, there are *expansion loads.* Expansion loads are those loads due to displacements of piping. Examples are thermal expansion, seismic anchor movements, thermal anchor movements, and building settlement.

Service Limits

Service levels and their limits are defined for nuclear power plant safety-related piping by the ASME Boiler and Pressure Vessel Code, Section III.[3] They are described in the following list:

1. *Level A service limits.* The piping components or supports must satisfy these sets of limits in the performance of their specified service function. Examples of level A loadings are operating pressure and weight loadings.

2. *Level B service limits.* The piping component or support must withstand these loadings without damage requiring repair. Examples of level B loadings are fluid transients such as water hammer and relief valve discharge, and *operating-basis earthquake (OBE),* defined as the maximum likely earthquake postulated to occur during plant design life or one-half of the safe shutdown earthquake (see definition below), whichever is higher.

3. *Level C service limits.* The occurrence of stress up to these limits may necessitate the removal of the piping component from service for inspection or repair of damage. An example of level C loading is the combination of fluid transient loads occurring simultaneously with the operating-basis earthquake.

4. *Level D service limits.* These sets of limits permit gross general deformations with some consequent loss of dimensional stability and damage requiring repair, which may require removal of the piping component from service. An example of level D loading is the loading associated with a loss-of-coolant accident or a

safe-shutdown earthquake (SSE), which is defined as the maximum possible earthquake postulated to occur at the site of the plant at any time.

Code Requirements

There are various ASME and ANSI codes which govern the stress analysis of diferent kinds of pressure piping. These codes contain basic reference data, formulas, and equations necessary for piping design and stress analysis.

Each power plant is committed to a particular edition of a code for different types of piping. For example, the nuclear Class 1, 2, and 3 piping of a power plant may be committed to comply with the ASME Boiler and Pressure Vessel Code, Section III, 1974 edition, while the nonnuclear piping may be committed to ANSI B31.1 *Power Piping Code,* 1973 edition.

The following sections provide summaries of the ASME and ANSI codes.

ASME Boiler and Pressure Vessel Code, Section III, Subsection NB.[3] This subsection provides the code requirements of nuclear piping designated as Class 1. The loadings required to be considered for this subsection are the effects of pressure, weight (live and dead loads), thermal expansion and contraction, impact, earthquake, and vibrations. The stress limits which must be met are as follows:

1. *Primary stress intensity.*   The primary stress intensity must meet the following requirement:

$$B_1\left(\frac{PD_o}{2t}\right) + B_2\left(\frac{D_o}{2I}\right)M_i \leq kS_m \qquad \text{(B4.3)}$$

where B_1, B_2 = primary stress indices for specific piping components under investigation
P = design pressure, psi
D_o = outside diameter of pipe, in
t = nominal wall thickness, in
M_i = resultant moment due to combination of design mechanical loads, in · lb
I = moment of inertia, in^4
kS_m = $1.5S_m$ for service level A; $1.8S_m$ for service level B but not greater than $1.5S_y$; $2.25S_m$ for service level C but not greater than $1.8S_y$; and $3.0S_m$ for service level D but not greater than $2.0S_y$
S_m = allowable design stress intensity, psi
S_y = yield strength value taken at average fluid temperature under consideration, psi

2. *Primary plus secondary stress intensity range.*   The following equations are used to evaluate a stress range as the piping system goes from one service load set (pressure, temperature, and moment) to any other service load set which follows in time. For each specified pair of load sets, the stress range S_n is calculated:

$$S_n = C_1\left(\frac{P_0D_o}{2t}\right) + C_2\left(\frac{D_o}{2I}\right)M_i + C_3E_{ab}|\alpha_aT_a - \alpha_bT_b| \qquad \text{(B4.4)}$$

where C_1, C_2, C_3 = secondary stress indices for specific component under consideration

P_0 = range of service pressure, psi
M_i = resultant range of moment, in · lb
E_{ab} = average modulus of elasticity of two sides of a gross structural discontinuity or material discontinuity at room temperature, psi
α_a, α_b = coefficient of thermal expansion on side a or b of gross structural discontinuity or material discontinuity at room temperature, in/(in · °F)
T_a, T_b = range of average temperature on side a or b of gross structural discontinuity or material discontinuity, °F

And S_n has the following limit: $S_n \leq 3S_m$.

If this requirement is not met for all pairs of load sets, then the piping component may still be qualified by using the simplified elastic-plastic discontinuity analysis described below; otherwise, the stress analyst may proceed to the fatigue analysis.

3. *Simplified elastic-plastic discontinuity analysis.* If $S_n > 3S_m$ for some pairs of load sets, a simplified elastic-plastic analysis may be performed if the thermal stress ratchet is not present. This analysis is required only for the specific load sets which exceeded $3S_m$. The following two equations must be satisfied:

$$S_e = C_2 \left(\frac{D_o}{2I} \right) M_i^* \leq 3S_m$$

$$C_1 \left(\frac{P_0 D_o}{2t} \right) + C_2 \left(\frac{D_o}{2I} \right) M_i + C_3 E_{ab} |\alpha_a T_a - \alpha_b T_b| \leq 3S_m$$

(B4.5)

where S_e = nominal value of expansion stress, psi
M_i^* = resultant range of moments due to thermal expansion and thermal anchor movements, in · lb
M_i = resultant range of moment excluding moments due to thermal expansion and thermal anchor movements, in · lb
C_3 = stress index for specific component under consideration

For later editions of the code, if $S_n > 3S_m$, the thermal stress ratchet must be evaluated and demonstrated to be satisfactory before a simplified elastic-plastic discontinuity analysis can be done. This ratchet is a function of the $|\Delta T_1|$ (see definition below) range only. The following requirement must be met:

$$|\Delta T_1| \text{ range } \leq \frac{y' S_y C_4}{0.7 E \alpha}$$

(B4.6)

where
$$y' = \begin{array}{ll} 3.33 & \text{for } x = 0.3 \\ 2.00 & \text{for } x = 0.5 \\ 1.20 & \text{for } x = 0.7 \\ 0.80 & \text{for } x = 0.8 \end{array}$$

$x = PD_o/(2tS_y)$
S_y = yield strength value taken at average fluid temperature under consideration, psi
C_4 = 1.1 for ferritic material and 1.3 for austenitic material
$E\alpha$ = modulus of elasticity E times mean coefficient of thermal expansion α, both at room temperature, psi/°F
P = maximum pressure for set of conditions under consideration, psi
FIGURE B4.4 Decomposition of temperature distribution range. (*Figure NB-3653.2(b)-1, Section III, Division 1, ASME B & PV Code, 1989. Courtesy of ASME.*)

4. *Peak stress intensity range and fatigue analysis.*   For each specified loading condition, peak stress is calculated as follows:

$$S_p = K_1 C_1 \left(\frac{P_0 D_o}{2t} \right) + K_2 C_2 \left(\frac{D_o}{2I} \right) M_i$$

$$+ \frac{K_3 E \alpha |\Delta T_1|}{2(1 - \nu)} + K_3 C_3 E_{ab} |\alpha_a T_a - \alpha_b T_b| + \frac{E \alpha |\Delta T_2|}{1 - \nu}$$

$$(B4.7)$$

where K_1, K_2, K_3 = local stress indices for specific component under consideration

ν = Poisson's ratio of material

$|\Delta T_1|$ = absolute value of range of temperature difference between temperature of outside surface and inside surface of pipe wall, assuming moment generating equivalent linear temperature distribution, °F (see Fig. B4.4)

$|\Delta T_2|$ = absolute value of range of that portion of nonlinear thermal gradient through wall thickness not included in ΔT_1, °F (see Fig. B4.4)

For each S_p, an alternating stress intensity S_{alt} is determined by

$$S_{alt} = \frac{K_e S_p}{2} \qquad (B4.8)$$

where

$$K_e = \begin{cases} 1.0 & \text{for } S_n \leq 3 S_m \\ 1.0 + (1 - n)[S_n/(3 S_m) - 1]/[n(m - 1)] & \text{for } 3 S_m < S_n < 3 m S_m \\ 1/n & \text{for } S_n \geq 3 m S_m \end{cases}$$

m, n = material parameters given in Table B4.1

The alternating stress intensities are used to evaluate the cumulative effect of the stress cycles on the piping system. This evaluation is performed as follows:

a. The number of times each stress cycle of type 1, 2, 3, etc., is repeated during the life of the system shall be called n_1, n_2, n_3, and so on. Cycles shall be superimposed such that the maximum possible peak stress ranges are developed.

TABLE B4.1   Values of m, n, and T_{max} for Various
Classes of Permitted Materials

Materials	m	n	T_{max},°F
Carbon steel	3.0	0.2	700
Low-alloy steel	2.0	0.2	700
Martensitic stainless steel	2.0	0.2	700
Austenitic stainless steel	1.7	0.3	800
Nickel-chromium-iron	1.7	0.3	800
Nickel-copper	1.7	0.3	800

Source: Table NB-3228.5(b)-1, Section III, Division 1, ASME
B & PV Code, 1998. (*Courtesy of ASME.*)
  Note: (°F − 32)/1.8 = °C).

b. For each type of stress cycle, determine the alternating stress intensity S_{alt}.

c. For each value of S_{alt}, use the applicable design fatigue curve from the code to determine the maximum number of cycles permitted if this were the only cycle occurring. These numbers shall be designated N_1, N_2, N_3, and so on.

d. For each type of stress cycle, calculate the usage factor:

$$U_1 = \frac{n_1}{N_1} \qquad U_2 = \frac{n_2}{N_2} \qquad U_3 = \frac{n_3}{N_3} \qquad \cdots$$

e. The cumulative usage factor U is the sum of the individual usage factors:

$$U = U_1 + U_2 + U_3 + \cdots$$

ASME Boiler and Pressure Vessel Code, Section III, Subsections NC and ND.[3]   These two subsections give the code requirements of nuclear piping designated as Class 2 and Class 3, respectively. The loadings required to be considered for Subsections NC and ND are the effects of pressure, weight, other sustained loads, thermal expansion and contraction, and occasional loads. The stress limits to be met are as follows:

1. *Stresses due to sustained loads.*   The calculated stresses due to pressure, weight, and other sustained mechanical loads must meet the allowable $1.5S_h$, that is,

$$\frac{B_1 P D_o}{2t} + \frac{B_2 M_A}{Z} \leq 1.5 S_h \qquad \text{(B4.9)}$$

where P = internal design pressure, psi
  D_o = outside diameter of pipe, in
  t = nominal wall thickness, in
  Z = section modulus of pipe, in^3
  M_A = resultant moment loading on cross section due to weight and other sustained loads, in · lb
  S_h = basic material allowable stress at design temperature, psi

2. *Stresses due to occasional loads.*   The calculated stress due to pressure, weight, other sustained loads, and occasional loads must meet the allowables as follows:

$$\frac{B_1 P_{max} D_o}{2t} + \frac{B_2(M_A + M_B)}{Z} \leq k S_h \qquad (B4.10)$$

where M_B = resultant moment loading on cross section due to occasional loads, such as thrusts from relief and safety valves, loads from pressure and flow transients, and earthquake, if required. For earthquake, use only one-half the range. Effects of anchor displacement due to earthquake may be excluded if they are included under thermal expansion

P_{max} = peak pressure, psi

kS_h = $1.8S_h$ for service level B (upset condition) but not greater than $1.5S_y$; $2.25S_h$ for service level C (emergency condition) but not greater than $1.8S_y$; and $3.0S_h$ for service level D (faulted condition) but not greater than $2.0S_y$

S_h = material allowable stress at temperature consistent with loading under consideration, psi

S_y = material yield strength at temperature consistent with loading under consideration, psi

3. *Stresses due to thermal expansion*

   a. Thermal expansion stress range must meet the allowable S_A, that is,

$$\frac{i M_C}{Z} \leq S_A \qquad (B4.11)$$

where S_A = allowable stress range for expansion stresses

= $f(1.25S_c + 0.25S_h)$, psi

f = stress range reduction factor, as in Table B4.2

M_C = range of resultant moment due to thermal expansion, in · lb; also include moment effects of anchor displacements due to earthquake if anchor displacement effects were omitted from occasional loadings

S_c = basic material allowable stress at minimum (cold) temperature, psi

TABLE B4.2   Stress-Range Reduction Factors

Number of equivalent full-temperature cycles N	f
7,000 and less	1.0
7,000 to 14,000	0.9
14,000 to 22,000	0.8
22,000 to 45,000	0.7
45,000 to 100,000	0.6
100,000 and over	0.5

Source: Table NC-3611.2(e)-1, Section III, Division 1, ASME B & PV Code, 1998. (*Courtesy of ASME.*)

S_h = basic material allowable stress at maximum (hot) temperature, psi
i = stress intensification factor

b. If Eq. (B4.11) is not met, the piping may be qualified by meeting the following equation:

$$\frac{P D_o}{4t} + \frac{0.75i\, M_A}{Z} + \frac{i\, M_C}{Z} \le S_h + S_A \qquad (B4.12)$$

where 0.75i shall not be less than 1.0.

4. *Stresses due to nonrepeated anchor movement.*   The effect of any single nonrepeated anchor movement (such as building settlement) must meet 3.0S_c,

$$\frac{i\, M_D}{Z} \le 3.0 S_c \qquad (B4.13)$$

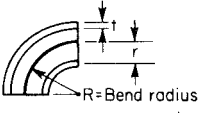
where M_D = resultant moment due to any single nonrepeated anchor movement (e.g., predicted building settlement), in · lb.

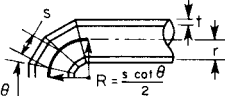
5. The *stress-intensification factor (SIF)* is defined as the ratio of the maximum stress intensity to the nominal stress, calculated by the ordinary formulas of mechanics. It is used as a safety factor to account for the effect of localized stresses on piping under a repetitive loading. In piping design, this factor is applied to welds, fittings, branch connections, and other piping components where stress concentrations and possible fatigue failure might occur. Usually, experimental methods are used to determine these factors.

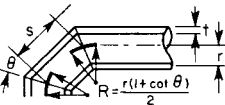
It is recognized that some of the SIFs for the same components are different for different codes. In some cases, different editions of the same code provide different SIFs for a given component. The way that the SIFs are applied to moment loadings is also different for different codes. The B31.1 and ASME Section III codes require that the same SIF be applied to all the three-directional moments while the B31.3, B31.4, B31.5, and B31.8 codes require that different SIFs be applied to the in-plane and out-of-plane moments, with no SIF required for torsion (see Fig. B4.5a and figure note 10).

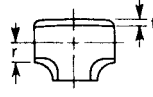
Therefore, the stress analyst has to ensure that the appropriate SIFs from the applicable code (i.e., committed code) are used. The formulas for SIFs in the ASME Section III code (1989 edition) are given in Fig. B4.5c for reference.

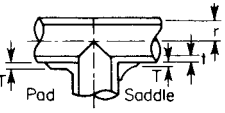
Recommended SIFs for some piping components which are not addressed in the code are listed below:

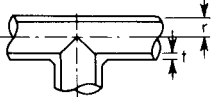
a. Weldolets or sockolets[4]












(1) If $r/R > 0.5$,

$$i = \frac{0.9}{h^{2/3}} \qquad \text{where} \qquad h = \frac{3.3t}{R} \qquad (B4.14)$$

where r = mean radius of branch pipe, in
t = wall thickness of run pipe, in
R = mean radius of run pipe, in

Item	Description	Flexibility factor n	Stress int. factor i [Notes (9), (10)]	
			In-plane i	Out-of-plane i_o

12	Corrugated straight pipe, or corrugated or creased bend[7]	5	2.5	

FIGURE B4.5a   Flexibility factor n and stress intensification factors i_i and i_o per ASME B31.3, B31.4, B31.5, and B31.8 codes.

Flexibility characteristic h	Sketch
$\dfrac{tR}{r^2}$	
$\dfrac{\cot\theta}{2}\dfrac{ts}{r^2}$	
$\dfrac{1+\cot\theta}{2}\dfrac{t}{r}$	
$4.4\dfrac{t}{r}$	
$\dfrac{(t+\frac{1}{2}T)^{5/2}}{t^{3/2}r}$	
$\dfrac{t}{r}$	

Meaning of symbols:

r = mean radius of matching pipe

t = (for elbows, bends, and miter bends) nominal wall thickness of elbow, bend, or miter bend; see Note 5

t = (for tees and nozzles), the nominal wall thickness of the matching pipe

R = bend radius of pipe bend or elbow

θ = one-half angle between adjacent miter axes

s = miter spacing at center line

T = pad or saddle thickness, in.

NOTES:

1. The flexibility factors n and the stress-intensification factors i in the table apply to bending and in no case shall be taken less than unity. Factors for torsion equal unity. Both factors apply over the effective arc length (shown by heavy center lines in the sketches) for curved and miter elbows and to the intersection point for tees.

2. Those flexibility and stress intensification factors which are proportional to a power of the characteristic h may be read from the graph of Fig. B4-5b.

3. Where flanges are attached at one or both ends, the values of n and i in the table shall be corrected by the multiplicative factors C_f given by the formulas:

$$C_f = h^{1/6} \text{ (one end flanged)}$$
$$C_f = h^{1/3} \text{ (both ends flanged)}$$

4. Also includes single-miter joint.

5. Cast butt-welding elbows may have considerably heavier walls than that of the pipe with which they are used. Large errors may be introduced unless the effect of such greater thickness is considered.

6. $h = 4.05t/r$ for $T > 1\frac{1}{2}t$

7. Factors shown apply to bending; flexibility factor for torsion = 0.9.

8. In large-diameter thin-wall elbows and bends internal pressure can significantly decrease both flexibility and stress intensification factors. To correct values obtained from above tabulation so as to account for internal pressure, divide the flexibility factor by the quantity

$$[1 + 6(P/E)(r/t)^{7/3}(R/r)^{1/3}]$$

and divide the stress intensification factor by the quantity

$$[1 + 3.25(P/E)(r/t)^{5/2}(R/r)^{2/3}]$$

where P = internal gage pressure and E = Young's modulus.

9. For items 2 and 3, $i_o = 0.9/h^{2/3}$ per ASME B31.3 and B31.8 codes.

10. For ASME B31.3 and B31.8 piping, a single intensification factor equal to $0.9/h^{2/3}$ may be used for both i_i and i_o if desired.

FIGURE B4.5a (*Continued*) Flexibility factor n and stress intensification factors i_i and i_o per ASME B31.3, B31.4, B31.5, and B31.8 codes.
FIGURE B4.5b Flexibility and stress intensification factors for those cases where result is a power of the characteristic h, defined in Fig. B4.5a. Key: a = no flanges; b = one flange; c = two flanges; i = in plane; o = out of plane.

(2) If $r/R \leq 0.5$,

$$i = 1.5 \left(\frac{R}{T} \right)^{2/3} \left(\frac{r}{R} \right)^{1/2} \frac{t}{T} \frac{r}{r_p} \tag{B4.15}$$

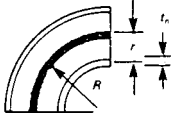
or

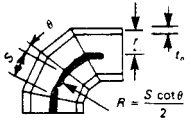
$$i = \frac{0.9}{(3.3T/R)^{2/3}} \tag{B4.16}$$

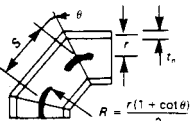
whichever is less and

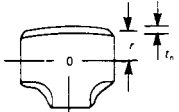
where R = run pipe mean radius, in
T = run pipe wall thickness, in
r = branch pipe mean radius, in
t = branch pipe wall thickness, in
r_p = outer radius of weldolet, in

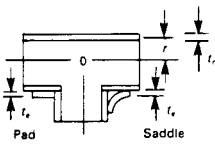
SIF values for typical weldolet branch connections with $r/R \leq 0.5$ are tabulated in Tables B4.3a to B4.3l.

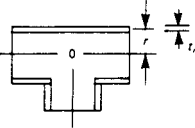
b. *Half-Couplings (Welding Boss).* For half-couplings with $r/R \leq 0.5$, use the above branch connection Eq. (B4.15) or the unreinforced fabricated tee equation, whichever is less. For half-coupling with $r/R > 0.5$, use the unreinforced fabricated tee formula. Tables B4.4a to B4.4f give SIFs for commonly used half-coupling configurations. If the half-coupling rating is not known,












Description	Flexibility Characteristic h	Flexibility Factor k	Stress Intensification Factor i	Sketch

FIGURE B4.5c   (*Continued*) Flexibility and stress intensification factors ($D_o/t_n \leq 100$). (*Figure NC-3673.2(b)-1, Section III, Division 1, ASME B & PV Code, 1998. Courtesy of ASME.*)

assume a Class 3000 half-coupling, since this will give the more conservative value.

c. Sweepolets.   For branch:

$$i = 0.45\left(\frac{R}{T}\right)^{2/3}\left(\frac{r}{R}\right)^{1/2}\frac{t}{T}F_1 F_s \tag{B4.17}$$

(1) The following nomenclature applies:
   r = mean radius of pipe, in. (matching pipe for tees and elbows)
   t_n = nominal wall thickness of pipe in. [matching pipe for tees and elbows, see Note (9)]
   R = bend radius of elbow or pipe or d, in.
   θ = one-half angle between adjacent miter axes, deg.
   s = miter spacing at center line, in.
   t_e = reinforced thickness, in.
   δ = average permissible mismatch at girth butt welds as shown in Fig. NC-4233-1. A value of δ less than $\frac{1}{32}$ in. may be used provided the smaller mismatch is specified for fabrication. For "flush" welds, as defined in Fig. NB-3683.1(c)-1, δ may be taken as zero, i = 1.0, and flush welds need not be ground.
   D_o = outside diameter, in.
(2) The flexibility factors k and stress intensification factors i apply to bending in any plane for fittings and shall in no case be taken less than unity. Both factors apply over the effective arc length (shown by heavy center lines in the sketches) for curved and miter elbows, and to the intersection point for tees. The values of k and i can be read directly by entering with the characteristic h computed from the equations given.
(3) Where flanges are attached to one or both ends, the values of k and i shall be corrected by the factor c given below.
   (a) One end flanged, $c = h^{\frac{1}{6}}$
   (b) Both ends flanged, $c = h^{\frac{1}{3}}$
(4) Also includes single miter joints.
(5) When $t_e > 1.5t_n$, $h = 4.05t_n/r$
(6) The equation applies only if the following conditions are met.
   (a) The reinforcement area requirements of NC-3643 are met.
   (b) The axis of the branch pipe is normal to the surface of run pipe wall.
   (c) For branch connections in a pipe, the arc distance measured between the centers of adjacent branches along the surface of the run pipe is not less than three times the sum of their inside radii in the longitudinal direction or not less than two times the sum of their inside radii along the circumference of the run pipe.
   (d) The inside corner radius r_1 [Fig. NC-3673.2(b)-2] for nominal branch pipe size greater than 4 in. shall be between 10% and 50% T_r. The radius r_1 is not required for nominal branch pipe size smaller than 4 in.
   (e) The outer radius r_2 is not less than the larger of $T_b/2$, $(T_b + Y)/2$ [Fig. NC-3673-2(b)-2 sketch (c)] or $T_r/2$.
   (f) The outer radius r_3 is not less than the larger of
       (1) $0.002\theta\ d_o$
       (2) $2 (\sin \theta)^3$ times the offset for the configurations shown in Fig. NC-3673.2(b)-2 sketches (a) and (b).
   (g) $R_m/T_r \le 50$ and $r'_m/R_m \le 0.5$.
   (h) The outer radius r_2 is not required provided an additional multiplier of 2.0 is included in the equations for branch end and run end stress intensification factors. In this case, the calculated value of i for the branch or run shall not be less than 2.1.
(7) The equation applies only if the following conditions are met.
   (a) Cone angle α does not exceed 60 deg.
   (b) The larger of D_1/t_1 and D_2/t_2 does not exceed 100.
   (c) The wall thickness is not less than t_1 throughout the body of the reducer, except in and immediately adjacent to the cylindrical portion on the small end, where the thickness shall not be less than t_2.
   (d) For eccentric reducers, α is the maximum cone angle.
(8) Factors shown apply to bending; flexibility factor for torsion equals 0.9.
(9) The designer is cautioned that cast butt welding elbows may have considerably heavier walls than that of the pipe with which they are used. Large errors may be introduced unless the effect of these greater thicknesses is considered.
(10) The stress intensification factor i shall in no case be taken as less than 2.1.
(11) In Fig. NC-4427-1(c-1) and (c-2), C_x shall be taken as $X_{m,n}$ and $C_x \ge 1.25\ t_n$. In Fig. NC-4427-1 (c-3), $C_x \ge 0.75\ t_n$. For unequal leg lengths use the smaller leg length for C_x.

FIGURE B4.5c (*Continued*) Flexibility and stress intensification factors ($D_o/t_n \le 100$). (*Figure NC-3673.2(b)-1, Section III, Division 1, ASME B & PV Code, 1998. Courtesy of ASME.*)

For run:

$$\text{For } \frac{r}{R} > 0.5 \qquad i = 0.40\left(\frac{R}{T}\right)^{2/3}(F_2)(F_s) \qquad \text{(B4.18)}$$

$$\text{For } \frac{r}{R} \le 0.5 \qquad i = 0.8\left(\frac{R}{T}\right)^{2/3}\left(\frac{r}{R}\right)F_s \quad \text{but not less than 1.5} \quad \text{(B4.19)}$$

where $F_1 = F_2 = 1.0$ for flush or dressed insert welds
       $= 1.6$ for as-welded insert welds
       $F_2 = (0.5 + r/R)$, but not less than 1.0 for as-welded insert welds
       $F_s = 1 + 0.05(r - 3)$, but not less than 1.0
       R = mean radius of run pipe, in

where t = run pipe wall thickness, in
 r = run pipe mean radius, in
 r_b = branch pipe mean radius, in

These equations are for integrally reinforced branch connections such as latrolets. By the analogy used in Fig. NC-3673.2(b)-1 in Section III of the ASME Code, the SIF for unreinforced 45° branch connections (stub-ins) can be obtained by multiplying the factors obtained above by $(4.4)^{2/3} = 2.685$.

of this code cover those for pipe, flanges, bolting, gaskets, valves, relief devices, fittings, and the pressure-containing portions of other piping components. It also includes hangers and supports and other equipment items necessary to prevent overstressing the pressure-containing components.

The loadings required to be considered are pressure; weight (live, dead, and under test loads); impact (e.g., water hammer); wind; earthquake (where applicable); vibration; and those loadings resulting from thermal expansion and contraction.

4. *The requirement for the effects of any single nonrepeated anchor movement is not specified.*

ASME B31.3 Process Piping Code.[9]   This code governs all piping within the property limits of facilities engaged in the processing or handling of chemical, petroleum, or related products. Examples are a chemical plant, petroleum refinery, loading terminal, natural gas processing plant, bulk plant, compounding plant, and tank farm. Excluded from the B31.3 code are piping carrying nonhazardous fluid with an internal gauge pressure less than 15 psi (103.5 kPa) and a temperature below 366°F (186°C); plumbing; sewers; fire protection systems; boiler external piping per B31.1 as well as pipelines per B31.4 or B31.8.

1 in = 25.4 mm

The loadings required to be considered are pressure, weight (live and dead loads), impact, wind, earthquake-induced horizontal forces, vibration, discharge reactions, thermal expansion and contraction, temperature gradients, and anchor movements.

The governing equations are as follows:

1. *Stresses due to sustained loads.*　The sum of the longitudinal stresses S_L due to pressure, weight, and other sustained loads must not exceed S_h (basic allowable stress at maximum metal temperature). The thickness of pipe used in calculating S_L shall be the nominal thickness minus mechanical, corrosion, and erosion allowances.

1 in = 25.4 mm

2. *Stresses due to occasional loads.* The sum of the longitudinal stresses due to pressure, weight, and other sustained loads and of the stresses produced by occasional loads such as earthquake or wind shall not exceed $1.33S_h$. Earthquake and wind loads need not be considered as acting simultaneously.

3. *Stress range due to expansion loads.* The displacement stress range S_E shall not exceed S_A:

$$S_E \leq S_A \qquad (B4.28)$$

where $S_E = (S_b^2 + 4S_t^2)^{1/2}$
S_b = resultant bending stress, psi
$= [(i_i M_i)^2 + (i_o M_o)^2]^{1/2}/Z$

1 in = 25.4 mm

crude oil, condensate, natural gasoline, natural gas liquids, liquefied petroleum gas, liquid alcohol, liquid anhydrous ammonia, and liquid petroleum products between producers' lease facilities, tank farms, natural gas processing plants, refineries, stations, ammonia plants, terminals, and delivery and receiving points. Excluded from B31.4 are auxiliary piping such as water, air, steam, lubricating oil, gas, and fuel; piping with an internal gauge pressure at or below 15 psi (103.5 kPa) regardless of temperature; piping with an internal gauge pressure above 15 psi (103.5 kPa) and a temperature below −20°F (−29°C) or above 250°F (121°C); and piping for petroleum refinery, gas transmission and distribution, ammonia refrigeration, and so on, that is covered by other ASME B31 sections.

The limits of calculated stresses are as follows:

1. *Stresses due to sustained loads.*   The sum of the longitudinal stresses due to pressure, weight, and other sustained external loads shall not exceed $0.75S_A$, where $S_A = 0.72S_y$ (specified minimum yield strength).

2. *Stresses due to occasional loads.*   The sum of the longitudinal stresses produced by pressure, live and dead loads, and those produced by occasional loads, such as wind or earthquake, shall not exceed $0.8S_y$.

3. *Stresses due to expansion loads*

   a. *Restrained lines.*   The net longitudinal compressive stress due to the combined effects of temperature rise and fluid pressure shall be computed from the equation.

   $$S_L = E\alpha(T_2 - T_1) - \nu S_H \qquad \text{(B4.29)}$$

   where S_L = longitudinal compressive stress, psi
   S_H = hoop stress due to fluid pressure, psi
   T_1 = temperature at time of installation, °F
   T_2 = maximum or minimum operating temperature, °F
   E = modulus of elasticity, psi
   α = linear coefficient of thermal expansion, in/(in · °F)
   ν = Poisson's ratio = 0.30 for steel

   Then the equivalent tensile stress is calculated as

   $$S_{\text{eqiv}} = S_H + S_L < 0.9S_y \qquad \text{(B4.30)}$$

   where S_{eqiv} = the equivalent tensile stress, psi. Beam bending stresses shall be included in the longitudinal stress for those portions of the restrained line which are supported aboveground.

   b. *Unrestrained lines.*   Stresses due to expansion for those portions of the piping without substantial axial restraint shall be combined in accordance with the following equation:

   $$S_E = \left(S_b^2 + 4S_t^2\right)^{1/2} < S_A \qquad \text{(B4.31)}$$

   where S_E = stress due to expansion, psi
   $S_b = [(i_iM_i)^2 + (i_oM_o)^2]^{1/2}/Z$
   = equivalent bending stress, psi
   $S_t = M_t/(2Z)$ = torsional stress, psi
   M_i = in-plane bending moment, in · lb
   M_o = out-of-plane bending moment, in · lb
   M_t = torsional moment, in · lb
   i_i = in-plane stress intensification factor obtained from Fig. B4.5a
   i_o = out-of-plane stress intensification factor obtained from Fig. B4.5a
   Z = section modulus of pipe, in³

ASME B31.5 Refrigeration Piping Code.[11]   The scope of this code covers refrigerant and secondary coolant piping for temperatures as low as −320°F (196°C). Excluded from this code are piping designed for external or internal gauge pressure not exceeding 15 psi (103.5 kPa) regardless of size; water piping; and any self-

contained or unit systems subject to the requirements of Underwriters' Laboratories or other nationally recognized testing laboratory.

The limits of calculated stresses are as follows:

1. *Stresses due to expansion loads.* The expansion stress range S_E shall not exceed the allowable stress range S_A:

$$S_E < S_A = f(1.25S_c + 0.25S_h) \qquad \text{(B4.32)}$$

where S_E = expansion stress range = $(S_b^2 + 4S_t^2)^{1/2}$, psi
S_b = resultant bending stress
    = $[(i_iM_i)^2 + (i_oM_o)^2]^{1/2}/Z$, psi
S_t = torsional stress = $M_t/(2Z)$, psi
M_i = in-plane bending moment, in · lb
M_o = out-of-plane bending moment, in · lb
M_t = torsional moment, in · lb
i_i = in-plane stress intensification factor obtained from Fig. B4.5a
i_o = out-of-plane stress intensification factor obtained from Fig. B4.5a
Z = section modulus of pipe, in³
S_c = basic material allowable stress at minimum (cold) normal temperature, psi
S_h = basic material allowable stress at maximum (hot) normal temperature, psi
f = stress range reduction factor obtained from Fig. B4.5d
FIGURE B4.5d Stress range reduction factors. (*Extracted from Refrigeration Piping Code, ASME B31.5 1992. Courtesy of ASME.*)

2. *Stresses due to sustained loads.* The sum of the longitudinal stresses due to pressure, weight, and other sustained external loading S_L shall not exceed S_h. Where $S_L > S_h$, the difference $S_h - S_L$ may be added to the term in parentheses in Eq. (B4.32).

3. *Stresses due to occasional loads.* The sum of the longitudinal stresses produced by pressure, live and dead loads, and occasional loads, such as wind or earthquake, may not exceed $1.33S_h$. It is not necessary to consider wind and earthquake as occurring concurrently.

TABLE B4.5 Temperature Derating Factor T for Steel Pipe

Temperature, °F (°C)	Temperature derating factor T
250 or less (121.1 or less)	1.000
300 (148.9)	0.967
350 (176.7)	0.933
400 (204.4)	0.900
450 (233.2)	0.867

Note: For intermediate temperatures, interpolate for derating factor.
Source: ASME B31.8, 1995. *Gas Transmission and Distribution Piping Systems.* (*Courtesy of ASME.*)

ASME B31.8, Gas Transmission and Distribution Piping Code.[12]   This code governs most of the pipelines in gas transmission and distribution systems up to the outlet of the customer's meter set assembly. Excluded from this code are piping with metal temperatures above 450°F (232.2°C) or below −20°F (−29°C); piping beyond the outlet of the customer's meter set assembly; piping in oil refineries or natural gas extraction plants, gas treating plants, and so on, which is covered by other ASME B31 codes; waste gas vent pipe operating at atmospheric pressures; and liquid petroleum transportation piping. The governing equations are as follows:

1. *Stresses due to pressure and external loads.*   The sum of the longitudinal pressure stress and the longitudinal bending stress due to external loads such as weight, wind, and so on, S_L, shall not exceed $0.75S_y\,FT$:

$$S_L \leq 0.75S_y FT \qquad (B4.33)$$

where S_y = specified minimum yield strength, psi
T = temperature derating factor obtained from Table B4.5
F = construction-type design factor obtained from Table B4.6. The construction types are associated with the population density of the surrounding area as follows:
Type A: Sparsely populated areas such as deserts, mountains, and farmland
Type B: Fringe areas around cities or towns

TABLE B4.6 Values of Design Factor F

Construction type	Design factor F
A	0.72
B	0.60
C	0.50
D	0.40

Source: ASME B31.8, 1995. (*Courtesy of ASME.*)

Type C: Cities or towns with no buildings over three stories tall
Type D: Areas with taller buildings

2. *Stress range due to expansion loads.*   The maximum combined expansion stress range S_E shall not exceed $0.72S_y$:

$$S_E = \left(S_b^2 + 4S_t^2\right)^{1/2} < 0.72S_y \qquad \text{(B4.34)}$$

where S_b = resultant bending stress = iM_b/Z, psi
$\quad\quad S_t$ = torsional stress = $M_t/(2Z)$, psi
$\quad\quad M_b$ = resultant bending moment, in · lb
$\quad\quad M_t$ = torsional moment, in · lb
$\quad\quad\; i$ = stress intensification factor obtained from Fig. B4.5*a* (see figure note 10)
$\quad\quad Z$ = section modulus of pipe, in^3

3. *Stresses due to pressure, external loads, and expansion loads.*   The sum of the longitudinal pressure stress, the longitudinal bending stress due to external loads, and the combined stress due to expansion shall not exceed S_y.

STRESS INTENSIFICATION FACTORS (SIF) FOR NONSTANDARD FITTINGS

Stress intensification factors for fittings such as Wye (Y) connections and latrolets are not available in the current editions of codes. The following subsections provide data for obtaining appropriate SIFs for various nonstandard fittings.

SIF for 90-Degree Wye Connection

The following SIF (*i*) which can be used is based on a comparative finite element analysis study[13] of a Wye connection and a Tee connection. See Fig. B4.5*i*.

i for forged Wye connection = 1.0 (*i* of WTEE)

for all moments except for torsion and out-of-plane bending moment components from branch side

i_{ob} for forged Wye connection = 3.3 (*i* of WTEE)

for out-of-plane bending moment components from branch side

i_{tb} for forged Wye connection = 1.1 (*i* of WTEE)

for torsional moment components from branch side

Use UTEE (unreinforced tee) instead of WTEE (welding tee) in the above expressions if the Wye connection is a fabricated Wye.[13]

SIF for Weldolets, Sockolets, and Half-Couplings

$$i_r = 0.8\left(\frac{R}{T}\right)^{2/3}\frac{r}{R} \geq 2.1 \quad \text{(for run side)}$$

$$i_b = 1.5\left(\frac{R}{T}\right)^{2/3}\left(\frac{r}{R}\right)^{1/2}\frac{t}{T}\frac{r}{r_p} \geq 1.5 \quad \text{if } \frac{r}{R} \leq 0.9 \quad \text{(for branch side)}$$

$$i_b = 0.9\left(\frac{R}{T}\right)^{2/3}\frac{t}{T}\frac{r}{r_p} \geq 1.0 \quad \text{if } \frac{r}{R} = 1.0 \quad \text{(for branch side)}$$

For branch-side stresses, branch-side section modulus should be used.

For insert or contour weldolets, the coefficients in the above equations 0.8, 1.5, and 0.9 are replaced by 0.4, 0.75, and 0.45, respectively.

R, T = mean radius and wall thickness of run pipe
  r, t = mean radius and wall thickness of branch pipe
    r_p = outside radius of the reinforcement on nozzle or branch

The above equations are based on Refs. 14 and 15.

SIF for 45-Degree Latrolets

Forged latrolet: $i = 0.5727\ (R/T)^{2/3}$ based on $h = 1.97\ (T/R)$

Fabricated lateral: $i = 1.5378(R/T)^{2/3}$ obtained by multiplying the SIF of forged latrolet by $(4.4)^{2/3}$

See Ref. 16.

SIF for Reducers

Even though the reducer is a standard fitting and the formula for SIF is available in the codes,[17] the cone angle is not readily available. The following SIF formula from the codes can be used for large-bore concentric and eccentric reducers. Using data from Ref. 18, the following expressions can be used for the cone angle, α:

$$i = 0.5 + 0.01\alpha\left(\frac{d_2}{t_2}\right)^{0.5} \qquad (1.0 < i \leq 2.0)$$

$$\alpha_1 = \left(80.4\ \frac{D}{d}\right) - 62.9 \quad \text{for} \quad 1 < \frac{D}{d} < 1.3$$

$$\alpha_1 = \left(28.3\ \frac{D}{d}\right) + 2.9 \quad \text{for} \quad \frac{D}{d} \geq 1.3$$

$$\alpha = \frac{\alpha_1}{2} \quad \text{for concentric reducers}$$

$$\alpha = \alpha_1 \quad \text{for eccentric reducers}$$

where α = cone angle in degrees

D, d = mean diameter of large and small ends of reducer, respectively

d_2, t_2 = outside diameter and thickness of small end of reducer, respectively

See Refs. 17 and 18.

LOCAL STRESSES

In addition to the general pipe stresses (the pressure stress and the moment stress) as described in the previous sections, there are certain local pipe wall stresses produced by (1) restraint of the pipe radial thermal and internal pressure expansion of pipe-through-structural-steel type of anchors, (2) the transfer of load from the supporting surface to the pipe surface over a contact length along the axis of the pipe, or (3) attachments welded to pipe (e.g., lugs and trunnions).

Local Stresses and Code Requirements

The local stresses S_L, S_L^*, S_L^{**}, and S_L^{***} can be expressed as follows:

$$S_L, S_L^*, S_L^{**}, \text{ or } S_L^{***}$$
$$= \max\left[|\sigma_1 + \sigma_1'|, |\sigma_2 + \sigma_2'|, |\sigma_2 + \sigma_2' - (\sigma_1 + \sigma_1')|\right] \quad \text{(B4.35)}$$

where S_L = local stress due to deadweight, psi

S_L^* = local stress due to deadweight, seismic inertia, and other dynamic loads, psi

S_L^{**} = local stress due to thermal expansion and seismic anchor movement, psi

S_L^{***} = local stress due to concurrently acting loads, psi

σ_1 = longitudinal membrane stress, psi

σ_2 = circumferential membrane stress, psi

σ_2' = circumferential bending stress, psi

σ_1' = longitudinal bending stress, psi

Strictly speaking, the present piping codes give no specific limits for local stresses. As an industry practice, the calculated local stress is added to the general pipe stress and then compared with the pipe stress allowables specified by the applicable code. As an example, the total (general plus local) pipe stresses for ASME Class 2 and 3 piping shall satisfy the following equations [see Eqs. (B4.9), (B4.10), (B4.11), (B4.12) for definitions of symbols]:

1. *Design loading*

$$\frac{B_1 P D_o}{2t} + \frac{B_2 M_A}{Z} + \frac{2}{3}S_L \leq 1.5S_h \quad \text{(B4.36)}$$

2. *Service loadings*

$$\frac{B_1 P_{\max} D_o}{2t} + \frac{B_2(M_A + M_B)}{Z} + \frac{2}{3} S_L^*$$

$$\leq \begin{cases} 1.85 S_h, & \text{but not greater than } 1.5 S_y \text{ for level A and B loadings} \\ 2.25 S_h, & \text{but not greater than } 1.8 S_y \text{ for level C loadings} \\ 3.0 S_h, & \text{but not greater than } 2.0 S_y \text{ for level D loadings} \end{cases}$$ (B4.37)

3. *Sustained and thermal expansion loading:*   Either of the following equations shall be satisfied:

$$\frac{i M_C}{Z} + \frac{1}{2} S_L^{**} \leq S_A$$ (B4.38)

or

$$\frac{P D_o}{4t} + \frac{0.75 i M_A}{Z} + \frac{i M_C}{Z} + \frac{2}{3} S_L + \frac{1}{2} S_L^{**} \leq S_h + S_A$$ (B4.39)

4. *Local stress limit loading*

$$S_L^{***} < 2.5 S_y$$ (B4.40)

Local Stress Due to Restraint of Pipe Radial Expansion

The membrane and flexural stresses can be calculated as follows[19]:

$$\sigma_1 \text{ is negligible}$$

$$\sigma_1' = \frac{\pm 12 D \lambda^2 (\delta_{\widehat{P}} + \delta_T)}{t^2}$$ (B4.41)

$$\sigma_2 = \frac{-(\delta_P + \delta_T)E}{R} + \nu \sigma_1$$ (B4.42)

$$\sigma_2' = \nu \sigma_1'$$ (B4.43)

$$\delta_P = \frac{P R^2}{E t}$$ (B4.44)

$$\delta_T = \alpha R \Delta T$$ (B4.45)

where P = internal pressure of pipe, psi
R = pipe outside radius, in
E = modulus of elasticity of pipe, psi
t = pipe wall thickness, in
α = coefficient of thermal expansion of pipe, in/(in $\cdot$ °F)
ΔT = range of thermal expansion temperatures, °F
ν = Poisson's ratio

$$D = Et^3/[12(1 - v^2)]$$
$$\lambda = [3(1 - v^2)/(Rt)^2]^{1/4}$$

In the case of the local stress produced by restraint to the pipe radial expansion, $S_L = S_L^* = 0$. For fillet weld, $i = 2.1$ should be used. In addition, the stress check on limit loading is required. Here, $S_L^{***} = S_L^{**}$.

Local Stress Due to Contact

The membrane and flexural stresses can be calculated as follows[19]:

1. *For line contact*

$$\sigma_1 = -0.52F(R_m)^{1/4}L^{-1/2}t^{-7/4} \tag{B4.46}$$

(*Note*: σ_1' is considered to be included in this equation.)

$$\sigma_2 = -0.496F(R_m)^{3/4}L^{-3/2}t^{-5/4} \tag{B4.47}$$

$$\sigma_2' = \pm 2\sigma_1 \tag{B4.48}$$

where F = support load, lb
R_m = mean radius of pipe, in
L = contact length, in
t = pipe wall thickness, in

2. *For point contact.* σ_1 and σ_1' are negligible compared to $\sigma_2 + \sigma_2'$:

$$\sigma_2 = \frac{0.4F}{t^2} \tag{B4.49}$$

$$\sigma_2' = \frac{2.4F}{t^2} \tag{B4.50}$$

3. In the case of contact stress, the minimum nominal general pipe stress (i.e., the unintensified general pipe stress) may be used in Eqs. (B4.36) to (B4.39) to calculate the total pipe stress. In addition, the stress check on limit loading is not required.

Other Types of Local Stresses

The two types of local stresses previously described are commonly encountered by stress analysts. Detailed descriptions and analysis methods for other types of local stresses such as the local stresses at integral welded attachments to pipe (e.g., lugs and trunnions) can be found in technical publications, *Welding Research Council Bulletins 107 and 198,* and ASME Code Cases.[21–23]

ANALYSIS OF INTEGRAL WELDED ATTACHMENTS (IWA)

Integral Welded Attachments are often used to support piping systems. The local stresses in the piping at IWA locations are commonly evaluated using the Welding

Research Council (WRC) Bulletin #107 approach,[21] which is based on Bijlaard's work. Generally, the various methods for local stress evaluations can be categorized in accordance with the following list. (Friction-induced loads due to weight and thermal expansion, if applicable, should be included.)

1. Stress intensification factor (SIF) approach for certain configurations
2. WRC Bulletin #107 approach with limitation on β (attachment parameter) and γ (shell parameter) parameters
3. ASME Code cases approach
4. Approach based on utilization of any available finite element analysis (FEA) results or published data
5. Rigorous FEA approach

SIF Approach

In this method, the local stresses are not evaluated directly but are indirectly accounted for by applying a SIF to the general piping stresses.

The SIF approach has the following limitations:

- Applicable to some specific IWA configurations only
- Not applicable to lugs, irregular shapes, and so forth

The SIF approach is applicable in the following situations:

- *360° (full) wrapper plates.* This configuration is no longer a local stress problem. A SIF (i) of 2.1 or 1.3 can be applied, depending on the applicable code.
- *180° wrapper plates.* The following SIFs are recommended by Rodabaugh (see Fig. B4.5e):

  $i = 4.2$ for the run pipe torsional moment (M_{tr}) component

  $i = 2.1$ for the run pipe out-of-plane bending moment (M_{obr}) component

  $i = 1.3$ for the run pipe in-plane bending moment (M_{ibr}) component
- *Circular trunnion/stanchions on straight pipe.* Consider the configuration as a
FIGURE B4.5e 180° wrapper plate (IWA).

reinforced tee (RTEE) and intensify the general piping stresses using a SIF (i) of RTEE per the applicable code requirements. Since there is no hole made in the pipe's pressure boundary, the run pipe thickness can be considered as a reinforcement. If there is a pad, the pad thickness can be considered as an additional reinforcement. Of course, the codes limit the effective thickness of reinforcement [$(t_e)_{max} = 1.5 \times t$].

- *Attachments on fittings.* Cross multiplication of SIFs (for example, a round attachment on elbow or on a tee) can be used (elbow SIF $\times$ RTEE SIF or TEE SIF $\times$ RTEE SIF).

WRC Bulletin #107 Approach

This is based on the analytical work performed by Professor P. P. Bijlaard of Cornell University and subsequently generated experimental data. The results are presented in WRC Bulletin #107 (WRC-107) as nondimensional curves based on β and γ parameters for three different types of loading. The local stresses can be evaluated by hand by filling out the computation sheets for local stresses as given in the WRC-107 bulletin or utilization of commercially available computer program software which has stored the nondimensional curves as digitized data. The WRC-107 method generally yields conservative results. The following additional information relates to this approach:

- *Basis.* Bijlaard's approach is based on shell theory and some simplifications for radial load (P), longitudinal moment (M_L), and circumferential moment (M_C).
- *Strength-of-materials formulas.* Simple strength-of-materials formulas are used to compute shear stresses due to longitudinal shear load (V_L), circumferential shear load (V_C), and torsional moment (M_T) loadings.
- *Shell and attachment parameters and loadings.* The shell, attachment parameters, and loadings are as follows (see Figs. B4.5f and B4.5g):

  shell parameter $\gamma = D_m/(2T)$ where $D_m = D_o - T$
FIGURE B4.5f IWA notations.
FIGURE B4.5g   IWA notations (*continued*).

attachment parameter (β):

For circular attachment $\beta = 0.875 \, (d_o/D_m)$

For square or rectangular attachment

$$\beta_1 = C_1/D_m$$

$$\beta_2 = C_2/D_m$$

Caution: WRC-107 uses C_1 and C_2 to represent one-half of the attachment dimensions in circumferential and longitudinal directions, while here C_1 and C_2 are used for the full attachment dimensions.

- *Limitations.*   The WRC Bulletin #107 approach has the following limitations:

$$0.01 \leq \beta \leq 0.5$$

$$5 \leq \gamma \leq 300$$

$$\tfrac{1}{4} \leq \beta_1/\beta_2 \leq 4 \text{ for } M_c$$

$$\tfrac{1}{4} \leq \beta_2/\beta_1 \leq 4 \text{ for } M_L$$

- *Shear stresses.*   The formulas for shear stress calculations are as follows:

	Square/rectangular IWA	Circular IWA
V_L	$\tau = V_L/(2C_2 T)$	$\tau = 2V_L/(\pi d_o T)$
V_C	$\tau = V_C/(2C_1 T)$	$\tau = 2V_C/(\pi d_o T)$
M_T	$\tau = M_T/F^*$ (see Ref. 22)	$\tau = 4M_T/[2\pi(d_o)^2 T]$

*

$$F = \text{larger of} \begin{cases} T\{[C_{max} + C_{min}](C_{min}/2)\}; \text{ or} \\ \{[1.57 + 0.093(C_{max}/C_{min})](C_{min})^2(C_{max})/8\} \end{cases}$$

where C_{max} = maximum of C_1 and C_2
C_{min} = minimum of C_1 and C_2

- *Attachments on elbows.*   To evaluate local stresses in elbows with attachments, the following approach can be utilized. Attachment loads (P', M'_L, M'_C) can be resolved at the elbow/attachment interface to components P, V_L, M_C, M_T, M_L.
$$P = P' \sin \theta \quad ; \quad V_L = P' \cos \theta$$

$$M_L = M'_L$$

$$M_C = M_C' \sin \theta \quad ; \quad M_T = M_C' \cos \theta$$

Where; $\cos \theta = R / (R + r_o)$; R = radius of Elbow;
$\quad\quad r_o$ = Outside radius of Pipe

FIGURE B4.5h   IWA on elbow.

An equivalent straight pipe with the attachment and resolved loads can be considered in local stress evaluation using WRC-107 (see Fig. B4.5h).

Approach Based on ASME Code Cases

The Welding Research Council (WRC) Bulletin #198[22] fitted equations with some inherent conservatism to curves of WRC Bulletin #107. The results are published as ASME Code cases. Interested readers can refer to the ASME Code cases listed in the following table[23] for details and limitations of their applicability. Generally speaking, the local stress results from Code cases are more conservative than WRC Bulletin #107 results.

	ASME Code Class 1	ASME Code Classes 2 and 3
Rectangular attachments	Code Case # N-122 (1745)	Code Case # N-318
Hollow circular attachments	Code Case # N-391	Code Case # N-392

Approach Based on Available FEA Results

For some commonly utilized configurations and sizes, FEA was performed and the results were compared with WRC-107 results. Reduction factors are supplied relative to WRC-107 results. See Ref. 24.

Based on extensive finite element analysis studies of certain sizes, shapes, and configurations of attachments, the factors in the following tables are generated. The P, M_L, M_C loads can be reduced by dividing them with the applicable factors, and then the WRC-107 approach can be used. The γ value should be limited to the following range: $3.5 \leq \gamma \leq 31.5$.

Factors for Attachments on Straight Pipe

		P		M_L		M_C	
		σ_m	$\sigma_m + \sigma_b$	σ_m	$\sigma_m + \sigma_b$	σ_m	$\sigma_m + \sigma_b$
Small attachments	S	1.23	1.28	1.11	1.36	1.00	1.21
$\beta \leq 0.5$	C	1.56	2.25	1.03	1.42	1.00	1.46
	R	1.17	1.46	1.08	1.36	1.00	1.32
	R (Note 1)	1.00	1.46	1.00	1.36	0.42	1.32
Large attachments	R	1.80	1.50	1.25	2.02	1.15	1.89
$0.5 < \beta \leq 0.7$	C	1.30	1.99	1.00	1.35	0.74	1.47
Note 2							
Large attachments	R	1.81	2.58	1.94	3.53	1.70	2.41
$\beta > 0.7$	C	2.29	3.33	1.80	2.57	1.23	2.22
Note 2							
Large attachments	R	3.6	4.0	4.61	4.86	7.52	19.04
$\beta > 0.7$ and extending 180° circumferentially	C	1.07	2.12	7.77	14.57	3.87	15.14
Note 2							

Notes: 1. Factors for rectangular attachments when $3.5 \leq \gamma < 5$ and $\beta \leq 0.5$.

2. Apply these factors to the loads when actual $\beta > 0.5$ and evaluate the local stress based on WRC-107 utilizing artificially reduced attachment size to correspond to $\beta = 0.5$.

Notation: S: square attachments

R: rectangular attachments

C: circular attachments

σ_m: membrane stress

σ_b: bending stress

P: radial load

M_L: longitudinal moment

M_C: circumferential moment

See ASME paper listed in Ref. 24.

Factors for Circular Attachments on Long-Radius Elbows

	P		M_L		M_C	
	σ_m	$\sigma_m + \sigma_b$	σ_m	$\sigma_m + \sigma_b$	σ_m	$\sigma_m + \sigma_b$
$0.5 < d_o/D_o \leq 0.8$	2.00	3.60	1.53	2.66	1.61	2.87
$0.8 < d_o/D_o \leq 1$	3.14	4.88	2.42	3.53	2.52	4.37

Notes: Apply these factors to the loads (divide the loads by these factors) and perform WRC-107 evaluation using attachment size reduced to correspond to $\beta = 0.5$.

   Notation: d_o: outside diameter of circular attachment

   D_o: outside diameter of pipe

See ASME paper listed in Ref. 24.

Rigorous FEA Approach

For this approach, a 3-D finite-element model of the shell and attachment has to be built. A portion of the pipe, attachment, and pipe/attachment interface can be modeled and loadings applied. FEA analysis can be performed and the local stresses can be evaluated.

Although cumbersome and time-consuming, FEA is becoming a viable option due to the availability of commercial FEA software which can run on personal computer platforms. Personal computers have become very powerful tools.
FIGURE B4.5i   Wye connection.

TYPES OF PIPE LOADING CONDITIONS

1. *Types of loads.*   As previously mentioned in the subsection ''Classification of Loads,'' piping loads are classified into three types: *sustained loads, occasional loads,* and *expansion loads.* These three types of loads and the corresponding analysis will be discussed in this section in detail.

2. *Method of analysis.*   The piping stress analysis to be performed could be a simplified analysis or a computerized analysis. The choice of the proper analysis depends on the pipe size and the piping code. For small (nominal diameter 2 in and under) pipe except nuclear Class 1 pipe, a cookbook-type, simplified analysis could be performed. For nuclear Class 1 piping, since the requirements are more stringent, a computerized analysis is required. A detailed description of a cookbook-type, simplified analysis and a brief description of a computerized analysis are given in the section that follows, ''Methods of Analysis.'' Generally, before computerized analysis is performed, pipe supports may be located using the cookbook method.

Sustained Load: Pressure

Internal pressure in piping usually induces stresses in the pipe wall rather than loads on the pipe supports. This is because pressure forces are balanced by tension in the pipe wall, resulting in zero pipe support loadings. A discussion of unbalanced forces in the pipe created by pressure waves during fluid transients is given in the subsection ''Dynamic Loads.''

Pressure Stress.   The longitudinal stress developed in the pipe due to internal pressure can be calculated as follows:

$$S_{LP} = \frac{PD}{4t}$$

or

$$S_{LP} = \frac{Pd^2}{D^2 - d^2} = P\left(\frac{A_f}{A_m}\right) \tag{B4.51}$$

where S_{LP} = longitudinal stress, psi
P = internal design pressure, psig
D = outside diameter, in
d = inside diameter, in
A_f = flow area, in^2
A_m = metal area, in^2
t = pipe wall thickness, in

The second equation gives pressure stress in terms of the ratio of pipe flow area to metal area. It also provides a more accurate result. Both equations are acceptable to the code.

Expansion Joint.   In piping design, elbows, bends, and pipe expansion loops normally provide adequate flexibility for piping thermal expansion and contraction. However, in some cases this flexibility may not be adequate. As a solution, expansion joints may be used to absorb the expansion and contraction of pipe.

In general, expansion joints are used for the following applications:

1. Where thermal movements would induce excessive stress in normal piping arrangements
2. Where space is inadequate
3. Where reactions transmitted by pipe supports or anchors create large loads on supporting structures
4. Where reactions to equipment terminals are in excess of allowables

When expansion joints are used in piping, the pressure forces can no longer be balanced by tension in the pipe wall, and the pressure forces will be resisted by pipe supports and anchors.

There are many types of expansion joints available, ranging from a piece of rubber hose to metal bellows. The metal bellows expansion joint is most commonly used for power or process piping. Figure B4.6 shows the various components of a bellows expansion joint.
FIGURE B4.6   Bellows expansion joints.

Expansion joints do not have the capability to transmit large pressure forces. Restraints are usually installed on both sides of the expansion joint to prevent the pressure force from pulling the joint apart. The pressure force developed in the expansion joint is equal to the internal pressure times the maximum cross-sectional area over which it is applied. Since an expansion joint increases the flexibility of a piping system, the flexibility (spring rate) of the expansion joint should be incorporated in the piping stress analysis. Typical axial spring rates of bellows can be found in Ref. 25.

Sustained Load: Weight

The total design weight load of pipe supports includes the weight of the pipe, fittings, insulation, fluid in pipe, piping components such as valves, valve operators, flanges, and so on, and the supports themselves. Supports should be located as specified in Chap. B5.

Hydrotest and Other Occasional Loadings. To assure the integrity and leak tightness of a piping system designed to Section III of ASME Boiler and Pressure Vessel Code or ASME B31.1, the codes require that a pressure test be performed prior to placing the system in service. The most commonly used test is the hydrostatic test. When a steam or gas piping system is to be hydrotested, the effects of the weight of the water on the system and its supports must be considered. A hydroweight stress analysis should be performed to assure that the pipe supports, which have been designed for the normal operating condition, are able to withstand the hydrotest loads. If permanent supports cannot withstand these hydrotest loads, temporary supports may be added. Spring supports are available with hydrostatic test stops, which, in effect, transform the units into rigid supports.

Whether or not required by code, other conditions, such as the added weight of a cleaning medium of density greater than that of the process fluid, must be considered in a manner similar to that discussed above. Both dynamic and static loading analyses may be impacted by flushing and blowing-out activities during construction or after major rework.

Thermal Expansion Loads

For weight analysis, the more pipe supports installed, the lower the stress developed in the pipe. However, the opposite is true for the case of piping thermal expansion. When thermal expansion of the piping due to fluid or environmental temperature is restrained at supports, anchors, equipment nozzles, and penetrations, large thermal stresses and loads are caused.

Thermal Modes. Piping systems are generally analyzed for one thermal condition or mode, that is, the maximum operating temperature. However, piping systems that have more than one operating mode with different operating temperatures concurrently in different parts of the piping system should be analyzed for these operating thermal modes.

With the aid of system flow diagrams or *piping and instrumentation drawings (P&ID),* the stress analyst can determine the thermal modes required for a particular piping system. For B31.1 piping and ASME Class 2 and 3 piping, the required thermal modes can be determined by using good engineering judgment in selecting

the most severe thermal conditions. For ASME Class 1 piping, the required thermal modes can be determined by examining the load histograms specified in the design specification.

Free Thermal Analysis. During the initial stage of piping analysis, an unrestrained (i.e., no intermediate pipe supports) or free thermal analysis may be performed. This analysis is performed for the worst thermal mode and includes only terminal points such as penetrations, anchors, and equipment nozzles. The result of this free thermal analysis usually gives useful information, which can be utilized by the stress analyst in the later stages of the piping analysis. Generally, a resulting thermal expansion stress < 10 ksi (68,948 kPa) means adequate flexibility exists in the piping system. The piping locations with low resulting thermal displacements would be good locations where rigid supports may be installed without adversely affecting the flexibility of the piping system. The resulting equipment nozzle loads could be used to evaluate the capabilities of the equipment for meeting the equipment manufacturer's nozzle allowables.

Imposed Thermal Movements. Thermal expansion of equipment causes displacements in the attached piping. Thermal stresses may also be caused due to thermal anchor movements at terminal ends and intermediate restraints. Therefore, appropriate thermal analysis for thermal anchor movements relating to the respective thermal modes should also be performed. Sometimes, it is possible for thermal anchor movements to exist when the piping is cold. In such cases, analysis in the cold condition, with only the thermal anchor movements as input, may be required.

LOCA Thermal Analysis. In nuclear power plants, following a *loss-of-coolant accident (LOCA),* the containment (the building structure designed to contain fission products) expands due to the rise in temperature and pressure inside the containment. This containment thermal growth results in large containment penetration anchor movements which affect the connected piping. It is not required to qualify the piping for this faulted condition. Thermal analysis for these LOCA anchor movements is used only for the evaluation of flanges, equipment nozzle loads, and pipe support loads.

Temperature Decay. For piping systems having a portion of the system with stagnant branch lines (dead legs) as shown in Fig. B4.7, it is necessary to consider
FIGURE B4.7 Temperature decay at dead leg.

the temperature decay in the piping. One simple approach to this temperature attenuation problem is as follows:

1. For a piping system with water, the temperature of the branch pipe is assumed to be the same as the run pipe up to a length equivalent to 10 times the inside pipe diameter. The remaining portion of the branch pipe may be considered at ambient temperature.

2. For a piping system with steam or gas, the temperature of the branch pipe is considered the same as the run pipe up to the closed valve.

For cases such as thermal transient analysis of ASME Class 1 piping, where a more accurate temperature profile along the branch pipe may be required, the approach described in Ref. 26 should be used.

Stress Ranges. The thermal stresses developed in the pipe are in fact "stress ranges," that is, the difference between the unit thermal expansion for the highest operating temperature and for the lowest operating temperature.

For piping systems that do not experience temperatures below ambient temperature, the stress range is the difference between the unit expansion for the maximum thermal mode and that for 70°F (21°C). (See later subsection "Seismic Anchor Movement and Building Settlement Analysis.")

For systems with supply from a pool or river which might go below 70°F (21°C) in the winter, negative coefficients of expansion should be considered in evaluating the stress range.

Occasional Loads: Seismic

The code of Federal Regulation 10CFR Part 50 requires that safety-related piping in nuclear power plants be designed to withstand seismic loadings without loss of capability to perform their function.[27] For nonnuclear piping in regions of high seismic activity, this design requirement should also be considered.

OBE and SSE. Nuclear piping systems and components classified as Seismic Category I are designed to withstand two levels of site-dependent hypothetical earthquakes: the *safe-shutdown earthquake* (*SSE*) and the *operational-basis earthquake* (*OBE*).[28]

For conservatism, the OBE must usually be equal to at least one-half of the SSE. Their magnitudes are expressed in terms of the gravitational acceleration *g*. Their motions are assumed to occur in three orthogonal directions: one vertical and two horizontal.

Seismic Category I systems are defined as those necessary to assure:

1. The integrity of the reactor coolant pressure boundary

2. The capability to shut down the reactor and maintain it in a safe shutdown condition

3. The capability to prevent or mitigate potential off-site radiation exposure

Types of Seismic Analysis. Generally, piping seismic analysis is performed through one of three methods: *time-history analysis, modal response spectrum analysis,* or *static analysis.*

The equation of motion for a piping system subjected to an externally applied loading (seismic excitation) may be expressed as

$$M\ddot{\mathbf{x}} + C\dot{\mathbf{x}} + K\mathbf{x} = \mathbf{f} \tag{B4.52}$$

where M = mass matrix of system
C = damping matrix
K = stiffness matrix
$\ddot{\mathbf{x}}$ = acceleration vector
$\dot{\mathbf{x}}$ = velocity vector
$\mathbf{x}$ = displacement vector
$\mathbf{f}$ = external loading vector, function of time

This equation could be solved by time-history analysis.

Time-History Analysis. Time-history analysis is based on hypothetical earthquake data in the form of ground displacement, velocity, or acceleration versus time. The piping system is represented by lumped masses connected by massless elastic members. The analysis is performed on this mathematical model by the direct numerical integration method.[29,30] At each time step, the piping stresses, displacements, and restraint loads are calculated. Time history simulates the behavior of the piping system during the seismic excitation. The main advantage of time-history analysis is that analytically it is more accurate and less conservative compared to other approaches. The main disadvantages of time-history analysis are the excessive computational time required and the difficulty of obtaining a realistic earthquake input time function.

Modal Response Spectrum Analysis. The seismic response spectrum is a plot of the maximum acceleration response of a number of idealized single-degree-of-freedom oscillators attached to the floor (structure) with certain damping.

These response spectra are based on design response spectra and specified maximum ground accelerations of the plant site. Usually, a series of curves with different damping values for operating and design basis earthquakes for each orthogonal direction are generated, as shown in Fig. B4.8.

In the modal response spectrum analysis, the piping system is idealized as lumped masses connected by massless elastic members. The lumped masses are carefully located to adequately represent the dynamic properties of the piping system.

After the stiffness and mass matrix of the mathematical model are calculated, the natural frequencies of the piping system and corresponding mode shapes for all significant modes of vibration are also determined using the following equation:

$$\left(K - W_n^2 M\right)\phi_n = 0 \tag{B4.53}$$

where K = stiffness matrix
W_n = natural circular frequency for the nth mode
M = mass matrix
ϕ_n = mode shape matrix for the nth mode

The modal spectral acceleration taken from the appropriate response spectrum is then used to find the maximum response of each mode:

$$(Y_n)_{\text{max}} = \frac{\phi_n^t M D S a_n}{W_n^2 M_n} \tag{B4.54}$$
FIGURE B4.8   Response spectrum curves.

where Sa_n = spectral acceleration value for the nth mode
      D = earthquake direction coefficient
      ϕ_n^t = transpose of the nth mode shape
      M_n = generalized mass of the nth mode
      Y_n = generalized coordinate for the nth mode

Using the maximum generalized coordinate for each mode, the maximum displacements, the effective inertia forces, the effective acceleration, and the internal forces and moments associated with each mode are calculated as follows:

$$X_n = \phi_n (Y_n)_{\max}$$

$$F_n = K X_n$$

$$a_n = M^{-1} F_n$$

$$L_n = bF_n \qquad\qquad (B4.55)$$

where X_n = displacement matrix due to nth mode
      F_n = effective inertia force matrix due to nth mode
      a_n = effective acceleration matrix due to nth mode
      M^{-1} = the inverse of mass matrix
      L_n = internal force and moment matrix due to nth mode
      b = force transformation matrix

These modal components are then combined by the appropriate method (see later subsection "Methods for Combining System Responses") to obtain the total displacements, accelerations, forces, and moments for each point in the piping system.

   Two types of response spectrum analyses can be performed depending on the pipe routing and attachments to buildings and structures.

   Single-Response Spectrum Analysis.   This type of analysis is performed using an enveloped response spectrum curve that covers all buildings and elevations to which the piping system is attached.

   Multiple-Response Spectrum Analysis.   This type of analysis is used where the piping is attached to various buildings or structures that have a wide variation in the amplitude or frequency of accelerations. In such cases, various response spectra curves may be applied at corresponding support and anchor points in the piping system.[31,32]

   Static Analysis.   Static analysis may be used to evaluate power piping or some piping systems in nuclear power plants. It is performed by analyzing a piping system for the statically applied uniform load equivalent to the site-dependent earthquake accelerations in each of the three orthogonal directions. All rigid restraints and snubbers supporting the pipe in the direction of the earthquake acceleration are included in the analysis. The total seismic effect is obtained by combining the results of the three directions.

   The minimum earthquake force for structures described in ANSI A58.1[33] is also one form of static seismic analysis. The code recommends that a lateral seismic force will be assumed to act nonconcurrently in the direction of each of the main axes of the structure in accordance with the formula:

$$V = ZIKCSW \qquad (B4.56)$$

where V = lateral seismic force, lb

Z = numerical coefficient, dependent upon the earthquake zone (see Fig. B4.9), 0.1 for Zone 0, 0.25 for Zone 1, 0.50 for Zone 2, and 1.00 for Zone 3
FIGURE B4.9   Map for seismic zones, contiguous 48 states. (*ANSI A58.1, 1982. Courtesy of ANSI.*)

TABLE B4.7 Dampling Values (Percent of Critical Damping)

Structure or component	Operating-basis earthquake or ½ safe-shutdown earthquake	Safe-shutdown earthquake
Equipment and large-diameter piping systems, pipe diameter greater than 12 in	2	3
Small-diameter piping systems, diameter equal to or less than 12 in	1	2
Welded steel structures	2	4
Bolted steel structures	4	7
Prestressed concrete structures	2	5
Reinforced concrete structures	4	7

Source: U.S. Nuclear Regulatory Commission. Regulatory Guide 1.61.

I = occupancy importance factor, usually between 1.0 and 1.5
K = horizontal force factor, dependent upon the arrangement of lateral force-resisting elements, usually between 0.67 and 2.50
C = $1/(15T^{1/2})$ but not to exceed 0.12
T = fundamental period of structure, s
S = soil factor, dependent upon the soil profile type, usually between 1.0 and 1.5
W = total dead weight of structure, lb

Damping. Damping is the phenomenon of dissipation of energy in a vibrating system. Each damping value expressed as a percentage of the critical damping is represented in the seismic response spectrum by a separate curve. The higher the damping value, the lower would be the effects of the seismic excitation. The damping values to be used for different levels of the earthquake are given by the NRC (U.S. Nuclear Regulatory Commission) Regulatory Guide 1.61,[34] as shown in Table B4.7.

When a system has both categories of pipe sizes mentioned in the table, dual damping values should be considered in the analysis.

Alternative damping values for response spectrum analysis of ASME Classes 1, 2, and 3 piping are given in ASME Code Case N-411-1,[35,36] as shown in Fig. B4.10. These damping values are applicable to both OBE and SSE. They are also independent of pipe size. As can be seen from Fig. B4.10, the damping values of Code Case N-411-1 are generally higher than the damping values given in Regulatory Guide 1.61. The industry has been applying these higher damping values to existing piping systems to reduce the number of snubbers installed in the plants in order to save snubber maintenance cost. The use of Code Case N-411-1 is acceptable to the NRC subject to the conditions described in the NRC Regulatory Guide 1.84.[37]

Mass Point Spacing. In a seismic analysis, the piping is represented by lumped masses connected by massless elastic members. The locations of these lumped masses are referred to as the *mass points*. In order to accurately represent the piping, the mass points on straight runs of pipe should be no farther apart than a length of pipe which would have a fundamental frequency of 33 Hz (see the later subsection "Cookbook-Type Analysis"). Mass points should also be located at all supports, concentrated weights such as valves, valve operators, flanges, and strainers,
FIGURE B4.10   Code Case N-411 damping values. (*ASME B & PV Code, Case N-411-1, February 1989. Courtesy of ASME.*)

and at the end of cantilevered vents and drains. At least two mass points should be placed between supports in the same direction.[38]

Cutoff Frequency, Rigid Range, Zero Period Acceleration, and Missing-Mass Effect.   Generally, the piping response spectrum analysis is terminated at a frequency called the *cutoff frequency*. The cutoff frequency is usually specified as the frequency beyond which the spectral acceleration remains constant, and this constant spectral acceleration is known as the *zero period acceleration (ZPA)* (see Fig. B4.8).

Supposing a piping system is so designed and supported that the first mode is higher than the cutoff frequency; then as far as the computer program is concerned, this piping system does not receive seismic excitation at all. Consequently, the result of this seismic analysis is invalid because of the artificial constraint specified by the stress analyst.

This phenomenon, known as the *missing-mass effect,*[39,40] could also occur in the following cases:

1. On pipe runs with axial restraint (support, anchor, or nozzle) where the longitudinal frequency could be higher than the cutoff frequency
2. Concentrated masses in a piping system supported in such a manner that the frequency of that portion of piping is high

Most of the computer programs normally used for piping stress analysis have the capability to evaluate the missing-mass effect. These programs usually utilize the acceleration from the spectrum at the cutoff frequency (ZPA) to calculate the missing-mass effect.

Methods for Combining System Responses. In general, there are two approaches for the combination of system responses. One approach, the *absolute sum method (ABS),* adds the peak system responses. The second approach, *square root–sum-of-squares method (SRSS),* gives a combined response equal to the square root of the sum of the squares of the peak responses. The SRSS method is preferred over the ABS method because not all the peak responses occur simultaneously.

In a response spectrum modal analysis, if the modes are not closely spaced (two consecutive modes are defined as closely spaced if their frequencies differ from each other by less than 10 percent of the lower frequency), responses could be combined by taking the SRSS method. For closely spaced modes, the NRC suggests that the method of combining the responses by the SRSS method may not be conservative. An acceptable method of grouping the closely spaced modes of vibration and combining the responses is described in the NRC Regulatory Guide 1.92.[41,42]

Seismic Anchor Movement and Building Settlement Analysis

A piping system, supported from two seismically independent structures that move out of phase during a seismic event, will experience stresses due to the differential displacement of the supports.

Buried pipe could be considered as supported by the soil. A differential movement during a seismic event between the soil and the building to which the pipe is routed could also cause stresses in the pipe.

Similarly, the differential settlements between two structures or between a building and the adjacent soil will induce stresses in piping which is routed between them.

Seismic Anchor Movement (SAM) Analysis. A seismic anchor movement analysis is required on a piping system where:

1. The piping is supported from two seismically independent structures, or
2. The piping is attached to large equipment having its own modes of vibration (e.g., steam generator, pressurizer, reactor vessel, or reactor coolant pump).

SAM analysis is performed by applying the corresponding seismic displacements of the building and structures at the pipe support and anchor locations. It is usually analyzed by a static method. However, dynamic supports such as snubbers and rigids (including anchors and nozzles) will be active while spring supports remain passive.

SAM displacements from the same building or structure are generally in phase, while those from different buildings or structures are considered out of phase.

When a terminal end of a piping system being analyzed is at a large pipe, the seismic movements from the large pipe analysis should be applied as a SAM displacement in the analysis.

The code allows the consideration of the stress due to SAM as either primary stress [see Eq. (B4.10)] or secondary stress [see Eq. (B4.11)]. However, it will usually be evaluated as secondary stress. Since the stress due to SAM is a cyclic type of stress, it should be combined with other cyclic-type secondary stresses such as thermal expansion stresses.

The total secondary stress range should include the thermal and SAM stress range. If the SAM stress is less than the thermal stress range, the effective secondary stress range is the sum of the SAM stress and the thermal stress range, as shown
(a)
(b)

FIGURE B4.11   Effective secondary stress range.

in Fig. B4.11*a*. If the SAM stress is higher than the thermal stress range, the effective secondary stress range then equals twice the SAM stress, as shown in Fig. B4.11*b*.

Building Settlement Analysis.   ASME Boiler and Pressure Vessel Code Section III requires that the stresses due to building settlement be evaluated and be considered as secondary stresses. However, the stress due to building settlement is a one-time (single nonrepeated) anchor movement. Therefore, it is not required to combine it with other stresses. From Subsection NC-3653.2(b) of the code, the effects of any single nonrepeated anchor movement shall meet Eq. (B4.13).

Dynamic Loads

The dynamic loads discussed herein are limited to occasional loads (other than seismic loads) frequently encountered in piping stress analysis.

Safety Relief Valve Discharge Analysis.   Safety-relief valves are installed for the purpose of protecting the fluid system from accidental overpressure, or venting the fluid generated in excess of requirement.

The general requirements pertaining to the design of the pressure relief discharge piping are provided in Appendix II of ASME B31.1, Subsections NC-3677 and NB-3677 of the ASME Code for different pipe classes.

There are two types of pressure relief valve discharge, namely, *open discharge* and *closed discharge,* as shown in the figures of Chap. B3.

Open Discharge.   A typical open discharge is the transient due to discharging of steam from a steam line to the atmosphere through relief valves or safety valves. When the steam line pressure reaches the valve set point, the valve opens and decompression waves will travel both upstream and downstream of the valve. This flow transient sets up pressure imbalances along each pipe segment (a straight run of pipe bounded by elbows). The transient forces can be calculated by a computerized method as described in the later subsection ''Steam Hammer–Water Hammer Analysis,'' while the reaction force at the valve exit due to steady-state flow is determined relatively easily.

Closed Discharge.   In a closed-discharge system, the fluid is transmitted to its terminal receiver through continuous discharge piping. A typical closed discharge is the transient induced by a sudden opening of the relief and safety valves located on top of the pressurizer in a power plant. A water seal, which is maintained upstream of each valve to minimize leakage, driven by this high discharge pressure, generates a transient thrust force at each pipe segment. The water seal is discharged ahead of the steam as the valve disk lifts. For discharge piping with a water seal, only the first cycle of each event has a transient force based on water in the seal. The remaining cycles would be based on steam occupying the seal piping, and the transient forces would be reduced in magnitude.

Static Analysis.   The static method of open discharge described in Appendix II of ASME B31.1 can be summarized as follows:

1. The reaction force F due to steady-state flow following the opening of the valve may be computed by

$$F = \frac{WV}{g} + (P - P_a)A \qquad (B4.57)$$

   where F = reaction force at exit, lbf
   W = mass flow rate, lbm/s
   V = exit velocity, ft/s
   g = gravitational constant
   $\quad$ = 32.2 lbm · ft/lbf · s^2
   P = static pressure at exit, psia
   P_a = atmospheric pressure, psia
   A = exit area, in^2

2. The dynamic load factor (DLF) is used to account for the increased load caused by the sudden application of the discharge load. The DLF value will range

between 1.1 and 2.0, depending on the time history of the applied load and the natural frequency of the piping.[43] If the run pipe is rigidly supported and the applied load could be assumed to be a single ramp function, the DLF may be determined in the following manner:

a. Calculate the safety valve installation period T:

$$T = 0.1846 \left(\frac{Wh^3}{EI} \right)^{1/2} \tag{B4.58}$$

where T = safety valve installation period, s
W = weight of safety valve, installation piping, flanges, attachments, etc., lb
h = distance from run pipe to centerline of outlet piping, in
E = Young's modulus of inlet pipe, psi, at design temperature
I = moment of inertia of inlet pipe, in^4

b. Calculate the ratio t_o/T where t_o is the time the safety valve takes to go from fully closed to fully open (seconds).

c. For the ratio t_o/T, determine the DLF from data given in Appendix II of ASME B31.1, as shown in Fig. B4.12.

3. The moment due to valve reaction force is calculated by simply multiplying the force times the distance from the point in the piping system being analyzed, times a suitable DLF. The stress is then calculated accordingly.
FIGURE B4.12   Hypothetical dynamic load factor (DLF).

Dynamic Analysis. The reaction force effects are dynamic in nature. A time-history dynamic analysis of the discharge piping is considered to be more accurate. Furthermore, closed-discharge systems do not easily lend themselves to simplified analysis techniques. A time-history analysis (such as the one described in the following subsection) is required to achieve realistic results.

Steam Hammer–Water Hammer Analysis. The steam hammer–water hammer event is often initiated by intentional actuation of certain flow control devices (main steam stop valve closure, feedwater pump trip, etc.), but in other cases a transient event could be introduced unintentionally as the result of some unforeseen operating condition, component malfunction, or accident (e.g., feedwater line check valve slam following a pipe break upstream of the check valve).[44,45] While these events may produce very complex transient fluid flow, the pipe stress analyst is interested in just the unbalanced force along the pipe segment tending to induce piping vibration.

Calculation of Unbalanced Forces. These time-history unbalanced forces are usually generated through a two-step computerized calculation. The fluid system is modeled as an assemblage of control volumes (e.g., piping volumes or steam generator) interconnected by junctions (e.g., valves, pump, or break). Piping fluid flow data, such as flow area, friction losses, valve closing-opening time, feed pump characteristics, or break characteristics, together with fluid initial conditions (flow rate, pressure, temperature, and mixture quality) are supplied as input to a thermal hydraulic finite difference computer program.[46]

Using this input information and a built-in steam table (fluid thermodynamic state), the first step solves the three equations of conservation (mass, momentum, and energy) at each time step for fluid properties such as pressure, velocity, internal energy, and mixture quality. A typical stop valve closure time history and its associated dynamic pressure time history are shown in Fig. B4.13. The second step utilizes a postprocessor. This postprocessor then accepts the output information from the first step and computes the unbalanced forces in piping segments by applying the momentum theorem.

Static Analysis. Static analysis is simple and saves computer time. It is used when the unbalanced forces are small and the total transient time is long. In the analysis, the peak values of the time-history fluid forcing functions at pipe segments are applied statically to the piping. The piping stress, deflections, and support-nozzle loads are then calculated by the computer program.

To obtain a conservative result for the static analysis, care must be taken in applying a proper dynamic load factor to the unbalanced forces.

Dynamic Analysis. The dynamic analysis generally utilizes either the direct step-by-step integration method (as described in the subsection ''Pipe Break Analysis'') or the modal-superposition method. In the dynamic analysis, the piping system is idealized as a mathematical model consisting of lumped masses connected by weightless elastic members. These lumped masses are carefully located to adequately represent the dynamic characteristics of the piping system. For computer programs utilizing the modal-superposition method, enough modes (or appropriate cutoff frequency) should be specified in the computer input such that the dynamic response of the piping system can be truly represented. There are no specific guidelines to damping values used in piping fluid transient dynamic analysis in the ASME Code or NRC published material. Therefore, it is recommended to use the OBE damping values prescribed in the NRC Regulatory Guide 1.61. Alternative damping values of Code Case N-411-1 are not applicable to the dynamic analysis.

The time-history unbalanced forces are applied to all pipe segments. Snubbers and rigid supports are effective restraints for transient forces. However, axial sup-

DYNAMIC PRESSURE TIME HISTORY

STOP VALVE CLOSURE TIME HISTORY
FIGURE B4.13   Steam hammer flow transients.

ports should be avoided in general. An axial support not only requires welded attachments on the pipe but also a pair of supports, which doubles the cost. To support the pipe axially, lateral supports can be used around the elbows. In addition, snubbers should not be located in the immediate vicinity of equipment nozzles. Snubbers located in such areas may not be activated during a fluid transient because of the dead band (built-in manufacturing tolerance) of the snubber hardware.

Stress Allowables.   For the steam hammer–water hammer (e.g., feed pump trip) event, the pipe stress from the analysis is combined with stresses due to pressure, deadweight, and OBE in meeting the upset stress allowable. For piping in the turbine building, OBE stress is not included in the stress combination. For some water hammer (e.g., check valve slam) events, the stress from the analysis is combined with stresses due to pressure and deadweight in meeting the faulted stress allowable.

LOCA Analysis.   LOCA (loss-of-coolant accident) is a postulated accident that results from the loss of reactor coolant, at a rate in excess of the capability of the reactor coolant makeup system, from breaks in the reactor coolant pressure boundary. Analyses should be performed by the *nuclear steam supply system (NSSS)* vendor to confirm the structural design adequacy of the reactor internals and reactor

coolant piping (unbroken loop) to withstand the loadings of the most severe LOCA in combination with SSE per the requirements of 10CFR Part 50, Appendix A,[20] and the NRC Standard Review Plan 3.9.2.[47]

The integrity of the secondary system piping (main steam, feedwater, blowdown lines) off the steam generators also has to be assured by the architect-engineer (AE). Additional analyses to demonstrate the structural adequacy of some of the branch piping attached to the broken loop may be required by the NSSS vendor.[48] The information provided herein is limited to the secondary system piping off the steam generators.

Static Analysis.   If a substantial separation between the forcing frequencies of the LOCA loading and the natural frequencies of the piping system can be demonstrated, a static analysis may be performed. In the static analysis, the maxima of each of the LOCA displacement components (three deflections and three rotations) are separately applied to the junctions of the *reactor coolant loop (RCL)* and the secondary system piping. The results should be combined absolutely and multiplied by an appropriate dynamic load factor.

Dynamic Analysis.   The dynamic analysis can be performed in one of the following two ways:

Time-History Analysis.   The LOCA displacement time history is applied dynamically to the junctions of the RCL and the secondary system piping. The damping value prescribed in the NRC Regulatory Guide 1.61 for SSE is suggested for this dynamic LOCA analysis. The detailed analysis method is similar to that described in the following subsection "Pipe Break Analysis."[49]

Response Spectrum Analysis.   Compared to the time-history analysis, the response spectrum method is favorable for its low computer cost. However, this method may be unnecessarily conservative since the same loading has to be applied to the entire piping system. Because of the nature of the LOCA break and the impacting of the gapped RCL supports, the LOCA motion has much higher frequency content than the seismic excitation. The ZPA of a typical LOCA motion spectrum for a RCL junction is usually higher than that of a typical SSE response spectrum. Therefore, a higher cutoff frequency should be used in the analysis.[50]

Stress Allowables.   The resulting stress from the LOCA analysis for the secondary piping system is combined with the stresses due to pressure, dead weight, and SSE in meeting the faulted stress allowables.

Pipe Break Analysis.   Although it is extremely improbable that a pipe break will occur as postulated, public safety and the NRC licensing requirements make it necessary that such events must be considered in the design of high-energy piping systems.

A *high-energy piping system* is a piping system that, during normal plant conditions, is maintained at a temperature $> 200°F$ (93.3°C), or a pressure > 275 psig (1896.1 kPa).

Pipe Break Locations.   Pipe breaks are postulated in high-energy piping based on the primary plus secondary stresses and the cumulative usage factor.

1. *ASME Section III, Class 1 Pipe:*   Pipe breaks are postulated to occur at terminal ends (the extremities of piping connected to structures, components, or anchors) and at all intermediate locations where:

   a. The primary plus secondary stress intensity range, as calculated by Equation (10) of Subsection NB-3653 [i.e., Eq. (B4.4) of this chapter], exceeds $2.4S_m$ and either Equation (12) or (13) [i.e., Eq. (B4.5) of this chapter] exceeds $2.4S_m$.

   b. Cumulative usage factor exceeds 0.1.

2. *ASME Section III, Class 2 and 3 Pipe:*   Pipe breaks are postulated to occur at terminal ends and at all intermediate locations where the primary plus secondary stresses, as calculated by the sum of Equations (9) and (10) of Subsection NC-3653 [i.e., Eqs. (B4.10) and (B4.11) of this chapter], exceed $0.8(1.2S_h + S_A)$.

3. *Nonnuclear piping:*   If a rigorous analysis, including seismic loading condition, is done on a high-energy ASME B31.1 piping, the requirements of the Class 2 and 3 piping mentioned above will apply. If no analysis is performed, breaks are postulated at the following locations:

   a. Terminal ends

   b. At all fittings, welded attachments, and valves

The detailed pipe break design criteria and guidelines are given in the NRC Standard Review Plan No. 3.6.1 and 3.6.2.[51,52]

No-Break Zone.   In the design of nuclear power plants, the region of piping in the containment building penetration areas between the isolation valves requires extra protection so that neither the leak-tight integrity of the containment nor the operability of the containment isolation valves is jeopardized. The extra protection consists of the following:

1. Installing special whip restraints, called *isolation restraints,* to mitigate the effects of the postulated pipe breaks located beyond this region

2. Keeping the primary plus secondary stresses and the cumulative usage factor below certain conservative values

3. Holding the piping stress, the isolation valve acceleration, and the stress at the valve-pipe weld below specified limits during a postulated pipe break outside this region

4. Special construction (welding) requirements and in-service inspection procedures

Because of the stringent design requirements, no pipe breaks are assumed to occur in this region. This area of piping is often referred to as the *no-break zone,* the *break exclusion region,* or the *superpipe area.*

No-Break Zone Piping Analysis.   An analysis is required to determine the stresses in no-break zone piping and the accelerations of isolation valves due to a postulated break located beyond this region. During the pipe break event, a portion of the piping and the isolation restraints may enter the inelastic region because of the large pipe break loads imposed on the piping system. A static method, or the energy balance method, is acceptable but usually not used because necessary information on the no-break zone such as isolation valve acceleration is impossible to determine. Therefore, a nonlinear dynamic analysis utilizing the direct step-by-step integration method is necessary for the no-break zone analysis.[53] Computer programs based upon the direct integration method with linear elastic and nonlinear inelastic capabilities are often used for this type of analysis.[54,55]

In the analysis, the piping structural model is similar to that described in the subsection "Steam Hammer–Water Hammer Analysis." The nonlinear effects are accounted for by updating the system stiffness matrix at the end of each time step. The integration time step must be short enough to permit a reliable and stable solution. In addition, suitable system damping values should be used to obtain numerical stability. The time-history pipe break forcing function can be calculated by thermal-hydraulic computer programs as described in the subsection "Steam Hammer–Water Hammer Analysis," or obtained from the acceptable simplified method specified in Appendix B of ANSI/ANS 58.2.[56]

Wind Loads. The wind possesses kinetic energy by virtue of the velocity and mass of the moving air. If an obstacle is placed in the path of the wind so that the moving air is stopped or is deflected, then all or part of the kinetic energy of the wind is transformed into the potential energy of pressure.

A piping system which is located outdoors is usually designed to withstand the maximum wind velocity expected during the system operating life.

Dynamic Pressure. The intensity of wind pressure depends on the shape of the obstacle, the angle of incidence of the wind, and the velocity and density of the air.

For standard air (density of the air = 0.07651 lb/ft³, temperature = 59°F), the expression for the wind dynamic pressure could be adapted from Bernoulli's equation for fluid flow as follows[33,57]:

$$p = 0.00256V^2C_D \tag{B4.59}$$

where p = dynamic pressure, lb/ft²
  V = basic wind speed, mi/h
  C_D = drag coefficient, dimensionless

For the case of piping under wind loading, Eq. (B4.59) can be rewritten as

$$F = 0.000213V^2C_D D \tag{B4.60}$$

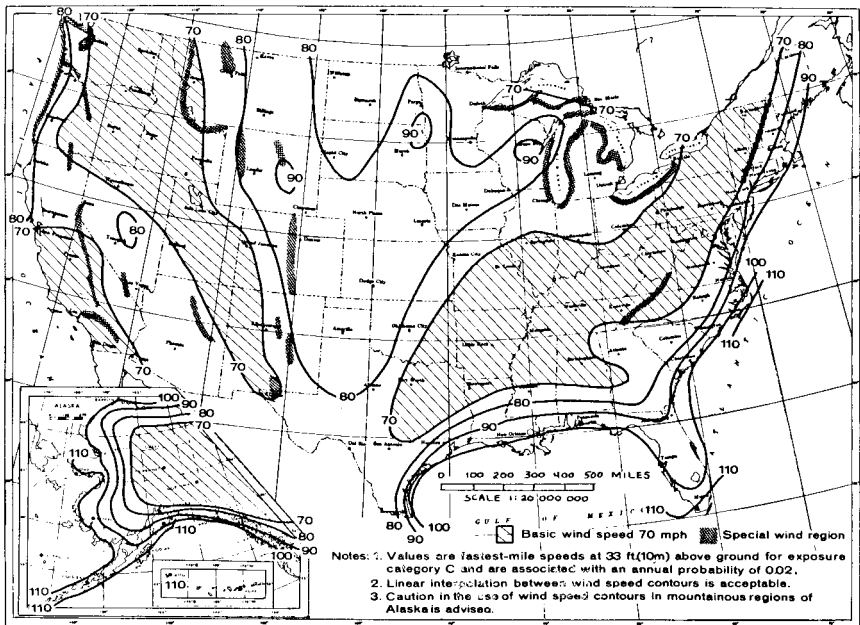
where F = linear dynamic pressure loading on projected pipe length, lb/ft
  D = pipe diameter, including insulation, in


FIGURE B4.14 Basic wind speed (miles per hour). (*ANSI A58.1, 1982. Courtesy of ANSI.*)
FIGURE B4.15   Drag coefficients for spheres and long cylinders. (*Task Committee on Wind Forces, "Wind Forces."*[30] Courtesy of ASCE.)

Basic Wind Speed.   The basic wind speed V is the fastest wind speed at 33 ft above the ground in open terrain with scattered obstructions having heights less than 30 ft, as given in Fig. B4.14 for the United States.[33] The basic wind speed used for design shall be at least 70 mi/h.

Drag Coefficient.   The drag coefficient C_D is a function of the shape of the structure and a fluid flow factor called the *Reynolds number*. The Reynolds number R is the ratio of the inertial force to the viscous force which a fluid stream exerts on an object. For standard air, the Reynolds number R could be expressed as

$$R = 780V D \qquad (B4.61)$$

The drag coefficient C_D for a cylinder (i.e., a pipe) is given versus the Reynolds number in Fig. B4.15.

Wind Loading Analysis.   The piping wind loading analysis is usually performed by a static method. In the analysis, the wind loading F is modeled as a uniform load acting over the projected length of the pipe, parallel to the direction of the wind. Two horizontal directions of wind loads (north-south and east-west) are included in the analysis. The design loads are based on the worst case of the two directions. Similar to the case of earthquake, the wind loading is considered reversing. For load combination, the wind and the earthquake are assumed to not

happen at the same time. A safety factor, the gust response factor G, should also be considered in the analysis. This factor is used to account for the fluctuating nature of wind and its interaction with structures. Its value depends on the exposure categories as shown in Table B4.8, where:

1. *Exposure A:*   Large city centers with at least 50 percent of the buildings having a height in excess of 70 ft
2. *Exposure B:*   Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger
3. *Exposure C:*   Open terrain with scattered obstructions having heights generally less than 30 ft
4. *Exposure D:*   Flat, unobstructed coastal areas directly exposed to wind flowing over large bodies of water

METHODS OF ANALYSIS

Cookbook-Type Analysis

The following cookbook-type method is mainly for supporting 2-in and smaller Nuclear Class 2, 3, and B31 piping under gravity, thermal expansion, and seismic

loadings. This method is based on standard support span tables. It covers a simplified weight analysis, a simplified thermal analysis, as well as a simplified seismic analysis.

A simplified seismic analysis often requires many pipe supports that are designed to large loads. The cost saving in engineering is offset by increased fabrication and installation cost. The current approach is to analyze the nonseismic piping by simplified methods and all seismic piping by computerized analysis. This greatly reduces the number of required seismic supports and gives an overall cost saving.

Simplified Weight Analysis. A simplified weight analysis is performed by locating the gravity supports based on gravity pipe spans. The maximum gravity pipe spans can be calculated from the following formula:

$$L = \left(\frac{SZ}{1.2W} \right)^{1/2} \tag{B4.62}$$

where L = maximum gravity pipe span, ft
  Z = section modulus of pipe, in^3
  W = distributed weight, lb/ft
  S = pipe stress due to gravity, psi

and the corresponding stress S is

$$S = \frac{M}{Z} = \frac{1.2WL^2}{Z} \tag{B4.63}$$

where M = bending moment, in · lb.

Alternatively, the bending stress in empty pipe may be read from Fig. B4.16, and the bending stress in water-filled pipe from Fig. B4.17. The deflection of empty pipe can be read from Fig. B4.18.

The distributed weight of pipe includes the weight of metal, the weight of pipe contents, and the weight of insulation. Pipe material weights are subject to tolerance of applicable manufacturing specifications.

Weights of insulation depend on the composition of insulation material and should be obtained from the insulation manufacturer. Weights of weatherproof protection, if specified, must be added. Insulation thicknesses recommended by insulation manufacturers do not necessarily agree with insulation specifications for a particular job. Insulation specifications should be reviewed prior to development of final weights of piping.

Weights of insulation should be added to weights of flanges, valves, and fittings. Flange, flanged valve, and flanged fitting weights should include weights of bolts and nuts.

Valve weights vary among particular manufacturers' designs and should include weights of electric-motor operators (if any) or other devices which may be specified for particular valves. It is suggested that, wherever possible, valve weights should be obtained from the manufacturer of the particular valves which are to be installed in the piping.

Equation (B4.62) is based on the combination of a simply supported beam model and a fixed-end beam model because the behavior of pipe lies somewhere between these two models.

A table of suggested maximum spans between supports of pipe based on a formula similar to Eq. (B4.62) is given in ASME Codes,[58,59] as shown in Fig. B5.1

Bending stress in empty pipe, standard weight, caused by load between supports – based on single span with free ends.

$$S = \frac{W\ell^2}{8S_m}$$

of Chap. B5. These spans have been calculated by considering insulated, standard wall thickness and heavier pipe, limited to a maximum stress of 1500 psi (10,350 kPa) and maximum pipe sag of 0.1 in (0.25 mm). For small pipe where socket welds are used, Eq. (B4.63) can be rewritten as

$$S = \frac{0.75iM}{Z} = \frac{1.89WL^2}{Z} \tag{B4.64}$$

and

$$L = \left(\frac{SZ}{1.89W}\right)^{1/2} \tag{B4.65}$$

where i = the stress intensification factor (SIF), 2.1 for socket welds per ASME B31.1 and ASME Section III piping codes.

Figures B5.2 and B5.3 of Chap. B5 give the maximum spans for water and steam, air, or gas filled steel pipe, respectively. These tables are based on a pipe stress S of 2000 psi (13.790 MPa) and a socket weld SIF of 2.1. When these suggested weight spans are adhered to, the stress in the piping system due only to gravity load usually need not be explicitly calculated.

Load Calculation by Weight Balance.   The following example is used to illustrate a method by which hanger loadings may be determined. The method consists of locating the center of gravity of the specific piping configuration and then, by equating moments, to determine the resultant loads at particular hangers.

A single-plane bend is shown in Fig. B4.19. Hangers are indicated as H-1, H-2, H-3, and H-4. The effects of uniform and concentrated loads are indicated at the points at which these loads act; it is noted that the weight of the 90° bend acts at the centroid of a quarter circle which, in this example, is located 1.8 ft distant from the centerline of the pipe run. The straight pipe length between hangers H-3 and H-4 is not included in this calculation because it can be analyzed by simple straight-beam theory.

For the piping section which lies between equipment flange F and hanger H-3, moments are taken about the Y-Y and Z-Z axes. As an example, let the center of gravity of this configuration be located Y ft from the Y-Y axis. Then, from equilibrium considerations, the following equation may be written:

$$2436(0) + 910(1.8) + 2320(15) + 436(25) = 6102Y$$

A solution to this equation results in $Y = 7.75$ ft.

Similarly, the distance from the Z-Z axis to the center of gravity is found to be 6.43 ft.

For convenience, the calculations are made frequently in a tabular fashion as shown in Fig. B4.19.
FIGURE B4.19   One-line piping diagram for illustration of load calculation by weight balance.

Construct the triangle H-I, H-2, H-3 superimposing
location of C.G. and calculate reactions at H-1, H-2 and H-3
Reaction at $H-1 = \dfrac{a}{b} \times 6102 = \dfrac{7.75}{23} \times 6102 = 2055$ lbs

$H-2 = \dfrac{c}{d} \times 6102 = \dfrac{7.17}{13.25} \times 6102 = 3301$ lbs

$H-3 = \dfrac{e}{f} \times 6102 = \dfrac{2.37}{19.35} \times 6102 = 746$ lbs

$F = \underline{\hspace{2cm}} \quad 0$ lbs

6102 lbs

Total load on $H-3 = 746 + \dfrac{2320}{2} = 1906$ lbs

FIGURE B4.20   Hanger load calculations for system of Fig. B4.19. Three hangers with zero reaction at flange *F*.

Let it be now required to determine hanger loadings for the piping configuration of Fig. B4.19 with the stipulation that no load due to weight be imposed on the equipment flange *F*. This is accomplished easily by use of simple geometrical relationships, and the solution is as indicated in Fig. B4.20.

If it were desired to support the piping with two, rather than three, hangers, it would be convenient to eliminate *H*-1 and to relocate *H*-2 to a position at which it would be colinear with the center of gravity and hanger *H*-3. The construction for this arrangement and the associated hanger-load calculations are shown in Fig. B4.21.

In each of the two above cases, one-half of the 2320-lb load between *H*-3 and *H*-4 has been included in the calculations for hanger loading on *H*-3. Thus *H*-4 would be required to support 1160 lb plus, of course, any additional piping load to the right of *H*-4 in Fig. B4.19.

H–I – eliminated
H–2 – relocated
H–3 – remaining in same position
H-2 will be relocated on axis
Z-Z, at a distance (J) from axis
Y-Y, proportioned thus :

$$J : a = h : g$$

$$J = \frac{a h}{g} = \frac{7.75 \times 26}{19.57} = 10.3'$$

$$\text{Reaction at } H\text{-}2 = \frac{19.57}{26} \times 6102 = 4595 \text{ lbs}$$

$$H\text{-}3 = \frac{6.43}{26} \times 6102 = \underline{1507 \text{ lbs}}$$

$$6102 \text{ lbs}$$

$$\text{Total load on } H\text{-}3 = 1507 + \frac{2320}{2} = 2667 \text{ lbs}$$

FIGURE B4.21   Hanger load calculations for system of Fig. B4.19 except that one hanger has been eliminated.

Simplified Thermal Expansion Analysis.   This simplified analysis is based on the guided cantilever method. The *guided cantilever* is a cantilever beam restrained in such a way that its free end will not rotate when it is deflected in a direction perpendicular to the longitudinal axis of the beam, as shown in Fig. B4.22.

For piping systems under thermal expansion loads, the behavior of the piping approximates that of a guided cantilever. The thermal growth forces the pipe leg
FIGURE B4.22   Guided cantilever.

to translate while pipe rotations are restricted by piping continuity. Therefore, this method can be used to check the flexibility of a piping system.

For a guided cantilever, the moment induced by an imposed deflection is

$$M = \frac{6EI\Delta}{L^2} \qquad (B4.66)$$

where M = induced moment, in · lb
E = modulus of elasticity, psi
I = moment of inertia, in⁴
Δ = deflection, in
L = length of pipe leg perpendicular to deflection, in

The corresponding stress is then

$$S = \frac{iM}{Z} = \frac{6EI\Delta i}{ZL^2} = \frac{3ED\Delta i}{L^2} \qquad (B4.67)$$

where S = induced stress, psi
D = outside diameter of pipe, in
Z = section modulus of pipe, in³
i = stress intensification factor

Solving the equation for the beam length L gives

$$L = \left(\frac{3ED\Delta i}{S} \right)^{1/2} \qquad (B4.68)$$

By determining the proper allowable stress and taking into account the appropriate stress intensification factor, Eq. (B4.68) gives an estimate of the minimum allowable offset pipe span L required to sustain a piping thermal movement Δ normal to the piping.

Tables B4.9 and B4.10 give the minimum allowable offset span for steel piping ($E = 27.9 \times 10^6$ psi) with socket welds ($i = 2.1$) and without socket welds, respectively. These tables are based on allowable stresses S of 22,500 psi.

Thermal Movement Calculations. The simplified method shown below is one which gives satisfactory approximations of the piping movements. Whenever differences occur between the approximations and actual movements, the approximation of the movement will always be the greater amount.

Step 1. The piping system of Fig. B4.23 is drawn, and on it are shown all known vertical movements of the piping from its cold to hot, or operating, position. These movements will include those supplied by the equipment manufacturers for the terminal point connections. For the illustrated problem, the following vertical movements are known:

Point *A*—2 in up, cold to hot

Point *B*—1⅙ in up, cold to hot

Point *C*—⅛ in down, cold to hot

H-4—0 in cold to hot

TABLE B4.9 Thermal Expansion Minimum Allowable Offset Span (Feet-Inches), Straight Steel Pipe with Socket Welds

3.00	11-8¼	13-0¾	14-7¼	17-7	19-8

1 in = 25.4 mm
1 ft = 0.3048 m

The operating temperature of the system is given as 1050°F (566°C), and the coefficient of expansion for low-chrome steel at 1050°F (566°C) is 0.0946 in/ft.

The movements at points D and E are calculated by multiplying the coefficient of expansion by the vertical distance of each point from the position of zero movement on the riser DE:

$$55 \text{ ft} \times 0.0946 \text{ in/ft} = 5.20 \text{ in } up \text{ at } D$$

$$20 \text{ ft} \times 0.0946 \text{ in/ft} = 1.89 \text{ in } down \text{ at } E$$

Step 2. A simple drawing is made of the piping between two adjacent points of known movement, extending the piping into a single plane as shown for the portion of the system between A and D.

The vertical movement at any hanger location will be proportional to its distance from the endpoints:

$$\Delta_1 = {}^4\!/_{31} \times 3.20$$

$$\Delta_1 = 0.41 \text{ in}$$

TABLE B4.10 Thermal Expansion Minimum Allowable Offset Span (Feet-Inches), Straight Steel Pipe, No Socket Weld

1.50	5-8½	6-4¾	7-1¾	8-7	9-7¼
1.75	6-2¼	6-10¾	7-8½	9-3½	10-4½
1.90	6-5¼	7-2¼	8-0½	9-8	10-9¾
2.00	6-7¼	7-4½	8-3	9-11	11-1
2.50	7-4¾	8-3¼	9-3	11-1½	12-5
3.00	8-1¼	9-0¾	10-1¾	12-2¼	13-7½

1 in = 25.4 mm
1 ft = 0.3048 m

The vertical movement at *H*-1 = 0.41 in + 2 in:

$$\Delta H\text{-}1 = 2.41 \text{ in up}$$

$$\Delta_2 = {}^{22}\!/_{31} \times 3.20$$

$$\Delta_2 = 2.27 \text{ in}$$

The vertical movement at *H*-2 = 2.27 in + 2 in:

$$\Delta H\text{-}2 = 4.27 \text{ in up}$$
(*a*)

Step 3.   To calculate the vertical movement at *H*-3, multiply its distance from *H*-4 by the coefficient of expansion:

$$40 \text{ ft} \times 0.0946 \text{ in/ft} = 3.78 \text{ in}$$

$$\Delta H\text{-}3 = 3.78 \text{ in up}$$

Step 4.   The next section of pipe on which there are two points of known movement is the length *E-J*. The movement at *E* was calculated as 1.89 in down:

The movement at *J* is equal to the movement at the terminal point *C* (⅛ in down) plus the amount of expansion of the leg *C-J*:

$$\Delta J = 0.125 \text{ in} + 3.5 \text{ ft} \times 0.0946 \text{ in/ft}$$

$$\Delta J = 0.46 \text{ in down}$$

$$\Delta_7 = {}^{3.5}\!/_{42} \times 1.43 = 0.12 \text{ in}$$

$$\Delta H\text{-}7 = 0.12 \text{ in} + 0.46 \text{ in}$$

$$\Delta H\text{-}7 = 0.58 \text{ in down}$$

$$\Delta_6 = {}^{17}\!/_{42} \times 1.43 = 0.58 \text{ in}$$

(b)
(a)
(b)

$$\Delta H\text{-}6 = 0.58 + 0.46 \text{ in}$$

$$\Delta H\text{-}6 = 1.04 \text{ in down}$$

$$\Delta_f = {}^{30}\!/_{42} \times 1.43 = 1.02 \text{ in}$$

$$\Delta F = 1.02 + 0.46$$

$$\Delta F = 1.48 \text{ in down}$$

$$\Delta_5 = {}^{32}\!/_{42} \times 1.43 = 1.09 \text{ in}$$

$$\Delta H\text{-}5 = 1.09 + 0.46$$

$$\Delta H\text{-}5 = 1.55 \text{ in down}$$

Elevation

(c)

Step 5.   In the section *G-H,* the movement at *G* is equal to the movement at *F minus* the expansion
FIGURE B4.23 One-line piping diagram for calculation of hanger movements. Points *A, B,* and *C* are equipment connections. *H*-1, *H*-2, and so on, represent hanger locations.

of the leg *GF:*

$$\Delta G = 1.48 \text{ in down} - 4 \text{ ft} \times 0.0946 \text{ in/ft}$$

$$\Delta G = 1.10 \text{ in down}$$

The movement at *H* is equal to the movement of the terminal point *B* (¹⁄₁₆ in up) *plus* the expansion of the leg *B-H*:

$$\Delta H = 0.0625 \text{ in up} + 9 \text{ ft} \times 0.0946 \text{ in/ft}$$

$$\Delta H = 0.91 \text{ in up}$$

Since *H*-9 is located at point *H,*

$$\Delta H\text{-}9 = \Delta H = 0.91 \text{ in up}$$

$$\Delta_y = \frac{12 \times 2.01}{23.1} = 1.04 \text{ in}$$

$$\Delta H\text{-}8 = 1.10 - 1.04$$

$$\Delta H\text{-}8 = 0.60 \text{ in down}$$

(a)   (b)
After calculating the movement at each hanger location it is often helpful, for easy reference when selecting the appropriate type hanger, to make a simple table of hanger movements.

Hanger number	Movement, in
H-1	2.41 up
H-2	4.27 up
H-3	3.78 up
H-4	0
H-5	1.55 down
H-6	1.04 down
H-7	0.58 down
H-8	0.06 down
H-9	0.91 up

1 in = 25.4 mm

Calculation of Hanger Loads.   A 6-in medium-temperature steam piping system is shown in Fig. B4.24. Terminal movements at equipment flanges *A* and *B* are indicated; dimensions of system components and physical data are also given. It is required to determine hanger loadings and also to determine movements at each of the hangers *H*-1 through *H*-7.

It is noted that hanger *H*-3 on the vertical leg has been located 20 ft (6.0 m) above the lower horizontal pipe run. Calculations would indicate that the center of gravity of the vertical leg is 16.16 ft (5.0 m) above the lower horizontal run. It would not be desirable to place the hanger at the center of gravity because the hanger would then act as a pivot point and would not resist sway. If the hanger *H*-3 were placed below the center of gravity, an unstable turnover condition would result. The most desirable location is above the center of gravity; hanger *H*-3 has thus been placed arbitrarily a distance of 20 ft (6.0 m) above the lower horizontal piping run.

Starting with equipment flange *A,* the system is broken up into component parts between hangers and hanger reactions are calculated. The procedure is indicated in Figs. B4.25*a* to B4.25*g*, and the results are listed in Table B4.11. Hanger deflections, or movements, are determined as shown in Figs. B4.26*a* and B4.26*b*.

Simplified Seismic Analysis.   A simplified seismic analysis utilizing simple beam formulas and response spectrum curves is given here. The maximum support spac-
FIGURE B4.24   One-line piping diagram for calculation of hanger loadings and deflections.

ings are selected from Tables B4.12 to B4.14 so that the fundamental frequency of the span is in the rigid range of the response spectrum.

These seismic spans are based on the following formula:

$$L = \left(\frac{1}{12}\right)\left(\frac{\pi}{2f}\right)^{1/2}\left(\frac{12gEI}{W}\right)^{1/4} \tag{B4.69}$$

where L = maximum seismic spacing, ft
 f = desired frequency, cycles/s
 g = 386 in/s^2
 E = modulus of elasticity, psi
 I = moment of inertia, in^4
 W = distributed weight, lb/ft

For a system with seismic supports designed in the rigid range, the seismic acceleration of the system is low and consequently the design loads for the system decrease.

The corresponding seismic stress is then

$$S = 0.75i(12)\left(\frac{WL^2}{8Z}\right)(1.5G) \tag{B4.70}$$

where Z = section modulus of pipe, in^3
 G = seismic acceleration (OBE or SSE) in gs
 i = stress intensification factor

The number 1.5 in Eq. (B4.70) is a factor to account for the contribution from the higher modes.[47,60]

Computerized Method

Types of Computer Programs.   The microcomputer has become the daily tool and workstation of the piping stress analyst. Files which contain data for piping stress analysis are created, edited, and saved at this workstation. These files are later transferred to the mini- or mainframe computer for the calculation of piping stresses and support loads.

Most of the computer programs for piping stress analysis such as ADLPIPE, NUPIPE, and SUPERPIPE were developed for use on mainframe computers. With the introduction of many powerful microcomputers in the mid-1980s, microcomputer-based programs for piping stress analysis were also developed such as AU-TOPIPE and CAESAR II. Some of these new programs are menu driven and user friendly. Refer to Appendix E9. They help save engineering time and cost. In general, these computer programs may be divided into four classes:

1. Programs that can perform pressure, thermal expansion, deadweight, and external forces (e.g., wind) analyses for ASME Section III, Class 2, 3, ASME B31.1,

and plastic analysis; steady-state and transient heat transfer; steady-state fluid flow analyses; and nonlinear time-history analyses. There are 40 different finite elements available for static and dynamic analysis. Dynamic analyses can be performed either by modal superposition or direct integration.[54]

4. Specialized programs such as PIPERUP. PIPERUP performs nonlinear elastic-plastic analyses of piping systems subjected to concentrated static or dynamic time-history forcing functions. These forces result from fluid jet thrusts at the location of a postulated break in high-energy piping. PIPERUP is an adaptation of the finite element method to the specific requirements of pipe rupture analysis.[55]

Method of Analysis.   The piping system is modeled as a series of masses connected by massless springs having the properties of the piping. The mathematical model should include the effects of piping geometry changes, elbow flexibilities, concentrated weights, changes in piping cross sections, and any other parameters affecting the stiffness matrix of the model. Mass point spacing should follow the guidelines specified above. Valves should be modeled as lumped masses at valve body and operator, with appropriate section properties for valve body and valve topworks. Rigid supports, snubbers, springs, and equipment nozzles should be modeled with appropriate spring rates in particular degree of freedom. Stress intensification factors should be input at the appropriate locations (elbows, tees, branch connections, welds, etc.). Piping distributed weight should include pipe weight, insulation weight, and entrained fluid weight.

Once an accurate model is developed, the loading conditions are applied mathematically:

1. Statically applied loads (deadweight, wind loads, pressure thrust, etc.)
2. Thermal expansion
3. Statically applied boundary condition displacements (seismic anchor movement, LOCA containment displacement, etc.)
4. Response spectrum analysis (seismic, etc.)
5. Dynamically applied boundary condition displacements (LOCA motion, etc.)
6. Dynamically applied forcing functions (steam hammer, etc.)

The results of the analyses should be examined in order to determine if all allowables are met (i.e., piping stress, valve acceleration, nozzle loads, etc.). The loads must be combined using the appropriate load combinations and submitted to structural designers for their analysis.

PROCEDURES FOR THE DESIGN OF RESTRAINED UNDERGROUND PIPING

This section is reproduced by the courtesy of ASME B31.1.

Foreword

The B31.1 Code contains rules governing the design, fabrication, materials, erection, and examination of power piping systems. Experience over the years has demonstrated that these rules may be conservatively applied to the design and analysis of buried piping systems. However, the ASME B31.1 rules were written for piping suspended in open space, with the supports located at local points on the pipe. Buried piping, on the other hand, is supported, confined, and restrained continuously by the passive effects of the backfill and the trench bedding. The effects of continuous restraint cannot be easily evaluated by the usual methods applied to exposed piping, since these methods cannot easily accommodate the effects of bearing and friction at the pipe/soil interface. Accordingly, this section has been prepared to illustrate and clarify the application of B31.1 Code rules to restrained buried piping.

All components in the buried piping system must be given consideration, including the building penetrations, branches, bends, elbows, flanges, valves, grade pene-

trations, and tank attachments. It is assumed that welds are made in accordance with the B31.1. Code and that appropriate corrosion protection procedures are followed for buried piping.

This section provides analytic and nomenclature definition figures to assist the designer, and is not intended to provide actual design layout.

Scope

The scope of this section is confined to the design of buried piping as defined in Pa+ expansion in buried piping affects the forces, the resulting bending moments and stresses throughout the buried portions of the system, particularly at the anchors, building penetrations, buried elbows and bends, and branch connections, and it is the designer's responsibility to consider these forces. This section, however, deals only with the buried portions of the system, and not the complete system.

The design and analysis of buried piping requires that careful attention be paid to:

1. All loads acting on the system
2. The forces and the bending moments in the piping and piping components resulting from the loads
3. The loading and stress criteria
4. General design practices

Definitions

Confining Pressure   the pressure imposed by the compacted backfill and overburden on a buried pipe. Confining pressure is assumed to act normal to the pipe circumference.

Flexible Coupling   a piping component that permits a small amount of axial or angular movement while maintaining the pressure boundary

Friction   the passive resistance of soil to axial movement. Friction at the pipe/soil interface is a function of confining pressure and the coefficient of friction between the pipe and the backfill material. Friction forces exist only where there is actual or impending slippage between the pipe and soil.

Influence Length   that portion of a transverse pipe run which is deflected or "influenced" by pipe thermal expansion along the axis of the longitudinal run

Modulus of Subgrade Reaction   the rate of change of soil bearing stress with respect to compressive deformation of the soil. It is used to calculate the passive spring rate of the soil.

Penetration   the point at which a buried pipe enters the soil either at grade or from a wall or discharge structure

Settlement   the changes in volume of soil under constant load which result in the downward movement, over a period of time, of a structure or vessel resting on the soil

Virtual Anchor   a point or region along the axis of a buried pipe where there is no relative motion at the pipe/soil interface

Nomenclature

a, b, c = quadratic equation functions

A = cross-sectional metal area of pipe, in^2

A_c = surface area of a 1-in long pipe segment, in^2

B_d = trench width at grade, in

C_D = soil bearing parameter from Table B4.15, dimensionless

C_k = horizontal stiffness factor for backfill [61],[2] dimensionless

D = pipe outside diameter, in

dL = length of pipe element, in

E = Young's modulus for pipe, psi

f = unit friction force along pipe, lb/in

f_{min}, f_{max} = minimum, maximum unit friction force on pipe, lb/in

F_f = total friction force along effective length, lb

F_{max} = maximum axial force in pipe, lb

H = pipe depth below grade, in

I = pipe section moment of inertia, in^4

k = soil modulus of subgrade reaction, psi

k_h = soil horizontal modulus of subgrade reaction, psi

$k_{i,j}$ = orthogonal soil springs on pipe, lb/in

k_v = soil vertical modulus of subgrade reaction, psi

L_1 = length of transverse pipe run, in

L_2 = length of longitudinal pipe run, in

L_m = minimum slippage length of pipe, in

L' = effective slippage length for short pipes, in

L'' = effective slippage length for long pipes, in

n = number of modeling elements for pipe springs, dimensionless

N_h = horizontal force factor,[61] dimensionless

P = maximum operating pressure in pipe, psi

P_c = confining pressure of backfill on pipe, psi

S_A = allowable expansion stress range, psi

SE = expansion stress, psi

S_h = basic material allowable stress at T degrees fahrenheit, psi

t = pipe wall thickness, in

T = maximum operating temperature, °F

T_o = ambient temperature of pipe, °F

w = soil density, pcf, pci

W_p = unit weight of pipe and contents, lb/in

α = coefficient of thermal expansion of pipe, in/in/°F

β = pipe/soil system characteristic,[62] in^{-1}

ε = pipe unit thermal expansion, in/in

μ = coefficient of friction, dimensionless

Ω = effective length parameter, in

1 inch = 25.4 mm

1 lb = 4.448 N

1 psi = 6894.8 Pa

deg F = 1.8 deg C + 32

Loads

Thermal Expansion. Thermal displacements at the elbows, branch connections, and flanges in a buried piping system and the forces and moments resulting from the displacements may be determined by analyzing each buried run of pipe by the method described in this section.

Installations with Continuous Runs. For buried piping installations that contain continuous runs without flexible couplings, the passive restraining effects of soil bearing on the transverse legs at the ends of long runs subject to thermal expansion may be significant and result in high axial forces and elbow or branch connection bending moments.

Installations with Flexible Couplings. For buried piping installations that incorporate flexible couplings into the pipe runs subject to thermal expansion, the bending moments and stresses may be substantially reduced. However, the flexible couplings must be chosen carefully to accommodate the thermal expansion in the pipe, and the friction forces or stiffness in the coupling must be considered.

Installations with Penetration Anchors. For buried piping systems in which the building penetration provides complete restraint to the pipe, it is necessary to calculate the penetration reactions to thermal expansion in the initial buried run. If this run incorporates flexible couplings, piping reactions at the penetration resulting from unbalanced forces due to internal pressure must be considered.

Installations with Flexible Penetrations. For buried piping systems in which the building penetrations permit some axial or angular movements, the interaction between the buried run outside the penetration and the point-supported portion of the system inside the building must be considered.

Pressure.   Pressure loads in buried piping are important for two primary reasons:

1. In pipe runs which incorporate flexible couplings, there is no structural tie between the coupled ends, with the result that internal pressure loads must be reacted externally. External restraint may be provided by thrust blocks, external anchors, soil resistance to elbows or fittings at each end of the pipe run, or by control rods across the coupling. Where one or both of the ends terminate at a penetration or an anchor, or at connected equipment such as a pump or vessel, the pressure forces can be quite high and must be considered in the anchor or equipment design.

2. For discharge structures, the reaction forces due to upstream pressure and mass flow momentum in the discharge leg may be high and must be considered in the design of the last elbow or bend before the discharge.

Earthquake.   An earthquake subjects buried piping to axial loads and bending moments from soil strain due to seismic waves, or from ground faulting across the axis of the pipe. The seismic soil strain can be estimated for a design earthquake in a specific geographical region, from which design values for forces and moments in buried piping can be calculated. However, consideration of the magnitude and effects of seismic ground faulting on buried piping is beyond the scope of this section.

Calculations

The calculations for stresses in restrained underground piping are carried out in four steps, as follows.

Assembling the Data.   The pipe material and dimensions, soil characteristics, and operating conditions must be established:
   Pipe Data

1. Pipe outside diameter D, in
2. Wall thickness t, in
3. Length of pipe runs L_1 (transverse) and L_2 (longitudinal), in
4. Young's modulus E, psi
5. Pipe depth below grade H, in

   Soil Characteristics

1. Soil density w, pcf (from site tests)
2. Type of backfill
3. Pipe trench width at grade B_d, in
4. Range of coefficient of friction μ between pipe and backfill

   Operating Conditions

1. Maximum operating pressure P, psi
2. Maximum pipe temperature T, °F
3. Ambient pipe temperature T_o, °F
4. Pipe coefficient of thermal expansion α, in/in/°F

Calculations of Intermediate Parameters. The following parameters must be calculated:

Maximum Relative Strain ε at the Pipe/Soil Interface, in/in. For thermal expansion, this is the unit thermal elongation of the unrestrained pipe,

$$\varepsilon = \alpha(T - T_o) \tag{B4.71}$$

where α = coefficient of thermal expansion
$T - T_o$ = difference between operating and installation temperatures

Modulus of Subgrade Reaction k, psi. This is a factor which defines the resistance of the soil or backfill to pipe movement due to the bearing pressure at the pipe/soil interface. Several methods for calculating k have been developed in recent years by Audibert and Nyman, Trautmann and O'Rourke, and others.[63–67] For example,[61] for pipe movement horizontally, the modulus of subgrade k_h may be found by

$$k_h = C_k N_h w D \text{ psi} \tag{B4.72}$$

where C_k = a dimensionless factor for estimating horizontal stiffness of compacted backfill. C_k may be estimated at 20 for loose soil, 30 for medium soil, and 80 for dense or compacted soil.
w = soil density, lb/in³
D = pipe outside diameter, in
N_h = a dimensionless horizontal force factor from Fig. 8 of Ref. 61. For a typical value where the soil internal friction angle is 30°, the curve from Ref. 61 may be approximated by a straight line defined by

$$N_h = 0.285H/D + 4.3$$

where H = the depth of pipe below grade at the pipe centerline, in

For pipe movement upward or downward, the procedures recommended in Ref. 63 may be applied. Conservatively, the resistance to upward movement may be considered the same as for horizontal movement with additional consideration for the weight of the soil. Resistance to downward movement may conservatively be considered as rigid for most expansion stress analysis.

Unit Friction Force at the Pipe/Soil Interface f.

$$f = \mu(P_c A_c + W_p) \text{ lb/in} \tag{B4.73}$$

where μ = coefficient of friction between pipe and soil
P_c = confining pressure of soil on pipe, psi
A_c = surface area of a pipe segment, in²
W_p = unit weight of pipe and contents, lb/in

For piping which is buried within 3 pipe diameters of the surface, confining pressure P_c may be estimated by

$$P_c = wH \text{ lb/in}^2$$

where w = the soil density, lb/in
H = the depth below grade, in

For piping which is buried more than 3 pipe diameters below grade, confining pressure P_c is found by using the modified Marston equation[67]:

$$P_c = wC_D B_D \ \text{lb/in}^2$$

where C_D = a dimensionless parameter obtained from Table B4.15
B_D = the trench width, with a maximum value of 24 in plus the pipe diameter

TABLE B4.15 Approximate Safe Working Values of C_D for Use in Modified Marston Formula

Pipe/Soil System Characteristic[62]

$$\beta = [k/(4EI)]^{1/4} \ \text{in}^{-1} \tag{B4.74}$$

where k = soil modulus of subgrade reaction k_h or k_v, psi
E = Young's modulus for pipe, psi
I = area moment of inertia for pipe, in^4

Minimum Slippage Length L_m[68]

$$L_m = \varepsilon A E/f \ \text{in} \tag{B4.75}$$

where A = pipe cross-section area

Maximum Axial Force F_{max} in the Longitudinal Pipe Run. The maximum axial force in a pipe long enough for friction force to develop to the point where a region of the pipe is totally restrained longitudinally by the soil is found by

$$F_{\max} = fL_m = \varepsilon AE \text{ lb} \tag{B4.76}$$

Classification of the Pipe Runs

Purpose. The classification and subclassification of the buried pipe elements is used in choosing the proper equation for effective slippage length L' or L'' which is then used in calculating piping forces and stresses. The pipe segment identified by the dimension L' or L'' always begins at either an elbow, bend, tee, or branch connection and terminates at the point (described below as the *virtual anchor*) at which there is no slippage or relative movement at the pipe/soil interface.

Classification of the Pipe Elements. It is in the bends, elbows, and branch connections that the highest stresses are found in buried piping subject to thermal expansion of the pipe. These stresses are due to the soil forces that bear against the transverse run (the run running perpendicular or at some angle to the direction of the pipe expansion). The stresses are proportional to the amount of soil deformation at the elbow or branch connection.

Piping elements are divided into three major categories depending upon what type of transverse element is being analyzed, as follows:

Category A. Elbow or bend (see Fig. B4.27)
FIGURE B4.27   Element category A, elbow or bend.

Category B. Branch pipe joining the longitudinal run (see Fig. B4.28)
FIGURE B4.28   Element category B, branch pipe joining the P leg.

Category C. Longitudinal run ending in a tee (see Fig. B4.29)
FIGURE B4.29   Element category C, tee on end of P leg.

Category D. Straight pipe, no branch or transverse run (see Fig. B4.30)
NOTE :
(1) Expansion joint pressure load plus sliding or convolution loads.

FIGURE B4.30   Element category D, straight pipe.

Categories A, B, and C are further divided into three subcategories depending on the configuration of the pipe run at the end opposite that being analyzed. The piping elements are classified as follows:

A1, B1, C1. Other end free or terminating in a flexible coupling or joint

A2, B2, C2. Other end contains an elbow or tee

A3, B3, C3. Other end is anchored

Category D elements include straight runs between an anchor (either actual or virtual) and a free end or a pipe section that is connected to an expansion joint.

The elements are further broken down into subtypes depending upon whether the longitudinal run (the pipe or P leg) and the transverse run (called the T leg) are long or short with respect to certain criteria. The transverse or T leg is the run against which the soil bears, producing an in-plane bending moment in elbow, branch, or tee. (Category D elements have no transverse leg.)

The strict criterion for a long or short transverse leg is whether the length of the transverse run L_1 is longer or shorter than $3\pi/4\beta$, the length at which the hyperbolic functions in Hetenyi's equations,[62] approach unity. The critical value for L_1 is often called the *influence* length, or that portion of transverse or T run which is deflected or "influenced" by seismic soil strain or pipe thermal expansion along the axis of the longitudinal or P run. In practice, a critical influence length L_1 of $1/\beta$ to $1.2/\beta$ may often be used, since there is very little deformation or load in that portion of the transverse run which exceeds this length. This implies that the vast majority of the bearing load on the transverse or T leg occurs in the first several feet of the pipe at the bend or branch. In summary, a transverse pipe is "long" if

$$L_1 \geq 3\pi/4\beta \text{ (conservative)}$$

or

$$L_1 \geq 1/\beta \text{ to } 1.2/\beta \text{ (usually acceptable)}$$

The criterion for a short or long P leg is whether its length L_2 is sufficiently long to experience the maximum force that can develop at the friction interface. For full maximum friction force ($F_{\max} = \varepsilon A E$) to occur in a straight pipe axially free at each end, its length L_2 would have to equal or exceed $2L_m$ with L_m calculated by Eq. (B4.75). If one end terminates in an elbow or a tee, with the other end remaining axially unrestrained, the total length L_2 necessary for full friction to develop is $L'' + L_m$; the friction force over L_m is equal to the soil bearing force S plus the

friction force acting on the length L' or L'', which is called the *effective slippage length*. The effective slippage length is the maximum length along which slippage occurs at the pipe/soil interface of a pipe with a transverse leg or branch. The effective slippage length L'' for long pipes with long transverse legs is calculated by

$$L'' = \Omega[(1 + 2F_{max}/f\Omega)^{1/2} - 1] \text{ in} \tag{B4.77}$$

where $\Omega = AE\beta/k$ and F_{max} is calculated by Eq. (B4.76).

Equation (B4.77) applies to bends, tees, and branches. Although Eq. (B4.77) was developed for the case where $L_2 = L'' + L_m$, it applies also for any case where $L_2 > L'' + L_m$, since the length of the region where there is zero slippage at the friction interface is immaterial.[68] Using L'' as calculated by Eq. (B4.77), it can now be established that a P leg is classified long if it meets these criteria:

1. For Types A1, B1, C1, $L_2 \geq L_m + L''$;
2. For Types A2, B2, C2, $L_2 \geq 2 L''$;
3. For Types A3, B3, C3, D, $L_2 \geq L''$.

That point which is located a distance L' or L'' from the bend, branch, or tee, is called the virtual anchor, since it acts as if it were a three-axis restraint on the pipe.

Locating the Virtual Anchor. Calculation of the forces and moments in buried piping at the changes in direction requires that the location of the virtual anchor (the effective slippage length L' away from the bend or branch element) in the P run and the deformation δ of the soil at the buried element be established. For elements of all types with long P legs, L'' may be calculated by Eq. (B4.77).

For Types A1, B1, and C1 elements (with one end of the P leg free or unrestrained axially) with "short" P legs, L' must be found by a less direct method as follows[68]:

$$L' = [-b + (b^2 - 4ac)^{1/2}]/2a \text{ in} \tag{B4.78}$$

where $a = 3f/(2AE)$
$b = \varepsilon - fL_2/(AE) + 2f\beta/k$
$c = -f\beta L_2/k$

However, the most highly stressed runs in a buried piping system typically are restrained at both ends, either by a combination of transverse runs or a transverse run and an anchor (either real or virtual).

For Types A2, B2, and C2 elements with short P legs, L' is expressed by

$$L' = L_2/2 \text{ in} \tag{B4.79}$$

For Types A3, B3, C3, and D elements with short P legs, L' is expressed by

$$L' = L_2 \text{ in} \tag{B4.80}$$

Computer Modeling of Buried Piping

Determination of Stresses. With f, k, and L' or L'' established, the stresses in a buried pipe due to thermal expansion can be determined with a general purpose pipe stress computer program. A buried piping system can be modeled with a

typical mainframe or microcomputer pipe stress program by breaking the buried portions into elements of convenient length and then imposing a transverse spring at the center of each element to simulate the passive resistance of the soil. The entire pipe can be divided into spring-restrained elements in this manner; however, the only regions of the pipe that really need to be modeled in this manner are the lengths entering and leaving elbows or tees. The analyst should refer to the program users' manual for guidance in modeling soil springs.

All pipe stress computer programs with buried piping analysis options require that the following factors be calculated or estimated:

1. Location of the virtual anchor (dimension L' or L'')

2. Soil spring rate $k_{i,j}$, which is a function of the modulus of subgrade reaction k.

3. Influence length, also a function of k.

Some programs ignore the friction at the pipe/soil interface; this is conservative for calculating bending stresses on the buried elbows and branch connections, but may be unconservative for calculating anchor reactions.

Determination of Element Lengths.   The element lengths and transverse soil spring rates for each element are calculated by the following procedure:

1. Establish the element length dL and the number n of elements, as follows:
(*A*) Set the element length to be equal to between 2 and 3 pipe diameters. For example, dL for a NPS 6 may be set at either 1 ft or 2 ft, whichever is more convenient for the analyst.
(*B*) Establish the number n of elements by:

$$n = (3\pi/4\beta)/dL \tag{B4.81}$$

This gives the number of elements, each being dL inches in length, to which springs are to be applied in the computer model. The number n of elements is always rounded up to an integer.

2. Calculate the lateral spring rate $k_{i,j}$ to be applied at the center of each element.

$$k_{i,j} = kdL \text{ lb/in} \tag{B4.82}$$

where k = the modulus of subgrade reaction calculated from Eq. (B4.72).

3. Calculate the equivalent axial load necessary to simulate friction resistance to expansion. The friction resistance at the pipe/soil interface can be simulated in the computer model by imposing a single force F_f in a direction opposite that of the thermal growth.

$$F_f = fL'/2 \text{ or } fL''/2 \text{ lb} \tag{B4.83}$$

4. Incorporate the springs and the friction force in the model. The mutually orthogonal springs $k_{i,j}$ are applied to the center of each element, perpendicular to the pipe axis. Shorter elements, with proportionally smaller values for the springs on these elements, may be necessary in order to model the soil restraint at elbows and bends. The friction force F_f for each expanding leg is imposed at or near the elbow tangent node, opposite to the direction of expansion.

Determination of Soil Parameters.   Soil parameters are difficult to establish accurately due to variations in backfill materials and degree of compaction. Consequently, values for elemental spring constants on buried pipe runs can only be considered as rational approximations. Stiffer springs can result in higher elbow stresses and lower bending stresses at nearby anchors, while softer springs can have the opposite effects. Backfill is not elastic; testing has shown that soil is stiffest for very small pipe movements, but becomes less stiff as the pipe movements increase. References 61, 63, and 66 discuss soil stiffness and recommend procedures for estimating values for k which are consistent with the type of soil and the amount of pipe movement expected. The analyst should consult the project geotechnical engineer for assistance in resolving any uncertainties in establishing soil parameters, such as the modulus of subgrade reaction k, confining pressure p_c, and coefficient of friction μ.

Pipe with Expansion Joints.   An expansion joint must be considered as a relatively free end in calculating stresses on buried elbows and loads on anchors. Since incorporation of expansion joints or flexible couplings introduces a structural discontinuity in the pipe, the effects of the unbalanced pressure load and the axial joint friction or stiffness must be superimposed on the thermal expansion effects in order to determine the maximum pipe stresses and anchor loads.

Pipe Stresses at Building Penetrations.   Stresses at building penetrations can be calculated easily after the reactions due to thermal expansion in the buried piping have been determined. If the penetration is an anchor, then the stress due to the axial force F_{max} and the lateral bending moment M can be found by

$$S_E = F_{max}/A + M/Z \text{ psi} \qquad (B4.84)$$

If the penetration is not an anchor, but is instead a simple support with a flexible water seal, it is necessary to determine the stiffness affects of the water seal material in order to calculate the stress in the pipe at the penetration. Differential movement due to building or trench settlement can generate high theoretical stresses at piping penetrations to buildings. Calculation of such stresses is beyond the scope of this section.

Allowable Stress in Buried Pipe

Buried piping under axial stress can theoretically fail in one of two ways: either by column buckling (pipe pops out of the ground at midspan) or local failure by crippling or tensile failure (much more serious than column buckling). Since buried piping stresses are secondary in nature, and since the piping is continuously supported and restrained (see Fig. B4.31), higher total stresses may be permitted
FIGURE B4.31   Plan of example buried pipe.

as follows:

$$S_C \leq S_A + S_h \tag{B4.85}$$

where S_A and S_h are as defined in Para. 102.3.2 of B31.1 Code.

CHAPTER B5
PIPING SUPPORTS

L. Di Giacomo, Jr.
Senior Engineer, Bechtel Power Corporation, Frederick, MD

J. R. Stinson
Supervisor, Engineering, LISEGA Inc., Newport, TN

INTRODUCTION

The correct and economical selection of the supports for any piping system usually presents difficulties of varying degrees, some relatively minor and others of a more critical nature. Proper support selection should be the objective of all phases of design and construction.

Many pipe support problems may be minimized or avoided if proper attention is given to the means of support during the piping layout design phase. The piping designer's familiarity with support problems, accepted practices, and commercially available pipe support components and their applications is extremely important. Good pipe support design begins with good piping design and layout. For example, other considerations being equal, piping should be routed to use the surrounding structure to provide logical and convenient points of support, anchorage, guidance, or restraint, with space available at such points for use of the proper component. Parallel lines, both vertical and horizontal, should be spaced sufficiently apart to allow room for independent pipe attachments for each line.

Pipe support specifications for individual projects must be written in such a way as to ensure proper support under all operating and environmental conditions and to provide for slope, expansion, anchorage, and insulation protection. Familiarity with standard practices, customs of the trade, and types and functions of commercial component standard supports and an understanding of their individual advantages and limitations, together with knowledge of existing standards, can be of great help in achieving the desired results.

Reference Codes and Standards

In the United States the pipe support standards and their publishers are

- MSS SP-58, *Materials and Design of Pipe Supports*
- MSS SP-69, *Selection and Application of Pipe Supports*

- MSS SP-89, *Fabrication and Installation of Pipe Supports*
- PFI ES-26, *Welded Load Bearing Attachments to Pressure Retaining Boundaries*
- WRC Bulletin 198
- National Fire Protection Association (NFPA)
- American Welding Society (AWS)
- American Institute of Steel Construction (AISC)

In Britain the pipe support standards are

- BS 3974, *Specification for Pipe Supports, Parts 1, 2, and 3*
- BS 5135, *Process of Arc Welding of Carbon and Carbon Manganese Steels*

In Germany the pipe support standards are

- VGB-R510L
- DIN EN 288, *Specification and Approval of Procedures for Welding Metallic Materials*

In Japan it is *Meeting Notification 501*.

Piping systems must comply with the code(s) of jurisdiction.

Unless complete design details are provided by the engineer or piping system layout designer, the final responsibility for selection and design of pipe supports capable of completely satisfying the system requirements and job specifications rests with the pipe support engineer and/or designer. Any piping system is inoperable until the pipe hangers and supports have been selected and installed. Experience shows that a high percentage of pipe support problems cannot be recognized during a cursory examination of the piping drawings but await a detailed analysis by those responsible for the design of the support and the preparation of specific material lists and details. In the interest of properly coordinating support installations with the piping erection schedule, priority should be given to the selection, design, and procurement of pipe support components.

The dollar value of the support system is generally outweighed many times by the value of pipe, valves, and fittings which are to be supported. Failure to allow sufficient time for the design, procurement, and fabrication of the supports can lead to costly erection delays and the use of temporary supports.

Pipe supports are generally identified by a specification type number, such as a type 3 double-bolt pipe clamp, as in MSS SP-58, or by a manufacturer's part number, a descriptive name, and size. The latter depends upon the type of component; e.g., pipe attachments, such as clamps, are prescribed by pipe size, upper attachments are identified by rod size, and variable springs are sized by the calculated load to be supported. In addition, pipe support components vary in their load-carrying capacity. The load capacity of each type of pipe support component is given in most manufacturers' catalogs, load capacity data sheets, or design report summaries. Various components and their functions will be discussed in greater detail in subsequent sections.

General Design Considerations

Hangers and supports must be designed to meet all static as well as dynamic operational conditions to which the piping and equipment may be subjected. The

support system must provide for and control, subject to the requirements of the piping configuration, the movement due to the thermal expansion and contraction of the piping and connected equipment. Proper design necessitates a thorough knowledge of the complete cyclical behavior of each section of piping to be supported as well as an awareness of the proximity of the pipe with respect to building structure, other piping systems, and equipment in the immediate vicinity.

A substantial reduction in the complexity of support design can be realized when piping support requirements are coordinated properly with the plant and piping design phases. Initial plant design should recognize that the support designer requires access to the piping, sufficient space in which to install the supporting equipment, and adequate structure from which to support the piping. Ideally the support designer should have the opportunity to offer comments on the piping design from the initial layout.

Starting with any given set of piping and structural drawings, it is necessary for the support designer to become familiar with the overall design concept and any special requirements that may be called for in the specifications.

- When one is dealing with a number of piping systems in an area, it is advisable to superimpose the piping (using a single-line representation) on the structural drawings.

- A preliminary study very often reveals that consideration has been given to the supporting phase and provisions have been made in the form of steel work patterns, anchor bolts or inserts in concrete, or runs of piping purposely routed near suitable supporting structure. Naturally, full advantage should be taken of such conditions.

- The piping should also be studied from the standpoint of possibly coordinating supports for one system or pipe run with those of another, thereby providing an orderly supporting arrangement. On the other hand, it may also be necessary, because of loading conditions, to purposely stagger supports in order to distribute the loads on the supporting structures.

All the above should be determined prior to the start of detailed support design for any piping system.

Once a tentative overall pattern of supports for a particular area has been established, it is advisable to begin specific design with the most critical or largest piping systems, thereby reserving the best possible supporting conditions for the most critical lines.

Location of Supports

Of prime consideration in design is the determination of support location. Although supports are located ideally to suit the requirements of the piping configuration, some degree of compromise may be required to take the fullest advantage of the available supporting structure. First the piping system should be investigated as a whole. With the use of the allowable support spacing as dictated by code, practice, or special calculation (see Chap. B4), the support points are tentatively located, taking into consideration division of straight runs, concentrated loads, elimination of excessive overhanging sections or bends, and loads on terminal connections.

Next, the tentative locations are compared with the available supporting structure, modified as required, and recorded on the superimposed piping previously

sketched on the structural drawings. The recording of each support location, along with an indication of any supplementary steel required, serves as a valuable aid in checking clearances and coordinating supports during the course of design, especially when a number of designers are working on the same project.

It should be emphasized that the location of pipe supports is an iterative process in which several support configurations are investigated in succession, with the results of the analysis of one configuration being factored into the selection of the next configuration, until a satisfactory solution is reached.

Loading Considerations

Once a satisfactory pattern of support locations has been established, the next step is to determine the loading and movement conditions existing at each support point. Here, coverage will be confined to the general considerations regarding only loads and movements. Recommended methods for obtaining or calculating specific loads and movements are covered later under ''Determination of Loads and Movements.''

The magnitude and direction of the design load as determined by the methods of Chap. B4 are used to select and design the proper support or restraint at each selected point along the piping system.

Seismic, Dynamic, or Other Loadings

The design of pipe support components and structural steel must include provisions for seismic, dynamic, or other occasional loadings where required. Applicable codes generally permit some increase in allowable stresses for seismic and dynamic loading conditions. Spring supports should be evaluated to determine if additional dynamic movement can be tolerated; if not, additional means such as limit stops or dynamic snubbers may be required.

Overloading from Various Causes

ASME B31.1, *Power Piping Code,* allows an increase in the allowable stress values of 20 percent for short-time overloading during operation. However, it is appropriate to point out that where there is a possibility of two or more causes of short-time overloading (e.g., ice, wind, seismic shock, or vibration) occurring simultaneously, the combined overloading in excess of 20 percent must be added to the design load.

DETERMINATION OF SUPPORT LOCATIONS

Support locations are dependent on many considerations, such as pipe size, piping configuration, the location of heavy valves and fittings, and the structure that is available for support. No firm rules or limits exist which will positively fix the location of each support in a piping system. Instead, the engineer must exercise judgment to determine appropriate support locations.

TABLE B5.1   Suggested Piping Support Spacing

NPS (DN)	Suggested maximum span, ft (m)	
	Water service	Steam, gas, or air service
1 (25)	7 (2.13)	9 (2.74)
2 (50)	10 (3.05)	13 (3.96)
3 (80)	12 (3.66)	15 (4.57)
4 (100)	14 (4.27)	17 (5.18)
6 (150)	17 (5.18)	21 (6.40)
8 (200)	19 (5.79)	24 (7.32)
12 (300)	23 (7.01)	30 (9.14)
16 (400)	27 (8.23)	35 (10.7)
20 (500)	30 (9.14)	39 (11.9)
24 (600)	32 (9.75)	42 (12.8)

Pipe Support Spacing

The suggested maximum spans between supports listed in Table B5.1 reflect the practical considerations involved in determining support spacings on straight runs of standard wall piping. The spans are based on a combined bending and shear stress of 1500 psi (10.35 MPa) when the pipe is filled with water, and $\frac{1}{10}$- in (2.54-

TABLE B5.2   Gravity Steel Pipe Support Spacing (Contents = Water)

Nominal pipe size, NPS	(DN)	Pipe sch.	Pipe span, ft-in (m)			
			No insul.	1-in (25 mm) insul.	1½-in (40 mm) insul.	2-in (50 mm) insul.

mm) sag is allowed between supports. Table spans do not apply where concentrated weights such as valves or heavy fittings exist, or where changes in direction of the piping system occur between support points.

Supports should be placed as close as possible to concentrated loads in order to keep piping stresses to a minimum. Where changes in piping direction occur between supports, it is good practice to keep the total length of pipe between the supports equal to or less than 0.75 times the full spans listed in Table B5.1. When practical, a support should be located immediately adjacent to any change in direction of the piping.

For economy in the support of low-pressure, low-temperature systems, support spans may be based on the code-allowable total stresses of the pipe and the amount of allowable deflection between supports.

In steam lines with long spans, the deflection caused by piping weight may be large enough to cause an accumulation of condensate at the low points. During plant start-up, these pockets of condensate can cause flashing and can result in undesirable dynamic loads on the system. Natural drainage can be provided by erecting the line with a slope in such a manner that succeeding supports are lower than the points of maximum deflection in preceding spans.

For fluids other than water, the bending stress can be found by using the formulas in Chap. B4. Spans for typical small-diameter piping based on the equations in Chap. B4 are found in Tables B5.2 and B5.3.

TABLE B5.3 Gravity Steel Pipe Support Spacing (Pipe Empty, Air, Steam)

			Pipe span, ft-in (m)

		160	11-10 (3.61)	11-0 (3.35)	10-6 (3.20)	10-0 (3.05)

DETERMINATION OF LOADS AND MOVEMENTS

The anticipated movement at each support point dictates the basic type of support required. Each type of support selected must be capable of accommodating movements obtained by one of the methods outlined later in this section. It is a good practice to select first the most simple or basic rigid support type and to add to the complexity only as conditions warrant. No advantage will be realized in upgrading a support when a simpler, more economical type can be shown to satisfy all the design requirements. Both vertical and horizontal movement must be evaluated.

When piping vertical movement is small, the use of simple rod hangers should be adequate. With small vertical movement and significant horizontal movement, the simple rod hanger will still suffice, provided the overall length is sufficient to keep the angular swing of the rod within reasonable limits—normally accepted as being 4° from the vertical. When one is calculating the total movement experienced by the support, both horizontal displacements and the vertical displacement must be combined and normalized to the axis of the support. Consideration should be given to relocating the upper connection some percentage (usually two-thirds) of the total movement as a means for reducing the angularity in the hot position. For piping supported from below, some form of slide must be incorporated to provide for the horizontal movement; or, in the case of ensured longitudinal movement, a pipe roll may be used. Rollers are usually only used on long runs of piping supported on racks such as found in refinery piping. Suspended hangers with considerable horizontal movement and low headroom will require either single- or double-direction trolleys or rollers. Where both longitudinal and lateral movements are large, consideration may be given to the use of a single-direction trolley oriented on the resultant movement vector.

Use of Variable Spring and Constant Spring Supports

Piping which is subject to significant vertical movement requires the incorporation of variable springs or constant support springs. Variable supports will normally suffice for spring hangers except for certain systems in power plants, refineries, and some specialized lines in process and chemical plants which may have large vertical movements where the change in load between installed and operating is unacceptable. (In these cases, the use of constant supports is required.) As the name *variable support* implies, the supporting effect varies in relation to the vertical movement of the suspended piping and the resultant compression or extension of the spring coil. The change in supporting force is in proportion to the spring rate and to the amount of movement. When variable supports are used, the loss or gain in supporting force should be considered with respect to added stress on the piping system. For normal installations, various industries have established conventions concerning the use of variable spring supports and constant spring supports which may be regarded as standard practice. For example, the following would be conventional guidelines for power plant piping:

At support locations subject to vertical movement, springs of suitable design to prevent excessive variation in supporting effect should be used to provide for the movement. The amount of variation that can be tolerated should be based on such considerations as pipe-bending effect, control of piping elevation, and allowable terminal connection loadings. In general, the deviation in supporting effect should be limited to ±6 percent for systems such as main steam, hot and cold reheat,

extraction lines over 750°F (400°C), discharge in the vicinity of the pumps, and boiler terminal connection. On other systems, the variations in supporting effect should be limited to 25 percent.

For all systems, a greater allowance in percentage variation is permissible at points of support where the variation in supporting effect is transferred directly to a rigid support or terminal connection specifically designed for the resulting loading condition.

When the load and movement at each selected support location are determined, detailed design of the individual supports can be undertaken. The movement determines the basic type of support (such as spring or rigid, slide or roller); the piping, its temperature, and ambient temperature determine the pipe attachment and remaining support material, respectively; the proximity to supporting structure and available clearance determines the support configuration such as single- or double-rod hanger, stanchion, or bracket-type support; and the load determines the required size for each component of the support.

The design should take full advantage of commercially available load-rated and tested support components to the greatest extent possible. An effort should be made to maintain uniformity and simplicity in design. The support should be functional, provide means for piping elevation adjustment, and be easily installed using normal field labor and equipment.

For economic reasons, the use of commercial catalog items available from piping support manufacturers eliminates the need for detail design of the numerous types and varying sizes of components required to complete a typical piping support installation.

MSS SP-58 Hanger and Support Types

Refer to Fig. B5.1.

Type 1   *Adjustable steel clevis hanger*
            A pipe attachment for suspension of horizontal stationary lines and providing a means for vertical adjustment.

Type 2   *Yoke-type pipe clamp*
            A pipe attachment for suspension of horizontal stationary insulated lines. This type of clamp is also made to accommodate pipe of nonstandard size when designed with a filler plate.

Type 3   *Carbon- or alloy-steel three-bolt pipe clamp*
            A pipe attachment for suspension of horizontal stationary lines.

Type 4   *Steel pipe clamp*
            A pipe attachment for suspension of horizontal stationary insulated lines.

Type 5   *Pipe hanger*
            A pipe attachment for suspension of horizontal stationary lines either using a hanger rod or bolting to wall from the T slot provided in the side of the strap.

Type 6   *Adjustable swivel pipe, split ring type or solid ring type*
            A pipe attachment for suspension of horizontal stationary lines.

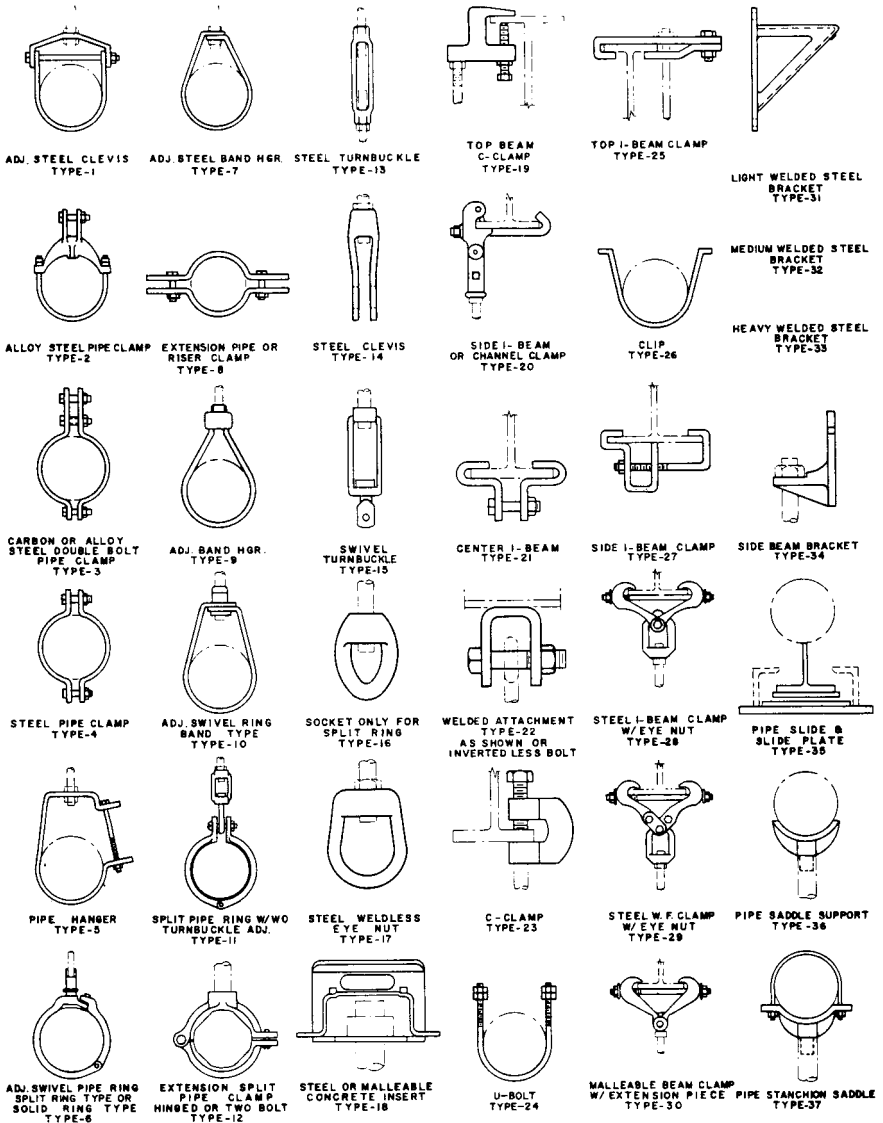
Type 7   *Adjustable steel band hanger*
            A pipe attachment for suspension of horizontal stationary lines and providing a means for vertical adjustment.


FIGURE B5.1 Type chart.

Types of pipe supports (MSS SP-58).

Type 8 *Extension pipe or riser clamp*
A pipe attachment for suspension of vertcal stationary lines without the use of hanger rods. The transfer of piping load is accomplished by resting the ears of the clamp on a bearing surface.

Type 9 *Adjustable band hanger*
A pipe attachment for suspension of horizontal stationary lines.

FIGURE B5.1 (*Continued*)   Type chart.

Type 10   *Adjustable swivel ring, band type*
            A pipe attachment for suspension of horizontal stationary lines and
            providing a means for vertical adjustment.

Type 11   *Split pipe ring with or without turnbuckle adjustment*
            A pipe attachment for suspension of horizontal stationary lines permit-
            ting installation before or after pipe is in place.

Type 12   *Extension split pipe clamp, hinged or two-bolt*
A pipe attachment for suspension of horizontal stationary lines used in conjunction with a pipe nipple.

Type 13   *Steel turnbuckle*
A device with one left-hand internal threaded end and one right-hand internal threaded end, used to join two threaded rods and providing for vertical adjustment.

Type 14   *Steel clevis*
A device which provides for the attachment of a threaded rod to a bolted or pinned connection.

Type 15   *Swivel turnbuckle*
A device which provides flexibility at the pipe connection and a means of vertical adjustment.

Type 16   *Malleable iron socket*
A device for attaching threaded rods to various types of building attachments.

Type 17   *Steel weldless eye nut*
A forged-steel device which provides for the attachment of a threaded rod to a bolt or pin connection.

Type 18   *Steel or malleable concrete insert*
A cast-in-place device which provides for a rod attachment capable of nominal lateral adjustment.

Type 19   *Top beam C-clamp*
A device requiring no welding which attaches to the top flange of a structural shape where the vertical rod is required to be offset from the edge of the flange.

Type 20   *Side beam or channel clamp*
A device requiring no welding which attaches to the bottom flange of a structural shape where the vertical rod is required to be at the edge of the flange.

Type 21   *Center beam*
A device requiring no welding which attaches to the bottom flange of a structural shape where the vertical rod is required to be centered on the structural shape.

Type 22   *Welded beam attachment (as shown or inverted less bolt)*
A structural attachment welded to the bottom of steel beams and used as a means for connecting hanger rods to the beams.

Type 23   *C-clamp*
A device requiring no welding which attaches to a flange of a structural shape and provides for attaching a threaded rod.

Type 24   *U-bolt*
A U-shaped rod with threaded ends used as a support or guide.

Type 25   *Top beam clamp*
A device requiring no welding which attaches to the top flange of a structural shape where the vertical rod is required to be at the edge of the flange.

Type 26   *Pipe clip*
A pipe attachment for suspension of horizontal stationary lines by

bolting the clip directly to a structure. Also referred to as a pipe strap or strap.

Type 27 *Side beam clamp*
A device requiring no welding which attaches to the bottom flange of a structural shape where the vertical rod is required to be offset from the center of the shape.

Type 28 *Steel beam clamp with eye nut*
A device requiring no welding which attaches to the bottom flange of a structural shape where the vertical rod is required to be centered on the structural shape.

Type 29 *Linked steel clamp with eye nut*
A device requiring no welding which attaches to the bottom flange of a structural shape where the vertical rod is required to be centered on the structural shape.

Type 30 *Malleable beam clamp with extension piece*
A device requiring no welding which attaches to the bottom flange of a structural shape where the vertical rod is required to be centered on the structural shape.

Type 31 *Light welded steel bracket*
A braced cantilever device intended for supporting a gravity load from rod-type hangers. This device is typically bolted to a wall and may be installed with the brace either above or below the horizontal member.

Type 32 *Medium welded steel bracket*
A braced cantilever device intended for supporting maximum gravity loads and/or horizontal loads up to 1500 lb (6670 newton, N). Loads may be applied anywhere along the main member. This device is typically bolted to a wall and may be installed with the brace above, below, or on either side of the main member.

Type 33 *Heavy welded steel bracket*
A braced cantilever device intended for supporting maximum gravity loads and/or horizontal loads up to 3000 lb (13,340 newton, N). Loads may be applied anywhere along the main member. This device is typically bolted to a wall and may be installed with the brace above, below, or on either side of the main member.

Type 34 *Side beam bracket*
A device requiring no welding which attaches to the sides of steel or wooden members and provides a means for vertical adjustment.

Type 35 *Pipe slide and slide plate*
A device for supporting piping having horizontal movements and where a low coefficient of friction is necessary.

Type 36 *Pipe saddle support*
A device having a curved base for cradling horizontal pipe and which slips into a nominal diameter pipe stanchion.

Type 37 *Pipe stanchion saddle*
A device having a curved base for cradling horizontal pipe and which slips into a nominal diameter pipe stanchion. The U-bolt yoke provides stability.

Type 38   *Adjustable pipe saddle support*
           A device having a curved base for cradling horizontal pipe and which
           threads into a nominal diameter pipe stanchion. This device provides
           vertical adjustment.

Type 39   *Steel pipe-covering protection saddle*
           A device used on insulated piping which is designed to minimize heat
           losses and prevent damage to insulation.

Type 40   *Protection saddle*
           A metal device intended to prevent crushing of insulation and/or
           breaching of the vapor barrier. It is typically used at support points.

Type 41   *Single pipe roll*
           A device used for supporting horizontal piping from two rods, allowing
           for vertical adjustment and consisting of a roller that allows for axial
           movement with virtually no frictional resistance.

Type 42   *Carbon- or alloy-steel riser clamp*
           A pipe attachment for supporting vertical piping through the use of
           shear lugs welded to the pipe. Load bolts are provided to transfer the
           pipe load to the rod hanger assembly.

Type 43   *Adjustable roller hanger with or without swivel*
           A device used for supporting horizontal piping from a single rod,
           allowing for vertical adjustment and consisting of a roller that allows
           for axial movement with virtually no frictional resistance.

Type 44   *Pipe roll complete*
           A device used for supporting horizontal piping where vertical adjust-
           ment is unnecessary and consisting of a roller that allows for axial
           movement with virtually no frictional resistance.

Type 45   *Pipe roll and plate*
           A device used to support horizontal piping, having minimal axial move-
           ment, from beneath and where no vertical adjustment is necessary.

Type 46   *Adjustable pipe roll and base*
           A device used to support horizontal piping, having axial movement,
           from beneath and where vertical adjustment is necessary.

Type 47   *Restraint control device*
           A rigid, mechanical, spring, or hydraulic device used for absorbing
           shock loading and/or controlling sway in piping systems.

Type 48   *Spring cushion*
           A noncalibrated, rod-type, single-coil spring support used where a
           cushioning effect is desired.

Type 49   *Spring cushion roll*
           A noncalibrated, rod-type, double-coil rod spring support used where
           a cushioning effect is desired along with a pipe roll.

Type 50   *Spring sway brace*
           A spring device used for absorbing shock loading and/or controlling
           sway in piping systems.

Type 51   *Variable spring hanger*
           A device having a single-spring coil which supports the gravity loads
           of piping systems that are subjected to vertical thermal movements.
           This device produces a varying load when the piping moves from the

cold position to the hot position. This type of spring hanger supports the pipe from above.

Type 52   *Variable spring base support*
A device having a single-spring coil which supports the gravity loads of piping systems that are subjected to vertical thermal movements. This device produces a varying load when the piping moves from the cold to the hot position. This type of spring hanger supports the pipe from below.

Type 53   *Variable spring trapeze hanger*
A device having double-spring coils which support the gravity loads of piping systems that are subjected to vertical thermal movements. This device produces a varying load when the piping moves from the cold position to its hot position. This type of spring hanger supports the pipe from above with two rods.

Type 54   *Constant support hanger, horizontal type*
A device having a single-spring coil working in conjunction with counterbalancing mechanisms to support the gravity loads of piping systems that are subjected to vertical thermal movements. This device produces a constant load when the piping moves from the cold position to the hot position. This type of constant hanger has the spring coil in the horizontal position and supports the pipe from above.

Type 55   *Constant support hanger, vertical type*
A device having a single-spring coil working in conjunction with counterbalancing mechanisms to support the gravity loads of piping systems that are subjected to vertical thermal movements. This device produces a constant load when the piping moves from the cold position to the hot position. This type of constant hanger has the spring coil in the vertical position and supports the pipe from above.

Type 56   *Constant support hanger, trapeze type*
A device having double-spring coils working in conjunction with counterbalancing mechanisms to support the gravity loads of piping systems that are subjected to vertical thermal movements. This device produces a constant load when the piping moves from the cold position to the hot position. This type of constant hanger has the spring coil in the vertical position and supports the pipe from below with two rods.

Type 57   *Plate lug*
A structural attachment which provides a means of connecting rod-type hangers to structural steel members via a pin or bolt through the hole of the lug.

Type 58   *Horizontal traveler*
A device which permits the structural attachment end of rod-type hangers to accommodate horizontal piping movements in conditions where offsetting of conventional structural attachments is not practical due to limited space.

SELECTION OF PIPE-SUPPORTING DEVICES

Piping Systems: Temperature Classification.   Piping systems, for the purposes of this chapter, are divided into the following temperature categories, in order to provide a basis for the selection of supports, anchors, or restraints and guides.

1. *Hot systems*

   Hot systems operate above 120°F (49°C) and are grouped as follows:

   a. The temperature range is from 120 to 450°F (49 to 232°C). Typical examples are low-pressure steam, hot water, and certain process piping.

   For Type 1a systems, MSS-SP-58 support Types 1 and 3 through 12 are used for suspending from above. Rollers, used for supporting from below, should be MSS-SP-58 Types 41, and 43 through 46 with appropriate saddles of MSS-SP-58 Type 39; and sliding supports should be of MSS-SP-58 Types 35 through 38.

   b. The temperature range is from 450 to 650°F (232 to 343°C). Typical examples are boiler plant and industrial steam and hot-water piping systems.

   For Type 1b systems, MSS-SP-58 support Types 1, 3, 4, and 42 are used. Rollers should be of MSS-SP-58 Types 41 and 43 through 46, with appropriate saddles of MSS-SP-58 Type 39.

   c. The temperature ranges from 750°F (400°C) upward. A typical example is a high-pressure steam power plant piping system.

   For Type 1c systems, alloy supports are used as required by the line temperature. Supports should be of MSS-SP-58 Type 2, 3, or 42 with saddles of MSS-SP-58 Type 39, and rollers of MSS-SP-58 Types 41 through 47. [In the temperature range 650°F (343°C) and higher, there is the possibility of metallurgical change if unalloyed carbon-steel components are used. It is suggested that those portions of hangers, anchors, and supports in direct contact with piping which operates at or above 650°F (343°C) be made of materials suitable for these extreme service temperatures.]

2. *Ambient systems*

   Ambient systems are systems in which the contents of the line are not heated or cooled by mechanical means. Temperatures range up to 120°F (49°C). Plant air and service water are typical systems.

   For Type 2 systems, hangers can be of MSS-SP-58 Types 1 and 3 through 12, with supports of MSS-SP-58 Types 24, 26, and 35 through 38.

3. *Cold systems*

   Cold systems typically operate below 70°F (21°C).

   a. The temperatures range from 32 to 70°F (0 to 21°C). A typical example is chilled water piping. Refer to Chap. C9.

   b. The temperature ranges from 32 to −20°F (0 to −29°C), as in brine systems. Refer to Chap. C9.

   c. Temperatures below −20°F (−29°C), as in cryogenic systems. Refer to Chap. C8.

   For Type 3 systems, the hanger or support must be outside the insulation, and the vapor barrier must be left undisturbed. An MSS-SP-58 Type 40 insulation protection shield (or similar device) must be used to distribute the loading on the insulation. Supports sized for the outside diameter of the insulation can be of MSS-SP-58 Type 1, 4, 6, 7, 9, 10, or 11. For Type 3c systems, the welded attachment must be of an alloy material which is compatible with the material of the piping system itself.

Pipe Attachments.   Supports for the various systems described above may be selected from Fig. B5.1.

Pipe-Covering Protection Saddles.   Where insulation is used on the piping system, it is frequently necessary to make some modification at the point of attachment of the support. Since different methods and practices exist for hot lines as contrasted to low-temperature lines (chilled water and brine), they should be treated separately.

Caution must be exercised in the support of insulated piping to ensure that a firm attachment is provided. Particularly, with respect to high-temperate lines, provision in the form of pipe protection saddles is made to ensure that the pipe supports do not become overheated. Protection saddles, Type 39 for use with high-temperature insulation, should be 12 in (305 mm) long and have approximately 60° of arc. Metal is normally ⅛ in (3 mm) thick for pipe sizes up to 5 in (125 mm) and ³⁄₁₆ in (5 mm) thick for larger pipe sizes. These saddles and matching rollers are available commercially for most sizes and insulation thicknesses. Refer to Chap. B7 for insulation thicknesses.

For support from above, either a conventional type of pipe clamp may be used directly on the pipe and the arms of the clamp (MSS-SP-58 Type 3) extended outside the insulation, or a larger clamp (MSS-SP-58 Type 1 or 4) may be used and lined with saddles or noncrushable insulation material.

Lugs may be welded to the pipe and extended outside the insulation to a steel clevis (MSS-SP-58 Type 14) or, if supported from below, to a sliding shoe or guided roller. The important point is to have the actual attachment or supporting member outside the insulation so that movement of the line will not result in insulation damage.

For low-temperature service, in addition to heat loss or gain, the problem of atmospheric condensation must be considered, and such lines are usually insulated with a material that has an outer covering or seal called a *vapor barrier*. This barrier prevents the insulation from absorbing moisture. For this reason it is not permissible to penetrate the insulation with load-carrying members such as the legs of a conventional high-temperature saddle or a pipe clamp. Since most low-temperature insulations have low compressive strength, it is necessary to provide shields to line the piping insulation and to spread out the bearing area sufficiently to prevent crushing of the insulation. Such shields should fit the outer diameter of the insulation and cover 180° of arc. Shield lengths and thicknesses are given in Table B5.4, taken from MSS-SP-69.

TABLE B5.4 Minimum Dimensions: Shields for Insulation Protection

NPS (DN)	Skill length, in (mm)	Thickness, in (mm)
½ to 3½ (15 to 90)	12 (300)	0.048 (1)
4 (100)	12 (300)	0.060 (2)
5 (125)	18 (450)	0.060 (2)
6 (150)	18 (450)	0.060 (2)
8 (200)	24 (600)	0.075 (2)

Attachments to Buildings or Other Structures.   When piping is to be hung from steel, Types 20 through 23, 25, and Types 27 through 30 beam clamps and Type 57 plate lug should be used.

When piping is hung from concrete, malleable iron or steel inserts of Type 18 or a continuous strip insert may be used. Embedded anchor bolts may also be used under specific conditions. For wall supports on either concrete or steel brackets, Types 31 through 33 may be used.

In many cases, it is necessary to provide additional structure as a means of upper attachment. Such structure must be designed for the particular load and can be of structural angle, beam, or channel.

Structural steel for pipe supports must meet the allowable stress requirements of the AISC specification.

Multiple-Pipe Runs

Where the bottoms of the various lines are approximately at the same elevation, common supports are advantageous. The supports take the form of trapeze hangers fabricated from structural-steel shapes. Multiple-pipe runs are also supported on fabricated bents or frames. This is quite common for oil refinery or tunnel work where multiple runs of pipe are relatively near grade. Steel or concrete sleepers are used.

On all multiple-pipe runs, provisions should be made to keep the lines in their relative positions by the use of either clamps or clips. Lines subject to thermal expansion must be free to slide or roll.

Spring Supports

When there is an appreciable temperature difference between the operating and nonoperating conditions of a piping system, there is a resultant expansion or contraction of the pipe caused by the thermal change. When the system consists entirely of horizontal piping, the differential expansion can be taken care of entirely by means of rollers or by swinging rods of sufficient length. For vertical portions of the piping system, the thermal change in length causes elevation changes. Movement of terminal points or of the structure to which the supports are attached will also result in elevation changes. These elevation changes must be accommodated by some sort of variable spring or constant support.

Helical-coil springs are commonly used for such supports. The degree of variation to be provided by the spring support depends on the conditions of the piping system. For systems which operate at temperatures below 750°F (400°C), a good rule is that the variation in supporting force be limited to 25 percent of the load. It is important to select a spring coil which has been age-processed to eliminate residual stresses resulting from the coiling operation. A conventional helical coil which has not been age-processed will lose more than 10 percent of its supporting effect over its life.

It is not economical to design custom springs. A more prudent approach is to select spring devices which are available commercially. Commercial spring supports are made in three general types. *Spring cushion hangers,* MSS-SP-58 Types 48 and 49, are made for light to medium loads and for ¼-in (6-mm) maximum vertical movement. Generally, this type is used in systems in which the temperature does not exceed 450°F (232°C).

Variable spring supports, MSS-SP-58 Types 51, 52, and 53, are available for a wide range of loads, from about 50 to 30,000 lb (222 to 133,446 N). This type of hanger is used on piping systems in which the resulting variation in supporting force can be tolerated. The commercial varieties available provide a selection of variability.

Constant load supports, MSS-SP-58 Types 54, 55, and 56, are spring devices in which the varying force of the spring is compensated so that the support variability

is within the range of ±6 percent. This type of support is used on systems in which there are large thermal movements or critical stress conditions or a combination of both. Such conditions exist on high-pressure, high-temperature steam lines in electric generating stations. These supports are made for loads of approximately 50 to 50,000 lb (222 to 222,410 N) and for vertical movements up to 16 in (406 mm). The variability of these supports is not dependent on vertical movement, and the support is adjusted at the factory for specified load and travel. Therefore, extreme care should be taken in determining loads and travel for the selection of hanger size.

Vibration arising from pump pulse and similar conditions can be a problem in piping systems. Where such vibrations are in resonance with a spring-supported system, the results can be serious. Such conditions can usually be avoided by judicious use of commercially available spring hangers. Systems that respond to exciting vibrations can be controlled satisfactorily by the use of dampening devices. There are two general types to consider: the coiled spring and the hydraulic vibration dampener.

There are two types of coiled-spring vibration dampeners: the opposed-spring type and the double-acting spring type, MSS-SP-58 Type 50. These devices should be arranged so that the springs are in the neutral position during normal operating conditions of the system.

The hydraulic vibration control is a unit which operates by means of a controlled flow of fluid through an orifice. Resistance to movement increases with the speed of displacement. One distinct advantage of the hydraulic device is that there is a minimum of resistance to thermal movement of the piping.

Both spring and hydraulic cylinder devices may be used to control sway and absorb shocks. These same devices may be used to resist reactions from safety valve discharges and similar applications. Both the spring and hydraulic types are available commercially in several sizes. Manufacturers' literature gives comprehensive data for selection and performance characteristics.

Hanger Rod

Rods used for pipe support purposes are usually hot-rolled steel with standard 60° cut threads conforming to ASME B1.1, *Unified Inch Screw Threads,* coarse thread series (UNC). Rolled threads to the same standard may be used. It must be pointed out that the length of a rolled thread cannot be increased by running a die over it, since the basic diameter of the rod is less than the size of the threaded portion (smaller than the thread major diameter).

Safe load capacities of threaded rods are based on the area at the root of the thread. A generally accepted standard for such capacities is given in Table B5.5, taken from MSS-SP-58.

For convenience in ordering and assembling various items, most cataloged pipe support products have a definite relationship between rod size and pipe size, as shown in Table B5.6.

Table B5.6 conforms to Underwriters' Laboratories and Factory Mutual requirements in pipe sizes up to NPS 12 (DN 300). In general, rod sizes less than ⅜ in (10 mm) should never be used to support piping, regardless of its diameter. However, this does not hold true for supports designed for a thoroughly analyzed piping system (i.e., computer-modeled and analyzed). Where exact loads are calculated, the rods and springs are selected on the basis of the load and movement, not pipe size.

TABLE B5.5 Load Rating of Threaded Hot-Rolled Steel Conforming to ASTM A36 or A575 Grade 1020

Nominal rod diameter, in (mm)	Root area of thread		Maximum safe load at rod temp of 650°F (343°C)	
	in²	(mm²)	lb	(Newton)
¼ (6)	0.027	(17)	240	(1,068)
⁵⁄₁₆ (8)	0.046	(30)	410	(1,824)
⅜ (10)	0.068	(44)	610	(2,713)
½ (15)	0.126	(81)	1,130	(5,026)
⅝ (16)	0.202	(130)	1,810	(8,051)
¾ (20)	0.302	(195)	2,710	(12,055)
⅞ (22)	0.419	(270)	3,770	(16,770)
1 (25)	0.552	(356)	4,960	(22,063)
1¼ (32)	0.889	(574)	8,000	(35,586)
1½ (40)	1.293	(834)	11,630	(51,733)
1¾ (44)	1.744	(1,125)	15,690	(69,792)
2 (50)	2.292	(1,479)	20,690	(92,033)
2¼ (57)	3.021	(1,949)	27,200	(120,991)
2½ (65)	3.716	(2,397)	33,500	(149,015)
2¾ (70)	4.619	(2,980)	41,600	(185,045)
3 (80)	5.621	(3,626)	50,600	(225,079)
3¼ (83)	6.720	(4,335)	60,500	(269,116)
3½ (90)	7.918	(5,108)	71,260	(316,979)

Snubbers

A snubber, or shock arrestor, MSS-SP-58 Type 47, is a mechanical or hydraulic type of support that is used to restrain dynamic loads. Such loads can result from a seismic event, water hammer, steam hammer, or relief valve thrust.

The primary advantage of the snubber is that it can be installed at locations where thermal displacement precludes the use of a "rigid" support. Under the slow and gradual displacement of the pipe due to thermal action, a snubber is designed to slowly telescope (in or out) to accommodate the movement of the pipe. When, however, a sudden impact load acts upon the snubber, internal braking devices

TABLE B5.6 Relation between Pipe and Rod Sizes

NPS	(DN)	Rod size, in (mm)
2 and smaller	(50 and smaller)	⅜ (10)
2½ to 3½	(65 to 90)	½ (15)
4 and 5	(100 and 125)	⅝ (16)
6	(150)	¾ (20)
8 to 12	(200 to 300)	⅞ (22)
14 and 16	(350 and 400)	1 (25)
18 and 20	(450 and 500)	1¼ (29)
24	(600)	1½ (40)

engage, thus controlling the movement of the pipe. The snubber is said to "lock up." In this condition, the snubber acts as though it were a rigid restraint.

Snubbers are not capable of supporting gravity loads. Under certain circumstances, the weight of the snubber bearing on the pipe should be included in the piping stress analysis.

Riser Supports

A riser or vertical section of a piping system often creates special support problems. The support of service water lines and fire protection systems is governed in the first case by the local building codes and in the latter case by National Fire Protection Association (NFPA) codes. These codes dictate the type and frequency of riser supports used on those systems; however, piping systems that are subject to thermal movement present more complicated support problems, and each case must be considered separately.

Risers are equivalent to concentrated loads in a piping system; however, in the support of this load, several important points must be considered:

1. Is the support to take the entire riser weight, or is the riser weight to be distributed among several supports?

2. Are hydrostatic test conditions more severe than service conditions? That is, will the cold-water-filled condition impose stresses on the support higher than allowable (in cold condition), compared with the hot operating condition and the imposed stresses? When this decision is made, the system erection sequence should be considered and a determination made of whether other supports are effective or ineffective during hydrostatic testing.

3. Is the support to be located at a point of zero vertical movement and hence to be considered a rigid support? If this is the case, then the horizontal and vertical movements of riser end points must be analyzed. Pure horizontal movement can be provided for by long support rods that are allowed to swing. However, if vertical movement exists, it may cause tipping, and then it must be assumed that the entire load can transfer to one support rod. In this case, the riser support should be designed for twice the calculated load.

The support arms of the pipe attachment or the riser clamp, MSS-SP-58 Type 42, must extend out from the pipe far enough to clear any insulation. If springs are part of the support assembly, then the arms must be long enough to provide clearance between the pipe insulation and the springs used.

The final consideration in the design of a riser support is its attachment to the pipe. Since a thermal change occurs between the operating and nonoperating conditions of the pipe, the frictional grip of the clamp on the pipe cannot be relied upon, and there must be some positive means of engagement between the pipe and the clamp. Sometimes a complete ring is welded to the pipe. The more usual procedure is to use four lugs welded to the pipe, positioned at points which bear on the clamp. These lugs are normally made of material compatible to the pipe material and are to be welded on three sides. Suggestions for the selection of welded lugs can be found in PFI ES-26.

SUPPORT REQUIREMENTS FOR SPECIFIC PIPING MATERIALS

Ductile-Iron Pressure Pipe

Hanger sizes depend upon the outer diameter of pipe which is to be supported. The diameter of cast-iron pressure pipe exceeds that of nominal-size steel pipe and varies with its class or intended service. Therefore, selection of supports must take into consideration the actual outside diameter of the piping being installed.

Ductile-Iron Soil Pipe

Support sizes correspond to sizes for steel pipe. MSS-SP-58 Types 1, 7, 8, and 11 are normally used.

Asbestos-Cement Pressure Pipe

Support sizes depend upon the class of pipe to be supported. The outer diameter of this pipe exceeds that of steel pipe and varies with its class or service.

For all three categories (i.e., ductile-iron pressure pipe, ductile-iron soil pipe, and asbestos-cement pressure pipe) support spacing should provide at least one support for each length of pipe (piping lengths are a maximum of 20 ft, or 6.1 m, with the support preferably located adjacent to the joint). Also, each change of direction or branch connection should be supported.

For ductile-iron pipe with bell and spigot ends, using either a push-on type of joint or a mechanical joint, the pipe support engineer must consider the following:

- Both joint types use a rubber gasket to seal the joint, and they allow a certain amount of deflection and longitudinal displacement while maintaining the seal.
- To prevent leaks caused by misalignment of the pipe section at a joint, pipe supports are positioned immediately behind the pipe bell.
- Supports are normally not placed under spigots adjacent to bells, owing to possible undesirable effects on the joint.
- Pipe supports should cradle the pipe in a saddle.
- The saddle must follow the contour of the pipe in order to minimize stress concentrations.
- A saddle angle between 90° and 120° is desirable, with a minimum saddle width (i.e., the length along the longitudinal axis of the pipe) of

$$(2Dt_e)^{0.5}$$

where D = actual outside diameter of pipe, in (mm); t_e = nominal pipe wall thickness, in (mm).

Pipe supports should prevent any lateral and vertical movement of the pipe in order to prevent possible failure of the pipeline. Thermal expansion of ductile-iron pipe is not usually a concern because of the nature of the push-on or mechanical joint.

Buried lines are usually supported by tamped backfill, except that lines buried

under building slabs are sometimes supported from the slab with hairpin straps or rods suitable to the soil characteristics.

Special consideration is required in cases where movement occurs either at the terminal points or in the structure to which supports are attached. Spring hangers may be required to allow for deflection.

Copper Tubing

Since supports made for copper tubing are designed to fit the tubing diameter, it is not recommended that supports which have been formed for piping be improvised as tubing supports. Most supports for copper tubing are electroplated with copper for easy identification. MSS-SP-58 Types 1, 8, 9, 10, 11, and 12 are available in tubing sizes.

Where there are indications that electrolysis may occur because the support and tubing are made of dissimilar metals, the support should be lined to prevent such action.

Fire Protection Systems

Sprinkler supports will usually be subject to the consideration and approval of the same insurance agencies that have jurisdiction over the sprinkler-system piping and layout. The supports will be required to conform closely to the standards specified in the National Fire Codes published by the National Fire Protection Association.

Some of the important fire protection codes and standards of concern to the pipe support engineer follow:

- NFPA 11, *Foam Extinguishing Systems*
- NFPA 12, *Carbon Dioxide Extinguishing Systems*
- NFPA 12 A/B, *Halon Fire Extinguishing Systems*
- NFPA 13, *Sprinkler Systems*
- NFPA 14, *Standpipe and Hose Systems*
- NFPA 15, *Water Spray Fixed Systems*
- NFPA 16, *Foam-Water Sprinkler and Spray Systems*
- NFPA 17, *Dry Chemical Extinguishing Systems*

If the system is other than a standard building water-sprinkler system, the particular standard should also be consulted; e.g., in the design or selection of supports for a foam fire extinguishing system, NFPA 11 should be consulted.

The rules are explicit with respect to support spacing, fasteners, and method of fastening. NFPA also regulates the material used in the construction of supports. Underwriters' Laboratories, Inc., Factory Mutual Engineering Division, and Underwriters' Laboratories, Inc., of Canada have tested and listed or approved all types of supports necessary to meet the various conditions of construction.

The placing of supports along the pipe is an important consideration to ensure adequate support for the piping. In addition to the consideration of pipe support, consideration must be given to sway bracing especially in deluge systems, riser supports, soundness of the attachment, vibration, and pipe slope for drainage. The stability of the support during a fire, corrosion, and aging are also of prime impor-

tance. A sprinkler system may be installed for many years before it is operated, and it must always operate in the manner for which it was designed.

Plastic Pipe

There are many types of plastic pipe, both rigid and semirigid. Under normal conditions, rigid plastic pipe can be supported using conventional supports with the spacing half that used with steel pipe or as recommended by pipe manufacturers. The support of plastic pipe or tubing should be continuous if, owing to the nature of the plastic, it will become flexible from elevated temperatures or from line contents. The continuous support can be in the form of a light angle or channel into which the plastic pipe is laid.

In some cases, wear shoes or pads should be added to plastic pipe where it may rub against steel supports. The use of wear pads will prevent the abrasive action caused by thermal movement, thus preventing damage to the pressure boundary.

It is suggested that recommendations of the manufacturer of the specific plastic pipe also be followed. Refer to Part D of this handbook.

Glass Pipe

Glass pipe is used for laboratory service, food processing, and many industrial applications which require the durability or chemical resistance of glass pipe. Because of the nature of glass, special consideration of supports and attachments is necessary.

Standard pipe support components can be used; however, in all cases the support, even if it is painted or electroplated, must have a padding or cushion to avoid scratching the pipe. The support should fit loosely around the pipe, yet contact the pipe in a manner to distribute the load over the largest possible area. Point loading must be avoided. The system of supports must be designed with the fewest rigid anchor points possible.

Glass pipe will generally require two supports per 10-ft (3.05-m) section. One extra support will be required if there are three or more couplings in a 10-ft (3.05-m) section. For maximum protection and accessibility, supports should be placed about 1 ft (0.3 m) from each joint or coupling.

Glass pipe supports and layouts should be designed in accordance with general fundamentals applicable to other piping materials. However, extreme care must be taken to minimize strain and scratching of the glass. The pipe manufacturer and reputable support manufacturers should be consulted in the design of support systems for glass pipe.

DESIGN DETAIL CONSIDERATIONS

ASME Code for Pressure Piping

Specific design requirements for piping support are included in the sections of ASME B31, *Code for Pressure Piping*, listed below:

- B31.1, *Power Piping*
- B31.2, *Fuel Gas Piping*

- B31.3, *Process Piping*
- B31.4, *Liquid Transportation Systems for Hydrocarbons, Liquid Petroleum Gas, Anhydrous Ammonia, and Alcohols*
- B31.5, *Refrigeration Piping*
- B31.8, *Gas Transmission and Distribution Piping Systems*
- B31.9, *Building Services Piping*
- B31.11, *Slurry Transportation Piping Systems*

In addition, ASME Boiler and Pressure Vessel Code, Section III, defines rules for piping supports used in nuclear power plants.

These requirements must be adhered to on piping installations when piping must conform to these codes. In most cases, supports conforming to MSS-SP-58 are acceptable for these installations.

Government Specifications

The Federal Specification WWH-171, of the latest issue and entitled ''Hangers and Supports, Pipe,'' is the governing specification for all federal agencies. This specification illustrates types of pipe hangers and supports and lists the requirements of certain applications.

Design Temperature

Design temperatures for parts of hangers and supports in direct contact with pipe shall be the temperature of the fluid contained in the pipe. Parts of hangers and supports not in direct contact with pipe may be designed to a temperature reduced by 100°F per 1 in (55°C per 25 mm) away from the pipe wall. Allowable stresses for materials commonly used in the design of pipe hangers and supports are listed in applicable codes and standards.

Welded Fabrication

Welded fabrication shall be accomplished with good engineering practice as prescribed by the appropriate welding code. In the United States, the American Welding Society (AWS) and the American Society of Mechanical Engineers, Section IX, are the governing codes. In Germany, DIN EN 288 controls welding, and in Britain it is BS 5135. Attachments welded directly to the pipe must be of appropriate (compatible) chemical composition, and the process of attachment must conform to the requirements for fabrication of the pipe regarding preheating, welding, and stress relieving.

Cold Spring

The cold-springing procedure for piping systems involves, basically, the cutting short of each segment of piping in an amount equal to some specific percentage of the normal thermal growth of the segment, with proper allowance to compensate

for possible terminal connection movements. The cumulative effect results in an offset gap between the piping ends at the point of final field closure. The drawing together and alignment of the piping ends by the application of required forces and moments are called *cold pull* and result in a slight relocation of all points along the entire piping system. This relocation is the only effect that cold springing has on supports. The piping is then considered to be in the cold-sprung position, which is equivalent to the cold operating position. The movement at all support points from the erected to the cold-sprung position must be calculated, and provision made for this movement in the form of hanger rod adjustment.

Adjustment

It is necessary to provide vertical adjustment to attain the desired elevation of the piping system. On piping supported from above, it may suffice to adjust an MSS-SP-58 Type 1, 5, 6, 9, or 10 support through the yoke portion by raising or lowering the nut on the rod. For larger ranges of adjustments, it is necessary to provide a turnbuckle, MSS-SP-58 Type 13 or 15, in the hanger rod. It is also practical to select a top attachment whereby adjustment can be made at the top of the hanger rod.

On piping which is supported from below, provision for adjustment can be made with screw thread stanchions, MSS-SP-58 Type 38, or by shims or grout.

Protective Coatings

Protective coatings are normally applied to pipe supports for corrosion resistance. Metallic coatings may be applied by either the electroplating or the hot-dip process. Nonmetallic coatings, if selected for specific purposes, should be applied as recommended by the manufacturer. Consideration must be given to coatings used on threaded parts that are to be assembled after coating.

OTHER PIPE SUPPORT CONSIDERATIONS

Transportation and Storage

Transportation and storage should be carried out with care to avoid damage to the hanger components, especially load calibration bolts and connection threads. If stored in the open, all components should be protected from dirt and water.

Assembly

All items should be assembled as completely as possible on the ground. Hanger rod threads should be greased prior to assembly to allow easy adjustability under load.

Installation

Locate, position, and connect the structural attachment to the steel or concrete. Be careful to orient the structural attachment pin or bolt in the right direction.

Next, move the hanger assembly into position and secure, using the connection parts. When installing an item which contains a nameplate, load scale, adjustment bolts, travel stops, or other device which requires accessibility, be sure to install the item so that these features are visible and accessible. Locate the position for the pipe attachment and assemble it to the pipe. Complete the connection between the hanger and the pipe attachment.

Adjustment

Adjust the hanger rods or adjustment parts to take up the pipe load by the hanger components. Be sure to achieve minimum thread engagement before taking up full load. When installing springs, continue to take up on the load until the spring setting balances with the supporting load. When all adjustments and evaluations are complete, lock all required items using locknuts, retainers, clips, or other locking item supplied. After all pipeline testing is complete and prior to operation, adjust the springs until the travel stops can be removed by hand. Remove the travel stops prior to operation to allow the spring to move freely.

Inspection

The following items should be verified prior to operation:

1. The support is installed in the correct location.
2. The travel and load positions are correct for springs.
3. The travel stops are removed, and the spring is ready for operation.
4. The minimum thread engagement is met on all threaded items.
5. All locknuts or other locking devices are in place.
6. All connection pins and connection bolts are properly loaded and secured.

CHAPTER B6
HEAT-TRACING OF PIPING SYSTEMS

Chet Sandberg, P.E.

The term *heat-tracing* refers to the continuous or intermittent application of heat to a pipeline or vessel in order to replace heat loss to ambient.[1] The major uses of heat-tracing include freeze protection, thawing, maintenance of fluids at process temperature (or at pumping viscosities), prevention of fluid component separation, and prevention of gas condensation.

The following examples are typical of the diversity of heat-tracing applications: freeze protection of piped water; transfer of molten process chemicals such as phosphoric acid, sulfur, and *p*-xylene; low-viscosity maintenance of pumped fluids including petroleum products, vegetable oils and syrups, polymeric and resinous materials, and aqueous concentrates and slurries; avoidance of condensation and subsequent improper burning of fuel gas in refineries; preventing moisture from condensing out of piped natural gas; preventing freezing of control valves and compressor damage; elimination of pipeline corrosion due to wet hydrogen sulfide resulting from condensed moisture.[2]

Heat-tracing may be avoided in situations where heat loss to the environment can be effectively minimized. In cold climates or areas with severe winters, water pipes are often buried below the frost line. Alternatively, they may be kept from freezing by running them through heated buildings.[3]

In cases where flow is intermittent, tracing might be avoided by designing a self-draining system such as those used for steam condensate returns. Pipes may also be cleared after use by means of compressed air, steam, or solvent flushing or "pigging." The self-draining method is suitable only for infrequently used pipes

due to the high labor costs involved in cleaning and the potential cost and scope of repair, should a pipe not empty properly.[4]

A third approach in the avoidance of tracing is to design for 100 percent flow. This practice is not recommended since equipment breakdown or process interruption may result in an irreversible drop in the temperature of the piped fluid.

TYPES OF HEAT-TRACING SYSTEMS

Heat-tracing systems can be divided into two broad classes, electric and fluid. Fluid heat-tracing systems utilize heating media at elevated temperatures to transfer heat to a pipeline. The fluid is usually contained in a tube or a small pipe attached to the pipe being traced. If steam is the tracing fluid, the condensate is either returned to the boiler or dumped. If an organic heat-transfer fluid is employed, it is returned to a heat exchanger for reheating and recirculation. In general, heating of tracing fluids can be provided by waste heat from a process stream, burning of fossil fuels, steam, or electricity.

Electric heat-tracing systems convert electric power to heat and transfer it to the pipe and its contained fluid. The majority of commercial electric heat-tracing systems in use today are of the resistive type and take the form of cables placed on the pipe. When current flows through the resistive elements, heat is produced in proportion to the square of the current and the resistance of the elements to current flow. Other specialized electric tracing systems make use of impedance, induction, and skin conduction effects to generate and transfer heat.

Table B6.1 lists the operating and exposure temperatures and the principal characteristics of the different types of heat tracing.

FLUID HEAT-TRACING

Steam

A number of desirable features made steam the original heat-tracing system of choice to maintain process temperature and provide freeze protection. Steam's high latent heat from vaporization is ideal for heat-transfer applications. Only a small quantity is required for a large heating load; and it can heat a line quickly, condense at constant temperature, and flow to the point of use without pumping. Steam is universally available and nontoxic.[5]

Today, energy efficiency and minimization of expensive labor are priority considerations in selecting an economical heat-tracing system. With the advent of highly reliable electric heat-tracing, the popularity of steam heat-tracing is declining.

Steam is more expensive to install and maintain than electric resistance heaters. Periodic leaks and failed steam traps in a steam-traced system waste energy and demand additional labor costs for repair and replacement. In addition, a single steam tracer provides 2 to 10 times more heat than most applications require. By contrast, electric tracing systems provide better temperature control and much more efficient utilization of energy. This means that even though the cost per unit energy is lower for steam, total energy costs for electric tracing are usually significantly lower.[6]

In most heat-tracing applications, saturated steam is supplied at pressures of 30 to 150 psig (210 to 1035 kPa) (298°F/147°C and 367°F/186°C). The ability to

TABLE B6.1 Comparison of Heat-Tracing Methods

Heat-tracing method	Max. operational temp.	Max. exposure temp.	Advantages	Disadvantages
Heat transfer fluids				
Steam	400°F (204°C)	None	Takes advantage of waste steam, explosion environment safe, high heat-transfer rates	Nonuniform heat distribution; expensive to install and maintain; imprecise temperature control; wastes energy
Organics	500–750°F (260–400°C)	None	Moderate temperature control, wide temperature range, low freezing temperatures	Relatively expensive; needs a circulating system; leaks can be hazardous
Glycols	250°F (121°C)	325°F (160°C)	Moderate temperature control; depresses freezing point, providing protection against freezing when not in use; lower operating cost than steam	Relatively expensive (glycols are cheaper than heat process fluids); high installed costs; needs a circulating system; leaks can be hazardous
Electric				
Self-regulating	150–300°F (65–149°C)	185–420°F (85–215°C)	Will not burn out—most reliable electric heating cable; energy efficient	Limited temperature range
MI cable	1190°F (590°C)	1500°F (800°C)	Rugged; capable of high temperature and high power	Difficult to field cut; a break in the cable causes an open circuit; should not be crossed over itself; can be damaged by moisture penetration
Zone	150–400°F (65–204°C)	250–1000°F (121–538°C)	Can be field cut; if a heating element fails, circuit is maintained	Relatively fragile; can self-destruct from its own heat; can burn out if crossed over itself
Skin effect	400°F (204°C)	450°F (232°C)	Simple components; rugged; needs relatively few energy inputs; can be part of a prefabricated insulated pipe bundle	Impractical for applications less than 5000 ft long; design is complex
Impedance	Up to failure of supply cable and connections	None	High heat-transfer rates and close temp. control; high temp. capability, heating structure; element cannot burn out	Expensive custom design; entire pipeline must be electrically isolated from the support
Inductance	Up to Curie point	None	High-temperature capability; high heat-transfer rates	Very expensive; difficult custom design, not commercially exploited
FIGURE B6.1 Typical components of a steam-tracing system. (*I. P. Kohli, "Steam Tracing of Pipelines,"* Chem. Eng., *March 26, 1979, p. 158, Fig. 1.*)

continuously remove condensate via a steam trap assembly allows the steam tracer to provide a constant-temperature source of heat.

The overwhelming majority of steam-traced piping systems employ external tracing. Straight runs of the steam pipe or tubes are attached to the pipe, and the entire assembly is covered with preformed sectional insulation (see Fig. B6.1). Valves, fittings, and instruments are *heat sinks* (system components of large surface area and exposed metal surfaces to which system heat will flow and be lost to the environment); and to deliver the requisite amount of heat, several loops of the tracing tube are coiled around them before being covered with insulation. This configuration helps reduce *tailing*, i.e., the tendency of steam to lose heat and condense along the line with loss of pressure (see Fig. B6.2).

In the majority of applications such as freeze prevention and viscosity mainte- nance in smaller-diameter pipes, a single tracer provides more than the required heat. However, for processes requiring greater heat input, the heat-transfer charac- teristics of steam tracers can be significantly improved by placing heat-transfer cement between the trace and the pipeline, greatly increasing the amount of surface for conductive heat transfer.[7] Temperatures of steam-tracing systems can vary by as much as $+10°F$ ($6°C$) between underground pipelines and $+20°F$ ($11°C$) for pipelines running aboveground. The inability to achieve precise temperature control is attributed to three factors operating in tandem.[8]

1. Saturated steam is delivered at the desired pressure by means of a pressure-
FIGURE B6.2   "Coiling" arrangement for tracing valves, flanges, casings, and instruments. Coils act as expansion joints for steam tracing systems. (*I. P. Kohli, "Steam Tracing of Pipelines,"* Chem. Eng., *March 26, 1979, p. 159, Fig. 3.*)

reducing valve. As the pressure is reduced, the saturated steam becomes super-heated. The excess heat is rapidly dissipated in the system.

2. Uneven contact between the steam tracer and process pipe produces an uneven distribution of temperature. This effect becomes more significant as the temperature difference between pipe and tracer increases. When the steam becomes superheated, the temperature difference reaches a maximum.

3. Tailing also affects the temperature of the surrounding steam.

A more precise control of steam tracer temperature can be achieved by the use of steam jacketing (see Fig. B6.3) or temperature-sensitive steam valves. However, these methods are rarely used as they provide a level of temperature control inferior to that of electric heat-tracing, and at a significantly greater cost.

Circulating Media

Circulating media are the most expensive heat-tracing systems and are specified for special-process or ambient conditions (see Table B6.1 and Ref. 9). The virtue of circulating fluids is the ability to provide protection and reasonable control at temperatures above and below those achievable with steam-tracing. Circulating media systems can be separated into two classes; oils and organic heat-transfer
FIGURE B6.3 Steam jacketing is expensive and employed only in special high-heat-demand situations. (*I. P. Kohli, "Steam Tracing of Pipelines,"* Chem. Eng., *March 26, 1979, p. 159, Fig. 2.*)

fluids suitable for high-temperature applications, and glycols with antifreeze properties that make them especially useful in cold climates, where they will not freeze even when used intermittently.

ELECTRIC RESISTANCE HEAT-TRACING

Introduction

Significant commercial use of electric heat-tracing began to take hold in the 1950s. Electric heat-tracing served as a visible alternative in situations where steam could not be used or was impractical. Typical early applications included the electric tracing of transfer lines for oil, asphalt, and waxes. Electric tracing proved especially useful for long runs of pipe. [Steam tracers are generally limited to runs of 100 to 200 ft (30 to 60 m). Tracing long or multiple pipe runs with steam can significantly increase both tracing complexity and cost.]

At the outset, hardware had to be adapted from other resistance heating applications. Lead-sheathed soil-heating cable was used extensively for waterline freeze protection while longer runs of pipe were traced with mineral-insulated copper-sheathed cable. For higher-temperature service, tubular heaters (normally used for immersion and clamp-on applications) were converted for pipe tracing, and controllers were adapted from furnaces and consumer appliances in order to control temperature.

Self-Regulating Heaters

Since their introduction in 1971, self-regulating heaters have become the most popular form of electric heat-tracing and are currently offered by most major

vendors of industrial heat-tracing. Self-regulating heat-tracing has an advantage with respect to other heat-tracing products because this technology eliminates the possibility of heater burnout due to the inability to dissipate internally generated heat—the most common cause of heater failure (Fig. B6.4).
FIGURE B6.4 Components of a self-regulating parallel resistance heat-tracer. (*Chet Sandberg,* Electrical Heat Tracing Systems for Use in Pulp and Paper Plants; Considerations for the 1990's. *ISA Pulp and Paper Industries Division Symposium (in conjunction with TAPPE), Nashville, TN, March 1993.*)

Self-regulating tracers are usually provided in the form of a heater strip consisting of two parallel 20 to 10 American wire gauge (AWG) bus wires embedded in a conductive polymer core, which serves as the heating element and over which a polymeric insulator is extruded. The entire assembly is then covered with a metal braid to provide grounding and additional mechanical protection. Another polymer jacket can be added (see Fig. B6.4). The heater core consists of carbon particles embedded in a polymer matrix. Heat is generated by resistance to current flowing through the conductive polymer heating element. As the temperature of the conductive core increases, so does the electric resistance. The result is a diminishing output of heat for each successive increment of temperature elevation. Since power output is a function of temperature at any location in the element, the conductive core behaves as a temperature-sensitive rheostat guarding against low- as well as high-temperature failure (see Figs. B6.5 and B6.6).

Self-regulating tracers can be cut to any desired length and field-installed within the limitations of the voltage drop on the bus wires. They have good impact resistance and are routinely handled in the field. The self-regulating feature pro-
FIGURE B6.5 Relationship of resistive properties to changes in polymer structure with temperature in the conductive core of a self-regulating parallel resistance heat-tracing tape. (*Karen Henry,* Introduction to Heat Tracing, *Cold Regions Research and Engineering Lab, Report No. CRREL-TD-86-1, June 1986, p. 13.*)

vides a tremendous boost to operational reliability while cutting installation, maintenance, and energy costs. It also adds a dimension of safety unavailable with any other form of electric resistance tracing product because the heater cannot be destroyed by its own heat output.

The only serious drawback of self-regulating tracers is the upper limit on operating temperatures, 366°F (186°C) for constant exposure and 420°F (215°C) for intermittent exposure.[13] Self-regulating tracers can fail as a result of exposure to excess heat from the piped fluid or from steam cleaning. For this reason, the tracer must be selected to conform to actual process conditions.
FIGURE B6.6   Graph of resistance versus temperature for a self-regulating parallel resistance heat-tracer. (*G. R. Dixon*, Steam versus Electric Process Heat Tracing. *Mississippi Department of Energy and Transportation Annual Conference, April 22–24, 1987, p. 5, Fig. 4.*)

Zone Heaters

First introduced in 1971, zone heaters were initially the most popular form of parallel resistance heaters; and by the mid-1970s, they were being used in a large percentage of electric heat-tracing applications. Since that time, they have been increasingly replaced by self-regulating heaters.

A typical zone heater consists of two insulated bus wires wrapped with a small-gauge (38 to 41 AWG) nichrome heating wire, covered with polymer insulation and sheathed in a metallic braid covered with an optional polymer jacket. The heating wire is connected to alternate bus wires at nodes every 1 to 4 ft (0.3 to 1.2 m), and the distance between connections constitutes a (heating) zone.[14,15,16] Heat is generated by current flowing between the bus wires through the heating wire (see Fig. B6.7).
FIGURE B6.7   Components of a zone-type parallel resistance heat-tracer. (*G. B. Dixon*, Steam versus Electric Process Heat Tracing, *Mississippi Department of Energy and Transportation Annual Conference, April 22–24, 1987, p. 5, Fig. 5.*)

The parallel circuit configuration of zone heaters means that output is independent of cable length and that systems can be designed and adapted by purchasing cables of a specific wattage which are cut to length in the field. (It is important to remember that the length of cable between the cut and the nearest node will not receive power and should not be depended upon for heater service.) As a result,
FIGURE B6.8 Simplified circuit diagram for a zone-type parallel resistance heater. (*Karen Henry*, Introduction to Heat Tracing. *Cold Regions Research and Engineering Lab, Report No. CRREL-TD-86-1, June 1986, p. 8, Fig. 3c.*)

design and installation costs are significantly reduced.[17] Zone heaters use standard voltages, and their parallel circuitry preserves system function in the event of individual heater element failure (see Fig. B6.8)—an important advantage over series circuits (see Fig. B6.9).[18]

Zone heaters use thinner resistive wires than series heaters and are more susceptible to damage from impact.[19,20,21] Fiberglass-insulated cables are available with an exposure temperature up to 1000°F (538°C), but they are susceptible to moisture.
FIGURE B6.9 Simplified circuit diagram for a series-type resistance heater. (*Karen Henry*, Introduction to Heat Tracing. *Cold Regions Research and Engineering Lab, Report No. CRREL-TD-86-1, June 1986, p. 8, Fig. 3a.*)

The addition of a fluoropolymer jacket for moisture protection reduces the exposure temperature rating to 545°F (285°C). Perhaps the biggest drawback of zone heaters is their susceptibility to burnout. With their combination of constant wattage and polymer insulation, zone heaters are vulnerable to destruction from self-generated overheating.[22] As with all constant-wattage heaters, zone heaters to be used in hazardous (classified) areas require factory calculations to determine if the system conforms to the prescribed T rating (see the later section "Area Classification").

Mineral-Insulated Cable (Constant-Wattage Series) Heater

Mineral-insulated (*MI*) *cable* was introduced in the early 1950s as an electric powered alternative to steam and liquid heat-tracing.[23] MI cable is a constant-wattage, series resistance heater in which the entire circuit acts as a continuous heating element.

Heat is generated by current flowing through a nichrome, copper, or other metal
FIGURE B6.10   Components of mineral-insulated heat-tracing cable. (*G. B. Dixon*, Steam versus Electric Process Heat Tracing, *Mississippi Department of Energy and Transportation Annual Conference, April 22–24, 1987, p. 4, Fig. 2.*)

conductor, insulated with magnesium oxide and encapsulated in an outer metallic sheath of copper, stainless steel, Inconel, or other suitable metals (see Fig. B6.10).[24]

MI cable is capable of carrying high heating loads. Given the proper conductor and sheath alloys, it can be used in applications up to 1500°F (800°C).[25]

Its high impact resistance and general ruggedness allow it to stand up to the rough handling in the field. Circuits usually are factory-fabricated to length prior to installation, which can be a source of problems when piping changes are made since cables are difficult to modify in the field. Field fabrication of circuits is sufficiently complex that the training of installation personnel should be supervised by a trained factory technician.[26,27] MI cable system circuits must be individually designed, or variable-voltage controls must be provided to set circuit parameters. Voltage control may also be required for short lengths due to the low resistance.[28]

As with all series circuits, a single break in the cable causes the entire system to fail (breaks in the outer sheathing can cause failure due to absorption of moisture and subsequent loss of insulating properties).[29,30] Another disadvantage of MI cable is the risk of overheating from excessive currents or poor thermal dissipation. Hazardous-area installations must be factory-calculated to ensure conformance with the proper *T* rating (see later section "Area Classification").

Series Resistance Polymer-Insulated Cable

Polymer-insulated series resistance cables can be used with various conductor materials. Nichrome is suitable for short circuits, but the length must be either predetermined to suit the available voltage or field-cut and provided with a variable-voltage supply. Conductors such as copper offer a measure of self-limiting heater properties, since their resistance increases with temperature. This allows greater latitude of use, and copper conductors with their 600-V limitation and relatively low cost (even with the mandatory metallic braid and optional overjacket) are especially favored for long-line applications with this type of heater.

The circuits must be designed and controlled to minimize high temperature, because a failure at one spot disables the complete circuit. The possibility of catastrophic failure (series circuit) due to overheating and melting of the polymer insulation puts this type of tracing in unfavorable competition with parallel resistance heat-tracing systems, which dominate in the low- to moderate-temperature application ranges.

SKIN EFFECT TRACING

Skin effect systems are primarily applicable to the tracing of long pipelines. The *skin effect* is based on the tendency of an alternating current to flow in the layers near the surface (skin) of a current-carrying ferromagnetic conductor (see Fig. B6.11). In a typical skin effect tracer, the heating element is a carbon-steel pipe of small diameter welded to the fluid-carrying pipeline to be traced. Running through the heat tube is an insulated, low-resistance copper wire. The alternating magnetic field created by this alternating-current-carrying conductor causes the return current in the small heat tube to be concentrated toward the inner wall of the tube. This phenomenon is called the *proximity effect*. Because almost no current flows on the outer surface of the heat tube, there is no measurable potential there and the entire piping system can be grounded at any number of points.[31,32]
FIGURE B6.11   Components and electrical flow in skin effect heat-tracing (*N. B. Carson*, A New Method for Heat Tracing Long Pipelines, *ASME, Petroleum Mechanical Engineering Conference, Dallas, Texas, September 1974, p. 1, Fig. 3.*)

The requirement for custom system design makes skin effect systems costly, notwithstanding the ability to make use of ordinary low-cost materials, including prefabricated components and standard construction techniques. The method maintains a low-temperature difference between fluid and tube circuit wall (18°F/10°C),[33] is considered reliable, and is easy to repair. Single-circuit envelopes of up to 25,000 ft (7500 m) are feasible with supply voltages of 3000 V. Higher supply voltages make even longer circuits possible.[34] One reference reports a single power station capable of supplying service up to 30 mi (48 km) of pipeline.[35] On the other hand, Carson qualifies this with a practical limitation of 10 mi (16 km), since above the 5-kV supply required for a line of this length, cable and switchgear costs become an increasing consideration.[36] This seems to be confirmed by Ando and Takki,[37] who report the construction of a 68-mi (108-km) skin effect heat-tracing system powered by 12 substations with a transformer voltage of 13,800 V.[37]

Skin effect heat-tracing is generally not cost-effective for pipelines shorter than 5000 ft (1500 m),[38] its upper temperature limit of approximately 400°F (204°C) is set by the maximum exposure temperature of the conducting wire insulation,[39] and the method is not adaptable for complex piping. Installations cannot be modified, and the complete system fails with a single line break.

IMPEDANCE HEAT-TRACING

In impedance heating, the pipe itself becomes the heating element. The generation of heat is produced by resistance to current flow (see Fig. B6.12).[40] Impedance heat-tracing has the ability to reach very high operating temperatures, limited only by the design and contents of the piping system. Since the pipe is the heating element, it is the supply cable and connections which can be vulnerable to burnout.[41] This technique has high heat-transfer rates and uniform heat distribution and provides excellent temperature control at the control point, using any one of several automatic control methods.[42,43]
FIGURE B6.12 Components and electrical and magnetic interaction in impedance heat-tracing. (*George Koester, II, "Pipe Heat Tracing with Electric Impedance Heating,"* Plant Engineering, *vol. 32, no. 24, November 23, 1978, p. 113, Fig. 1.*)

Impedance tracing is costly and has limited application. Systems are almost exclusively vendor-designed, and the engineering can become complicated, especially in attempting to achieve an electrical balance in piping systems with multiple branches. Because significant current flows through the pipe, the entire pipeline must be electrically isolated from the support structure and shielded from personnel contact. As a precaution, impedance-traced pipelines are normally operated at 30 V or less.[44] Voltages at 80 V are allowed if ground fault protection is supplied.

INDUCTION HEATING

Induction heat-tracing uses a metallic pipeline as a heating element by placing it in the magnetic field of an alternating-current source. Low-resistance wire is wound

around a conductive pipeline or vessel, and the alternating current flowing through the coils generates a rapidly changing magnetic field that induces eddy currents and hysteresis losses in the pipeline wall.[45] Induction heating has been most frequently employed for melting metals[46] and most likely would be considered for high-temperature, high-power heat-tracing applications. The absence of thermal resistance between heat source and pipeline allows very rapid heating. Present systems would involve considerable expense and custom design and would require power inputs at short intervals along the pipeline. Induction methods do not easily lend themselves to the production of uniform heating, and IEEE rates the method as providing only moderate system efficiency.[47]

SELECTION CRITERIA FOR TRACING SYSTEMS

Assuming that methods for avoiding the need for tracing have been considered and rejected, the first step in matching the heat-tracing to the piping system requires an analysis of fundamentals. These include the type of application, suitability and relative cost of different types of heat-tracing, availability of steam and/or electricity, amount of heat loss which must be made up, requirements for temperature control, and classification of the traced area as a hazardous or ordinary environment due to the presence of flammable substances.

AREA CLASSIFICATION

Areas are classified according to their potential fire hazard as defined by Articles 500 to 505 of the National Electrical Code (NEC).[48] [In industrial applications, verification that electric components meet NEC hazardous-area requirements is issued by a nationally recognized testing laboratory (NRTL).] Under this system, there are classified and unclassified (ordinary) areas. Hazardous areas have two different classification systems, the old class/division method and the new zone system. The zone system has been used in Europe for many years and is now being included in the International Electrotechnical Committee (IEC) specifications.

The old Class/Division system rates locations by class, division, and group. The area class determines the category of combustible atmosphere: flammable gases, vapors, or liquids (Class I); combustible dust (Class II); and combustible fibers (Class III). The division indicates the likelihood of a hazard to be present under different conditions. Hazardous atmospheres with similar combustion properties are listed in the same group.

To ensure that the heat-tracing system selected will operate safely in a hazardous environment, it must also be classified according to its NEC temperature identification number, or T rating.[49] The NEC specifies that the temperature of the exposed surface of the (electric) equipment not be in excess of 80 percent of the ignition temperature of the combustible atmosphere.

The Zone System offers more methods of protection of areas from both equipment failure and excessive temperatures. The T rating system is used, although there are not as many T ratings in the IEC system. The available ones, however, match those of the NEC exactly. The zone system has the possibility of being less expensive to install in some instances, and that is its attraction, especially on a worldwide design basis.

By comparing the T rating to the area classification, an assessment can be made as to heater eligibility for a particular piping system. See the later section "Design Considerations" for a further discussion of T ratings and sheath temperature calculations. For a more detailed explanation of classes and zones, see Ref. 59.

ENVIRONMENTAL CONSIDERATIONS

Environmental factors include whether the area is dry or wet, moderately or severely corrosive or noncorrosive, and whether the tracing will experience rough handling or mechanical abuse during installation, operation, or maintenance. These considerations are primarily related to the performance of electric heat tracers. Electric heaters exposed to any of the environmental stresses listed above must be protected accordingly: A metal sheath of a material is able to withstand the corrosive agent for MI cable; a braided sheath covered by a polymer jacket formulated for protection from particular classes of corrosives is required for polymer-insulated types of heating cables (jacket of modified polyolefin for resistance to moisture and inorganic chemical agents; fluoropolymer for resistance to organic chemicals). The heater must be rated to withstand anticipated maximum exposure temperatures.

HEATER RELIABILITY AND CONSEQUENCE OF FAILURE

In addition to selection of a system with the appropriate T rating, environmental protection, and proper installation, a heat-tracing system must be evaluated in terms of the risk and consequence of failure. Savings in front-end costs may not be justified if the failure of a tracing system incurs the far larger expense of disrupting a process which depends on maintaining an acceptable temperature in the traced piping or requires removal and replacement of the thermal insulation and tracing system.

Steam tracing systems have high maintenance costs, but system failure is generally not a concern. The major cause of electric tracing system failure is compromised insulation. Zone heaters and self-regulating heaters have parallel circuits. Failure of a single heating element does not bring down the entire system, and repairs can be made in the field. The series circuitry of MI and polymer-insulated cable allows no such flexibility. A single failure brings the entire system down. MI and polymer-insulated cable is difficult to field-repair, requiring the services of a trained technician. See the section "Types of Heat-Tracing Systems" for detailed characteristics of different heat-tracing systems.

TRACING OPTIONS FOR DIFFERENT TEMPERATURE RANGES

Table B6.1 classifies heat-tracing technologies according to operating temperature ranges and maximum exposure temperature.

TABLE B6.2 Selected Examples of Time versus Temperature Loss in an Insulated Pipe

Pipe fluid	Light fuel oil	Water
Analysis ambient temperature	Static aboveground 0°F (−18°C)	Static aboveground −20°F (−29°C)
Wind speed	20 mi/h (32.2 km/h)	20 mi/h (32.2 km/h)
Pipe	Carbon steel	Carbon steel
Nominal diameter	4 in (10 cm)	2 in (5 cm) and 0.5 in (1.25 cm)
Insulation type and thickness	Fiberglass 2 in (5 cm)	Fiberglass 1 in (2.5 cm)
Initial temperature	140°F (60°C)	50°F (10°C)
Final temperature	90°F (32°C)	32°F (0°C) frozen solid
Time to final temperature	7 h	21 h for 2 in, 4 h for 0.5 in

Note: In practice, an occasional short interruption of power will not be a serious concern in the selection of electric heat-tracing. Heat loss from a fluid-filled pipe is sufficiently slow that intermittent power outages are unlikely to cause a serious lowering of temperature.

Source: *Heat-Up/Cool Down Analysis Program*, Raychem Corp., Menlo Park, CA.

AVAILABILITY OF STEAM AND ELECTRICITY

In process plants, steam is almost universally available. And except in regions with substantially developed hydroelectric power, electricity is invariably generated from steam.

When one is considering the use of electric heat-tracing, especially in some developing countries, the reliability of the power for uninterrupted delivery, available voltages, and the consequences of outages must be evaluated. In practice, heat loss from a fluid-filled, insulated pipe is a rather slow process. It will take many times longer than the duration of an intermittent power outage to suffer a serious lowering of temperature.

For example, an aboveground NPS 2 (DN 50) in carbon-steel pipe with 1 in (25 mm) of fiberglass insulation containing static water at an initial temperature of 50°F (10°C) will take 21 h to freeze when the ambient temperature is −20°F (−29°C) (see Table B6.2). Unless power disruption is expected to be of long duration (an exceedingly rare occurrence), reliability of the power supply is not a determining consideration. One exception to this is the tracing of instrument lines. Because of their small size, instrument lines will freeze much more quickly. In the above example a 0.5-in instrument line would freeze solid in 4 h (see Table B6.2). While this is much quicker than a pipe, it is still generally less than the duration of the typical short-term power failure.

The most significant factor in a decision between steam and electric tracing is the cost of installing and operating the system, and these costs depend on factors such as the geometry of the piping system, cost of labor and energy, and local tracing practice.[50]

INSTALLED AND OPERATING COSTS

In general, installation of steam tracing is more labor-intensive (½-in copper tubing is more difficult to install than the more flexible electric cable). In high-labor-cost areas, such as Europe and North America, the expense of labor can easily offset the higher material cost of electric tracing. In areas where labor costs are consider-

ably lower, steam may have an economic advantage. This is especially true in South America, where steam tracing predominates and the practice is well established.[52]

Since most electricity is produced from steam with about a 40 percent conversion efficiency, raw energy cost will always favor steam by a factor of 2 to 3. However, steam tracers have inherent disadvantages that usually make electric tracing more cost-effective in overall energy utilization. Maintenance costs also tend to favor electric tracing. As with installation, the maintenance cost differential between electric and steam tracing will tend to be greatest in high-priced labor markets.[53]

The above tradeoffs generally apply to both pipe tracing and the tracing of instrument lines. Because they are smaller, instrument lines require less energy, but this causes only a slight decrease in costs for both steam tracing and electric tracing. One major disadvantage steam tracing has in tracing instrument lines is that care must be taken to ensure that the steam tracer does not overheat the line. It is possible for a steam tracer to actually boil a small instrument line. This is generally not a concern with electric tracing as self-regulating heaters can be used.

TABLE B6.3 Comparison of Electric and Steam Tracing Freeze Protection Costs

Steam tracing		
Installed costs, $/ft of tracing

Maintenance, total		1.32
Total operating cost of electric tracing		$1.43

Metric conversion: Multiply per-foot cost by 3.28 to obtain per-meter cost per year.

COMPUTER SELECTION PROGRAMS[54]

Computer programs now exist which can greatly simplify the work of determining the economics of steam versus electric heat-tracing. Many heat-tracing vendors provide user-friendly heat-tracing selection programs for use with their lines of products. Input involves supplying answers to a series of fill-in-the-blank questions covering size, diameter, and geometry of the piping to be traced; ambient and maintenance temperatures; control requirements; labor costs; and exchange rates. The program then calculates worst-case heat loss, determines the components needed to build a steam or electric tracing system to maintain the pipe at the required temperature, and calculates the associated material, installation, and operational costs for both cases.

Cost Comparison of Steam and Electric Tracing

In a study presented at a September 1990 meeting of the IEEE,[55] a major chemical company compared the installed and operating costs of both steam tracing and electric tracing for a freeze protection system and for a process temperature maintenance system.

An existing electric tracing system was used for the freeze protection analysis. The actual costs of installing and operating this system were compared with detailed engineering estimates of the costs of installing and operating a steam tracing system to do the same task. For the process temperature maintenance study, the costs of an existing steam tracing system were compared to detailed engineering estimates of the costs of a similar self-regulating electric tracing system.

The results of this study are summarized in Tables B6.3 and B6.4, and they demonstrate that the electric tracing system is less costly to install and operate. It is interesting to note that even if the higher energy costs for steam are disregarded, the steam systems still have higher operating costs due to the expensive maintenance required. This suggests that the availability of excess low-pressure steam is not necessarily an adequate justification to select a steam tracing system instead of an electric tracing system.

STEAM OR ELECTRIC TRACING: DESIGN CONSIDERATIONS

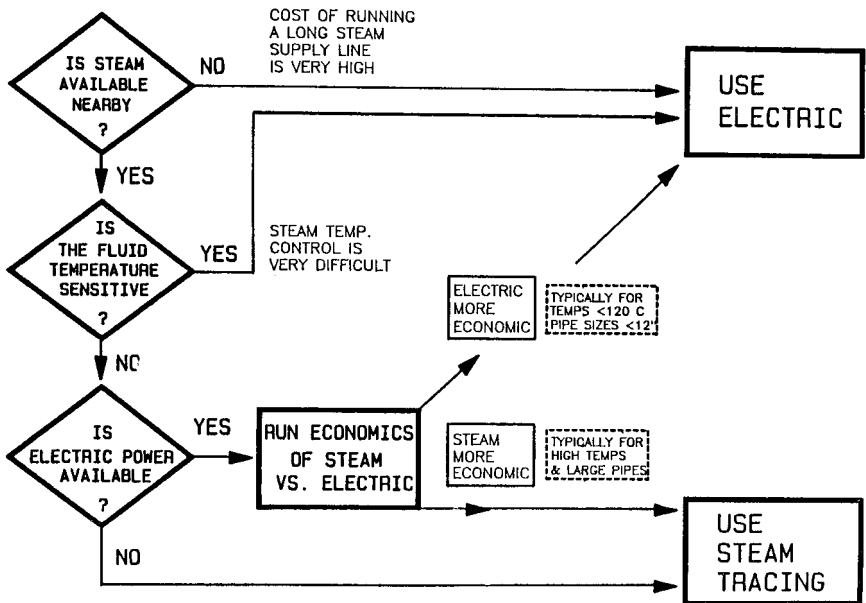
Figure B6.13 provides a flow diagram designed to assist in choosing between steam and electric tracing. In addition to the distinctions made in the first two sections


FIGURE B6.13   Steam-electric selection flow diagram. (*Raychem Corp., Menlo Park, CA.*)

of this chapter, several factors must be considered in determining the type of tracing selected:

- If steam is not available in the vicinity of the pipe being traced, the prohibitive cost of running a long steam supply line to the site usually eliminates the use of steam tracing from further consideration. By the same token, electric power must be available at the site to use electric tracing. When neither steam nor electricity is available, it is usually much cheaper to run electricity than to bring a supply of steam to a remote location.[56]

- Economics usually favor electric tracing for lines smaller than NPS 12 (DN 300) that maintain temperatures below 248°F (120°C).

ELECTRIC SYSTEM DESIGN

Electric heat-tracing is usually marketed through manufacturers' representatives. Major manufacturers of heat-tracing have representatives throughout North America and in many other parts of the world, and most are capable of designing heat-tracing systems and training plant engineers to design their own systems. Many heat-tracing manufacturers are staffed by professionals who are extremely knowledgeable in heat-tracing practice. Purchasers of heat-tracing products and systems can and often do take advantage of the design expertise and related experience that these companies make available to their customers.

Computer programs which assist in the development of heat-tracing designs are available from several manufacturers of heat-tracing products. Computer design programs allow for the rapid and comprehensive evaluation of the changes in heat loss resulting from the alteration of system variables. The ease of performing multiple computer evaluations allows more extensive exploration in design optimization, and often leads to improvements which might not be accessible if these computations had to be carried out in a less automated fashion. See Tables B6.5 and B6.6.

The following example demonstrates how a program is used in developing a heat-tracing design. In addition to calculating heat loss, these programs provide a checklist of the information required.

Data Collection

Once the information has been entered, the program will use the data to automatically select the optimum system components. While not all the requested information is always required, the use of a comprehensive inquiry form or a computer program helps ensure that all relevant data are collected.

Comment. Both T_m and T_a are needed to calculate the heat loss.

Maximum temperature that the heater will be exposed to due to process upsets or steam cleaning:

$$T_e = 140°F \quad (60°C)$$

Comment.   The design calculation compares T_e with the maximum intermittent exposure temperature of the heater to ensure that adequate safeguards are built in to protect the heater from damage and subsequent failure. This is a serious concern in the case of heat-sensitive polymer-insulated heaters.

Process normal operating temperature:

$$T_p = 50°F \quad (10°C)$$

Comment.   This temperature is required to ensure that the heater selected can continuously withstand the operating temperature.

System limit temperature (imposed by process fluid, insulation, pipe material, or safety considerations):

$$T_l = 500°F \quad (260°C)$$

Comment.   This temperature is required to protect the rest of the system from high temperatures created by the heater. Such temperatures may be a concern where plastic pipes or temperature-sensitive fluids are to be traced. (Most heat-traced fluids are not temperature-sensitive and are transferred in steel pipe, so this variable is often of no concern in design considerations.)

2. Pipe Data and Insulation Data

Outside pipe diameter:

$$D_1 = 4 \text{ in}$$

Comment.   Tables and programs are based on nominal pipe size; actual diameter is required for use in the heat-loss equation.

Outside diameter of insulated pipe:

$$D_2 = 6 \text{ in}$$

Comment.   Tables and programs are based on insulation thickness equal to $(D_2 - D_1)/2$ and thermal conductivity k of the insulation material or type.

$$FG = \text{fiberglass}$$

The following values are needed to calculate the pipe heat loss: D_1, D_2, and k [$= 0.25$ Btu/(h·°F·ft²/in)].

The values of k are taken at the mean temperature between the inner and outer surfaces of the insulation. Note that the thermal conductivity of the insulation material varies with the mean temperature.

Comment.   Computer programs calculate the heat loss based on the insulation type. The thermal conductivity is estimated for a mean insulation temperature; k is temperature-dependent, although the variation is small for low and moderate temperatures. Changes in k should be considered for medium- and high-temperature applications.

Pipe length:

$$L_p = 230 \text{ ft (70 m)}$$

Comment. This value is needed to estimate the length of tracing cable required.

Valves and other heat sinks: Include type and number of flanges, valves, hangers, fittings shoes, and anything that could require additional heat-tracing.

3. Service Environment Data and Classification.[57] Areas are classified on the basis of the severity of the fire and/or explosion hazard, which may be present. It is essential that the heater selected be used only in areas with classifications for which it has been approved.

Standard Area Classification

- *Ordinary area (nonhazardous)*: Areas not having explosive vapors, dust, or fibers.
- *Class I, II, III, Division 2*: Areas where explosive concentrations of vapors, dust, or fibers may be present in unusual circumstances. Special heat-tracing strip, usually equipped with a metal braid and an outer jacket, is used in these areas.
- *Class I, II, III, Division 1*: Areas where explosive concentrations of vapors, dust, or fibers may be present in usual circumstances. Measures considerably more stringent than those taken for Division 2 are required in Division 1.
- The computation example is for a Class 1, Division 2 area, a classification that is typical for the vast majority of hazardous-area designations.

Chemical Exposure

- Dry location (indoors)
- Wet location or limited exposure to aqueous inorganic chemicals
- Exposure to organic chemicals, greases, oils, or solvents

(Some types of heat-tracing can withstand corrosive inorganic chemicals, but not organics.)

Most heaters are designed for use in wet environments. Some heaters will need additional outer jackets if they are to be exposed to organic compounds.[58] The computation example is for an outdoor environment with potential exposure to organic chemicals.

4. Available Voltage. Heaters generally operate on 120 or 240 V. Most 240-V heaters are designed to operate at voltages from 208 to 277 V with some variations in power output. Generally 240-V heaters are preferred in industrial installations because they can support circuit lengths approximately twice as long as 120-V heaters can. This allows most jobs to be done with fewer circuits, considerably lowering the overall cost. Both 120- and 240-V systems are available in the computation example.

Heat Loss

The next step in the design of electric heat-tracing is the calculation of the maximum heat loss from the pipe. This is the heat loss from the pipe when the pipe is at its design temperature (maintain temperature), the ambient temperature is at its lowest, and the wind is blowing (comparable to the coldest day of the year with a maximum wind chill). Under these worst-case conditions, the heater must be capable of replacing the heat loss in order to maintain the desired temperature.

In the majority of cases, heat loss in electric tracing applications is usually estimated from tables provided by tracing manufacturers or by means of computer programs. Table B6.7 is a typical heat-loss table from a heat-tracing manufacturer. Several things should be noted about this table:

- It is based on fiberglass insulation. Correction factors for other types of insulation are given in the lower left-hand corner.

- A 10 percent safety factor has been included. This is fairly standard practice in the industry.

- The table is based on a 20-mi/h (36-km/h) wind. In the absence of wind (indoors), the heat loss will be reduced by about 10 percent. Wind speeds above 20 mi/h (36 km/h) will have very little additional effect on the total heat loss, generally less than 1 percent when one is dealing with an insulated pipe. Although the resistance of the air film can change, the total resistance—insulation plus air film—will not be altered significantly since most of that resistance is provided by the insulation.

- The amount of additional heat-tracing needed for valves is indicated in the Valve Heat-Loss Factors table in the lower right-hand corner of Table B6.7. Several additional feet of tracing will be needed for each controller in an insulated enclosure.

The heat loss per foot of pipe is calculated from Table B6.7 by following the procedure indicated in the thermal design guide chart (Fig. B6.14) as follows:

- First, move across the top to locate the 4-in-pipe column.

- Next, moving down the column, stop at the row corresponding to 1 in of insulation (left vertical axis).

- Following the calculation instruction method, a temperature differential $T_m - T_a$ of 50°F yields a heat loss of 5.4 W/ft.

- Since the actual temperature differential is 40°F or 5°C (40°F or 5°C maintain, 0°F or −18°C minimum ambient), interpolation is required, and the final result is 5.4 W/ft × 40/50 = 4.3 W/ft.

This, then, is the heat loss; including a 10 percent safety factor, of the pipe with the ambient temperature at 0°F, the pipe at 40°F (5°C), and the wind blowing 20 mi/h (32 km/h). The heater selected must be able to provide at least this much heat at a pipe temperature of 40°F (5°C).

The equation used to calculate heat loss from IEEE Standard 515–1983 is[59]:

$$q = \frac{T_m - T_a}{R_0 + R_1 + R_i + R_{co}} \tag{B6.1}$$

where q = heat loss per unit length of pipe at minimum ambient temperature, Btu/(h · ft)
T_m = pipe maintenance temperature, 40°F (5°C)
T_a = minimum ambient temperature, 0°F (−18°C)
R_0 = resistance to heat flow due to air film around outside insulation surface
R_1 = resistance of insulation to heat flow
R_i = resistance of inside air film between pipe and insulation
R_{co} = resistance to heat flow from fluid film on inner wall of pipe

Heater Cable Selection

After the data are collected, the procedure for selecting heating cables is as follows:

1. Select the heater family to be used based on the "maintain" and exposure temperatures. Table B6.8 shows the temperature ratings for a series of commercial heaters. Based on a maintenance temperature T_m of 40°F (5°C) and an exposure temperature T_e of 140°F (60°C), the economical choice is the heater family with lowest output capable of sustaining the required maintain temperature requirement and capable of withstanding the maximum intermittent exposure temperature.

Choice: Heater family with T_m = 150°F (66°C), T_e = 185°F (85°C) (B family).

2. Select the power output of the heater based on the heat loss and the desired maintain temperature. In the example computation, a power output of at least 4.3 W/ft at 40°F (5°C) is required. [Both the power output and the maintain temperature must be specified in order to select the correct heater. A power output of 4.3 W/ft, for example, at 140°F (60°C) instead of 40°F (5°C), would lead to the selection of an entirely different heater finally.] Figure B6.15 gives the power outputs for various families of heaters. Once again, the most economical selection is the heater with the minimum power output needed to make up the heat loss at a specified T_m of 40°F (5°C):

Choice: Heater with power output of 5.7 W/ft at 40°F (5°C). [Output specification is based on 1 ft (0.3 m) of heater per 1 ft (0.3 m) of pipe.]

In view of the heat replacement requirement, an alternate design solution could have employed a lower-cost heater with an output of only 3.5 W/ft in a spiral configuration of 1.23 ft (0.4 m) of heater per 1 ft (0.3 m) of pipe. The accepted practice of most experienced users in North America is to avoid spiraling.

Spiraling increases installation costs and time, and in many cases it also increases material costs. For example, analysis of the selection options above demonstrates that although the cost per foot of the 4.3 W/ft heater is about 10 percent greater than that of the 3.5 W/ft heater, the spiraling requirement increases the overall material cost of the latter by 23 percent. This comparison does not include the additional cost of labor required for a spiral installation. In areas with very low labor costs, the economics of spiraling can be more attractive. Spiraling is most often employed in high-heat-loss configurations where the alternative is the use of multiple strips to generate adequate heat.

In the event that a selection outcome indicates the need for more than one heater, it may be appropriate to review the heater family chosen. For example, while a heater output of 4.3 W/ft at 140°F (60°C) would require three strips of the heater selection E in Fig. B6.15, that same heat replacement could be more economically supplied by a single heater strip from selection D.

3. Select the voltage classification. The 240-V heaters have circuit lengths approximately twice as long as those of the 120-V heaters. Minimizing the number of circuits is one of the most effective ways to reduce the costs of an electric heat-tracing system.

Choice: 240-V heater.

Most 240-V heaters can be used at voltages ranging from 208 to 277 V, with some power adjustment factors (see Table B6.9).

For self-regulating heaters, it is important to obtain the power adjustment factor

Valve heat-loss factors	
Valve type	Heat-loss factor
Gate	4.3
Butterfly	2.3
Ball	2.6
Globe	3.9

Example:
Heat loss for a 2-in gate valve is 4.3 times the heat loss for 1 ft of pipe of the same size and insulation.

Pipe heat loss (Q_B) is shown in watts per foot. Heat-loss calculations are based on IEEE Std. 515—1983, Equation 1, with the following provisions: pipes insulated with glass fiber in accordance with ASTM C547; pipes located outdoors in a 20-mph wind; no insulating air-space assumed between pipe and insulation; no insulating air-space assumed between the insulation and outer cladding. A 10% safety factor has been included.

Source: Chemelex Auto-Trace Design Guide, *Raychem Corp., Chemelex Division, Menlo Park, CA.,* 1988, pp. 8—9.

| To calculate the heat loss that must be replaced by the heating cable, you need to know: | ▶ T_M Desired maintenance temperature (°F) ▶ T_A Minimum expected ambient temperature (°F) ▶ T_E Maximum intermittent exposure temperature (°F) ▶ Pipe or tubing size ▶ Thermal insulation type and thickness **Example:** T_M: 50°F T_A: −20°F T_E: 366°F (150 psig steam cleaning) Pipe size: 6″ steel Insulation: 2″ calcium silicate | |
(diagram labels: $T_{ambient}$, Thermal insulation, $T_{maintenance}$, Pipe or tubing)

STEP 1	Calculate temperature differential. $\Delta T = T_M - T_A$	Calculate $\Delta T = T_M - T_A$ $= 50°F - (-20°F)$ $\Delta T = 70°F.$
STEP 2	Determine pipe heat loss. From Table B6.7 (next page), match the pipe size and insulation thickness with the temperature differential (ΔT) to find the base heat loss of the pipe (Q_B). *Note:* Heat-loss calculations are based on IEEE Std. 515-1983, Equation 1.	From Table B6.7, 6″ pipe, 2″ insulation and $\Delta T=70°F$, Q_B must be calculated through interpolation: $Q_B = 4.2$ w/ft $+ 20/50 \times (8.8 - 4.2)$ $= 4.2 + 1.8$ $Q_B = 6.0$ w/ft. @ $T_M = 50°F$
STEP 3	Compensate for insulation type. Multiply the base heat loss of the pipe (Q_B) from Step 2 by the insulation compensation factor (f) from Table B6.7 to get the actual heat loss (Q_T). $Q_T = Q_B \times f$	From Table B6.7, f = 1.50 for calcium silicate: $Q_T = Q_B \times f$ $= 6.0$ w/ft. $\times 1.50$ $Q_T = 9.0$ w/ft. @ 50°F

from the manufacturer instead of calculating the factor by using the square of the voltage. Ohm's law ($P = V^2/R$) still applies; however, for self-regulating heaters, the electric resistance R does not remain constant. The result is an adjustment factor smaller than the change calculated from the square of the voltage.

4. Select the heater cable construction. The choice in cable construction is between a base heater with one insulating jacket and no braid or ground path, and a heater equipped with a braid and extra outer jacket. (A braid is required in all areas, both hazardous, i.e., classified area, and ordinary.)

Choice: Heater with a tinned braided, tinned copper (braid supplies the required ground path), and a fluoropolymer outer jacket for chemical resistance.

The heater cable selection is now complete. Tables B6.10, B6.11, and B6.12 are the outputs of the computer selection program run with the data used in the calculated example. As expected, the program arrived at the same heater selection as the manual technique employed in the above discussion. The program output also provides important information that augments the design selection function.

The design summary given in Table B6.10 provides the start-up load in amperes per foot as well as the operating load. The Min T maintained and Max T maintained are the maximum and minimum temperatures, respectively, the pipe can reach in this application in the absence of thermostatic control.

The Min T maintained 48°F (9°C) will be the pipe temperature on the coldest day [0°F (-18°C)] with the wind blowing and minimum heater output. The Max T maintained will be the pipe temperature on the warmest day [95°F (35°C)] with no wind and maximum heater output. These temperature values are useful in determining whether thermostats are needed. (See the later section "Control and Monitoring.")

The computer heat-tracing program can be used to implement a design change. The actual application for the computation example is a waterline in a process area where many of the process lines are regularly cleaned by purging with 150 psig (1035 kPa) steam at 366°F (186°C). It was concluded by the design team that a reasonable possibility existed that the traced line might be inadvertently steam-cleaned. What would the consequences be?

The new variable requires that the maximum heater exposure temperature be changed from 140°F (60°C) to 390°F (199°C), and the resulting output is given in Tables B6.13, B6.14, and B6.15. The most significant outcome of the requirement for a higher maximum temperature of exposure is the program's substitution of a heater designed to withstand the temperatures encountered during steam cleaning. The results of the new calculation show that the Min T maintained is relatively

unchanged at 47°F (8°C), but the Max T maintained has increased to 146°F (63°C). This increase in the maximum temperature is a function of the original heater's power temperature curve, which is considerably steeper when compared with the type selected for the new set of conditions. If a constant-wattage heater had been selected, the maximum temperature would be well above 146°F (63°C). The design change calculation illustrates two important rules to follow when using self-regulating heaters:

Rule 1.   Never risk exposing the heater to temperatures in excess of those for which the heater is rated. If the heater originally specified (T_e = 185°F, or 85°C) had been installed and the pipe were subsequently steam-cleaned, the heater would have suffered an irreversible resistance increase; i.e., it would no longer be functional. The cost of repair/removal of the lagging, removal and possible replacement of the insulation, replacement of the heater, followed by reinstallation of the entire system, would be more than the original price of the system. And this sum is in addition to process-related costs which might result from heater failure, such as the replacement of frozen and/or broken pipe, or in lengthy production downtime when a failed tracer shuts down a process.

Because of the potential costs resulting from tracer failure caused by inadvertent exposure to steam, experienced heat-tracing professionals generally use heaters capable of withstanding steam cleaning in any area where steam cleaning is practiced.

Rule 2.   Select the heater with the lowest temperature rating capable of withstanding the anticipated maximum exposure temperature.

1. The higher-temperature heaters are generally more expensive because they are made from more costly heat-resistant polymers.
2. The higher temperature generated by high-temperature heaters can cause safety problems. Unnecessary heating also increases the rate of corrosion and wastes energy. Higher-temperature heaters often require a more expensive heater control system.

While the potential savings in purchasing a low-temperature heater are not worth the risk of heater failure from steam cleaning, these additional costs are not justified in applications where there is no risk of steam exposure. Water pipe in a pollution control area where no steam is available is an example.

Component and Accessory Selection

The components necessary to provide power and to terminate, splice, and tee the heat-tracing are provided by the manufacturer. With self-regulating and zone, it is important to acquire components designed for the heat-tracing system selected, to ensure that the approvals are valid. Each supplier's system of components is unique and generally not interchangeable with that of other manufacturers. In some cases the components from one supplier may work in another's heat-tracing system, but they must be verified to be acceptable for such use. The components available in this example are shown in Fig. B6.16.

Each manufacturer provides or recommends a complete system of components and accessories to install the heater as part of a total tracing system. Table B6.12 (the design exhibit from the computer solution) shows a complete bill of material for the design example. In addition to the power connection and the end termination, a splice and/or a tee may be required. The other materials on the list are

• ETL (electric traced label). The National Electric Code requires that electric
FIGURE B6.16   Component selection guide. (Raychem Design Guide, *Raychem Corp., Menlo Park, CA,* © *1998.*)

traced pipes have signs on the outside of the lagging on alternating sides every 10 ft.

- GT66 glass tape for taping the heater to the pipe.
- PS-10 pipe straps to attach the power connection assembly to the pipe.

Control and Monitoring

Control and monitoring must be considered as part of the system design since these elements can have a significant effect on the circuit layout.

1. Control.   Control is the ability to interrupt and restore power to the heat tracer in order to maintain the temperature within a preset range and/or to save energy. Monitoring is any method that provides an ongoing indication of the heating system's operational status. The major control options are as follows:

No Control, or Self-Regulating Control.   The heater is constantly supplied with full power, and the self-regulating characteristics of the heater control the pipe temperature. In a limited number of tracing situations, a no-control configuration can also be used with constant-wattage heaters. If a circuit without controller is used in a hazardous area, the *T* rating must be calculated at 120 percent of the rated voltage. (See the earlier section "Area Classification.")

Self-regulating control offers the lowest installed cost and the highest reliability.

This system uses more energy because the heater is always on. Approximately 8 to 12 percent of the freeze protection systems and 10 to 15 percent of the process temperature systems use self-regulating control.

Ambient-Sensing Control.   A thermostat measures the ambient temperature. The heating system is energized when the ambient temperature drops below a preset level. Ambient sensing offers a degree of control for very little incremental cost (one thermostat and the required switching device). Of the freeze protection systems, particularly those that use self-regulating heaters, 70 to 80 percent use ambient-sensing control.

Line-Sensing Control.   A sensor measures the temperature of the pipe. Each heater circuit is individually controlled to maintain the design temperature by either varying or turning the circuit voltage on and off (see Fig. B6.17). Line sensing is often used for process control systems. It offers the highest degree of temperature control and the lowest energy use, but it also has the highest installed costs.[60]

Dead Leg Control.   A thermostat measures a section of traced pipe that cannot have fluid flow (a "dead leg"). The entire system is turned on when the temperature drops below the design temperature to be maintained. Dead leg sensing requires
FIGURE B6.17   Line-sensing circuit design for multiple flow paths. (*M. Sarfatti, editor. Raychem Engineering Manual for Electric Heat Tracing Systems, vol. 1, U.S. edition, pp. 2–27, Fig. 3-11.*)

only one thermostat and eliminates the need for the additional circuits required with line-sensing control. The downside of dead leg sensing is the inability of the system to reduce heat output even when flow conditions within the pipe would dictate such an adjustment. (By definition, the dead leg on which the sensor is placed is in a permanent no-flow condition.[61]) Presently, about 5 to 10 percent of the systems installed use dead leg control.

Proportional Ambient-Sensing Control (PASC).   A new addition to available control methods is proportional ambient-sensing control. This control will measure ambient, determine the heat-up and cool-down rates of the smallest pipe, and cycle the power to the heater circuit depending on these variables. This will impose a duty cycle on the heating system that decreases the variability of the temperature range. One can think of it as global control. If they are self-regulating heaters, they will provide a local override for much tighter temperature control. At minimum ambient temperature, the power is on 100 percent of the time. As the ambient temperature approaches the maintain temperature, the duty cycle decreases proportionally. If the maintain temperature is above the maximum ambient temperature, the controller never shuts off completely, and there will always be some proportion of the duty cycle maintained. With self-regulating heaters, this system also adjusts heat input for valves and supports, depending on their actual thermal characteristics instead of the design characteristics. If a valve is a little hot, the self-regulating heater supplies a little less heat; if the valve is a little cold, the heater supplies a little more heat.

This global system reduces circuit costs since now flow paths are not a critical part of the design. This method has been used with freeze protection systems with ambient control, and now this improved PASC version is available for process temperature maintenance systems. Significant cost savings and a tighter temperature control band are available. Figure B6.18 shows the relationship between control type and temperature variation for various electric heat-tracing control categories for a typical freeze protection application. The minimum ambient temperature is 0°F (−18°C) and the maintain temperature is 40°F (5°C). A new expert system design program (Ref. 54) is able to calculate various expected results when the design parameters are specified in the program. These programs will predict the

FIGURE B6.18   Temperature range for control options.

steady-state temperatures for various piping systems including the valves and supports.

Stabilized design temperatures for Zone 1 and Zone 2 are also calculated. The combination of PASC with self-regulating heaters gives the electric heat-trace designer an optimum system to develop cost-effective and reliable systems that provide significantly less temperature variation across the different thermal features of a typical piping system.

2. Monitoring. *Monitoring* is the term used to describe any mechanism that provides information about the functional state of the heat-tracing system.[62] Most heat-tracing systems employ one of the following monitoring methods:

No Monitoring. The vast majority of heat-tracing systems are not provided with monitoring. Users have found that properly installed heat-tracing systems are very reliable, and under these circumstances, the high cost of monitoring is not generally warranted.

Ground-Fault Monitoring. Leakage current from the heater strip can be monitored with a ground-fault circuit breaker. An annunciator is included to indicate when the breaker has tripped, or alternatively, a relay is switched in response to a loss of voltage. This method is also a good way to monitor the heater strip for mechanical abuse since significant mechanical damage to a braided heater will result in leakage current to the braid. Use of ground-fault breakers with annunciators or relays provides the highest value of added protection per monitoring dollar invested.

Voltage Monitoring. Voltage at the beginning of the circuit can be sensed by actuating a relay-driven alarm whenever there is no voltage from the circuit breaker. A signal light is the simplest technique for monitoring voltage at the end of the circuit. This system is often used for freeze protection applications with ambient-sensing control and either self-regulating heaters or zone heaters but not with MI cable, as MI cable usually requires line-sensing thermostats.

Although a light indicator is a low-cost system, it requires a visual inspection to detect voltage loss. Thus, there is a good chance that a cut line will lead to a failure before it is detected. The technique does not work well with line-sensing thermostats or dead leg control since there is no way to distinguish if the light is off because of a cut line or because of a cycling thermostat.

Voltage Sensing with Microprocessor-Based Monitoring and Control System. The best of these systems uses resistance temperature detectors (RTDs). (See Fig. B6.19.) Since the bus wires of the heaters are used to carry the detector signal, any cut in the line trips the alarm due to signal loss. Microprocessor-based monitoring and control systems are capable of providing very accurate information

Signal leads   Sensor
FIGURE B6.19 Resistance temperature device. (Chemelex Auto-Trace Installation and Operation Manual, *Raychem Corp., Process Division, Menlo Park, CA, p. 1.5.3.*)

about the condition of the heat-tracing system and the pipe temperature, but they often cost as much as the heat-tracing system itself. For this reason, they are generally used only for temperature-critical applications.

Temperature Sensing. Thermostats can be used to alarm when the temperature at any monitored point drops below the alarm temperature. This is a good technique when there is only one or two points (such as critical control valves) where the proper temperature must be maintained.

The current draw of the heat tracer can also be monitored with microprocessor-based systems using a simple ammeter to indicate the current draw of each circuit. Current monitoring works well with all types of heaters when line-sensing control is used, but is a poor choice in applications employing ambient-sensing control and self-regulating heaters.

Power Line Carrier

A distributed data acquisition system that uses the ac power lines as the data transmission medium is a new addition to the monitoring and control area. The system uses frequency shift keying to encode digital data onto the power line network. Digital 0s and 1s are transmitted by changing the frequency of the carrier (e.g., from 50 to 47.5 kHz). The digital data are transmitted in a message package that includes an error check to guarantee data integrity.

The system uses power from a parallel-circuit heat-tracing cable, measures the temperature at the end of the pipe, and transmits these data to a monitoring panel. If a signal is received, the user knows there is voltage to the end of the circuit. In addition, the temperature of the pipe is known. Alarm limits and automatic enunciation to a central location can be set. Significant savings are realized when both field power and instrument wiring are eliminated.

CHAPTER B7
THERMAL INSULATION OF PIPING

Kenneth R. Collier
Systems Engineer
Pittsburgh Corning Corporation
Pittsburgh, PA

Kathleen M. Posteraro
Systems Engineer
Pittsburgh Corning Corporation
Pittsburgh, PA

Thermal insulation serves many useful purposes in both industrial and commercial piping applications. In simplest terms, thermal insulation reduces heat flow from one surface to another. For hot, or above ambient, piping applications, thermal insulation reduces heat loss. On cold, or below ambient, piping applications, the insulation generally serves the purpose of minimizing heat gain.

In some cases the design purpose of the application may seem unrelated to heat loss or heat gain; however, the net result is that heat transfer is retarded. Two illustrations are insulation for personnel protection and insulation for condensation control.

For personnel protection there must be enough insulation to keep the surface temperature below a given design value—usually 140°F (60°C). For condensation control, there must be enough insulation to keep the surface temperature above the dew point. In both cases the insulation is used to control the surface temperature for a desired effect other than thermal conservation. The effect, however, is that in both cases insulation retards heat transfer enough to control the surface temperature at the given design criteria.

There is much more to correctly designing and specifying an insulation system than just selecting a particular insulation material to be used. This chapter will discuss some of the practical information necessary to initiate an effective insulation system design. The National Insulation Association (NIA) in its "Wheels of Learning" training program defines insulation as "those materials or combination of materials which retard the flow of heat." As noted in the NIA definition of insulation, a combination of materials may be used. The emphasis on the word *system* when referring to the purpose of this chapter signifies the importance of considering

all the materials, conditions, and parameters involved in insulation specification and design.

An insulation system is any combination of insulation materials used in conjunction with mastic, adhesives, sealants, coatings, membranes, barriers, and/or other accessory products to provide an efficient assembly for the reduction of heat flow. The engineering of insulation systems can frequently either determine or direct the ultimate performance of the process. Improperly engineered insulation systems are subject to damage and degradation. This degradation will compromise the performance characteristics of the insulation material and in many cases the entire process for which the insulation system was specified.

There are many different types of insulation materials available for commerical and industrial piping applications. Each material has its own set of properties and performance characteristics. And for each insulation material available, a correct application procedure and corresponding accessory materials, or ''system,'' are available.

Before we get into the essence of this chapter, which addresses some of the design parameters, materials, and systems that are commonly incorporated into insulation system design, it is necessary to review some fundamentals of heat transfer.

FUNDAMENTALS OF HEAT TRANSFER

The following definitions, taken from ASTM C168-88a, *Standard Definitions of Terms Relating to Thermal Insulating Materials,* and the NIA ''Wheels of Learning'' training program, will be useful in reviewing the fundamentals of heat transfer.

Btu (*British thermal unit*): the amount of energy required to raise 1 lb of water 1°F (The equivalent metric designation is a *joule,* which is defined as the work done when the point of application of a force of 1 N is displaced a distance of 1 m in the direction of the force. 1 cal = 4.1868 J: furthermore, 1 Btu = 1055.06 J.)

Conduction: the transfer of energy (heat) within a body (material) or between two bodies in physical contact.

Convection: the transfer of heat by movement of parts of a liquid or gas within the liquid or gas because of differences in the density, temperature, etc., of the parts.

Radiation: the transfer of energy (heat) from a higher-temperature body, through space, to another lower temperature body without warming the space between.

Thermal conductivity k: the time rate of steady state heat flow through a unit area of a homogeneous material induced by a unit temperature gradient in a direction perpendicular to that unit area. Units are commonly $Btu \cdot in$ (h $\cdot ft^2$ °F) [W/(m $\cdot$ K)].

Emittance E: the ratio of the radiant flux emitted by a specimen to that emitted by a black body at the same temperature and under the same conditions.

Radiance: the rate of radiant emission per unit solid angle and per unit projected area of a source in a stated angular direction from the surface (usually the normal).

Reflectance: the fraction of the incident radiation upon a surface that is reflected from the surface.

Heat flow or heat flow rate Q: the quantity of heat transferred to or from a system in unit time. Usually measured in Btu/h.

Thermal insulation: a material or assembly of materials used to provide resistance to heat flow.

Thermal insulation system: applied or installed thermal insulation complete with any accessories, vapor retarder, and facing required.

Heat is transferred by any one of, or combination of, conduction, convection, and/or radiation.

Conduction only occurs when there is physical contact. Heat is transferred through most metals very efficiently because metal is a good conductor. A good insulation material is a poor conductor. Convection, with respect to insulation systems, is the movement of air on or about the surface of an insulated body. And radiation is best described by referring to the warmth you feel when you stand in the sun or by a fire.

Heat transferred through insulation is primarily a function of the resistance of the insulation with respect to its thickness, the operating temperature of the surface being insulated, the surface characteristics of the outer membrane (see emittance above), and the ambient conditions involved.

Thermal conductivity, as defined above, is the rate of heat transfer in one direction (perpendicular to an area) per unit area, per unit temperature differential per unit thickness, per unit time. In the English system of units, typical dimensions are

$$|k| = \text{Btu}/(\text{h} \cdot {}^\circ\text{F} \cdot \text{ft}^2/\text{ft}) = \text{Btu}/(\text{h} \cdot \text{ft} \cdot {}^\circ\text{F}) \qquad [\text{W}/\text{cm} \cdot {}^\circ\text{C}]$$

or $$|k| = \text{Btu}/(\text{h} \cdot {}^\circ\text{F} \cdot \text{ft}^2/\text{in}) \qquad [\text{W}/(\text{m}^2 \cdot \text{K})]$$

or $$|k| = \text{Btu} \cdot \text{in}(\text{h} \cdot \text{ft}^2 \cdot {}^\circ\text{F}) \qquad [\text{W}/(\text{m}^2 \cdot \text{K})]$$

The units of measurement used have absolutely no effect on the fundamental equation of heat transfer. Heat transferred through flat surface geometry is most commonly represented by Eq. (B7.1):

$$Q = \frac{A(T_i - T_2)}{X/K + 1/f} \tag{B7.1}$$

where Q = total heat loss, Btu (h · ft²) (W/m²)
A = area of heat flow, ft² (m²)
T_i = inside operating temperature, °F (°C or K)
T_2 = outside ambient temperature, °F (°C or K)
X = insulation thickness, in (m)
k = thermal conductivity, Btu · in (h · ft² · °F) [W/(m · K)]
$1/f$ = surface resistance factor

Heat transferred through cylindrical, or pipe insulation, geometry is most commonly represented by Eq. (B7.2) and Fig. B7.1.

$$Q = \frac{2\pi K L(T_i - T_s)}{R_o \ln(R_o/R_i)} \tag{B7.2}$$
FIGURE B7.1   Cross-section of an insulated pipe.

where Q = total heat loss Btu/(h · ft²)
  k = thermal conductivity, Btu · in/(h · ft² °F) [W/(m · K)]
  L = lineal ft (m)
  T_i = inside operating temperature, °F (°C)
  T_s = outside ambient temperature, °F (°C)
  R_i = bare pipe radius, in (m)
  R_o = radius to insulated surface, in (m)
  ln = natural logarithm

Heat transferred through cylindrical, or pipe insulation, geometry with multiple layers of insulation is most commonly represented by Eq. (B7.3) and Fig. B7.2.

$$Q = \frac{T_i - T_s}{\left[R_s \ln\left(R_1/R_i\right)\right]/K_1 + \left[R_s \ln\left(R_2/R_1\right)\right]/K_2 + \left[R_s \ln\left(R_s/R_2\right)\right]/K_3 + 1/f}$$

(B7.3)

where Q = total heat loss, Btu/(h · ft²) (W/m²)
  k = thermal conductivity, Btu · in/(h · ft² · °F) [W/(m · K)]
  T_i = inside operating temperature, °F (°C)
  T_s = outside ambient temperature, °F (°C)
  R_i = bare pipe radius, in (m)
  R_1 = radius of outer surface of first layer in (m)
  R_2 = radius of outer surface of second layer, in (m)
  R_s = outside radius of outermost layer, in (m)
  ln = natural logarithm
  $1/f$ = surface resistance factor
FIGURE B7.2   Cross-section of an insulated pipe with multiple layers.

Surface resistance is represented by the inverse of the air film $(1/f)$ factor, as seen in Eqs. (B7.1) and (B7.3). When heat flows through a solid material and then out into another atmosphere (usually air), a resistance to heat flow created by the phase change at the interface between the two atmospheres is encountered at the surface separating the solid from the other atmosphere. Less heat will flow from the surface, therefore, than if no resistance were offered at this point.

In the case of good conductors of heat, surface resistance is the greater part of the total resistance of heat flow. In connection with efficient insulating materials, however, surface resistance is small compared with the resistance of the materials themselves.

Numerically, surface resistance is the reciprocal of the rate of heat transmission from surface to air. That is, if the rate of heat transmission from surface to air is 2.0 Btu/(ft$^2 \cdot$ °F $\cdot$ h) (W/m^2), the surface resistance is 0.5 (h $\cdot$ ft^2)/Btu (m^2/W). A higher rate of heat transmission from the surface indicates a lower surface resistance, and vice versa.

Air velocity has a significant impact on surface resistance. Figure B7.3 shows values of surface resistance sufficiently accurate for use in insulation calculations, where the surface resistance is usually less than 25 percent and frequently less than 10 percent of the total resistance.

Thermal conductivity is a specific property of a homogeneous material. Its value is, like that of density, not dependent on the area, thickness, or shape of the material.
FIGURE B7.3   Surface resistance $1/f$ at various velocities.

It is a rate and is therefore unaffected by geometry. Heat transmission, however, is dependent upon the geometry of the body to be insulated and is predominantly governed by the length of the path (thickness).

Thermal conductivity is dependent upon temperature, but this is also true of other specific properties of a material, e.g., density. Standard test methods for determining thermal transmission properties of insulation materials are covered in

- ASTM Standard Test Method C177, *Steady-State Thermal Transmission (Properties by Means of the Guarded Hot Plate)*
- ASTM Standard Test Method C518, *Steady-State Thermal Transmission Properties by Means of the Heat Flow Meter*

In Table B7.1, conservative thermal conductivity values are shown for several commonly used industrial and commercial insulation materials. The thermal conduc-

* For flat surfaces capped per ASTM C240 (hot asphalt, 15# felt).

† While compressive strength technically measures the stress at which a material fails under load, deformation monitors a material's structural distortion *with or without* actual failure. So, with compressible insulations, failure is recorded as the point at which an insulation's deformation reaches a percentage of its thickness—usually between 5 and 25 percent—for various densities.

tivity values are shown as a function of the mean temperature between the inner and outer surfaces of the insulation. This method of expressing thermal conductivities permits their use in the calculation of heat transfer through materials whether used singly or in combination with other materials.

DESIGN PARAMETERS

By providing a medium for retarding heat transfer, thermal insulation serves many useful functions in industrial and commercial piping applications. In specifying an insulation system, it is important to consider the parameters of your process and application needs. These are the whys of insulation system design. Why, or for what purpose, is the pipe going to be insulated? The following are some common design criteria used in insulation system design for piping applications:

- Controlling heat loss on hot piping
- Providing personnel protection
- Providing personnel comfort in commercial buildings
- Reducing heat gain on cold piping
- Limiting or retarding surface condensation
- Providing process control
- Economic optimization or energy conservation
- Providing fire protection
- Providing freeze protection
- Providing noise control

In many applications these criteria will overlap, and designing for one condition will benefit by the attainment of another. One example of such overlapping criteria occurs with the control of heat loss. In designing for a maximum heat loss of a given value, an added benefit may be that the surface temperature is sufficient to provide personnel protection. Another example of overlapping criteria is condensation control. In humid environments, when insulation is sized according to condensation control parameters, the added benefit will often be an economically optimum design for the reduction of heat gain on the cold pipe.

Environmental, physical, and mechanical conditions play an important role in insulation system design. Indoor applications, for example, generally do not require the complexity of design that outdoor applications require.

Similarly, below ambient designs are often more complicated than above ambient designs. The physical abuse and mechanical conditions that an insulation system is subject to are also important to consider in the design process.

The following paragraphs offer a brief explanation of the purpose of considering each of the above items.

Controlling Heat Loss on Hot Piping

The objective behind controlling heat loss on hot piping can be very narrow or, very broad in scope with multifaceted purposes. As mentioned in the introduction

to this chapter, insulation in any application serves one primary function: to reduce the heat flow from one surface to another.

Some of the areas that are listed above fall into the category of controlling heat loss on hot piping, i.e.,

- Providing personnel protection
- Providing personnel comfort in commercial buildings
- Providing process control
- Economic optimization or energy conservation
- Providing freeze protection

One of the most important things to understand about this particular subheading, ''Controlling Heat Loss on Hot Piping,'' is the word *control.* Insulation, by itself, does not have the ability to *maintain* or *hold* temperature within a system. Insulation can only provide a means for control. Insulation can *limit, retard, reduce, minimize,* or *slow down* the rate at which heat flows through or out of the system, but it cannot stop the process. Insulation is merely a resistor to heat flow; it is not a barrier to heat flow.

Insulation *systems,* however, can be designed to maintain a body or a mass at a given temperature. These systems require the use of additional energy input from any of a number of possible sources. Some of the more obvious sources of additional energy input are heat-tracing, pressure, and flow rate. Heat tracing, pressurized systems, and flow dependent systems will be discussed later in this chapter.

Personnel Protection. When providing for personnel protection, only enough insulation is applied to protect individuals from being burned by the heat of the pipe surface. Traditionally the upper temperature limit of the surface of the insulation, used as a guide-line for personnel protection, was 140°F (60°C). In recent years, however, a more conservative design temperature for personnel protection is 125°F (52°C).

The ASTM Standard Guide C1055, *Standard Guide for Heated System Surface Conditions That Produce Contact Burn Injuries,*[2] indicates that the normal metabolism threshold pain level occurs at approximately 111°F (44°C). At this point and up to 140°F (60°C), potential injury is still considered to be reversible. The maximum level of pain occurs at approximately 140°F (60°C), at which point injury from skin contact may have irreversible effects.

To date, there are no mandates or statutes that govern any upper temperature limit for personnel protection. However, many industries have accepted or adopted 125°F (52°C) as a common practice.

In some design applications where there is clearly no justification for insulation and insulation could actually be a detriment to the process, the fabricated guards are employed to provide personnel protection.

In other cases, where guards are impractical and insulation is more appropriate, the insulation is applied only to the piping that is within 7 ft (2.1 m) of the ground or platform in high risk areas. In a situation such as this where the insulation does not continue beyond the protected area, it is very important that the insulation system be properly flashed and sealed to prevent water ingress, as shown in Fig. B7.4.

In designing an insulation system for personnel protection, the outer surface conditions become very important. In general, on hot piping, less insulation is required with a painted metal or mastic finish than if a shiny metal finish is used.

Pipe

Steel banding strap

Fabricated metal collar

Sealant appropriate for temperature

Insulation

Insulation jacketing
FIGURE B7.4 Flashing and sealing.

This is a direct function of the emissivity of the surface material. The emissivity of the surface material is a function of the material's reflectivity and absorptivity. The emittance of a surface material is determined on a scale where a reflective material, not emitting any infrared energy, is rated 0 and a nonreflective material, emitting all its infrared energy, is rated 1. Both limits are impractical to attain. Figure B7.5 simplifies the expression of emittance performance as it relates to personnel protection.[3]

In situations where solar loads are high, highly reflective metal jacketing materials reflect much of the radiant heat, thus causing surfaces which are too hot to touch. Dull, textured finishes such as fabric reinforced mastic will tend to absorb more of the radiant heat and thus have a higher emittance value, creating a surface condition which is cooler to the touch.

Wind conditions also make up an important design criterion in designing for personnel protection. In open areas in coastal regions, for example, there is usually a prevailing wind that can be considered in the insulation system design. In this situation, less insulation would be required than if the piping system were in an enclosed space sheltered from the wind.

This provides an additional source of heat loss—convection—which occurs at
FIGURE B7.5   Emissivity illustration.

the surface in this case. This heat loss cools the surface of the insulation; however, it also decreases the effectiveness of the overall insulation system.

When designing for personnel protection on hot piping, these factors must be considered:

1. What are the worst case ambient temperature and wind conditions the system will be subjected to? Consider the ambient conditions which will create the hottest surface temperature for each application, such as summer weather with no wind and a metal jacketing material. Note that when designing for worst case weather conditions, in *most* applications it is best to use the average worst case conditions (i.e., average summer weather, average summer wind). If the absolute worst case condition is used as the design criterion, the system will usually have an uneconomical and even impractical insulation thickness.

2. What is the risk factor with respect to location of the piping to human contact? Consider the potential of human contact. If there is no opportunity for human contact, then insulation for personnel protection may not be necessary. Limited human presence may only require a sign or a fabricated guard. Frequent human presence will require insulation for personnel protection. And frequent human contact will require a thorough investigation into the most efficient insulation system for personnel protection.

Providing Personnel Comfort in Commercial Buildings.   In addition to personnel protection and in a similar capacity, insulation has traditionally been used to provide personnel comfort in enclosed spaces. Heat loss from hot piping in commercial and institutional buildings is primarily an economic consideration. Of course, heat loss into the environment in enclosed spaces can significantly impact the comfort of the personnel occupying the space; however, this heat is usually offset by the climate control systems.

For example, in hot summer conditions when air conditioning is required, heat loss into enclosed spaces will significantly impact the loads on air compressors and associated climate control equipment. The personnel occupying the space may never actually feel the heat loss from the piping, but it will be evidenced in higher equipment maintenance costs and utility bills.

When designing for personnel comfort in commercial buildings, these factors must be considered:

1. What are the worst case ambient weather conditions that the building will be subjected to? Generally when designing mechanical HVAC systems for commercial buildings, the worst case ambient temperature is taken as an average for the seasons. The worst case in Saskatoon, Saskatchewan, will be an average of the temperatures from December through March. The worst case in Miami, Florida, will be an average of the temperatures from June through September.

2. What will be the effect on the HVAC systems that will have to offset the heat loss? The additional energy requirement placed on evaporators, compressors, and water chillers can be substantial. Properly designing and insulating the hot water and chilled water lines in commercial buildings will help minimize this problem.

Process Control. Process control is a very critical design parameter in many industrial environments. Providing a stable temperature flow throughout a process system is in many cases more important than any other design criterion. For example, in the transport of liquid sulfur through a piping system, it is imperative that the temperature of the sulfur never drop below its freezing point. In this scenario, the time and energy required to get the frozen sulfur into a molten and flowing state again are more expensive than the cost to replace the transport piping altogether. In another example, providing a uniform temperature heat transfer medium (i.e., steam, synthetic heat transfer fluids, etc.) to a chemical reaction vessel is essential to a proper chemical reaction. Not enough heat or too much heat can completely change or even nullify the chemical reaction. In both these examples, the cost of improper consideration of process control requirements is significant.

In a paper entitled ''Thermal Insulation Design Concepts,''[4] Charles W. Sisler, of Monsanto, Inc., states the following relating to process control:

> Thermal insulation has a primary function of keeping the process of its equipment and piping hot enough or cold enough to meet operating requirements. This function takes precedence over all others when the following conditions must be controlled:
>
> 1. Process in elevated temperature service:
>   *a.* Excessive reflux condensation in distillation equipment.
>   *b.* Crystallization of solids on equipment or piping walls.
>   *c.* Yield loss or product deterioration from excessive heat input or pressure build-up to compensate for heat loss.

Process control is important in any piping system; however, it is not always the controlling design parameter. For example, a loss of process control in a hot water heating system in a commercial building will probably not cause the building to shut down until the process is stabilized. It may require that the climate control system operate longer and that the energy input be greater than it would normally be; however, it could conceivably operate under these conditions indefinitely.

As a controlling design parameter, the loss of process control would cause system shutdown, significant product loss, process or product failure, or a significant health and safety hazard.

When designing for process control with respect to heat loss on hot piping, these factors must be considered:

1. What is the worst case ambient temperature that the system will be subjected

to? For process control purposes, the worst case ambient temperature is the one which will most adversely affect the process. On hot piping applications, this will be the average winter weather conditions for the geographic location of the facility.

2. What are the temperature limitations of the process being controlled? Evaluate the insulation system based on the amount of temperature change that the process can tolerate. This will play an important role in how much insulation is required to control the process.

3. What are the consequences in terms of cost and safety of lost process control? If the system is allowed to extend outside the temperature limitations of the process, what will happen? A good example is steam. When allowed to cool, steam will begin to condense inside the pipe. If this is allowed to get out of control, it can cause serious process problems. Liquids do not convey as well as gases, the presence of liquids can cause corrosion problems, and it requires more energy to keep the liquid hot than it does to keep the gas hot.

Economic Optimization or Energy Conservation.   One of the most common reasons people think of for placing insulation on hot piping is *economic optimization*. Actually, however, it is much less common today than in the mid-1970s to see insulation used for this purpose.

Prior to the "energy crisis" of the early 1970s, thermal insulation used on hot piping applications served two primary purposes: personnel protection and process control. These two design parameters are discussed above.

When the cost of energy began to increase in the early 1970s, large energy and oil consumers began to look for a means to control costs. One of the most cost effective ways to control energy costs is to provide an efficient insulation system. An efficient insulation system is a theoretically static system surrounding a body such that the energy requirement to control the heat loss from that body is reduced by a given or predetermined design value.

To better understand this concept, it is useful to first examine heat losses from

TABLE B7.2   Heat Losses from Bare Surfaces

Hot surface temp (°F)	Temperature diff (°F)	Loss [Btu/(ft² · h)]	Hot surface temp (°C)	Temperature diff (°C)	Loss (W/m²)
100	30	50	38	17	157
200	130	295	93	72	930
300	230	654	149	128	2,061
400	330	1,145	204	183	3,609
500	430	1,806	260	239	5,693
600	530	2,666	316	295	8,404
700	630	3,765	371	350	11,869
800	730	5,126	427	406	16,160
900	830	6,799	482	461	21,434
1,000	930	8,885	538	517	28.010
1,100	1,030	11,400	593	572	35,939
1,200	1,130	14,394	649	628	45,378
1,300	1,230	17,896	704	683	56,418
1,400	1,330	21,758	760	739	68,594
1,500	1,430	25,983	816	795	81,913

Still-air conditions, air temperature 70°F (21.1°C), surface emittance = 0.95.

bare surfaces. The rates of heat loss from bare surfaces at temperature differences up to 1000°F (538°C) are shown in Table B7.2. These are average values for still-air conditions, and although there is some variation for different pipe sizes and for different absolute temperatures of surroundings, these variations are small as compared with those caused by comparatively low air velocities. Therefore, these average values are sufficiently accurate for engineering purposes.

Heat losses expressed only in British thermal units (Btu) are not usually so significant as when expressed in actual costs in dollars. In Fig. B7.6, the equivalent losses in dollars per square foot per year (8760 h) have been shown for various temperatures per 1,000,000 Btu (292,000 W · h). [And 1,000,000 Btu (292,000 W · h) is approximately equivalent to 1000 lb of steam at 350°F and 150 psig.]

The value of energy per 1,000,000 Btu either is known or may be computed readily for a given fuel of known cost and a given efficiency. Thus, this procedure renders Fig. B7.6 applicable to a wide range of fuels and conditions.

To approximate the most economically optimal insulation thickness, first the operating conditions and the environmental conditions must be defined. The op-
FIGURE B7.6 Equivalent loss in dollars per square foot at various fuel costs per 1,000,000 Btu.

erating conditions are the factors that make up the actual process (i.e., pipe size, contents, flow rate, operating temperature). The environmental conditions make up the atmosphere within which the insulated pipe will be operating (i.e., ambient temperatures, wind conditions, annual rainfall, humidity).

Example B7.1. Take as an example a 1-ft^2 surface area operating 7200 h/yr at 300°F (149°C) above the temperature of the surrounding air. Then the loss per year, at an energy value of $3.50 per 1,000,000 Btu, is $25.07 × 7200/8760= $20.60. Suitable insulation savings upward of 90 percent of this loss may be applied at a cost considerably less than 1 year's savings, when compared to the cost of the energy consumption required with no insulation at all. This illustrates the desirability of insulating such surfaces as boiler drum heads, manways, flanges, and fittings which are frequently left uninsulated, even though adjacent piping is provided with effective insulation.

The magnitude of losses from bare heated surfaces as compared with the relatively small losses from such surfaces when properly insulated is illustrated in Fig. B7.7. In this illustration, heat losses per degree of temperature difference from bare surfaces are shown by the upper curve, and heat losses from insulated surfaces are shown by the lower curve. The area between the two curves represents the savings due to insulation.

When designing for economic optimization with respect to heat loss on hot piping, these factors must be considered:

1. What are the average ambient temperature conditions that the system will be subjected to? In the case of economic optimization, processes are usually evaluated on an annual basis, or on a life cycle basis if operated only during portions of the year. Taking an average ambient condition over the course of time during which the process will be in operation will enable the designer to determine the economically efficient insulation thickness.

2. What are the operating temperatures of the process? Each range of temperatures that will be involved in the process should be evaluated on its own criteria. If the process swings through a range of temperatures (cyclical systems), the thickness should be based on the worst case condition on a time weighted basis.

3. What is the life expectancy of the system being designed? Life expectancy is a very important variable in the evaluation of economic insulation thickness. A longer life expectancy will justify a more sophisticated insulation system than a quick turnaround project.

4. Will insulation thicknesses specified for economic optimization be a detriment or an asset to efficient process control? In some cases, the insulation thickness required for economic optimization may not be ideally suited to process control. For example, in some very humid regions, the economic insulation thickness for a chilled water line may not be sufficient to provide adequate condensation control. Another example is hot piping in a quick turnaround project. The economic insulation thickness required to insulate a heat transfer pipe at 650°F (343°C) for a 2-yr life expectancy will be less than what is required to keep the heat transfer fluid at a uniform and stable condition. In both examples, the process control condition would prevail over the economic thickness.

Providing Freeze Protection. The final subject, as defined above, with respect to controlling heat loss is insulation system design for the prevention of freezing. Freeze
FIGURE B7.7   Heat-loss comparison.

protection can be provided by any of the following, but is usually a combination of three means:

1. Insulation thickness
2. Flow rate
3. Additional heat input

As mentioned earlier in this chapter, insulation alone cannot maintain a temperature. Regardless of the insulation thickness, if a fluid body is stagnant, there is no additional heat input, and the ambient temperature outside the pipe is below the freezing point of the fluid, then the fluid will eventually freeze. The thickness of the insulation can slow down the freezing process, but cannot stop it.

Fluid in motion takes much longer to freeze than stagnant fluid. Therefore, in the design of any freeze protection system, the flow rate must be factored in. If

there is no flow during significant time intervals, consideration must be given to additional heat input.

Additional heat input is provided by means of various types of heat tracing. Typically there is steam, electric resistance tapes, and heat transfer fluids. Of these three, the most common application for piping purposes is electric resistance tapes. Additional heat input requirements are usually provided as a complimentary service of heat tracing manufacturers and by some, but not all, insulation manufacturers. Refer to Chap. B6 for heat tracing of piping.

When designing to provide for freeze protection, some of the factors that must be considered are as follows:

1. What is the worst case ambient temperature condition that the system will be subjected to? For freeze protection, the coldest temperature for the longest amount of time must be considered. For example, an underground water pipe that has to traverse a river on the underside of a bridge would have two ambient conditions: the ground temperature at the pipe depth and the winter weather conditions in the geographic location of the bridge.

If the bridge is in Houston, Texas, the worst case condition might be 30°F (−1°C) for 1 day with a 15 mph (24 kmph) wind. If the bridge is in Bemidji, Minnesota, the worst case condition might be −10°F (−23°C) with a 10 mph (16 kmph) wind for 20 days.

2. What is the lowest allowable operating temperature of the process? All liquids have different freezing temperatures. For example, water freezes at 32°F (0°C), but molten sulfur freezes at 120°F (49°C). Both would require freeze protection in Bemidji, but the water line may not require it in Houston.

3. What is the normal operating temperatue of the fluid? It is possible in many processes that the normal operating temperature of the fluid is higher than the freezing temperature. In a freeze protection evaluation, the time to reach a freezing temperature must be considered in addition to the time to freeze. In the case of the water line in Houston, the normal operating temperature of the water may be 55°F (13°C), and due to a possible drop in temperature, depending on the size of the pipe, it may not even reach 32°F (0°C) much less freeze before the temperature gets back up above 32°F (0°C).

4. What are the physical properties (i.e., density, specific heat) of the fluid? It is useful to know the physical properties of the fluid being protected if a detailed analysis is to be performed. For example, a high density fluid will take longer to reach its freezing point than a low density fluid.

5. What is the flow rate of the fluid? Fluid in motion (with enough pressure behind it) will not freeze. Therefore, in many applications if the liquid can be kept flowing, the use of insulation for the sole purpose of freeze protection can be eliminated. In most instances, however, it is when the flow is interrupted that the freeze protection is required.

6. What is the maximum downtime that the fluid might remain in a stagnant state? If the maximum downtime that the fluid is stagnant is less than the time required to freeze under the given design conditions, then insulation requirements can be reduced or eliminated.

Reducing Heat Gain on Cold Piping

In cold piping applications, the main objective of providing insulation is the reduction of heat gain. This process is most often evidenced in terms of providing process

control and limiting or retarding surface condensation. The most important controlling factor in the effort to minimize heat gain on cold piping is the prevention of moisture migration into the insulation system, or water intake. This type of moisture migration will have a dramatic effect on system performance.

Process Control.   As mentioned earlier in this chapter, in the explanation of process control as it relates to hot piping, process control is often the most important guiding criterion relating to insulation system design. In cold piping applications, this statement is even more paramount than in hot piping applications.

In most cold processes (with the exception of chilled water piping in climate control systems), the maximum allowable heat transfer for process control purposes is 30 to 40 Btu/(h · ft^2) (95 to 126 W/m^2). The consequences of exceeding this limit are so costly that a safety factor of 4 is frequently employed, resulting in a design limitation of 8 to 10 Btu/(h · ft^2) (25 to 31.5 W/m^2). By comparison, chilled water piping systems are usually designed around 40 to 50 Btu/(h · ft^2) (126 to 158 W/m^2), and hot water and steam systems are often designed around 100 Btu/(hr · ft^2) (316 W/m^2) or more.

In another example, liquefied gases must be kept below their boiling points. This is usually accomplished with a combination of pressure and insulation. If the temperature of the liquid gas is allowed to exceed the process control design parameters, the consequence is either a costly loss of gas through vaporization or a potentially hazardous buildup of pressure.

Cold piping systems are subject to degradation from the environment, more so than hot piping systems. This stems primarily from the direction of the vapor driving force in these applications. On hot systems, the water vapor driving force is away from the pipe, and although the ingress of water into the insulation can adversely affect the insulation performance, it is generally considered to be temporary. Conversely, on cold systems, the water vapor driving force is inward toward the pipe. The ingress of water, therefore, into the insulation system will gradually increase with time; it will slowly deteriorate and eventually destroy the system.

For these reasons, it is extremely important that the total insulation system design be very thoroughly thought out, to counteract the potential effects of the environment. The use of vapor barrier mastics and low permeability joint sealants is essential to adequate system performance. From a process control standpoint, these materials are just as important as the insulation itself to the performance of the process.

Limiting or Retarding Surface Condensation.   Insulation systems can be designed to limit or retard surface condensation, but in most cases they cannot be designed to *prevent* condensation. In some very dry climates, insulation systems can be designed to prevent condensation most of the time; however, even in the driest desert, dew settles on the ground in the early morning hours. When dew settles on the surface of an insulation system, it is considered condensation.

In humid regions, it is not feasible to consider designing an insulation system to prevent condensation. In these areas the insulation thicknesses required of even the most efficient insulations available would be unrealistic from both a financial and a practical perspective.

Surface condensation can sometimes be a problem, primarily from a maintenance control perspective, but in the long term from an insulation efficiency standpoint as well. This is particularly a problem where absorptive insulation materials are present. Surface condensation can cause mold and mildew formation, which presents health and safety hazards. When metal jacketing is present, surface condensation

can cause pitting and corrosion of the membrane. And when condensation is allowed to remain present for extended periods of time, it can cause membrane degradation, leading to moisture ingress into the insulation.

As with personnel protection, the outer membrane selected for limiting condensation plays an important part in providing good condensation control. The surface temperature of the insulation system is the controlling factor in how often condensation will form and how long it will be present.

When designing to limit or retard surface condensation, some of these factors should be considered:

1. What are the average summer ambient temperature and wind conditions (not worst case) that the system will be subjected to? For retarding surface condensation it is very important that the average summer conditions are used, not the worst case. This is because the worst case ambient weather conditions in the summer months, particularly in the coastal regions, are such that it is unrealistic to try to achieve condensation control. The insulation thicknesses required of even the most efficient insulations systems available are economically infeasible and impractical for worst case summer conditions.

2. What is the operating temperature of the process? The operating temperature of the process will have a significant effect on whether condensation control needs to be considered. For example, on a cryogenic pipeline the insulation required to provide process control will usually exceed the insulation thickness required to provide condensation control.

3. How important is condensation control in the overall performance of the process? In many outdoor conditions, condensation control is not a particularly important design criterion. Condensation does not present as much of a process problem as it does an aesthetic problem. In indoor or rooftop applications, condensation can be a problem as it represents building or structural degradation potential.

Providing Fire Protection

As a general rule, insulation materials are better suited for use as thermal insulation than as fire protection. However, the National Fire Protection Association (NFPA) and the American Petroleum Institute (API) acknowledge conditions under which some insulation materials may provide "credit" in the design and sizing of pressure relief valves. Accordingly, there are several test methods, some private and others public, which are used to determine the suitability of insulation materials for fire protection applications.

The Flammable and Combustible Liquids Code, NFPA 30,[5] states in section 2-2.5.7(a) that

Insulation systems for which credit is taken shall meet the following performance criteria:

1. Remain in place under fire exposure conditions.
2. Withstand dislodgment when subjected to hose stream impingement during fire exposure. This requirement may be waived where use of solid hose streams is not contemplated or would not be practical.
3. Maintain a maximum conductance value of 4.0 Btu/(h · ft² · °F) (W/m²) when the outer insulation jacket or cover is at a temperature of 1660°F (904.4°C) and when the mean temperature of the insulation is 1000°F (537.8°C).

API Recommended Practice 521 requires the same basic performance criteria; however, it includes the following time limitation:

> Section 3.12.2.1 . . . This period of exposure may range from 20 minutes to one hour, depending on the adequacy of fire-fighting provisions, the accessibility of equipment, and the degree of skill and training of the fire-fighting group. . . .

In item 1 above, the requirement is that the insulation remain in place under the fire exposure conditions. This is usually accomplished by using a stainless steel jacketing material, of sufficient thickness (generally 0.015 in or greater) to withstand the flame intensity, with stainless steel banding and matching stainless steel clips.

Item 2 above is the hose stream dislodgment criterion. This criterion is not well defined in any text on this subject; however, API Recommended Practice 521,[6] section 3.12.2.2, states the following:

> The finished installation should ensure that the insulation will not be dislodged when subjected to the fire-water streams used for fire fighting, such as streams from hand lines or monitor nozzles, if installed.

Most insulations used in fire protection applications can withstand this criterion if jacketed and banded in place as described in the explanation of item 1 above.

Item 3 above requires a maximum conductance of 4.0 Btu/(h · ft^2 · °F) (W/m^2). Any insulation material suitable for use as fire protective insulation can meet this criterion.

Prior to specifying any insulation or accessory product material in a fire protection application, it is important to consult with the technical service department of the manufacturer and be advised of any special precautions that may be necessary.

Noise Control

Environmental acoustics is something that can be addressed in thermal insulation system design; however, serious noise problems should be treated as a separate and independent study. For the purpose of preliminary investigation, it is useful to know some basic concepts.

Sound absorption is both a process and a property of materials. Sound absorption is the process of dissipating sound energy as well as the property possessed by materials, objects, and structures, such as rooms, of absorbing sound energy. Sound attenuation is the reduction of the intensity of sound as it travels from the source to a receiving location.[2]

In thermal insulation design, sound attenuation is a natural by-product of the insulation application. Some insulation materials and accessory products provide greater sound attenuation due to their sound absorption characteristics than others. One of the best thermal insulation materials for sound attenuation is mineral wool. It is available in loose fill, rolls, blankets, boards, and preformed shapes. Therefore it can be applied in numerous different applications where sound absorption is a desired property of the insulation being applied.

The jacketing material used to cover the insulation can play an important role

in sound attenuation. For example, a fabric reinforced mastic finish over insulation has better sound absorption properties than does a metal jacket. The environment in which the materials are being used will limit their ability to be considered for sound attenuation characteristics in some cases; however, with composite system design in the planning stage of the process, a combination of materials can often be arranged to provide both thermal and acoustical benefits.

DESIGN CONDITIONS

In addition to defining the purpose of the insulation system, it is important to define the conditions under which the insulation system will be used. Some of the conditions to be considered are

- Indoors or outdoors
- Conditioned space or nonconditioned
- Geographic location (coastal regions, northern climes, southern climes, rainy, dry, etc.)
- Long, straight runs or frequent bends
- Personnel traffic area or unaccessible
- Aboveground or below ground

Numerous conditions or combinations of conditions require consideration in insulation system design. The above list represents just a few of the more obvious ones. Most of these are self-explanatory; however, some require some attention to detail. Following is a brief explanation of each item.

Indoors or Outdoors

Indoor applications, in general, are much simpler to specify than outdoor applications. The main reason for this difference is that indoor applications are not subjected to rain, snow, and solar loads. Indoor applications are subjected to vapor pressure differential problems, as are outdoor; however, this problem is not complicated by the other environmental difficulties, as the outdoor applications are. The reason that rain, snow, and solar loads are such a problem with insulation systems is moisture migration. The single most detrimental element in any insulation system is the migration of moisture into the insulation system. Water in insulation destroys the insulating value. Approximately 4 percent moisture by volume in an insulation material will increase the thermal conductivity by as much as 70 percent.[7]

Thermal insulations must be dry to function according to design. Water in the insulation causes part of or all the air spaces and gas spaces in the insulation to be filled with water. Its conductivity then approaches that of water instead of that of air or gas. The thermal conductivity of water at 70°F (21°C) is 4.1 Btu · in/(h · ft^2 · °F) (0.59 W/mK, compared to 0.17 Btu · in/(h · ft^2 · °F) (0.0245 W/mK) for air. The heat transmission, therefore, is about 24 times greater for water saturated insulation than for dry insulation.[1]

In addition to this significant drop in thermal performance of the insulation, water in insulation when in contact with metal piping can significantly increase the chance of, and even contribute to, severe corrosion problems. Water and snow,

therefore, should be avoided; every precaution should be taken to prevent moisture entry into the system. This is another reason why solar loads present problems in outdoor insulation systems.

As mentioned in the section addressing personnel protection, solar loads on the surface of the insulation can significantly increase its surface temperature, therefore increasing the risk of injury to personnel.

In addition to increasing surface temperature, solar loads on the surface of the insulation cause expansion and contraction of metal jacketing and premature aging of mastic finishes. The expansion and contraction of metal can cause joints to open up or "fish-mouth," creating paths for water to enter. They can also cause a gradual loosening up of the bands, leading to a movement of the jacket or loss in high-wind conditions. Premature aging of mastic finishes can lead to cracks or pits in the finish, which also creates a path for water migration into the insulation system.

When designing for indoor or outdoor applications, consideration must be given to the environmental conditions that the system will be subjected to.

Conditioned Space or Nonconditioned Space

This application differs slightly from that of indoor and outdoor in that either space would be considered indoor; however, nonconditioned space is not climate controlled. This has the advantage of not having to worry about liquid water or solar loads; however, the vapor pressure driving force is still present. This driving force can have a significant detrimental effect on chilled water and other low-temperature piping insulation systems. Water vapor tends to migrate in the direction of the coldest surface. Therefore, any below ambient piping application will have a positive water vapor pressure in the direction from the outside of the insulation to the surface of the pipe. Example B7.1 illustrates how this might occur on a chilled water pipe in the unconditioned space of a commercial building in a relatively temperate climate.

Example B7.1. *Chilled Water Pipe Insulation Water Intake.* In this illustration, a calculation is done to show how a typical chilled water pipe insulated with 2 in (51 mm) of polyurethane insulation might become saturated with water simply due to the water vapor driving force generated by the ambient conditions around the pipe and the operating conditions of the pipe.

Calculation for Amount of Condensation per Linear Foot of Piping per Year:

	Nominal	Actual
Outside diameter (OD) of pipe:	NPS 2 (DN 50)	2.375 in (60 mm)
Service temperature:	41°F (5°C)	
Ambient air temperature:	70°F (21.1°C)	
Ambient air relative humidity:	70%	
Insulation thickness:	2-in (51-mm) nominal polyurethane	
OD of polyurethane insulation:	6.63 in (168.4 mm)	
Outside finish:	All service vapor retarding (ASJ; formerly vapor barrier jacket): permeance = 0.6 perm	
Permeability of polyurethane:	4.321 perm · in (10.96 perm · cm)	

Water vapor flow:

$$G = \frac{\Delta P}{R_{\text{vapor}}}$$ (B7.4)

where

G = water vapor flow

ΔP = water vapor pressure difference, inches of mercury (inHg) (mmHg)

R_{vapor} = resistance to vapor diffusion for any given material, 1 inch/perm (1 cm/perm) or μ

$$= \frac{\text{thickness}}{\text{permeability}} = \frac{\text{in} \cdot \text{ft}^2 \cdot \text{h} \cdot \text{inHg}}{\text{gr} \cdot \text{in}} = \frac{\text{mm} \cdot \text{cm}^2 \cdot \text{h} \cdot \text{mmHg}}{\text{gr} \cdot \text{mm}}$$

$$= \frac{1}{\text{permeance}} = \frac{\text{ft}^2 \cdot \text{h} \cdot \text{inHg}}{\text{gr}} = \frac{\text{cm}^2 \cdot \text{h} \cdot \text{mmHg}}{\text{gr}}$$

Calculation for Pressure Drop across Insulation System:

P_r in ambient air = real partial pressure of water vapor in air

$$= R_H \times P_s$$ (B7.5)

P_s = partial pressure of water vapor in saturated air

R_H = relative humidity = 0.07

At 70°F (21° C)

$$P_s = 0.73964 \text{ inHg}^{\dagger} (18.79 \text{ mmHg})$$

$P_r = 0.7$ (relative humidity of 70%) $\times 0.73964$ inHg (18.79 mmHg)

$$= 0.517748 \text{ inHg} (13.15 \text{ mmHg})$$

So with a real pressure at 70 percent relative humidity of 0.517748 inHg (13.15 mmHg), the dew point temperature t_s is found to be

$$t_s = 59.8°\text{F} (15.3°\text{C})$$

At 41°F (5°C),

$$P_s = 0.25765 \text{ inHg} (6.544 \text{ mmHg})$$

Therefore,

$$\Delta P = P_r - P_s = 0.517748 \text{ inHg} - 0.25765 \text{ inHg}$$

$$= 0.26010 \text{ inHg} (6.61 \text{ mmHg})$$ (B7.6)

---

†See Ref. 8.

From here, the actual thickness of insulation on the insulated pipe must be converted to an equivalent thickness of insulation in flat-plane geometry, in order to be used further in the calculation.

Equivalent Thickness of Insulation:

$$\text{Equiv. thickness} = \frac{OD}{2} \ln \frac{OD \text{ insulation}}{OD \text{ pipe}}$$

$$= \frac{6.63 \text{ in}}{2} \ln \frac{6.63 \text{ in}}{2.375 \text{ in}} = \frac{168.4 \text{ mm}}{2} \ln \frac{168.4 \text{ mm}}{60.33 \text{ mm}} \quad (B7.7)$$

$$= 3.403 \text{ in} = 86.4 \text{ mm}$$

Total Resistance against Water Vapor Diffusion.   Determining the total resistance against water vapor diffusion is simply a matter of adding the total resistances from materials in the path of the vapor flow. This is calculated as follows for the vapor retarder:

$$R_{\text{vapor}} = \frac{1}{0.6 \text{ perm}} = 1.667 \frac{1}{\text{perm}} \qquad \text{(either units)}$$

and for thermal insulation:

$$R_{\text{vapor}} = \frac{3.403}{4.321} = 0.788 \text{ in/(perm} \cdot \text{in)} = 0.788 \text{ cm/(perm} \cdot \text{cm)}$$

Therefore, the total resistance

$$R_{\text{vapor}} = R_{\text{vapor}} \text{ (vapor retarder)} + R_{\text{vapor}} \text{ (thermal insulation)}$$

$$= 1.667 \frac{1}{\text{perm}} + 0.788 \frac{1}{\text{perm}} \qquad (B7.8)$$

$$= 2.455 \frac{1}{\text{perm}}$$

Now, given ΔP and R_{vapor}, we solve for G (water vapor flow) as follows, using Eqs. (B7.4), (B7.6), and (B7.8):

$$G = \frac{0.26010 \text{ inHg}}{2.455 \text{ perm}} = 0.1059 \text{ inHg} \cdot \text{perm} = 2.7 \text{ mmHg} \cdot \text{perm}$$

And

$$1 \text{ perm} = 1 \frac{\text{gr}}{\text{ft}^2 \cdot \text{h} \cdot \text{inHg}} = \frac{\text{ngr}}{\text{Pa} \cdot \text{s} \cdot \text{m}^2}$$

$$= 0.1059 \frac{\text{gr}}{\text{ft}^2 \cdot \text{h}} = 2.7 \frac{\text{ngr}}{\text{m}^2 \cdot \text{s}}$$

At this point the total vapor flow has been calculated and determined to be

$$0.1059 \frac{\text{gr}}{\text{ft}^2 \cdot \text{h}} = 2.7 \frac{\text{ngr}}{\text{m}^2 \cdot \text{s}}$$

The next step is to calculate the outside surface area in order to express the results in terms of square feet per lineal foot of insulation.

Calculation for the Outside Surface of Insulation Expressed in Square Feet per Lineal Foot:

$$6.63 \text{ in} \times \pi \times 12 \text{ in/ft} = 249.945 \text{ in}^2/\text{lin ft}$$

$$168.4 \text{ mm} \times \pi \times 1000 \text{ mm/m} = 592{,}044 \text{ mm}^2/\text{m}$$

or

$$\frac{249.945}{144} = 1.735 \text{ ft}^2/\text{lin ft} = \frac{592{,}044 \text{ mm}^2}{1{,}000{,}000} = 0.6 \text{ m}^2/\text{m}$$

And finally the calculation for the migration of water vapor that condenses in the system per year and per lineal foot of piping reveals the following:

Total water migration $=$ water vapor flow $G \times$ surface area per lineal foot $\times$

$$\text{hours/day} \times \text{days/year}$$

$$= 0.1059 \text{ gr/(ft}^2 \cdot \text{h}) \times 1.736 \text{ ft}^2/\text{ft} \times 24 \text{ h/d} \times 365 \text{ d/yr}$$

$$[2.7 \text{ ngr/(m}^2 \cdot \text{s}) \times 0.6 \text{ m}^2/\text{m} \times 86{,}400 \text{ s/d} \times 365 \text{ d/yr}]$$

$$= 1610.46 \; \frac{\text{ngr}}{\text{yr} \cdot \text{lin ft}} \quad \left(5.1 \times 10^7 \frac{\text{ngr}}{\text{yr} \cdot \text{lin m}} \right) \qquad \text{(B7.9)}$$

since

$$1 \text{ gr} = 1 \text{ lb/7000} \qquad (64.8 \text{ mg})$$

and

$$1 \text{ lb} = 16 \text{ oz}$$

Therefore,

$$\frac{1610.46 \times 16}{7000} = 3.681 \frac{\text{gr} \cdot \text{lb} \cdot \text{oz}}{\text{yr} \cdot \text{lin ft} \cdot \text{gr} \cdot \text{lb}}$$

Or the total amount of water that can pass through the existing water vapor retarder and the thermal insulation system in this illustration equals:

$$3.681 \; \frac{\text{oz}}{\text{yr} \cdot \text{lin ft}} \qquad \left(104{,}354 \; \frac{\text{mg}}{\text{yr} \cdot \text{lin m}} \right)$$

As represented above in this example, a large amount of moisture can be accumulated in an insulation medium over a relatively short time if the insulation system is not designed to prevent the ingress of water vapor. Even with the best application procedures, incorrect materials selection for the environment or service requirements can have very dramatic results in terms of performance losses and maintenance costs.

Geographic Location

The geographic location of the system being insulated is very important to factor into the design process. The National Weather Service has information available for climates all over the world. Seasonal averages, worst case conditions, annual rainfall, average and worst case humidities, and any other climatic data needed should be fully evaluated during the specification process.

Long, Straight Runs or Frequent Bends

The layout of the piping with respect to bends and straight runs needs to be considered for the purpose of expansion and contraction control. Depending on the temperature range of the process piping being insulated, expansion and contraction joints in the insulation system may need to be employed.

The differential expansion between the metal substrate of the pipe and the insulation can have critical significance depending on the length of the pipe run. Table B7.3 lists different metals and their expansion and contraction in inches per 100 ft through various temperature ranges. It is clear that on long runs of piping, provision must be made for differential expansion between the insulation and the pipe. This is accomplished through the use of control joints or expansion joints. Many different types of control joints are used in insulation specifications. One system for controlling contraction on cold piping is illustrated in Fig. B7.8. It is advisable to consult the insulation manufacturer for more specific recommendations which are application-dependent.

TABLE B7.3 Thermal Expansion and Contraction Properties

| Operating temperature (°F) | in/100 ft | | | | | | |

* Material not recommended for use in this temperature range.

† Material requires special precautions for use in this temperature range. Consult manufacturer for recommendations.

‡ Calcium silicate experiences a maximum of 2 percent shrinkage at 1200°F and less than that at lower temperatures. Calcium silicate manufacturers recommend that their materials be double-layered for operating temperatures greater than 500°F due to shrinkage cracks that form.

§ ASTM C547, *Standard Specification for Mineral Fiber Preformed Pipe Insulation,* indicates linear shrinkage as below 2 percent in accordance with the recommended temperature limits. Vitrification and compaction of binder materials may occur at elevated temperatures.

NIA: no information available.
FIGURE B7.8   Cross-section of a contraction control joint.

Personnel Traffic Area

High traffic areas require insulation that can take abuse. Although it is standard practice to install "Do Not Walk on Pipe" signs anywhere this might occur, the real-world situation is that people walk on insulated pipes. It is important, therefore, to consider the use of high compressive strength insulations and/or heavy duty jacketing or membrane covering in these areas.

Aboveground or Below Ground

Aboveground insulation applications can be complicated and require thorough design evaluation and analysis for proper specification. Below ground applications are very complicated, and mistakes can be extremely costly. It is absolutely essential that every possible condition be considered and a thorough analysis of all variables be done.

The two most common means for accommodating underground piping applications that require thermal insulation are precast trenches and direct burial.

Precast Trenches.   Precast trench systems provide a tunnel underground for the piping to be channeled through. In this type of application, the insulation system is generally designed exactly as it would be for an aboveground application. No special precautions are taken for expansion and contraction of the pipe because it is allowed to move freely within the trench, as any aboveground piping system would. The most important factor to keep in mind when designing an underground precast trench system is the groundwater.

Groundwater infiltration into the trench, depending on its magnitude can cause the piping system to become completely surrounded by water for extended periods. This can cause irreparable damage to protective membranes, it can cause the insulation to become saturated and literally fall off the pipe, and it can lead to serious

corrosion problems. Consideration should be given to the use of impermeable-type insulation materials with sealants, adhesives, and covering materials appropriate for the service temperature of the piping being insulated.

Direct Burial.   In direct-burial thermal insulation applications, most commonly, four types of systems are employed.

   1. Preinsulated.   Preinsulated piping systems for underground direct-burial applications generally consist of either plastic or steel piping which is covered with a foamed-in-place polyurethane insulation and then a high-impact-resistant formed plastic covering.

   This type of application would look in cross section very much like the cross section shown in Fig. B7.1. These types of systems are most commonly employed in hot water and chilled water piping services. They are not recommended for use on steam lines owing to the temperature limitations of the insulation. They can be used on condensate return lines; however, caution must be exercised to avoid overheating. Some condensate return lines are used to evacuate steam which might be released from the primary steam supply line if there is a pressure relief requirement. If this occurs one time on a preinsulated piping system, it can permanently affect the performance of the insulation and its protective coverings.

   2. Preinsulated Conduit with Annulus Airspace.   Preinsulated conduit with annulus airspace (conduit systems) has for many years been the primary system used for steam lines by the U.S. government. Thorough analysis of underground direct-buried piping systems during the late 1950s and the 1960s revealed that almost no insulation system performed well. The reason was that groundwater infiltration into the insulation materials was able to get close enough to the piping to vaporize, and the underground steaming caused everything to deteriorate. This led to the development of a system that provided an airspace which theoretically allowed any moisture that might enter the system to vent out of the system, enabling the insulation to dry out after saturation. Figure B7.9 shows a cross section of a conduit system.

   In actual application, it has been found that the annulus airspace is relatively ineffective in providing good moisture venting. However, these systems are still employed in many areas where high-temperature piping must be run underground and groundwater penetration is a concern.

   3. Field-Installed.   Field-installed insulation systems are one of the most cost-effective ways to insulate high-temperature lines which must be run underground. The most common material used for field installation is cellular glass, which can be used for operating temperatures up to 900°F (482°C). Cellular glass has a closed cell glass structure which resists penetration from any groundwater present. It is usually covered with an asphaltic membrane and sealed with sealants appropriate for the temperature range of the service piping.

   With any of the above three direct-burial piping systems, it is very important to consider the location of all pipe anchors, in-line guides, and expansion loops. A thorough pipe stress analysis must be performed to avoid uncontrolled pipe movement, which will destroy any underground thermal insulation system. It is also extremely important to provide good drainage for the piping to try to minimize the potential of groundwater infiltration. Figure B7.10 illustrates this type of drainage recommendation. It is best to consult individual manufacturers for their recommendations with respect to application and design.

   4. Pour-in Loose Fill.   The most common type of pour-in loose-fill insulation for underground applications is calcium carbonate powder. This type of loose-fill insulation is poured directly into the trench after the pipe is in position. The pipe is propped up off the ground with wooden blocks to allow the calcium carbonate
FIGURE B7.9   Cross-section of a conduit system.
FIGURE B7.10   Backfill detail.

powder to fill in underneath. The powder is then tamped into place with a mechanical tamper. The plastic bags that the powder comes in are placed on top of the calcium carbonate prior to backfilling, to help prevent the migration of water into the insulation.

Having the above design parameter information available will allow the specifying engineer to make an educated decision about the thickness for the insulation system used. There are a number of useful sources for information on calculating insulation thickness requirements for various applications. A few of the more common sources for this type of information are:

- *ASHRAE Fundamentals Handbook*[8]
- *Annual Book of ASTM Standards,* volume 4.06, *Thermal Insulation; Environmental Acoustics*[2]
- *Thermal Insulation Handbook*[9]

Some examples of heat flow calculations are as follows: Example. B7.2 shows how heat gain would be calculated on a typical chilled water pipe in an enclosed space (representing commercial or institutional type of construction).

Example B7.2   Typical Chilled Water Pipe Calculation

Pipe size:	NPS 2 (DN 50)
	2.375 = in (60 mm) actual OD
Operating temperature:	42°F (5.5°C)
Ambient temperature:	95°F (35°C)
Insulation thickness:	2 in (51 mm) nominal
	2.11 in (54 mm) actual
Insulation type:	Cellular glass
Length of pipe:	120 lineal ft (36.5 m)

From Eq. (B7.2),

$$Q = \frac{2\pi \, K L (T_i - T_s)}{R_o \ln (R_o/R_i)}$$

where K = 0.277 Btu $\cdot$ in (h $\cdot$ ft^2 $\cdot$ °F) = 0.0225 Btu/(h $\cdot$ ft $\cdot$ °F) (at 50°F mean temp.)
[0.039 W/(m^2 $\cdot$ K) = 0.0038 W/(m $\cdot$ K)]
T_i = 42°F (5.5°C)
T_s = 95°F (35°C)
R_i = 2.375 in/2 (60 mm/2)
R_o = (6.62 in/2) (168 mm/2)

$$Q = \frac{2\pi [0.0255 \text{ Btu}/(\text{h} \cdot \text{ft} \cdot \text{°F})](120 \text{ ft})(42\text{°F} - 95\text{°F})}{6.62 \ln [(6.62/2) \text{ in}/(2.375/2) \text{ in}]}$$

$$= \frac{6.2832(0.0255 \text{ Btu/h})(120)(-53)}{6.62 \ln (3.31/1.1875)}$$

$$= \frac{-1019.0 \text{ Btu/h}}{6.786} = -150.2 \text{ Btu/h}$$

Next, to determine the relative heat transfer with respect to area, the following calculation is used:

$$\text{Circumference} = \pi d = 3.14159(6.62 \text{ in}) = 20.80 \text{ in}$$

$$\text{Area} = \text{circumference} \times \text{length} = (20.80 \text{ in})(120 \text{ ft} \times 12 \text{ in/ft})$$

$$= 29{,}952 \text{ in}^2 = 208 \text{ ft}^2$$

So

$$-150.2 \text{ Btu/h}/208 \text{ ft}^2 = -0.72 \text{ Btu/(h} \cdot \text{ft}^2)$$

In this calculation, the minus sign in the final result indicates that the heat flow is in the direction of the pipe rather than away from the pipe. Therefore, there is a 0.72 Btu/(h · ft^2) heat gain in this illustration. And 0.72 Btu/(h · ft^2) is much greater than what would typically be employed for an application of this type, because chilled water piping cannot usually create a serious process upset condition. The thickness selected, therefore, is greater than is necessary, and further exploration of thickness requirements is needed.

The minimum thickness for cellular glass on a 2-in nominal pipe size pipe is 1 in (specified by cellular glass insulation manufacturers as a limiting factor for handling and durability). The calculation performed again using 1 in of cellular glass instead of 2 in reveals the following:

$$R_i = 2.375 \text{ in}/2 \qquad R_o = 4.50 \text{ in}/2$$

$$Q = \frac{2\pi [0.0255 \text{ Btu/(h} \cdot \text{ft} \cdot {}^\circ\text{F})](120 \text{ ft})(42{}^\circ\text{F} - 95{}^\circ\text{F})}{4.5 \ln [(4.50 \text{ in}/2)/(2.375 \text{ in}/2)]}$$

$$= \frac{6.2832(0.0255 \text{ Btu/h})(120)(-53)}{4.5 \ln (2.25/1.1875)}$$

$$= \frac{-1019.0 \text{ Btu/h}}{2.875} = -354.4 \text{ Btu/h}$$

Next, to determine the relative heat transfer with respect to area, the following calculation is used:

$$\text{Circumference} = \pi d = 3.14159(4.50 \text{ in}) = 14.14 \text{ in}$$

$$\text{Area} = \text{circumference} \times \text{length} = (14.14 \text{ in})(120 \text{ ft} \times 12 \text{ in/ft})$$

$$= 20{,}362 \text{ in}^2 = 141.4 \text{ ft}^2$$

So

$$\frac{-354.4 \text{ Btu/h}}{141.4 \text{ ft}^2} = -2.51 \text{ Btu/(h} \cdot \text{ft}^2)$$

A heat gain on chilled water piping of 2.51 Btu/(h · ft^2) is still conservative with respect to process control [it is typically 8 to 10 Btu/(h · ft^2) (25 to 31.5 W/m^2)]. The minimum thickness for this application therefore equals 1 in of cellular glass insulation.

Example B7.3 is a calculation of heat loss on a typical steam piping application.

Example B7.3   Typical Steam Pipe Calculation

Pipe size: NPS 6 (DN 150)
                                6.625 in (168 mm) actual OD
Operating temperature: 400°F (204°C)
Ambient temperature: 75°F (24°C)
Insulation thickness: 2 in (51 mm) nominal
                                2.11 in (54 mm) actual
Insulation type: Calcium silicate
Length of pipe: 75 lineal ft (22.8 m)

Using Eq. (B7.2) gives

$$Q = \frac{2\pi K L (T_i - T_s)}{R_o \ln (R_o / R_i)}$$

where $K = 0.501$ Btu $\cdot$ in (h $\cdot$ /ft^2 $\cdot$ °F) [0.072 W/(m $\cdot$ K)] (at 165°F mean temp.)
    $T_i = 400$°F (204°C)
    $T_s = 75$°F (24°C)
    $R_i = 6.625$ in/2 (168 mm/2)
    $R_o = 10.75$ in/2 (273 mm/2)

$$Q = \frac{2\pi [0.501 \text{ Btu}/(\text{h} \cdot \text{ft} \cdot °F)](75 \text{ ft}) (400°F - 75°F)}{10.75 \ln [(10.75/2)/(6.625/2)]}$$

$$= \frac{76,729.5 \text{ Btu}/(\text{h} \cdot \text{ft})}{5.2 \text{ ft}} = 14,755.6 \text{ Btu/h}$$

Therefore,

$$\frac{14,755.6 \text{ Btu/h}}{75 \text{ ft}} = 196.7 \text{ Btu}/(\text{h} \cdot \text{ft})$$

$$\text{Circumference} = \pi d = 3.14159(10.75 \text{ in}) = 33.77 \text{ in}$$

Therefore, the total surface area per lineal foot of insulation equals

$$\text{Circumference} \times 12 \text{ in/ft} = 405.27 \text{ in}^2/\text{lin ft}$$

and

$$\frac{405.27 \text{ in}^2}{144 \text{ in}^2/\text{ft}} = 33.72 \text{ ft}^2/\text{ft}$$

$$\text{Heat loss} = \frac{196.7 \text{ Btu}/(\text{h} \cdot \text{ft})}{2.81 \text{ ft}^2/\text{ft}}$$

$$= 70 \text{ Btu}/(\text{h} \cdot \text{ft}^2)$$

For most hot processes, both from a process control perspective and accounting for personnel protection, a desirable heat-loss range is between 100 and 150 Btu/(h $\cdot$ ft^2). Since 70 Btu/ (h $\cdot$ ft^2) is well below this rough guideline, it becomes necessary

to perform the calculation again. Solving for the same parameters with 1.5 of calcium silicate instead of 2 in reveals the following:

$$Q = \frac{2\pi[0.501 \text{ Btu/(h} \cdot \text{ft} \cdot °\text{F)}](75 \text{ ft})(400°\text{F} - 75°\text{F})}{9.62 \ln[(9.62/2)/(6.625/2)]}$$

$$= \frac{76,729 \text{ Btu/(h} \cdot \text{ft})}{3.58 \text{ ft}} = 21,432.7 \text{ Btu/h}$$

Therefore,

$$\frac{21,432.7 \text{ Btu/h}}{75 \text{ ft}} = 285.7 \text{ Btu/(h} \cdot \text{ft})$$

We solve for the surface area per lineal foot of insulation:

$$\text{Circumference} = \pi d = 3.14159(9.62 \text{ in}) = 30.22 \text{ in}$$

$$\frac{\text{Area}}{\text{Linear ft}} = \text{circumference} \times 12 \text{ in/ft} = 362.66 \text{ in}^2/\text{lin ft} = 2.51 \text{ ft}^2/\text{ft}$$

Therefore, the heat loss per square foot of surface area with the minimum amount of calcium silicate insulation is [285.7 Btu/(h · ft)] / (2.51 ft²/ft)=113.8 Btu/(h · ft²).

SERVICE CONSIDERATIONS

One other area that needs to be considered when properly designing an insulation system is the service that the piping is providing. Service is very important in designing insulation systems because of the different physical properties of the contents of the pipe. The following are some, but not all, generalized service types that are common to industrial and commercial construction:

- Hot water and chilled water
- Steam and condensate return
- Heat-transfer fluids
- Hot oils
- Liquefied gas (cryogenic service)
- Sanitary and sewerage water

Hot Water and Chilled Water. Hot water and chilled water lines are generally employed in commercial and institutional facilities as a means of providing climate control. The heated or cooled water is transported through a pipe loop system from the mechanical facilities room of the building or buildings and is used as a heat-transfer medium to provide either heating or cooling.

Geographic location is a very important consideration for this type of service. Insulation systems for chilled water piping in the state of Florida are very susceptible to problems with moisture infiltration. Insulation system design in this environment is of critical importance. The correct application of closed-cell impermeable insulation materials and highly flexible joint sealants with a vapor retarding membrane

is necessary to the success of the entire mechanical system operation. Incorrect application and specification in an environment like this can cost thousands of dollars in mechanical system maintenance and repair, water damage from soggy, dripping insulation, and high utility costs from overworking the mechanical systems. In very dry, or arid, regions of the world, critical attention to the materials is not as paramount. Water vapor is not as great a threat.

Steam and Condensate Return. Steam and condensate return lines will operate without insulation. Therefore, the chance of a process failure or process upset condition due to a poorly insulated steam line is rather small. However, the savings that can be achieved by properly insulating steam lines are substantial. This is graphically illustrated in Fig. B7.8 in a heat loss comparison of an uninsulated surface and an insulated surface.

Before the energy crisis of the mid-1970s, most steam lines that were insulated were done so without consideration of energy costs. The main purpose was to protect personnel from the extreme temperatures of the surface of a bare steam line. These personnel protection insulation thicknesses, many of which are still in use today, are not adequate for providing optimum energy conservation. One technique used somewhat commonly today to increase energy conservation is often referred to as *retrofitting* the existing insulation system. A retrofit procedure involves the use of composite insulation systems and/or materials. To retrofit in this sense of the word is to take the existing insulation system that may have been underdesigned at the time and add an extra layer of insulation.

There are several benefits that can be obtained by retrofitting insulation in this fashion. First, the additional insulation will reduce energy consumption; therefore, operating costs will go down. Second, the increased insulation thickness will provide better personnel protection due to a significantly lowered surface temperature. And third, but most importantly, by creating a retrofit system, there is an opportunity to take advantage of the optimum performance benefits of more than one material. An illustration of this ability to optimize efficiencies is given below.

Figure B7.11 shows the crossover point between thermal conductivity and mean operating temperature of two common industrial thermal insulation materials: cellu-
FIGURE B7.11 *K*-value crossover.
FIGURE B7.12   Cross-section of a retrofit system.

lar glass and calcium silicate. Figure B7.12 shows a cross-sectional view of what a typical retrofitted insulation system might look like and where the interface temperature will occur.

In this illustration, the crossover point of the two curves shows the ideal temperature at which each material's thermal performance characteristics can be maximized. The two curves cross over at a mean temperature of about 225°F (107°C). This shows that the cellular glass insulation has better thermal performance for mean operating temperatures at or below 225°F (107°C) and that the calcium silicate has better thermal performance for mean operating temperatures above 225°F (107°C). To maximize the performance of both materials, they can be used together in a composite retrofit system.

To use these two materials together and maximize their performance, the optimum interface temperature must be determined. The interface temperature is the point at which the two layers of insulation meet. Given that the crossover point between the two materials is at 225°F (107°C), the interface temperature can be determined by the calculation shown in Example B7.4.

Example B7.4   Desired Interface Temperature Calculation

Mean temperature = average temperature across insulation layer

In this example,

$$\text{Mean temperature} = \frac{\text{interface temperature} + \text{ambient temperature}}{2}$$

where mean temperature = 225°F (107°C)
  ambient temperature = 70°F (21°C)

Therefore,

$$225°\text{F} = \frac{\text{interface temperature} + 70°\text{F}}{2}$$

$$2(225°\text{F}) = \text{interface temperature} + 70°\text{F}$$

$$2(225°\text{F}) - 70°\text{F} = \text{interface temperature}$$

$$\text{Desired interface temperature} = 380°\text{F} \quad (193°\text{C})$$

Determining the appropriate thickness for the new retrofitted layer of insulation, in this case cellular glass, is an iterative process. Knowing that the interface temperature should be approximately 380°F (193°C) provides a target point to work toward. The following example shows the calculation process by which the correct thickness can be determined.

Example B7.5   Retrofit Layer Thickness Calculation.   In this example the following theoretical conditions will be employed:

Pipe size:	NPS 8 (DN 200), 8.625 in (219 mm) actual OD
Operating temperature:	600°F (315.5°C)
Ambient temperature:	70°F (21°C)
Calcium silicate thickness:	2 in (51 mm) nominal, 2.02 in (51.3 mm) actual

Equation (B7.5) will be used to find the actual interface temperature with the initial assumed insulation thickness of 2 in for the first iteration.

$$t_1 = t_i - Q \frac{R_s \ln (R_1/R_i)}{k_1} \tag{B7.10}$$

where Q = heat loss, Btu/(h · ft²)
  t_i = temperature of inner surface = 600°F (315.5°C)
  t_1 = temperature of interface between layers, °F (°C)
  t_s = temperature of ambient air = 70°F (21°C)
  R_i = inner radius of first layer = 4.3125 in
  R_1 = outer radius of first layer and inner radius of second layer = 6.375 in
  R_s = outer radius of second layer = 8.50 in
  k_1 = thermal conductivity of first layer
    = 0.52 Btu · in (h · ft² · °F) [0.075 W/(m · K)]
  ln = natural logarithm
  $1/f$ = surface resistance factor = 0.53 (approximated from Fig. B7.3)

In solving for interface temperature t_2, the heat loss Q of the total retrofitted system must first be calculated. Using Eq. (B7.3), the heat loss for the first trial,

assuming the initial iteration for the second layer with a nominal insulation thickness of 2 in, is as follows:

$$Q = \frac{t_i - t_s}{\dfrac{R_s \ln (R_1/R_i)}{k_1} + \dfrac{R_s \ln (R_s/R_1)}{k_2} + \dfrac{1}{f}} \qquad \text{(B7.11)}$$

where k_2 = thermal conductivity of second layer
$\quad\quad$ = 0.42 Btu · in/(h · ft^2 · °F) [0.061 W/(m · K)]

Thus

$$Q = \frac{600°\text{F} - 70°\text{F}}{\dfrac{8.50 \ln (6.375 \text{ in}/4.3125 \text{ in})}{0.52 \text{ Btu} \cdot \text{in}/(\text{h} \cdot \text{ft}^2 \cdot °\text{F})} + \dfrac{8.50 \ln (8.50 \text{ in}/6.375 \text{ in})}{0.42 \text{ Btu} \cdot \text{in}/(\text{h} \cdot \text{ft}^2 \cdot °\text{F})} + 0.53}$$

$$= \frac{530°\text{F}}{12.74 \text{ Btu}/(\text{h} \cdot \text{ft}^2 \cdot °\text{F})} = 41.60 \text{ Btu}/(\text{h} \cdot \text{ft}^2)$$

Therefore,

$$t_2 = 600°\text{F} - 41.60 \frac{(8.50 \text{ in}) \ln (6.375 \text{ in}/4.3125 \text{ in})}{0.52 \text{ Btu} \cdot \text{in}/(\text{h} \cdot \text{ft}^2 \cdot °\text{F})}$$

$$= 334.20°\text{F} \quad (168°\text{C})$$

Since this is lower than the desired interface temperature of 380°F (193°C), the iteration process can end at this step. To truly maximize the efficiency of the cellular glass and the calcium silicate, the next step would be to perform a second or third calculation with increasing thicknesses until an interface temperature at, or around, 380°F (193°C) is obtained. For this trial, however, the thickness of cellular glass used, 2 in, was sufficient to obtain a heat loss of 41.60 Btu/(h · ft^2) (131 W/m^2) which is well below what would normally be considered acceptable by today's standards for heat loss. If the interface temperature had come out greater than what was tried on the first iteration, the next step would have been to try again with a smaller thickness.

With an interface temperature of 334.2°F (168°C), the mean temperature can be recalculated to determine how close to the thermal conductivity crossover point the 2-in thickness provided. As shown above,

$$\text{Mean temperature} = \frac{\text{interface temperature} + \text{ambient temperature}}{2}$$

where interface temperature = 334.2°F (167.8°C) and ambient temperature = 70°F (21.1°C).

Therefore,

$$\text{Mean temperature} = \frac{334.2°\text{F} + 70°\text{F}}{2}$$

$$= 202.1°\text{F} \quad (94.5°\text{C})$$

This shows that the mean temperature across the outer layer of insulation is 202.1°F (94.5°C) which is only slightly below the crossover point.

Many old steam lines are insulated with a minimal amount of calcium silicate

insulation. As mentioned earlier in this chapter, this was done during times when there was not a heightened sense of insulation awareness. For these types of applications, this retrofitting option is a very efficient way to revitalize old insulation systems.

Heat-Transfer Fluids. Heat-transfer fluids are liquids that are used as a means of providing process control. These liquids are generally thermally stable fluids. They can be heated or cooled to a given design temperature and transported to its desired process control point while maintaining temperature stability. Insulation system design for heat-transfer fluids must take into account the temperature range that the fluid will be operating at and whether it is a constant temperature or a cyclical temperature.

Many catalyst reaction reactor vessels operate at temperatures that swing from as low as −60°F (−51°C) to as high as 450°F (232°C). This type of cyclical service presents a complicated insulation system design dilemma. Generally, insulation systems are designed to withstand the rigid environmental and process temperature conditions at either hot or cold operating conditions. When the operating conditions are both hot and cold, a thorough study of all possible combinations of ambient conditions and operating variabilities must be conducted.

In cold process applications, the insulation materials specified are usually either plastic foam insulation or cellular glass insulation. In hot process applications, the insulation materials specified are usually mineral fiber insulation, calcium silicate insulation, or cellular glass insulation.

In applications where process temperatures swing from below ambient to hot process over the course of an operating cycle, the insulation system needs to be designed to account for both ends of the cycle. These applications are typically insulated with double or multiple layers of insulation material. It is important to insulate with the proper thickness. The critical aspect of this calculation is that the thickness must be calculated to achieve a thermal gradient in the hot condition that will not cause damage to the joint sealant in the outer layer that is necessary for the cold end of the process. Careful consideration of the appropriate sealants, adhesives, and accessory materials for the process must be given. It is advisable to consult with insulation manufacturer's technical support groups for recommendations for these types of processes.

Another important consideration in specifying insulation systems for heat-transfer fluids is fire safety. Many of the common heat-transfer fluids, whether organic or inorganic, can present a very serious fire hazard if they are absorbed into a permeable insulation material. It has been shown that some of these fluids, although thermally very stable at their peak operating temperatures, become much less so when absorbed into insulation materials. Spontaneous heating is the problem. Another term for the condition is auto-ignition. Monsanto Industrial Chemicals Company manufactures a product called Therminol which is a very useful and highly effective heat-transfer fluid. In the Therminol technical data sheet a description of the problem is offered:[10]

> Organic heat transfer fluids such as Therminol exhibit a slow oxidation reaction with air in the presence of insulating materials when system temperatures are above 500°F (260°C). Porous insulation material such as calcium silicate offers a large reaction surface in the face of poor heat dissipation conditions, and this, along with possible catalysis from the insulation material can cause a temperature build-up. This temperature build-up can result in ignition of the fluid when the saturated insulation is exposed to air (i.e., should the insulation be opened for repair, etc.).

This phenomenon is not fully understood, but appears not to occur with cellular glass, possibly because of its closed cell structure. Cellular glass should be used in all areas where leakage is a possibility and the system temperature is greater than 400°F (240°C).

There are numerous other reference which relate similar, if not identical, information about this problem and the precautions that need to be taken in the design and application process. The Bibliography for this chapter contains a number of references on this subject. As in the case of cyclical service, it is important to contact the manufacturer before writing the insulation system specification for high-temperature heat-transfer fluid applications. The manufacturers of the heat-transfer fluid should also be consulted for their own precautions and recommendations.

Hot Oils.   Hot oil piping and equipment applications require the same attention to detail as do heat-transfer fluids with respect to insulation system design. For hot oils, even though they frequently do not operate at the temperature extremes of heat-transfer fluids, the auto-ignition can be just as serious. Fires have occurred in oils at temperatures as low as 176 to 302°F (80 to 150°C), in coal tar distillates at temperatures as low as 212 to 482°F (100 to 250°C), and in mineral oils at temperatures as low as 392 to 572°F (200 to 300°C).[11]

Liquefied Gas (Cryogenic Service).   Cryogenic temperatures range from −40°F (−40°C) down to absolute zero (−459°F, or −273°C). In this temperature range, the primary concern is the prevention of water vapor migration toward the pipe surface. Water vapor that is allowed to enter the insulation system will rapidly destroy the thermal performance of the insulation.

Cryogenic piping is usually insulated in multiple layers. The best vapor barrier joint sealants available remain flexible only down to a temperature of about −80°F (−62°C); therefore the inner layer of insulation is usually left unsealed. The outer layer or layers are completely sealed with vapor barrier joint sealants, and the final layer of insulation is usually covered with a vapor barrier mastic or membrane.

Plastic foam insulation must be covered with a complete vapor barrier envelope. Cellular glass insulation is sometimes just vapor-sealed over the joints and then covered with a weather barrier.

At extreme cryogenic temperatures, there is also the possibility of condensation of oxygen. This can occur anywhere below −290°F (−179°C). The National Fire Protection Association states[12]

Liquid oxygen is the most concentrated common source of oxygen. Contamination of liquid oxygen with most organic substances often renders the mixture subject to violent explosion.

An inadvertent oxygen enriched atmosphere can be created within insulation on piping and equipment containing materials at temperatures below the condensation temperature of oxygen (e.g., liquid hydrogen or nitrogen), if the oxygen in the atmospheric air is condensed within the insulation.

Therefore, there is a risk of liquid oxygen explosion with organic insulation materials and accessory products. Organic foam insulations, if used in the potential presence of condensing oxygen, require that the foam must be protected by a gas-impermeable membrane.[13]

Sanitary and Sewerage Water. Water lines and sewerage lines are generally insulated only as a means to prevent freezing. All the considerations appropriate for freeze protection requirements discussed earlier in this chapter should prevail.

MATERIALS

There are many different types of insulation materials available for both commercial and industrial piping applications. There are in fact too many to discuss in detail here. For the purposes of this chapter, a few of the more common commercial and industrial piping insulation types, or classifications, will be described. The following list, sorted alphabetically, comprises the material classifications most common to the industrial and commercial piping industry:

- Calcium silicate insulation
- Cellular glass insulation
- Elastomeric foam insulation
- Fiberglass and mineral wool insulations
- Perlite insulation
- Phenolic foam insulation
- Polystyrene foam insulation
- Polyurethane and polyisocyanurate foam insulations

Table B7.1 illustrates some of the properties of insulation materials that are commonly referred to in the insulation material selection process. Table B7.4 through Table B7.16 provide thickness guidelines for the materials referenced in

550	64	64	64	76	89	89	102	102	114	114	127	127	127	152

Maximum heat flow = 378.1 W/m² (highest heat flow of any in the table).

Table B7.1. Tables B7.17 through Table B7.22 provide thermal conductivity data for each of these materials. It is important to remember that the properties of the material alone should not control the specification process. It is the combined properties of the insulation material and the corresponding accessory products that make up the total system that should control.

Maximum heat flow = 474 W/m² (highest heat flow of any in the table).

Calcium Silicate Insulation.   Calcium silicate is a very rigid, high-density material used exclusively for applications above 250°F (121°C). This insulation material has been a standard for high temperature applications for many years. Compressive strengths are very good, and it is noncombustible. It is suitable for temperatures from 250°F (121°C) up to 1000°F (538°C). Calcium silicate is manufactured from a

900°F (538°C). Cellular glass insulation is all closed-cell glass with no organic binders or fillers. The closed-cell glass structure renders it impervious to liquid water and the driving force of water vapor pressure. It is manufactured in flat blocks which are then fabricated into any shape specified. Fabrication techniques are governed by ASTM Standard Recommended Practice for Inner and Outer Diameters of Rigid Thermal Insulation for Nominal Sizes of Pipe and Tubing. Cellular glass is

Maximum heat flow = 348.2 W/m² (highest heat flow of any in the table).

applied to cold piping in single or double layers and usually is used with a joint sealant and then covered with either a fabric-reinforced mastic or a metal jacket. On hot piping applications, cellular glass is applied to the pipe in single or double layers with metal bands. No sealants are used on hot applications. It is then covered with metal jacket.

TABLE B7.9   Fiberglass Insulation Thickness Table (Hot)
Recommended thickness table
Surface emittance = 0.4   Average wind velocity = 5.0 mph
Hot pipe worst-case ambient temperature of 80°F for a surface temperature of 140.0°F or less

450	38	38	51	51	51	51	64	64	64	64	76	76	76	89

Maximum heat flow = 428.5 W/m^2 (highest heat flow of any in the table).

Elastomeric Foam Insulation.   Elastomeric foams are used almost exclusively in commercial, institutional, and residential facilities. It is used primarily on hot water and chilled water lines, or for water and sewer lines for freeze protection. Elastomerics are extruded into pipe dimensions and generally available in ½-in (13-mm), ¾-in (19-mm), and 1-in (25-mm) thicknesses. It is available in sheet form for equipment. These foams are usually taped, wired, or glued in place.

TABLE B7.10 Perlite Insulation Thickness Table (Hot)

Recommended thickness table
Surface emittance = 0.4   Average wind velocity = 5.0 mph
Hot pipe worst-case ambient temperature of 90°F for a surface temperature of 140.0°F or less

Maximum heat flow = 366 W/m² (highest heat flow of any in the table).

Fiberglass and Mineral Wool Insulations.   Fiberglass and mineral wool are actually two separate and distinct types of insulation; however, many of their applications and physical properties are similar. These products are generally used in hot applications, but with some restrictions they can be used in cold applications as well. Fiberglass is often used from chilled water piping temperatures up to a maximum

TABLE B7.11 Perlite Insulation Thickness Table (Hot)

Maximum heat flow = 469 W/m^2 (highest heat flow of any in the table).

of 850°F (454°C). Mineral wool has a peak temperature limit of 1200°F (649°C). Fiberglass is made from glass fibers bonded together with resin binders. Mineral wool is made from rock slag fibers and bonded together with resin or clay binders. These materials are generally applied with metal bands or wire or tape and are covered with a metal or nonmetallic flexible jacket. On indoor applications they are frequently covered with an all-service jacket.

Perlite Insulation.   Perlite insulation is generally used in the same types of applications as calcium silicate. It is somewhat lighter in density and lower in compressive strength than calcium silicate; however, it usually is treated with a water inhibitor

which tends to keep it drier than calcium silicate. Perlite insulation is also made in molds to fit the range of pipe-covering shapes required by industry. It is usually applied with metal bands and covered with a metal jacket.

Phenolic Foam Insulation.   Phenolic foam is a very low thermal conductivity organic foam insulation used primarily for plastic piping in freeze protection applications. Phenolic foam insulation is made in a catalyst reaction bun and is cut in a fabrication process to the sizes needed for the applications. It is generally applied with tape or wire and covered with all-service jacket or metal jacket depending on the ambient conditions and the geography.

Polystyrene Insulation.   Polystyrene is a very inexpensive, efficient thermal insulation used almost exclusively in residential and food processing applications. It comes in expanded boards and extruded buns. The extruded buns are sometimes used to fabricate pipe covering for chilled water lines or water and sewer lines. In residential applications it is used in the wall panels. In food processing it is used in the walls

and on the roofs. It has a low permeability rating and is easy to work with. It is applied with bands, tape, wire, or glue depending on the application.

Polyurethane and Polyisocyanurate Foam Insulations.   Polyurethane and polyisocyanurate foams are two chemically different insulation materials; however, their cell structure and physical properties are so similar that they are usually lumped into a common category. This is probably not fair to polyisocyanurate foam insulation because it generally tends to be of higher quality. Both insulations have very good thermal properties. They are used from about −200°F (−129°C) up to 300°F (149°C) both indoors and outdoors. On cold applications they require multiple layers due to the contraction characteristics. These insulations are manufactured in batch bun processing and then sold to fabricators who cut them into various shapes and sizes depending on the applications. These insulation materials are usually applied with tape or wire and covered with either a fabric-reinforced mastic or a metal jacket.

The values of the thermal conductivity of the insulation shown above were determined by evaluating a polynomial at the insulation temperature. This polynomial, giving the thermal conductivity in Btu·in/ (h·ft²·°F) as a function of temperature in °F, is $K(T) = 0.3728 + 2.98\text{E-4}(T) - 2.3\text{E-8}(T^2) + 2.02\text{E-10}(T^3)$.

This curve is based on an insulation density of 16.0 lb/ft³ and may be subject to decreasing reliability outside the temperature range from 250.0 to 1000.0°F.

The values of the thermal conductivity of the insulation shown above were determined by evaluating a polynomial at the insulation temperature. This polynomial, giving the thermal conductivity in Btu·in/(h·ft²·°F) as a function of temperature in °F, is $K(T) = 0.195 + 4.25\text{E-4}(T) + 0.0000(T^2)$.

This curve is based on an insulation density of 5.63 lb/ft³ and may be subject to decreasing reliability outside the temperature range from 42.0 to 800.0°F.

1200.0	1.538	648.9	0.1908	922.2	0.2217

The values of the thermal conductivity of the insulation shown above were determined by evaluating a polynomial at the insulation temperature. This polynomial, giving the thermal conductivity in Btu·in/(h·ft²·°F) as a function of temperature in °F, is $K(T) = 0.228 + 3.72\text{E-}4(T) + 6.0\text{E-}7(T^2)$.

This curve is based on an insulation density of 11.7 lb/ft³ and may be subject to decreasing reliability outside the temperature range from 42.0 to 1100.0°F.

TABLE B7.21   Perlite Insulation K Value Table
Thermal conductivity as a function of temperature for perlite

1000.0	1.038	537.8	0.1287	810.9	0.1496

The values of the thermal conductivity of the insulation shown above were determined by evaluating a polynomial at the insulation temperature. This polynomial, giving the thermal conductivity in Btu·in/(h·ft²·°F) as a function of temperature in °F, is $K(T) = 0.4030 + 6.38\text{E-4}(T) - 3.56\text{E-7}(T^2) + 3.53\text{E-10}(T^3)$.

This curve is based on an insulation density of 12.0 lb/ft³ and may be subject to decreasing reliability outside the temperature range from 250.0 to 1000.0°F.

TABLE B7.22   Polyurethane or Polyisocyanurate Foam Insulation K Value Table
Thermal conductivity as a function of temperature for urethane

English units		Non-SI metric units		SI units	
At uniform temperature (°F)	Thermal conductivity [Btu·in/(h·ft²·°F)]	At uniform temperature (°C)	Thermal conductivity [kcal/(h·m²·°C)]	At uniform temperature (K)	Thermal conductivity [W/(m·K)]
−100.0	0.179	−73.3	0.0222	199.8	0.0258

300.0	0.470	148.9	0.0583	422.0	0.0677
350.0	0.710	176.7	0.0880	449.8	0.1023

The values of the thermal conductivity of the insulation shown above were determined by evaluating a polynomial at the insulation temperature. This polynomial, giving the thermal conductivity in Btu·in/(h·ft²·°F) as a function of temperature in °F, is $K(T) = 0.1735 − 1.549\text{E-}4(T) − 3.389\text{E-}7(T^2) + 8.377\text{E-}9(T^3) + 1.819\text{E-}11(T^4)$.

This curve is based on an insulation density of 2.0 lb/ft³ and may be subject to decreasing reliability outside the temperature range from −50.0 to 250.0°F.

ACCESSORY MATERIALS

The accessory materials referenced in the above paragraphs and throughout the chapter are a necessary part of the insulation system. There are many manufacturers and suppliers of these materials, and the quality can vary dramatically from one to another. The following are a few of the more common accessory materials used in industrial and commercial insulation system specifications. See also Table B7.23.

Acrylic Latex Mastic

Acrylic latex mastic is a heavy-bodied weather barrier coating used primarily to cover rigid insulations such as cellular glass and polyurethane. It is generally applied in two coats with a reinforcing mesh fabric for impact and tear resistance. This material does not provide vapor protection.

Aluminum Banding

Aluminum bands are used as securement for many types of insulation materials. The most common sizes specified are 0.5 in × 0.020 in (13 mm × 0.5 mm) aluminum bands with matching seals for piping vessels, or equipment with ODs of 48 in (1219 mm) or less. For larger ODs, use 0.75 in × 0.020 in) (19 mm × 0.5 mm) aluminum bands. These bands are secured in place with metal band clips or seals of common dimensions. Aluminum bands should not be used in applications where the insulation is being installed for fire protection applications.

TABLE B7.23   ASTM Specification Reference

Material	ASTM Specification
Calcium silicate	C533-95
Cellular glass	C552-91
Elastomeric foam	C534-94
Fiberglass and mineral wool	C553-92, C547-95, C612-93
Expanded perlite	C610-95
Phenolic foam	C1126-96
Polystyrene foam	C578-95
Polyurethane modified polyisocyanurate foam	C591-94
Aluminum jacketing and banding	C921-96
Stainless steel jacketing and banding	C921-96
FRP	C921-96
ASJ	C921-96
Asphalt cutback mastic	C647-95
Acrylic latex mastic	C647-95
Hypalon mastic	C647-95
6×6 mesh fabric	NA
10×10 glass scrim	D1668-86

Aluminum Jacketing

Aluminum jacketing comes in many different sizes and finishes. In piping applications, either smooth or slightly embossed jacketing of 0.016 in (0.4-mm) thickness is most common. When specifying aluminum jacketing for use with permeable and hygroscopic insulation materials, it is important to specify the jacketing with a factory-applied moisture barrier liner.

ASJ

ASJ jacketing stands for all-service jacket. This material is a Kraft paper/foil/scrim laminate material used exclusively on indoor commercial applications. ASJ jacketing is usually factory-applied and serves the primary function of providing protection to the outer insulation surface. These are classified as vapor retarders.

Asphalt Cutback Mastic

Asphalt cutback mastics are heavy-bodied asphalts that are cut with mineral spirits so they can be applied by spraying or with a trowel. When applied, the mineral spirits dissipate, and leave behind a hard asphaltic vapor barrier finish. It is generally applied in multiple coats used in conjunction with reinforcing fabric. Metal jackets are used to cover this finish on aboveground, outdoor applications for ultraviolet protection to the mastic.

FRP Jacketing

FRP stands for *fiber resin plastic* or *fiber-reinforced plastic.* Either definition is acceptable. The material is a hard plastic membrane reinforced with glass fibers. FRP jacketing can be used in many of the same applications where aluminum is used. FRP jacketing is often the material of choice in chemical resistance areas. The jacketing comes in sheet or rolled form, and the laps are sealed with a resin sealant recommended by the manufacturer.

Hypalon Mastics

Hypalon is a trade name for a highly flexible and durable vapor barrier mastic material. There are numerous products on the market that use this material in their compositions to form what are referred to as *elastomeric membranes.* These elastomeric membranes are referred to as *hypalons.* Hypalons are usually reinforced with a 10×10 or a 10×20 fiberglass fabric to provide stability and tear resistance. Hypalon mastics should not be used in conjunction with cellular glass.

Stainless Steel Banding

Stainless steel bands are used to support or secure insulation materials to piping, tanks, or vessels. Typical sizes specified are 0.5 in $\times$ 0.015 in (13 mm $\times$ 0.38 mm) stainless steel bands with matching clips or seals for caustic service or where the insulation is being used for fire protection applications.

Stainless Steel Jacketing

Stainless steel jacketing is used to cover insulation materials of all types for various applications. Due to the cost, stainless steel is generally used where it is required for its chemical or fire resistance. Stainless steel usually has a smooth finish and is 0.010 in (0.25 mm) thick. On some large diameter applications 0.015 in (0.38 mm) thick may be specified.

Stainless Steel Tie Wire

Wire may be used to secure fitings or insulation sections. Check with the insulation manufacturer for recommendations on its usage. Soft annealed wire is best suited for field conditions, so as not to work-harden in the field. Wire is typically utilized in 18 and 16 gage thicknesses.

Fiberglass-Reinforced Tape

Tape is typically 1-in (25 mm) wide, high-tensile-strength, fiber-reinforced, strapping tape. Tape is appropriate for providing temporary insulation securement for piping with insulation ODs 18 in (457 mm) or smaller as long as it is covered with metal jacket afterward. Tape is not acceptable as a primary means of securement if the insulation system is being designed to provide fire protection.

Mesh Fabric

A 6×6 mesh refers to the number of strands of primary fiber in 1 in^2 of fabric (2.4 meshes/cm^2). A 6×6 mesh will have six primary strands going in one direction and six primary strands perpendicular. In a polyester mesh fabric, the primary strands are woven together by a method designed to create a fabric that does not fray or pucker. This fabric is typically specified to accompany applications of heavy-bodied mastics such as acrylic latex and asphalt cutback.

Glass Scrim

Glass scrims come in many different configurations. The most common scrims used in industrial and commercial piping applications are the 10×10 (3.9 meshes/cm^2) or the 10×20. As with the mesh fabric, the numerical designation refers to the number of primary strands in 1 in^2 of fabric. Glass scrims are best suited to light-bodied mastics, paints, and elastomeric membranes.

CHAPTER B8
FLOW OF FLUIDS

Tadeusz J. Swierzawski
Consultant, Energy Systems
Burlington, Massachusetts

INTRODUCTION

The primary objective of this chapter is to show the user the most important logical milestones and the general background of equations and formulas recommended for specific practical applications of fluid flow in pipes, nozzles, and orifices. For details, Refs. 1 through 4 or other equivalent textbooks should be consulted.

Nomenclature

A nomenclature section is provided to minimize repeating of variable definitions. Unless otherwise stated, all symbols used in this chapter are defined as described in the following lists. Units presented here are mostly those of practical range of applications. The SI units of each physical quantity under consideration appear in parentheses; however, in all equations presented in this chapter only the base U.S. customary units (English units) must be used. For details see "Survey of Dimensions and Units."

Variables

a	Acceleration, ft/s^2 (m/s^2) (m = meter, s = second)
A	Cross-sectional area of pipe, flow duct, or orifice, ft^2 (cm^2)
A_f	Flow area occupied by liquid phase, ft^2 (cm^2)
A_g	Flow area occupied by gaseous phase, ft^2 (cm^2)
c	Velocity of sound, ft/s (m/s)
C	Flow coefficient defined by Eq. (B8.45), dimensionless
C_A	Allen flow constant defined by Eq. (B8.88)
C_c	Coefficient of contraction, dimensionless
C_d	Discharge coefficient, dimensionless

c_p	Specific heat at constant pressure, Btu/(lb$_m$·°F) (kJ/(kg·K)) (kJ = kilojoule, kg = kilogram, K = kelvin)
c_v	Specific heat at constant volume, Btu/(lb$_m$·°F) (kJ/(kg·K))
C_v	Velocity coefficient, dimensionless
d	Nozzle or orifice diameter, in (mm) (mm = millimeter)
d_g	Flow height for gaseous phase, in (mm)
D	Pipe inside diameter, ft, in (mm)
E	Energy, Btu, kWh (kJ, kWh)
$\dot{E}$	Energy flow rate, Btu/s, kW (kJ/s, kW)
f	D'Arcy-Weisbach friction factor, dimensionless
f_T	Friction factor in zone of complete turbulence (dimensionless)
F	Force, lb$_f$, (N) (N = newton)
F_a	Area factor for thermal expansion of primary elements (see Fig. B8.22)
Fr	Froude number, dimensionless
F_{wa}	Approach velocity factor defined by Eq. (B8.42), dimensionless
g	Acceleration due to gravity (local), ft/s^2 (m/s^2)
g_c	32.174 (lb$_m$·ft)/(lb$_f$·s^2), dimensional conversion factor (does not exist in SI units)
g_s	32.174 ft/s^2 (9.80665 m/s^2)—standard (normal) acceleration due to gravity (standard acceleration of free fall)
$\dot{G} = \dot{m}/A$	Mass flux, lb$_m$/(ft^2·s) (kg/(m^2·s))
$\dot{G}_c$	Maximum (critical) mass flux, lb$_m$/(ft^2·s) (kg/(m^2·s))
$\dot{G}_{fs}$	Superficial mass flux of liquid phase, lb$_m$/(ft^2·s) (kg/(m^2·s))
$\dot{G}_{gs}$	Superficial mass flux of gaseous phase, lb$_m$/(ft^2·s) (kg/(m^2·s))
h	Specific enthalpy (static), Btu/lb$_m$ (kJ/kg)
h_f	Specific enthalpy of liquid phase, Btu/lb$_m$ (kJ/kg)
h_g	Specific enthalpy of gaseous phase, Btu/lb$_m$ (kJ/kg)
h_{fg}	Latent heat of vaporization ($h_g - h_f$), Btu/lb$_m$ (kJ/kg)
h_0	Stagnation enthalpy, Btu/lb$_m$ (kJ/kg)
H	Enthalpy, Btu (kJ)
H_f	Loss of static pressure head, ft (m)
$j_f = \dot{G}_{fs} v_f$	Superficial velocity (volumetric flux) of liquid phase, ft/s (m/s)
$j_g = \dot{G}_{gs} v_g$	Superficial velocity (volumetric flux) of gaseous phase, ft/s (m/s)
J	778.169 ft·lb$_f$/Btu; mechanical equivalent of heat, dimensional conversion factor (does not exist in SI units)
k	C_p/C_v—isentropic exponent, dimensionless
K	Flow resistance coefficient (K-factor), dimensionless
L	Length, ft (m)
m	Mass, lb$_m$ (kg)
$\dot{m}$	Mass flow rate, lb$_m$/s (kg/s)

Ma	w/c—Mach number, dimensionless
p	Absolute pressure, lb_f/ft^2, lb_f/in^2 = psia (N/m^2 = Pa, kPa, bar; Pa − pascal, 1 bar = 10^5 Pa = 100 kPa)
p_g	$p - p_{amb}$, gauge pressure (p_{amb} is the ambient pressure expressed in the same units as p)
p_o	Stagnation pressure, lb_f/ft^2, lb_f/in^2 (N/m^2, kPa, bar)
P	Power, kW (kW)
q	Heat per unit mass, Btu/lb_m (kJ/kg)
Q	Heat, Btu (kJ)
$\dot{Q}$	Heat flow rate, Btu/s (kJ/s)
r_h	Hydraulic radius, ft (mm)
R	Gas constant, $(ft \cdot lb_f)/(lb_m \cdot °R)$ $((N \cdot m)/(kg \cdot K))$ where $1 \, N \cdot m = 1 \, J$
Re	Reynolds number, dimensionless
s	Specific entropy, $Btu/(lb_m \cdot °R)$ $(kJ/(kg \cdot K))$
s_f	Specific entropy of liquid phase, $Btu/(lb_m \cdot °R)$ $(kJ/(kg \cdot K))$
s_g	Specific entropy of gaseous phase, $Btu/(lb_m \cdot °R)$ $(kJ/(kg \cdot K))$
s_{fg}	$s_g - s_f$, $Btu/(lb_m \cdot °R)$ $(kJ/(kg \cdot K))$
s_0	Stagnation entropy, $Btu/(lb_m \cdot °R)$ $(kJ/(kg \cdot K))$
S	Entropy, Btu/°R (kJ/K)
S^*	Slip ratio, dimensionless
t	Time, s, h (s, h)
t_F	°F (t_C = Celsius temperature, °C)
T	Thermodynamic temperature, °R (K)
T_o	Stagnation temperature, °R (K)
u	Specific internal energy, Btu/lb_m (kJ/kg)
U	Internal energy, Btu (kJ)
v	Specific volume, ft^3/lb_m; (m^3/kg)
v_f	Specific volume of saturated liquid, ft^3/lb_m (m^3/kg)
v_g	Specific volume of saturated steam, ft^3/lb_m (m^3/kg)
v_{fg}	$v_g - v_f$, ft^3/lb_m (m^3/kg)
V	Volume, ft^3 (m^3, 1 = liter)
$\dot{V}$	Volumetric flow rate, ft^3/h $(m^3/h, l/s)$
w	Velocity, ft/s (m/s)
W	Work, $ft \cdot lb_f$ (kJ)
$\dot{W}_t$	Technical work rate (power), $ft \cdot lb_f/s$, kW (kW)
x	Mass quality of steam, dimensionless
y	Distance to fixed surface, ft (m)
z	Elevation, ft (m)

Greek Symbols

α	Void fraction, dimensionless
α_s	Quantity defined by Eq. (B8.61)
β	d/D, dimensionless diameter ratio
β_s	Critical pressure ratio, dimensionless
γ	Specific weight, lb_f/ft^3; (N/m^3)
ε	Absolute roughness, ft (the same unit as the pipe diameter D); (mm)
μ	Dynamic (absolute) viscosity, $(lb_f \cdot s)/ft^2$ $((N \cdot s)/m^2)$
μ_f	Dynamic viscosity of liquid phase, $(lb_f \cdot s)/ft^2$ $((N \cdot s)/m^2)$
μ_g	Dynamic viscosity of gaseous phase, $(lb_f \cdot s)/ft^2$ $((N \cdot s)/m^2)$
ν	Kinematic viscosity, ft^2/s (m^2/s)
ν_f	Kinematic viscosity of liquid phase, ft^2/s (m^2/s)
ν_g	Kinematic viscosity of gaseous phase, ft^2/s (m^2/s)
π	Pi, approximately 3.14159, dimensionless
ρ	Density, lb_m/ft^3; (kg/m^3)
ρ_f	Density of gaseous phase, lb_m/ft^3 (kg/m^3)
ρ_g	Density of liquid phase, lb_m/ft^3 (kg/m^3)
τ	Shearing stress, lb_f/ft^2 (N/m^2)
T	Thrust, lb_f (N)
Ψ_{LO}^2	Two-phase pressure drop multiplier, dimensionless
Ψ_s	Quantity defined by Eq. (B8.52)

Subscripts

f, l	Liquid or water phase, saturated liquid
g	Steam phase, saturated steam

Basic Fluid Properties

A *fluid* is a substance which can flow and which deforms continuously under the action of shearing forces. Fluids offer no resistance to distortion of form; they yield continuously to tangential forces, no matter how small. Ordinarily, fluids are classified as being liquids or gases. Some classifications also include the vapor form within the group of fluids.

Liquids change volume and density very slightly with considerable variation in pressure, and when the pressure is removed, they do not dilate significantly. They are practically incompressible.

A *gas* is a fluid which tends to expand to fill completely any vessel in which it is contained. It is easily compressed, and a change in pressure is accompanied by a considerable change in its volume and density.

A *perfect (or ideal) gas* satisfies two conditions: (1) it obeys the Clapeyron equation $pV = mRT$ at all pressures, and (2) its specific heats are constant regardless of pressures and temperatures. In (1) above, *p, V,* and *T* are pressure, volume, and absolute temperature, respectively, and *m* and *R* represent the mass of gas and the gas constant, all in proper units. From (2) it follows also that the specific-heat ratio, $k = c_p/c_v$, is also constant.

The behavior of real gases is more complex. Real gases at low pressure tend to obey perfect gas law. As the pressure increases, however, the discrepancy increases and becomes serious near the critical point. If higher degrees of accuracy are required, textbooks in thermodynamics list corrections (as, for example, van der Waals' equation) which take into account deviations from ideal conformance. For practical purposes, gas and steam properties are published in the form of tables, charts, and appropriate computer programs. For example, the ASME (American Society of Mechanical Engineers) steam tables[5] are accompanied by computer diskettes that contain a steam properties calculation program. This FORTRAN source code may be copied, compiled, and utilized in compiled code of other programs.

Survey of Dimensions and Units

Dimensions, although discussed in other sections of this handbook, are briefly reviewed here to recall some fundamentals. The proper use of units and dimensions will save time and avoid errors. It is a good practice to include the units of all physical quantities, as well as their magnitudes, in performed calculations.

A *dimension* is a general expression for a particular kind of physical quantity (e.g., length, mass, time). A *unit* is a reference standard used to measure a physical quantity (e.g., one meter, one inch, and one foot are alternative units of the dimension length).

Four fundamental dimensions are required for analyses of thermodynamic or/ and fluid flow systems. Length, mass, time, and temperature are usually chosen.

U.S. Customary Units. The U.S. Customary Units (English system of dimensions and units) belong to the group of engineering systems where force instead of mass is a base dimension and the mass unit is derived from Newton's relationship that force equals mass times acceleration:

$$F = ma \tag{B8.1}$$

Then, the derived unit of mass in this system is $(lb_f \cdot s^2)/ft = 1$ slug. A *slug* is the mass that can be accelerated at the rate of 1 ft/s² by a force of 1 standard pound-force. By definition, 1 standard pound-force will also accelerate 1 pound-mass at the rate of 32.174 ft/s². It follows that the slug is the mass of size 32.174 times that of the pound-mass (Fig. B8.1), and $g_c = 32.174 \ lb_m/\text{slug} = 32.174 \ (lb_m \cdot ft)/(lb_f \cdot s^2)$ is the dimensional conversion factor between the two systems of dimensions (based on mass versus that based on force). The density ρ is the mass per unit volume of the fluid and is not to be confused with specific weight γ, the weight per unit volume. The interrelation of density and specific weight is $\gamma = \rho g/g_c$. In thermodynamic calculations, this system is still using the unit of mass lb_m (for example, $Q = mc \ \Delta T$).

1 slug

1 lb$_m$
1 slug = 32.174 lb$_m$

Also, the interconversion between heat expressed by British thermal units, and work, expressed by ft · lb$_f$, is required in this dimensional system ($J = 778.169$ ft · lb$_f$/Btu).

International System. The International System "SI" (Systeme international d'unites) of units is founded on four base units: meter (m) of length, kilogram (kg) of mass, second of time, and kelvin (K) of thermodynamic temperature.[6] It must be explained that the Celsius temperature scale is the commonly used scale for temperature measurements in metric systems. The Celsius scale is not in itself part of the SI, but a difference of one degree on that scale equals one kelvin. Zero on the thermodynamic scale is fixed by convention to be 273.15 kelvin (K) below zero degrees Celsius.

When two or more units expressed in *base* SI units are multiplied or divided as required to obtain derived quantities, the result is a *unit value*. No numerical constant (dimensional conversion factor) is introduced. Such units are called *coherent*. SI is a coherent system of units. For some derived SI units, special names and symbols exist; for example, force expressed by 1 kg · m/s^2 has a derived name *newton* (N), pressure expressed by 1 N/m^2 has a derived name *pascal* (Pa), energy expressed by 1 N · m has a derived name *joule* (J), power expressed by 1 J/s has a derived name *watt* (W), and so forth. There are certain units outside the SI which are recognized as having to be retained because of their practical importance. As is general practice in the power industry worldwide, 1 bar = 10^5 Pa = 100 kPa (pressure expressed in bars is close to that expressed in *atmospheres*) has been used as the unit for absolute pressure. The symbol p$_g$ is recommended for gauge pressure, defined as p$_g$ = p−p$_{amb}$, where p$_{amb}$ is the ambient pressure. Other recognized units outside the SI are: 1 minute (min) = 60 s, 1 hour (h) = 60 min, 1 day (d) = 24 h, 1 litre (l) = 1 dm^3, 1 tonne (t) = 10^3 kg.

In order to avoid large or small numerical values, decimal multiples of the SI units are added to the coherent system within the framework of the SI. They are formed by means of the following SI prefixes. Some of them are: G (giga) = 10^9, M (mega) = 10^6, k (kilo) = 10^3, h (hecto) = 10^2, d (deci) = 10^{-1}, c (centi) = 10^{-2}, m (milli) = 10^{-3}, μ (micro) = 10^{-6}. Therefore, for example, the compound prefix for 1 mm^2/s = (10^{-3} m)^2/s is equal to 10^{-6} m^2/s. The choice of the appropriate multiple of an SI unit is governed by convenience. The multiple chosen for a particular application is the one which will lead to numerical values within a practical range. For certain quantities in particular applications, the same multiple is customarily used; for example, the millimeter is used for dimensions in most mechanical engineering drawings.

Because of the increasing international commitment of U.S. engineering, industry, and commerce, the need for an accelerated growth in acceptance of the capability of SI units by the engineering profession is recognized. However, for this edition of the *Piping Handbook,* the English units of the engineering system of dimensions and units have been recommended. As a result of this recommendation, all equations in this chapter are written in such a way that the dimensional conversion factors (g_c, J) must be used. In parentheses, after all, the corresponding SI units and calculated values are presented. For those who must deliver calculation results in other units, useful conversion factors are given in Tables B8.1 through B8.6.

THEORETICAL BACKGROUND

Some basic fluid properties used in this chapter are discussed in the following paragraphs; for more detailed information see Refs. 1 and 2 listed at the end of this chapter.

Viscosity

It is an experimental fact that a fluid in immediate contact with a solid boundary has the same velocity as the boundary itself. For the case of Fig. B8.2, in which a fluid separates closely spaced parallel plates, the force F applied to the upper, moving plate, is directly proportional to the surface area A of the upper plate and its velocity w, and is inversely proportional to the distance y between the plates. The last statement is expressed in the form of Newton's law of viscosity:

$$F = \mu \frac{Aw}{y} \tag{B8.2}$$

in which μ is the proportionality factor and is called the *dynamic (or absolute) viscosity* of the fluid. *Poise* (P) and *stokes* (St) are special names for CGS units. They and their multiples should not be used together with SI units. Conversion factors for dynamic viscosity, from other units, are presented in Table B8.5.

Water at 68°F (20°C) has a dynamic viscosity of 1.002 centipoise (0.001 N · s/m² or Pa · s). The viscosity of liquids decreases with increasing temperature, but the viscosity of a gas increases with increasing temperature.

Because the shear stress is $\tau = F/A$, Equation (B8.2) could be written as $\tau = \mu\, w/y$ or in differential form as $\tau = \mu\, dw/dy$. The ratio dw/dy is called the *rate of angular deformation* of the fluid for one-dimensional flow. *Viscosity* is that property
FIGURE B8.2   Established steady state velocity profile in the fluid.

of a fluid by virtue of which it offers resistance to shear. In Newtonian fluids, there is a linear relation between the applied shear stress and the resulting rate of deformation [μ = constant in Eq. (B8.2)]. In non-Newtonian fluids, this relationship is not linear. Gases and thin liquids tend to be Newtonian fluids, while thick hydrocarbons may be non-Newtonian.

The kinematic viscosity ν, which is the ratio of dynamic viscosity to mass density ρ, is:

$$\nu = \frac{\mu}{\rho} g_c \qquad (B8.3)$$

Conversion factors for kinematic viscosity are presented in Table B8.6.

Pressure Variation in a Static Fluid

The static pressure existing at a point within a fluid body is known also as the *hydrostatic pressure.* In the case of gaseous fluids, the density of the fluid column is relatively small unless great vertical heights are involved. In such cases the average density of fluid should be used for the static pressure calculation. With denser fluids such as liquids, the increase in pressure due to depth within the liquid can be of great significance. When applied to the two-fluid mixture in a container filled with a gas at the pressure p_1, as shown in Fig. B8.3, the expression for static pressure at a horizontal plane located at distance z below the free surface is:
FIGURE B8.3   Hydrostatic pressure in two-fluid system.

$$p = p_1 + \frac{g}{g_c}(\rho_1 z_1 + \rho_2 z_2) \qquad (B8.4)$$

Standard atmospheric pressure is defined as that pressure produced by a column of mercury of 760 mm length at a mercury density of 13.5950889 g/cm³ at 32°F (0°C) and at an acceleration due to gravity of g_n = 32.174 ft/s² (9.80665 m/s²). On this basis, then:

$$1 \text{ standard atmosphere} = 14.6959488 \text{ psia} (1.01325 \text{ bar})$$

For many engineering calculations, it is sufficiently accurate to use 14.7 psia as being equivalent to 1 standard atmosphere.

Continuity

Applying the law of conservation of mass to a flow process yields a mass balance, or continuity equation. The mass balance in physical processes is that the mass of
FIGURE B8.4   Energy balance in an open system.

substance added to the system is equal to the mass subtracted from the system, plus accumulation of any mass in the system.

Conservation of Energy

The first law of thermodynamics can be formulated as the principle of conservation of energy[2]:

$$E_{\text{in}} = \Delta E_s + E_{\text{out}} \qquad (B8.5)$$

where E_{in} represents all types of energy added to the system within a defined control boundary during a specified time interval, ΔE_s is the change in the total energy of the system, and E_{out} represents all kinds of energy substracted from the system in the same time interval. In the steady-flow system $\Delta E_s = 0$, and

$$\dot{E}_{in} = \dot{E}_{out} \qquad (B8.6)$$

With fluid flow through the system, as shown in Fig. B8.4, the energy entering (or leaving) this system by a duct (or a pipeline) will consist of potential (external), kinetic, and internal energy of the fluid, and also the external pumping work, the energy transmitted by a pump to force the fluid to flow continuously across the boundary of the system. Then the total rate of steady-flow energy transported in a duct (or a pipe) is:

$$\dot{E}_d = \dot{m}\left[\frac{1}{J}\left(pv + \frac{w^2}{2g_c} + \frac{g}{g_c}z\right) + u\right] \qquad (B8.7)$$

where $J = 778.169 \ (ft \cdot lb_f)/Btu$ (dimensional conversion factor).

The sum of the specific internal energy u and the external pumping work $(p\,v)/J$

$$h = u + \frac{pv}{J} \qquad (B8.8)$$

is called the *specific enthalpy*. Since, u, p, and v are all properties, then also h must be a state function or a property. The sum defined by h_o:

$$h_0 = h + \frac{w^2}{2g_c J} \qquad (B8.9)$$

is called the *stagnation enthalpy*.

Then, for a steady state flow system presented in Fig. B8.4, with a mass flow rate of $\dot{m} = \dot{m}_1 = \dot{m}_2$, by using Eqs. (B8.6), (B8.7), and (B8.8) the following is found:

$$\dot{Q} - \frac{\dot{W}_t}{J} = \dot{m}\left[(h_2 - h_1) + \frac{(w_2^2 - w_1^2)}{2Jg_c} + \frac{g}{Jg_c}(z_2 - z_1)\right] \qquad (B8.10)$$

In a differential form, per unit mass, this equation may be modified by introducing an internal friction term (viscous friction and other irreversible phenomena distinguishing a real fluid from an ideal one) to yield the following equation, which is known from literature as the *mechanical energy balance*:

$$d\left(\frac{w^2}{2g_c}\right) + \frac{g}{g_c}dz + vdp = -d'w_t - d'w_f \qquad (B8.11)$$

where $d'w_t$ = specific "technical work" transmitted across the boundary of the
system,

$d'w_f$ = specific work done against fluid friction.

STEADY SINGLE-PHASE INCOMPRESSIBLE FLOW IN PIPING

Characteristics of Incompressible Flow

Although there is no such thing in reality as an incompressible fluid, this term is applied to liquids. Yet sound waves, which are really pressure waves, travel through liquids. This is an evidence of the elasticity of liquids. In problems involving water hammer, it is necessary to consider the compressibility of the liquid. The compressibility of a liquid is expressed by its bulk modulus of elasticity which influences the wave speed in the liquid.

It should be explained here that when density changes of compressible fluids (gases or steam) are gradual and do not change by more than about 10 percent, the flow may be treated as incompressible with the use of an average density.

Bernoulli's equation is a special case of Eq. (B8.11) applied to nonviscous, incompressible fluids (ideal fluid) which do not exchange shaft work with surroundings:

$$v = \frac{1}{\rho} = \text{const}, \qquad d'w_f = 0, \qquad \text{and} \qquad d'w_t = 0$$

In real flow systems, however, the Bernoulli equation must be suplemented by a frictional head loss H_f (expressed in feet of a column of the fluid) and by a pump-head term H_p (total dynamic head, TDH, expressed in feet of a column of fluid). Then, for real systems the following is found:

$$\frac{w_1^2}{2g} + \frac{p_1}{\gamma} + z_1 + H_p = \frac{w_2^2}{2g} + \frac{p_2}{\gamma} + z_2 + H_f \tag{B8.12}$$

The frictional head loss is given by the following D'Arcy-Weisbach equation:

$$H_f = \frac{\Delta p}{\gamma} = f \frac{w^2}{2g} \frac{L}{D} \tag{B8.13}$$

and the corresponding pressure drop (expressed in lb_f/ft^2) is:

$$\Delta p = f \rho \frac{w^2}{2g_c} \frac{L}{D} \tag{B8.14}$$

where f is the D'Arcy-Weisbach friction factor, which is four times the Fanning friction factor used in some publications.

For laminar flow:

$$f = \frac{64}{\text{Re}} \tag{B8.15}$$

which plots as a straight line with a slope (-1) on the Moody diagram (Fig. B8.5). It applies to all roughnesses, as the head loss in laminar flow is independent of wall roughness. The Reynolds number is:

$$\text{Re} = \frac{Dw}{\nu} \tag{B8.16}$$
FIGURE B8.5 Moody diagram. (*From Ref. 1.*)

Expressions for calculating the loss of pressure in turbulent flow are based upon experimental data. An empirical transition function for commercial pipes for the region between smooth pipes and the complete turbulence zone (see the Moody diagram) has been developed by Colebrook:

$$\frac{1}{\sqrt{f}} = -0.86 \ln \left(\frac{\varepsilon/D}{3.7} + \frac{2.51}{\text{Re}\sqrt{f}} \right) \qquad \text{(B8.17)}$$

where the absolute roughness ε, expressed in feet (millimeters), is used as a measure of pipe wall irregularities of commercial pipes. Formula (B8.17) is the basis for the Moody diagram in the "transition zone" flow. The Moody diagram is widely accepted for hand calculations. For computerized calculations of the pressure drop, however, the Colebrook equation is built into the software.

Pressure losses which occur in piping systems due to bends, elbows, joints, valves, and so forth are called *form losses.* Recommended values of local flow resistance coefficients (K-factors) may be found in Refs. 7 and 8. Form losses may also be expressed in terms of the equivalent length L_e of pipe that has the same pressure-head loss for the same flow rate; thus

$$f \frac{L_e}{D} \frac{w^2}{2g} = K \frac{w^2}{2g} \qquad \text{(B8.18)}$$

After solving for L_e:

$$L_e = \frac{KD}{f} \qquad \text{(B8.19)}$$

Applications: Water Systems

General Design Considerations. Water system design requirements and design parameters are developed in the system descriptions which include piping and instrumentation diagrams (P&IDs), descriptions of the system individual components (pumps, valves, heat exchangers, etc.), design flow rates, valve alignments, control valve operation, and pipe sizes. Pipe sizes are determined by evaluation of water velocities in the system. Selection of velocities must consider many factors including:

- Pipe material
- Water quality
- System flow balance requirements
- Economic evaluation of pipe cost versus pumping costs
- Available pump head
- Water hammer prevention

Typical water flow velocities in ft/s (m/s) for various applications based on general industry practices are shown in Table B8.7.

A steady-state analysis of a water system is generally performed twice. The first calculation is needed to obtain data required for the purchase of the system components. This initial analysis is performed after the system description and

TABLE B8.7   Typical Water Flow Velocities

Condenser pump suction	3 ft/s (1 m/s)
Condenser pump discharge	10 ft/s (3 m/s)
Booster pump discharge	10 ft/s (3 m/s)
Feed pump suction (no deaerator)	10 ft/s (3 m/s)
(For systems with deaerators, the downcomer sizes should be optimized with a pump NPSH decay in mind—see section "Transient Flow Analysis")	
Feed pump discharge	20–25 ft/s (6–7.5 m/s)
Circulating water system	≤9 ft/s (3 m/s)
General service	5–10 ft/s (1.5–3 m/s)

Source: Stone & Webster

general arrangement drawings have been issued. The initial analysis proceeds as follows:

1. Issue the system description and general arrangement drawings.
2. Develop a preliminary piping layout based on P&IDs and general arrangement drawings.
3. Determine the system operating mode or modes (valve lineup, number of pumps, etc.) which are critical for equipment purchase.
4. Calculate the pressure drop in the piping for design flow rates.
5. Develop a system resistance curve.
6. Calculate the flow balance in branching systems.
7. Revise the system description (if required) to achieve desired system flow balance.
8. Develop a revised system resistance curve (if required).
9. Calculate values of parameters required for the purchase of system components (pump head, system pressures, control valve pressure drop, etc.).

The final steady-state hydraulic analysis of a system is usually performed after major equipment has been purchased and piping drawings have been prepared. This analysis is to confirm acceptable operation for all operating modes by reconciling the as-built piping and installed equipment with the initial analysis.

The final analysis proceeds as follows:

1. Determine the pressure drop in the system based on piping drawings and equipment suppliers data for design flow rates (if required).
2. Develop system resistance curves (if required).
3. Plot pump curves on the system resistance curve to determine the system flow rates.
4. Compare design flow rates with calculated flow rates for all operating modes.

Due to problems which occur during construction, the as-built drawings often differ from the piping drawings. In most instances, these changes are minor and do not affect the results of the analysis. Should any major changes occur during construction, the effect on the analysis results would need to be evaluated.

Piping Configurations.   Piping systems may be arranged in series, in parallel, or as branching pipes. For pipes in series, the total pressure head loss is the sum of head losses in the pipe sections, and the flow rate is the same at all sections. For pipes in parallel, the pressure head loss is the same for each flow path, and the total flow rate is the sum of flows in parallel sections. For branching pipes, the analyst must combine the above two principles. The total energy at a junction must be the same for all branches of the pipe.

Analysis of a piping system begins with a determination of the pressure drop (pressure head loss) due to friction losses, form losses (in various types of piping components) and pressure losses in equipment for the design flow rate. For ease in evaluating the total system performance, the head loss should be calculated for each pipe branch separately. The manual head loss calculations often are done on pressure drop sheets. Calculations of head loss should include a schematic sketch of the piping layout. The calculation should be a clear record of the design basis for head loss calculations in order that as the design evolves, the significance of pipe changes is apparent. A second head loss calculation may be required if the pipeline is expected to operate at flow rates considerably different from the design flow rate.

Having calculated the head loss in each branch of the system for the design flow rate, the performance of the entire system can be calculated. System resistance curves, flow balances, pump design points, and system pressures are some of the products of the system analysis.

The complexity of the system analysis depends on the number of pipes in series, pipes in parallel, and pipe branches. Obviously the greater the number of pipes, the more complex the analysis becomes. The analysis is done either by manual calculation or by computer analysis. Computerized calculations are preferable.

Manual calculations are suited for relatively simple piping systems. Manual analysis with the use of graphs provides an easy method for analyzing systems with a number of pipes in parallel, pipes in series, and branching pipes. This technique is based on the assumption that head loss varies with the square of velocity. Table B8.8 presents flow data for water through various sizes of Schedule 40 steel pipe.

The hydraulic grade line (HGL) and energy grade line (EGL) are two useful engineering tools in the hydraulic design of any system in which a liquid is in a dynamic state.[1] The graphical representation with respect to any selected datum, of the static head for each point along the pipe under consideration as ordinate, plotted against distance along the pipe as the abscissa is called the *hydraulic grade line.* Similar graphical representation of the total pressure (or Bernoulli head: static + dynamic), as described by Eq. (B8.12), is called the *energy grade line.* Figure B8.6 illustrates the HGL and EGL for a sample system.

Economic Optimization of Line Sizes.   The objective of this subject is balancing the savings in cost obtained by reduction in the size of the piping diameter against the increased cost of pumping equipment and power necessary to provide for increased pressure drop.

For given flows, as the pipe diameter decreases, the flow velocity increases, which decreases the cost of erected piping, including fittings, hangers, supports, and labor as represented by cost *a* in Fig. B8.7. However, the piping pressure drop ratio increases to the 5th power with reduction in the pipe internal diameter ratio, as shown in the accompanying table. The same is true with the pumping power, which is proportional to the pressure drop in the line, as represented by cost *b*

d2/d1	(d1/d2)⁵
0.99	1.050
0.98	1.106
0.97	1.165
0.96	1.230
0.95	1.292
0.90	1.694
0.80	3.052
0.70	5.950

in Fig. B8.7. In addition, there is the cost of the pump and the pump drive, which increases as greater pumping power is required, as represented by cost c.

The total cost, which is the sum of these three costs ($T_{COST} = a + b + c$) in $/year, is shown on Fig. B8.7 as reaching a minimum value at the optimum flow velocity. The analysis for each piping system should consider the optimization of flow velocity (optimum internal diameter) of the pipe under consideration. It is important to note that cost b depends strongly on the plant operating mode or the load factor, and on other economic indicators for a particular project. Industry data containing updated prices of equipment, piping, and labor are needed to implement this optimization procedure.

Sample Problem B8.1. What is the pressure drop $p_A - p_B$ (see Fig. B8.8), when water at 200°F (93.3°C) flows in a piping system at the rate of $\dot{m} = 450,200$ lb$_m$/h (204,207 kg/h), $p_A = 500$ psia (34.47 bar)?

Pipe Data. For 6-in nominal size, schedule 40 pipe, the internal diameter $d = 6.065$ in, $D = 0.5054$ ft, $A = 0.200$ ft².

Properties of Fluid. From the ASME Steam Tables software (Ref. 5) for $T = 200$°F and $p = 500$ psia, the dynamic viscosity of water (see attached computer printout, Table B8.9) is

$$\mu = 63.43 * 10^{-7} \; (\text{lb}_f \cdot \text{s})/\text{ft}^2$$

From the same computer printout, the specific volume of water at $T = 200$°F and $p = 500$ psia is

$$v = 0.01661 \; \text{ft}^3/\text{lb}_m$$

Then, the kinematic viscosity of water is [see Eq. (B8.3)]:

$$v = \frac{\mu}{\rho} g_c = (63.43 * 10^{-7})(0.01661)(32.174)$$

$$= 3.39 * 10^{-6} \; \text{ft}^2/\text{s}$$

The flow velocity is calculated from the continuity equation

$$w = \frac{\dot{m}}{\rho A}$$

$$\text{where } \dot{m} = \frac{450,200}{3600} = 125.06 \; \text{lb}_m/\text{s}$$

Useful conversion of units:
    1 inch = 25.4 mm; 1 ft = 0.3048 m; 1 ft³ = 0.02832 m³; t_C = 5/9 (t_F − 32); for pressure conversions to other units see Table B8.1.
    Note: For calculations for pipes other than Schedule 40, see explanation in Table B8.14.
    Note: For pipe lengths other than 100 ft, the pressure drop is proportional to the length. Thus, for 50 ft of pipe, the pressure drop is approximately one-half the value given in the table ... for 300 ft, three times the given value, etc. Velocity is a function of the cross-sectional flow area; thus, it is constant for a given flow rate and is independent of pipe length.

UNT PRESSURE TEMPERAT ENTHALPY		ENTROPY		QUALITY

Then:

$$w = \frac{125.06}{0.200} \, 0.01661 = 10.39 \text{ ft/s}$$

Using Eq. (B8.16), the Reynolds number is

$$\text{Re} = \frac{Dw}{\nu} = \frac{(0.5054)\,(10.39)}{3.39 * 10^{-6}} = 1.549 * 10^{6}$$

D'Arcy-Weisbach Friction Factor.   For commercial steel pipe from Ref. 7, the relative roughness is

$$\frac{\varepsilon}{D} = 0.00015/0.5054 = 0.0003$$

and the friction factor in zone of complete turbulence is

$$f_T = 0.015$$

From Eq. (B8.17), using, for example, the Newton-Raphson method for solving equations [or using the Moody diagram, Fig. (B8.5)], for calculated values of Re and ε/D, the D'Arcy-Weisbach friction factor, f, is found:

$$f = 0.0154$$

Flow Resistance Coefficients[7]:

Local disturbance	$K(f_T = 0.015)$
Entrance	$K = 0.04$
4 180° turns	$(4)(22.18 \, f_T) = 1.33$
1 globe valve (open)	$340 \, f_T = 5.10$
1 tee flow through run	$20 \, f_T = 0.33$
1 swing check valve (open)	$100 \, f_T = 1.50$
2 long radius elbows	$(2)(14f_T) = 0.42$
1 gate valve (open)	$8 \, f_T = 0.12$
Exit	$K = 1.00$
	$\Sigma\,K = 9.77$

Total Resistance

$$K_{\text{tot}} = \Sigma K + f \frac{L}{D}$$

$$= 9.77 + 0.0154 \, \frac{600}{0.5054}$$

$$= 28.05$$

"Friction" Pressure Drop in Pipe. From Eqs. (B8.14) and (B8.18):

$$\Delta p = K_{\text{tot}} \, \rho \, \frac{w^2}{2g_c}$$

$$= 28.05 \, \frac{(10.39)^2}{(0.01661)(2)(32.174)}$$

$$= 2833.08 \, \frac{\text{lb}_f}{\text{ft}^2}$$

$$= \frac{2833.08}{144} = 19.67 \text{ psi}$$

Pressure Difference $p_A - p_B$. From Bernoulli's equation (Eq. B8.12 with $H_f = 0$ and $H_p = 0$):

$$\frac{\rho_A \, w_A^2}{2g_c} + p_A + \frac{g}{g_c} z_A \, \rho_A$$

$$= \frac{\rho_B \, w_B^2}{2g_c} + p_B + \frac{g}{g_c} z_B \, \rho_B + \Delta \rho$$

Assuming $\rho_A = \rho_B = \rho$ and $g = 32.174 \, \dfrac{\text{ft}}{\text{s}^2}$

$$p_A - p_B = \frac{g}{g_c} (z_B - z_A) \frac{\rho}{144} + \Delta p$$

$$= \frac{100}{(144)(0.01661)} + 19.67 = 61.48 \text{ psi (4.24 bar)}$$

Applications: Oil and Other Liquid Systems

The calculation of oil flow through pipes is a much more complicated process than a similar calculation for water flow. Water properties are well-defined and many, including viscosity, are nearly constant within liquid temperature ranges, whereas oil is quite different. No two oils have the same physical properties, and any given oil is subject to important physical changes at expected variable temperatures. When considering oil flow in pipes, the most important variable physical property is viscosity.

Ordinary crude oil is not a homogeneous liquid; it is a very complex fluid composed of compounds of carbon and hydrogen which exist in petroleum in a wide variety of combinations. Physical properties change accordingly, and they also change as a result of temperature variations. Therefore, this handbook assumes that the user will research the fluid of interest in other sourcebooks (such as the *Petroleum Processing Handbook*[9]) to determine important properties including density and viscosity.

The "Viscosity" subsection in this handbook refers to Tables B8.5 and B8.6 for conversion among several common units of viscosity. The special names and symbols for derived CGS units (such as dyne, erg, poise, and stokes) should not be used

* To change capacities from gallons per minute to barrels (42 gal) per hour, multiply pressure drops by 1.43. To change from pressure drops per square inch per 100 ft to pressure drops per square inch per mile, multiply by 52.8.

Other important conversion relations:
1 US gallon = 0.00378541 m³, 1 ft = 0.3048 m,
1 inch = 25.4 mm, 1 mile = 1609.344 m.
For pressure conversions refer to TABLE B8.1.

with the SI. Apart from these, other units which do not belong to any coherent system should be defined in the oil-related problems. For readers who must use information from various existing sources, Table B8.10 is included. Together with Tables B8.5 and B8.6, this may lead to organized, easy-to-follow SI solutions to the encountered problems, especially in determining the pressure drop or flow rate of oil through pipes.

Typical pressure drops for oil flowing through pipes ranging from ½ to 12 inches in diameter appear in Table B8.11 for fluids with a density of approximately 7.78 lb_m/U.S. gal (0.932 kg/dm³).

Figures B8.9 through B8.15 provide pressure drops versus flow rates for fluids ranging from gasoline to those with 10,000 Seconds Saybolt Universal (SSU) viscosity through 2- to 12-in Schedule 40 pipe. To use these figures with SI units, the following conversion factors should be applied: 1 U.S. gallon = 3.78541 dm³, 1 U.S. mile = 1.609344 km (exactly), 1000 ft = 304.8 m (exactly). For pressure conversions see Table B8.1. The *specific gravity* of a substance is the ratio of its weight to the weight of an equal volume of water at chosen standard conditions.

Usually the engineer of an oil-burning plant will know only two things regarding the fuel oil supplied to him; namely, the specific gravity and the viscosity. The specific density or specific gravity can be used to convert volume measurements of fuel oil into mass, or vice versa. Using the API gravity system devised jointly by the American Petroleum Institute and the National Bureau of Standards (NBS), the API gravity of a mixture can be readily calculated proportionately (in degrees

API) from the respective gravities of the components. *Example:* What is the API gravity of a 40 percent mixture of a 10° API fuel and 60 percent of a 15° API fuel? Answer: $0.40 \times 10° + 0.60 \times 15° = 13°$ API.

A knowledge of viscosity and how it varies with temperature is essential for the easy handling and efficient utilization of fuel oil. Heavier fuel oils must be heated to the proper temperature in order to obtain a viscosity of 150 Saybolt Universal at the burners for the most efficient atomization. It is also important to determine to what temperature the oil should be heated in the bunkers so it can be readily pumped through the fuel oil system. Generally the maximum temperature that oil in the bunkers be heated to is 130°F (about 55°C) in an effort to reduce the viscosity for easier pumping.

When two or more oils are blended, it is necessary to determine the properties of the mixture. Several methods are available to achieve the important properties such as viscosity and most use some type of viscosity blending chart. The *Petroleum Processing Hanbook*[9] is one source of such a blending chart which is a semilogarithmic plot of kinematic viscosity versus either volume percent lower or higher viscosity liquid. A linear interpolation is used on this type of plot.

STEADY SINGLE-PHASE COMPRESSIBLE FLOW IN PIPING

Characteristics of Compressible Flow in Pipes

The term *compressible flow* implies variations in density of a fluid. These variations are the result of pressure and temperature changes from one point to another. The rate of change of density with respect to pressure is, therefore, an important parameter in the analysis of compressible flow, and it is closely connected with the velocity of sound.

Adiabatic, Constant-Area Flow with Friction. Adiabatic flow with friction is of interest in sizing safety valve discharge lines (vent lines) and other pipes where heat transfer may be neglected and where the flow may be restricted by sonic condition at the pipe exit (choked flow). Supersonic velocities will not be discussed here.

In this section, the flow of compressible gases and steam (small fluid densities) in ducts of constant cross-sectional area will be discussed. For adiabatic conditions (heat exchanged with surroundings $dQ = 0$), the energy equation for steady flow between two points, 1 and *x,* in a pipe may be written as follows:

$$h_x + \frac{w_x^2}{2g_c J} = h_1 + \frac{w_1^2}{2g_c J} = h_0 \qquad \text{(B8.20)}$$

where h_0 is the stagnation enthalpy [see Eq. (B8.9)]. Utilizing the continuity equation:

$$\dot{G} = \frac{\dot{m}}{A} = \frac{w_x}{v_x} = \frac{w_1}{v_1} \qquad \text{(B8.21)}$$

for constant values of flow rate $\dot{m}$, and area A, the following is found:

$$h_x + \left(\frac{\dot{m}}{A}\right)^2 \frac{v_x^2}{2g_c J} = h_1 + \frac{w_1^2}{2g_c J} = h_0 \tag{B8.22}$$

Equation (B8.22) represents the *Fanno line*[10] which is the locus of the conditions in a cylindrical pipe of constant diameter. Having fixed w_1 and h_1 at the starting point, the stagnation enthalpy h_0 is calculated. This enthalpy stays constant along the length L of the pipe. Choosing an arbitrary specific volume v_x, the corresponding value of h_x can be calculated from Eq. (B8.22). The intersection of v_x and h_x on the $h - s$ diagram represents a point on the Fanno line. The sonic (choked) condition at the pipe exit shown in Fig. B8.16 is defined by

$$\frac{ds}{dh} = 0 \tag{B8.23}$$
FIGURE B8.16   Fanno line on the *h-s* diagram.

Considering the work done against friction (an irreversible process with the change in entropy of the fluid within the system) and the heat generated within the fluid by internal friction during an adiabatic flow (heat exchanged with the surroundings $dq = 0$), the following expression is derived:

$$L_x = \frac{2g_c J}{f} D \int_{s_l}^{s_x} \frac{T}{w^2} ds \tag{B8.24}$$

Equation (B8.24) represents the length L_x of the pipeline, along which the pressure drops from p_1 to p_x. The described procedure yields a number of points on a Fanno line and also the coordinates of the function $T/w^2 = f(s)$. Integrating the function $T/w^2 = f(s)$ with fixed upper boundary (sonic conditions) and floating lower boundary of integration, the fluid parameters (static conditions) at any dis-
FIGURE B8.17   Integration of the function T/w^2.

tance L upstream of the sonic (choked) plane can be found (convergence on the given length L of the pipe). The procedure is explained in Fig. B8.17.

If the calculated pressure at sonic exit is lower than the receiver pressure, the additional length of the pipe required for choked conditions at the exit should be calculated. By adding this fictitious pipe length to the actual length of the pipe the "extended length" is found. This new length is now used for calculating the parameters at the start of the pipeline, after a valve, or at any distance from the choked exit.

For steam service, computerized calculations utilizing built-in steam tables (as in Ref. 5) are recommended. For most problems in gas dynamics, however, the assumption of the perfect gas law is sufficiently in accord with the properties of real gases to be acceptable.[11]

A simplified approach for frictional, adiabatic, constant-area flow (Fanno line analysis) of a perfect gas (that has constant specific heat) is presented in Ref. 11. The working formulas may be represented graphically or they may be used for computerized calculations to produce Fanno line tables for a perfect gas of any k and any assigned Ma values. As an example, see Table B8.12. It is important to notice that in Table B8.12, taken from Ref. 11, the Fanning friction factor is used (see Eq. B8.14 and lines below). Following are some of the working formulas suitable for practical computations, as presented in this reference book. The quantities marked with an asterisk (*) in written expressions (p^*, w^*, etc.) represent the values of the stream properties at the section in the pipe where Ma $= w/c = 1$ (sonic plane). Because the quantities marked with an asterisk are constants for a given adiabatic, constant-area flow, they may be regarded as convenient reference values for normalizing the equations.

Choke pressure:

$$p^* = \frac{\dot{m}}{A} \sqrt{\frac{2RT_0}{g_c k(k+1)}} \qquad \text{(B8.25)}$$

Source: Ref. 11

Static pressure, p, in the pipe cross section where the Mach number Ma < 1, may be found from the expression:

$$\frac{p}{p^*} = \frac{1}{\text{Ma}}\sqrt{\frac{k+1}{2\left[1+(k-1)/2\text{Ma}^2\right]}} \tag{B8.26}$$

Flow velocity:

$$\frac{w}{w^*} = \text{Ma}\sqrt{\frac{k+1}{2\left[1+(k-1)/2\,\text{Ma}^2\right]}} \tag{B8.27}$$

Maximum duct length:

$$f\frac{L_{\text{max}}}{D} = \frac{1-\text{Ma}^2}{k\text{Ma}^2} + \frac{k+1}{2k}\ln\frac{(k+1)\text{Ma}^2}{2[1+(k-1)/2\text{Ma}^2]} \tag{B8.28}$$

Equation (B8.28) gives the maximum value of $(f\,L)/D$ corresponding to any initial Mach number Ma. Notice, that for Ma = 1, the expression (B8.28) results in $(f\,L_{\text{max}})/D = 0$. The length of duct L required for the flow to pass from a given initial Mach number Ma_1 to a given final Mach number Ma_2 may be found from the expression:

$$f\frac{L}{D} = \left[f\frac{L_{\text{max}}}{D}\right]_{\text{Ma}_1} - \left[f\frac{L_{\text{max}}}{D}\right]_{\text{Ma}_2} \tag{B8.29}$$

In order to find the change in some stream property, say the pressure, between the sections where the Mach numbers are Ma_1 and Ma_2 respectively, the following expression is used:

$$\frac{p_2}{p_1} = \frac{(p/p^*)_{\text{Ma}_2}}{(p/p^*)_{\text{Ma}_1}} \tag{B8.30}$$
