where $(p/p^*)\text{Ma}_2$ is the value of the right-hand side of Eq. (B8.26) corresponding to Ma_2, and so forth.

Isothermal Flow in Long Pipelines. Isothermal flow with friction is of interest in connection with pipelines for transporting gas over long distances. When the lines are extremely long, there is sufficient area for heat transfer to make flow nonadiabatic and approximately isothermal, especially when the gas temperature is not much different from the temperature of the surroundings. In such cases, the flow may not be treated as incompressible and the D'Arcy-Weisbach equation cannot be used for calculating the pressure drop.

Using the assumptions of constant elevation, no work being done by the fluid, continuity, isothermal flow, and that the friction coefficient does not change with length of the pipe yields the following application equation:

$$\dot{m} = \frac{\pi}{4}\sqrt{\frac{2g_c}{fRT_1}}\sqrt{\frac{D^5}{L}p_{\text{ave}}\Delta p} \tag{B8.31}$$

For the same mass flow rate $\dot{m}$, the pipe diameter D may be decreased by increasing the average pressure p_{ave} in the pipeline and/or permitting a larger pressure drop Δp. One of the applications of Eq. (B8.31) is the economic analysis of long gas line systems requiring intermediate compression stations.

It has to be mentioned here that the Mach number

$$\text{Ma} = \frac{1}{\sqrt{k}} \tag{B8.32}$$

represents a limit for continuous isothermal flow, in the same way that $Ma = 1$ represents a limit for continuous adiabatic flow.[11] The working formula for determining the maximum pipe length beyond which the continuous isothermal flow may not proceed (ideal gas approximation) is given by the following expression:

$$f\frac{L_{\max}}{D} = \frac{1 - k\text{Ma}^2}{k\text{Ma}^2} + \ln(k\text{Ma}^2) \tag{B8.33}$$

where Ma is the Mach number at the pipe inlet. For greater lengths, choking occurs and the mass flow rate decreases.

Sample problems for this subsection are presented under ''Applications: Sample Problems B8.2–B8.7.''

Applications: Steam Systems

In a case of compressible fluids such as air or steam, when density changes are small the fluid may be considered as incompressible. Therefore, all design rules described in earlier sections are applicable to this case. For steam and gas systems, where the fluid density is small, static head is negligible and may be omitted in pressure drop calculations.

The typical velocities shown in Table B8.13 may be considered for preliminary line sizing, but economic size should be determined as a function of pressure drop, pipe cost, and so forth.

Special attention should be given to turbine main steam lines and to hot and cold reheat piping because pressure drop in those systems affects heat rate and plant performance. Cost of piping must be compared with these effects for most economical piping arrangement. Normally, total pressure drop in reheat piping and

TABLE B8.13 Typical Steam Velocity in Pipelines on Industrial Projects[1]

Steam pressure	Velocity	Pressure drop
50 psig (3.5 bar g) and lower	175 ft/s (~50 m/s)	0.4 psi/100 ft (~0.1 bar/100 m)
Over 50 psig (3.5 bar g) saturated steam	120 ft/s (~35 m/s)	1.0 psi/100 ft (~0.25 bar/100 m)
Over 50 psig (3.5 bar g) superheated steam	175 ft/s (~50 m/s)	1.0 psi/100 ft (~0.25 bar/100 m)

[1] Velocities are based on typical process industry practice.
Source: Stone & Webster.

the boiler reheater should be 7 to 9 percent of high pressure turbine exhaust pressure. It is desirable to use a smaller diameter hot reheat line and a larger diameter cold reheat line, taking a greater pressure drop in the more expensive, alloy, hot reheat line.

Extraction steam piping also affects heat rate and output, and norally this piping should be sized so that the pressure drop does not exceed about 5 percent of turbine stage pressure for the low pressure and 3 to 4 percent for the higher pressure lines.

Extraction steam lines should be designed for the pressure shown on full-load heat balance diagram at 5 percent overpressure and valves wide open (VWO).

Continuously operating steam lines in process projects shall be designed on the basis of reasonable total pressure drop and, except for short leads such as to turbines and pumps, shall not generally exceed the conditions noted in Table B8.13.

Applications: Air and Other Gas Systems

As indicated in the last section, ''Applications: Steam Systems,'' in a case of compressible fluids such as air or steam when density changes are small, the fluid may be considered as incompressible. Therefore, all design rules described in the subsections ''Characteristics of Incompressible Flow,'' ''Applications: Water Systems,'' and ''Applications: Steam Systems'' are applicable to this section. For steam and gas systems, where the fluid density is small, static head is negligible and may be omitted in pressure drop calculations.

Table B8.14 (from Ref. 7) presents pressure drop for some typical values of air flow rates through piping from ⅛ to 12 in diameter.

Applications: Sample Problems B8.2–B8.7

The most frequent application of single-phase compressible flow steam line analysis normally encountered by engineers is the sizing of safety valve vent lines. This analysis can be done either by using a computer program which is based on procedures discussed, or a hand calculation similar to that presented in this section. Users may compare their results with those obtained from an approximate, semi-empirical procedure based on tables in App. 11 of Ref. 12. It is the responsibility of the designer to make sure that the method used yields conservative results.

The primary consideration in these analyses is to ensure that the vent line will pass the required flow without exceeding recommended backpressure limitations on valves with solidly connected vents or without blowing back in the case of open vent stacks.

Problem B8.2.   During abnormal operation of a system, 72,000 lb_m/h (32,659 kg/h) of air must be released from a high-pressure air tank through a 4-in (Schedule 40) commercial steel bypass line (vent line) into the atmosphere. Stagnation conditions in the vessel during this operation are: p_o = 600 psig (41.4 bar gauge (kept at a constant level by compressors), t_F = 120°F (48.9°C). Equivalent length of the vent line is 90 ft (27.43 m). Calculate the pressure p_1 that exists at the valve discharge and make your comments on the vent line size. Air may be treated as a perfect gas. Assume that this is not a typical safety valve and that the valve backpressure should not exceed 50 percent of the valve set pressure. (The safety valve vent line design criteria are well documented in the ASME Boiler and Pressure Vessel Code.)

TABLE B8.14 Flow of Air Through Schedule 40 Steel Pipe

Pressure drop of air in pounds per square inch per 100 ft of Schedule 40 pipe — For air at 100 lb/in² gauge pressure and 60°F temperature

For lengths of pipe other than 100 ft, the pressure drop is proportional to the length. Thus, for 50 ft of pipe, the pressure drop is approximately one-half the value given in the table ... for 300 ft, three times the given value, etc.

The pressure drop is also inversely proportional to the absolute pressure and directly proportional to the absolute temperature.

Therefore, to determine the pressure drop for inlet or average pressures other than 100 psi and at temperatures other than 60°F, multiply the values given in the table by the ratio $[(100 + 14.7)/(P + 14.7)]$ $[(460 + t)/520]$ where P is the inlet or average gauge pressure in pounds per square inch, and t is the temperature in degrees Fahrenheit under consideration.

The cubic feet per minute of compressed air at any pressure is inversely proportional to the absolute pressure and directly proportional to the absolute temperature.

To determine the cubic feet per minute of compressed air at any temperature and pressure other than standard conditions, multiply the value of cubic feet per minute of free air by the ratio $[14.7/(14.7 + P)]$ $[(460 + t)/(520)]$.

Calculations for Pipe Other than Schedule 40

To determine the velocity of water, or the pressure drop of water or air, through pipe other than Schedule 40, use the following formulas, $v_a = v_{40}(d_{40}/d_a)^2$, $\Delta P_a = \Delta P_{40}(d_{40}/d_a)^5$, where v = velocity, ft/s; d = internal diameter of pipe, in; ΔP = pressure drop, lb/in^2.

Subscript a refers to the schedule of pipe through which velocity or pressure drop is desired. Subscript 40 refers to the velocity or pressure drop through Schedule 40 pipe.

Source: Ref. 7.
FIGURE B8.18 Reference for sample problem B8. 2.

$$\dot{m} = 72{,}000 \text{ lb/hr} = 20 \text{ lb}_m/\text{sec}$$

$$T_0 = 120°\text{F} = (460 + 120) = 580°\text{R}$$

$$p_0 = 600 \text{ psig} = 614.7 \text{ psia (assumed atmospheric pressure of 14.7 psia)}$$

Internal pipe diameter $D = 4.026$ in ($A = 0.0884$ ft²).

Critical pressure at the pipe discharge (see Fig. B8.18) is found by using Eq. (B8.25):

$$p^* = \frac{\dot{m}}{A}\sqrt{\frac{2RT_0}{g_c k(k+1)}} \text{ lb}_f/\text{ft}^2$$

$$= \frac{20}{0.0884}\sqrt{\frac{(2)(53.3)(580)}{(32.174)(1.4)(2.4)}}$$

$$= 5410.35 \text{ lb}_f/\text{ft}^2 = 37.57 \text{ psia}$$

The line is choked because $p^* > p_{amb} = 14.7$ psia. Pipe $f(L/D)$, from choked exit to the valve discharge, is calculated by assuming complete turbulence of flow. From Ref. 7, for a commercial steel pipe:

$$\frac{\varepsilon}{D} = \frac{(0.00015)(12.0)}{4.026} = 0.00045$$

and the friction factor $f = f_T = 0.017$. Then the value of $(f\,L)/D$, counting from the choked pipe exit to the valve outlet is:

$$f\frac{L}{D} = 0.017\frac{(90)(12)}{4.026} = 4.5604$$

Using a computerized method (for example the Newton-Raphson method) of solving Eq. (B8.28) (notice that for Ma $= 1$ at the pipe discharge, the second term on the right hand side of Eq.(B8.28) is zero), with $k = 1.4$, having on the left side of this equation the above calculated $(f\,L)/D = 4.5604$ and changing the Mach number, the value of Mach number for air entering the pipe, which satisfies the equation, is found to be:

$$\text{Ma} = 0.317$$

Substituting this Ma value into Eq. (B8.26) results in

$$\frac{p}{p^*} = \frac{p_1}{p^*} = 3.4193$$

and finally:

$$p_1 = p^* \left(\frac{p}{p^*}\right) = (37.57)(3.4193) = 128.46 \text{ psia } (8.86 \text{ bar})$$

Fanno line tables for $k = 1.4$ (Table B8.12) may be used instead, but this procedure would require cumbersome interpolations. Also, note that in Ref. 11 (the source of Table B8.12) the Fanning friction factor is used, which is four times less than that of D'Arcy-Weisbach. This is the reason why Table B8.12 uses 4 fL_{max}/ D) value in the last column.

Problem B8.3.   Twice as much flow rate must be released from the tank described in Problem B8.2. Check if the piping is adequate.

$$p^* = (2)(37.57) = 75.14 \text{ psia}$$

Then,

$$p_1 = (75.14)(3.4193) = 256.93 \text{ psia } (17.72 \text{ bar})$$

The piping is still adequate because the calculated $p_1 < 0.5\ p_0$.

Problem B8.4.   Keep the mass flow as in Problem B8.2, but double the length of the pipe. Check the pressure p_1:

$$fL/D = (2)(4.5604) = 9.1208$$

at this $f\ L/D$,

$$(p_1/p^*) = 4.4854$$

$$\text{Ma} = 0.243$$

and

$$p_1 = (37.57)(4.4854) = 168.52 \text{ psia } (11.62 \text{ bar})$$

which means that the line size is sufficient.

Problem B8.5.   For the same mass flow and the same pipe as in Problem B8.2, assume that the air temperature in the vessel $t_F = 500°F$ (260°C).

$$p^* = \frac{20}{0.0884} \sqrt{\frac{(2)(53.3)(460 + 500)}{(32.174)(1.4)(2.4)}}$$

$$= 6960.97 \text{ lb}_f/\text{ft}^2 = 48.34 \text{ psia}$$

$$p_1 = (3.4193)(48.34) = 165.29 \text{ psia } (11.40 \text{ bar})$$

The line size is sufficient.

Problem B8.6. For the same mass flow and the same pipe as in Problem B8.2, use the pipe diameter of 2 in (Schedule 40) and calculate p_1.

$$D = 2.067 \text{ in } (A = 0.0233 \text{ ft}^2)$$

$$p^* = 37.57 \frac{0.0884}{0.0233} = 142.54 \text{ psia}$$

$$f\frac{L}{D} = (0.019)\frac{(90)(12)}{2.067} = 9.9274$$

Then

$$(p/p^*) = 4.644$$

$$\text{Ma} = 0.235$$

and

$$p_1 = (142.54)(4.644) = 661.96 \text{ psia } (45.64 \text{ bar})$$

The calculated pressure p_1 is too high. It is even higher than the pressure p_0 within the vessel. This line cannot be used for releasing the required flow.

Problem B8.7. For the same flow and the same pipe length as in Problem B8.2, use the pipe diameter of 8 in (Schedule 40), and calculate p_1.

$$D = 7.981 \text{ in } (A = 0.3474 \text{ ft}^2)$$

$$f = f_T = 0.014$$

$$p^* = 37.57 \frac{0.0884}{0.3474} = 9.56 \text{ psia}$$

Because $p^* < p_{\text{atm}}$, the line is not choked. To calculate the pressure p_1 after the valve, the additional length, L_{add}, of the pipe, required for choked conditions at the exit, should be calculated first.
    Assuming

$$p_{\text{amb}} = p_{\text{atm}} = 14.7 \text{ psia}$$

$$\frac{p_{\text{atm}}}{p^*} = \frac{14.7}{9.56} = 1.5376$$

From Fanno line tables, for $(p/p^*) = 1.5376$, the following is found for the existing pipe outlet

$$f L_{\text{add}}/D = 0.2467$$

$$\text{Ma} = 0.6814$$

Therefore,

$$L_{\text{add}} = \frac{\left(f\frac{L_{\text{add}}}{D}\right)}{\frac{f}{D}} = \frac{(0.2467)(7.981)}{(0.014)(12)} = 11.72 \text{ ft}$$

and the fictitious pipe length from the choked pipe exit to the valve outlet

$$L_{\text{fict}} = 90 + 11.72 = 101.72 \text{ ft}$$

The corresponding $(f\,L/D)_{\text{fict}}$ value, starting from the choked exit to the valve, is

$$\left(f\frac{L}{D}\right)_{\text{fict}} = \frac{(0.014)(101.72)(12)}{7.981} = 2.1412$$

For this $(f\,L/D)_{\text{fict}}$, the following is obtained from the Fanno line computerized calculation, similar to that explained in Problem B8.2 (or from Fanno line tables for $k = 1.4$):

$$(p/p^*) = 2.6306$$

$$\text{Ma} = 0.4096$$

Therefore,

$$p_1 = (9.56)(2.6306) = 25.15 \text{ psia } (1.73 \text{ bar})$$

SINGLE-PHASE FLOW IN NOZZLES, VENTURI TUBES, AND ORIFICES

Theoretical Background

Liquid Service. A nozzle or an orifice in a tank or reservoir may be installed in the wall (Fig. B8.19) or in the bottom.

In the case of a nozzle, the fluid emerges in the form of a cylindrical jet of the same diameter as the throat of the nozzle, but in the case of a sharp-edged orifice, the jet contracts after passing through it, attaining its smallest diameter (vena contracta) and greatest velocity some distance (about one-half of a diameter) downstream from the opening. When installed in the bottom, the distance z from the opening in the bottom of the tank to the liquid free surface must include the length of a nozzle or the distance of the vena contracta from the bottom of the tank. The ratio of jet area A_2 at vena contracta to the area of an orifice A is called the *coefficient of contraction* C_c.

$$C_c = A_2/A \qquad\qquad (B8.34)$$

For a nozzle $C_c = 1$.

Bernoulli's equation [(Eq. B8.12) without H_p and H_f] applied from a point 1 on the free surface to the center of the vena contracta, point 2, yields the following
FIGURE B8.19 Typical nozzle and orifice.

expression for the theoretical (no friction) discharge velocity of fluid at the vena contracta ($w_1 = 0$)

$$w_2 = \sqrt{\frac{2g_c}{\rho}\left(p_1 - p_2 + \rho z\frac{g}{g_c}\right)} \text{ ft/s} \tag{B8.35}$$

where p_1 and p_2 are absolute static pressures (lb_f/ft^2) at the free surface in the tank and in the vena contracta respectively. If the fluid is discharged to the atmosphere, p_2 is the atmospheric pressure. For open vessels $p_1 = p_2$.

Hydraulic engineers sometimes prefer to use the following version of Eq. (B8.35):

$$w_2 = \sqrt{2g\left(\frac{p_1 - p_2}{\gamma} + z\right)} \text{ ft/s} \tag{B8.36}$$

Equation (B8.35) or (B8.36) describes the theoretical velocity because the pressure losses between the points 1 and 2 were neglected. The ratio of actual velocity w_a to the theoretical velocity w_t is called the *velocity coeffficient C_v.*

The actual volumetric discharge rate from the orifice is the product of the actual velocity at the vena contracta and the area of the jet at the vena contracta. Using the just-described coefficient of contraction C_c, the mass flow rate from the opening may be calculated from the following expression

$$\dot{m} = C_v C_c A \rho w_2 \tag{B8.37}$$

where

$$C_d = C_v C_c \qquad (B8.38)$$

is called the *discharge coefficient.*
FIGURE B8.20   Typical submerged nozzle or orifice

The velocities and quantities of liquid discharged from a submerged orifice or nozzle (Fig. B8.20) are determined by the same formulas as just presented. The different symbols in Eqs. (B8.35) and (B8.36) are understood in this case as follows:

$z = z_A$ Immersion depth of the center of the opening relative to the free liquid level in reservoir A, ft

$p_1 = p_A$ Static pressure at the free surface A in reservoir, $\mathrm{lb_f/ft^2}$

$p_2 = p_B + g\rho z_B$ Static pressure in the vena contracta jet, $\mathrm{lb_f/ft^2}$

It is preferable that the actual coefficient of discharge C_d of an orifice or a nozzle be determined by calibration. Such calibration should encompass the entire range of flow rates to be experienced. If an orifice or a nozzle is manufactured according to the ASME specification (Ref. 13), then the appropriate values of C_d, as described in Ref. 13 may be used for flow rate calculations.

Consider now a flow nozzle installed in a horizontal pipe (Fig. B8.21), where $z_1 = z_2 = \text{const}$. Because with an incompressible fluid (i.e., a liquid) the temperature does not change, the density is constant. Thus, the continuity equation becomes

$$w_1 \frac{\pi D^2}{4} = w_2 \frac{\pi d^2}{4} \qquad (B8.39)$$

and the Bernoulli equation applied from Section 1 to Section 2 is

$$\frac{w_1^2}{2g_c} + \frac{p_1}{\rho} = \frac{w_2^2}{2g_c} + \frac{p_2}{\rho} \qquad (B8.40)$$
FIGURE B8.21   Flow nozzle in a pipe.

Substituting w_1 from Eq. (B8.39) into Eq. (B8.40) the following expression for the theoretical velocity w_2 is obtained (no friction):

$$w_2 = \sqrt{2g_c \frac{p_1 - p_2}{\rho} \frac{1}{1 - \beta^4}} \quad \text{ft/s} \tag{B8.41}$$

where $\beta = d/D$, and the approach velocity factor, F_{wa}, is

$$F_{wa} = \frac{1}{1 - \beta^4} \tag{B8.42}$$

Because most materials expand or contract as their temperature changes, an area factor F_a (Fig. B8.22) for the thermal expansion of the primary element (nozzle or orifice) must be introduced in order to find an actual flow area. In general, the actual flow rate is less than the theoretical flow. Therefore, to obtain the actual flow, the discharge coefficient C_d must be introduced (empirical value) into the theoretical Eq. (B8.41):

$$C_d = \frac{\text{actual flow rate}}{\text{theoretical flow rate}} \tag{B8.43}$$

Thus, the actual mass flow rate through a flow nozzle is

$$\dot{m} = F_a A_2 \rho C_d w_2 \tag{B8.44}$$

Equation (B8.44), which was derived for a flow nozzle, holds equally well for horizontal Venturi tubes and for orifices. The following factor is frequently used in calculations and is called the flow coefficient:

$$C = \frac{C_d}{\sqrt{1 - \beta^4}} \tag{B8.45}$$

The values of C_d and C are different for each different type of primary element: Venturi tube, flow nozzle, and orifice. Also, with flow nozzles and orifices, the
FIGURE B8.22   Area factors, F_a, for the thermal expansion of primary elements. (*From Ref. 13.*)

values depend upon the locations of the pressure taps; and, with the orifice, the values differ with the type of inlet edge, whether square and thin or rounded.

Values of C for long-radius nozzles and square-edged orifices are available in Ref. 7. For a classical Venturi tube, the discharge coefficients C_d are[13]:

	C_d
Rough-cast entrance cone	0.984
Machined entrance cone	0.995
Rough-welded sheet metal entrance cone	0.985

Each obstacle in a flow path generates a permanent pressure drop Δp_p. The pressure profile in a pipe due to an orifice insertion is shown in Fig. B8.23.

The permanent pressure loss through a primary element of a *flowmeter*, with an orifice, a nozzle, or a Venturi tube, is shown in Fig. B8.24. The Venturi tube
FIGURE B8.23 Pressure profile in a pipe with an orifice. (*From Ref. 15.*)

has a low overall loss due to the gradually expanding conical section, which aids in efficient reconversion of the high kinetic energy at the throat into pressure.

Steam and Gas Service. Because the static head is not considered in gas systems, there is no need to distinguish the case of outflow from a reservoir from that of flow in a pipe.

Consider the flow of a perfect gas through a converging nozzle (Fig. B8.25). By applying Eqs. (B8.7) and (B8.8) to the inlet and outlet of a nozzle, and neglecting potential energy, the following result is found for an insentropic flow:

$$w_{2s} = \sqrt{2g_c J (h_0 - h_{2s})} \tag{B8.46}$$

where h_0 is the stagnation enthalpy at the nozzle inlet [see Eq. (B8.9)].

If there are no losses due to friction or heat transfer, the change of state of a gas is isentropic (s = const), and using the gas properties relationships (Ref. 2, typical), Eq. (B8.46) yields:

$$w_{2s} = \sqrt{2g_c J c_p T_0 \left(1 - \frac{T_{2s}}{T_0}\right)} \tag{B8.47}$$

or

$$w_{2s} = \sqrt{2g_c \frac{k}{k-1} p_0 v_0 \left[1 - \left(\frac{p_2}{p_0}\right)^{(k-1)/k}\right]} \tag{B8.48}$$
FIGURE B8.24   Permanent pressure loss through primary elements of flowmeters. (*From Ref. 13.*)

which was first derived by De St. Venant and Wantzel in 1839. Equation (B8.48) is written in terms of inlet stagnation conditions, where:

$$T_0 = T_1 + \frac{w_1^2}{2 g_c J c_p} \tag{B8.49}$$
FIGURE B8.25 Fluid flow in a converging nozzle.

and for an isentropic process of a perfect gas:

$$p_0 = p_1 \left(\frac{T_0}{T_1} \right)^{k/(k-1)} \tag{B8.50}$$

The mass flow rate of a gas through the cross section area A_2 can be calculated from:

$$\dot{m} = \frac{A_2 w_{2s}}{v_{2s}} = A_2 \Psi_s \sqrt{\frac{p_0}{v_0}} \ \mathrm{lb_m/s} \tag{B8.51}$$

where

$$\Psi_s = \sqrt{ 2g_c \frac{k}{k-1} \left[\left(\frac{p_2}{p_0} \right)^{2/k} - \left(\frac{p_2}{p_0} \right)^{(k+1)/k} \right] } \tag{B8.52}$$

Figure B8.26 shows the mass flow rate $\dot{m}$ plotted against p_2/p_0 for a specified gas which is characterized by its $k = c_p/c_v$ value. The flow rate becomes zero when $(p_2/p_0) = 1$. As the pressure p_2 decreases, the flow rate increases to its maximum value at p^*/p_0 (critical pressure ratio). At $(p_2/p_0) < (p^*/p_0)$, Eq. (B8.51) predicts decreasing flow to zero at $(p_2/p_0) = 0$. However, experiments show that in a flow through a convergent nozzle, the pressure at the exit cross section A_2 cannot fall below the value of p^* and the flow rate does not change, no matter how low the backpressure p_2. At the critical pressure ratio the mass flow rate reaches its maximum value and the flow is said to be *choked*. The maximum flow rate at the choke point is called the *critical flow rate*. Critical or mass limiting flow is characteristic of compressible fluid systems.
FIGURE B8.26 Mass flow rate versus p_2/p_0 ratio, and the pressure distribution within the nozzle versus p_2.

The value of the critical pressure ratio (p^*/p_0) may be found from the following conditions:

$$\frac{d\dot{m}_s}{d(p_2/p_0)} = 0 \quad \text{or} \quad \frac{d\Psi_s}{d(p_2/p_0)} = 0 \tag{B8.53}$$

Applying this condition to Eq. (B8.52) leads to the critical pressure ratio:

$$\beta_s = \frac{p^*}{p_0} = \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} \tag{B8.54}$$

where p_0 is described by Eq. (B8.50). Then, substituting the critical pressure ratio for p_2/p_0, Eq. (B8.52) yields:

$$\Psi_{s\,\text{max}} = \sqrt{g_c k \left(\frac{2}{k+1}\right)^{\frac{k+1}{k-1}}} \tag{B8.55}$$

and the corresponding maximum flow rate is

$$\dot{m}_{s\,\text{max}} = A_2 \Psi_{s\,\text{max}} \sqrt{\frac{p_0}{v_0}} \tag{B8.56}$$

For $(p_2/p_0) > p^*/p_0$, the mass flow rate must be calculated from Eq. (B8.51) or by the simplified equation presented by Bendemann in 1907.[10] It was proved by

Bendemann that the arc AC in Fig. B8.26 can be replaced with a high degree of accuracy by a quadrant of an ellipse:

$$\left(\frac{\dot{m}}{\dot{m}_{s\,\text{max}}}\right)^2 + \frac{\left(\frac{p_2}{p_0} - \beta_S\right)^2}{(1 - \beta_s)^2} = 1 \qquad \text{(B8.57)}$$

The remaining thermodynamic parameters (in addition to the critical pressure p^*) at the nozzle throat, corresponding to the maximum flow rate of an ideal gas, are the following:

1. Temperature may be determined by using the relation (see Ref. 11):

$$\frac{T^*}{T_0} = \frac{2}{k+1} \qquad \text{(B8.58)}$$

For T_0 see Eq. (B8.49).

2. Specific volume may be calculated from another relation for an isentropic expansion

$$\frac{v^*}{v_0} = \left(\frac{k+1}{2}\right)^{1/(k-1)} \qquad \text{(B8.59)}$$

3. The gas velocity may be calculated from the following expression

$$w_{2\,\text{max}} = \alpha_s \sqrt{p_0 v_0} \qquad \text{(B8.60)}$$

where

$$\alpha_s = \sqrt{2g_c \frac{k}{k+1}} \qquad \text{(B8.61)}$$

Because $p_0 v_0 = RT_0$, also

$$w_{2\,\text{max}} = \alpha_s \sqrt{RT_0} \qquad \text{(B8.62)}$$

It will be observed that for the same perfect gas (α_s, R) the maximum velocity depends only upon its initial stagnation temperature (before a nozzle). It can be shown that Eq. (B8.60) or (B8.62) represents a velocity of sound in the choked exit plane of a nozzle:

$$w_{2\,\text{max}} = \sqrt{g_c k R T^*} = \sqrt{g_c k p^* v^*} = c \qquad \text{(B8.63)}$$

The ASME report on fluid meters (Ref. 13) presents slightly modified equations which are more suitable for precise differential-pressure flow-metering techniques. See this document for procedures and more information about flow measurement using orifices, nozzles, or Venturi tubes.

Sample problems concerning ASME fluid meters may be found in Refs. 13 and 14.

Applications: Flow Restriction

Flow-restricting orifices are used where a continuous small flow of fluid (bleeding) is required. Flow-restricting orifices are usually not designed according to requirements of the ASME specification for fluid metering devices. In most cases, they are round openings drilled in an orifice plate. Their fluid entrance may be sharp-edged, beveled, or well-rounded.

It is suggested that reasonably accurate approximations in flow rate estimations may be obtained by using equations presented in the last subsection. If the entrance is well-rounded, C values would tend to approach those for ASME nozzles, whereas openings with square entrances would have characteristics similar to those for square-edged ASME orifices. The minimum allowable orifice size should be $\frac{1}{16}$ in to prevent clogging. The recommended thicknesses of orifice plates for carbon steel or chrome-moly steel are given in Table B8.15.

Applications: Fluid Flow Metering

Recommended conditions, procedures, and data for measuring the flow of fluids, particularly with the three principal differential-pressure meters—the orifice, the flow nozzle, and the Venturi tube—are presented in the ASME test codes.[13,14]

Applications: Sample Problem B8.8[15]

This could be a model for important safety related calculations.

Air is contained in a vessel having a volume of $V_{vess} = 80$ ft³ (2.27 m³). The initial state of the gas in the vessel corresponds to its pressure of $p_0 = 250$ psia (17.24 bar), and its temperature of $t_F = 70°F$ (21.11°C). The gas line of internal diameter $d = 1$ in (25.4 mm) broke off completely at the nozzle (well-rounded inlet) and air started to leak into the surroundings at the atmospheric pressure of $p_{atm} = 14.7$ psia (1.01 bar). Assume that due to a slow process of air expansion in the vessel, while the pressure within the vessel drops, its temperature remains constant (the vessel is not insulated, and air is absorbing heat from surroundings through the vessel walls). Also, assume that the air expansion in the nozzle is isentropic.

Calculate:

1. Time t_A required to reach the pressure $p_A = 50$ psia (3.45 bar) within the vessel
2. Time t_B required to reach the pressure $p_B = 20$ psia (1.38 bar) within the vessel

Solution:

1. For air ($k = 1.4$), the critical pressure ratio [Eq. (B8.54)] is

$$\beta_s = 0.5283$$

At the end of the time period t_A the nozzle pressure ratio is

$$\frac{p_{atm}}{p_A} = \frac{14.7}{50} = 0.294 < 0.5283$$

Source: Stone & Webster.

and therefore Eq. (B8.56) is here applicable. This means that the decrease in mass inventory of air in the vessel in time interval t_A may be expressed by the following differential equation:

$$dm = -\dot{m}_{s\,max}\,dt = -\Psi_{s\,max}\,A_2\,\frac{p}{\sqrt{RT_0}}\,dt \qquad (a)$$

Under assumption of $T_0 = $ const, the following is also true (the Clapeyron equation):

$$dm = \frac{V_{vess}}{RT_0}\,dp \qquad (b)$$

Then, from Eqs. (a) and (b), the following is derived:

$$dt = -\frac{V_{vess}}{\Psi_{s\,max}\,A_2\,\sqrt{RT_0}}\,\frac{dp}{p} \qquad (c)$$

For $k = 1.4$, Eq. (B8.55) yields

$$\Psi_{s\,max} = 3.8839$$

The nozzle flow area is

$$A_2 = \frac{\pi d^2}{4} = 0.00545\ \text{ft}^2$$

For air $R = 53.35\ (\text{lb}_f \cdot \text{ft})/(\text{lb}_m \cdot {}^\circ\text{R})$. Then, substituting all partial results into Equation (c), the following is found:

$$dt = -\frac{80}{(3.8839)\,(0.00545)\sqrt{(53.35)\,(460+70)}}\,\frac{dp}{p} = -22.476\,\frac{dp}{p}$$

and after integration:

$$t_A = 22.476\ln\frac{p_0}{p_A} = 22.476\ln\left(\frac{250}{50}\right) = 36.17\ \text{s}$$

2. As long as the pressure in the vessel is higher than

$$p_{lim} = \frac{p_{atm}}{\beta_s} = \frac{14.7}{0.5283} = 27.825\ \text{psia}$$

the air flow through the nozzle may be calculated by using Eq. (B8.56). For lower pressures in the vessel, however, the flow rate may be determined by using

$$p_{\text{lim}} = 27.825 \text{ psia} \\ (1.92 \text{ bar})$$

$$p_0 = 250 \text{ psia} \\ (17.24 \text{ bar})$$

$$p_A = 50 \text{ psia} \\ (3.45 \text{ bar})$$

$$p_B = 20 \text{ psia} \\ (1.38 \text{ bar})$$

t_A

t_B''

t_B'

t_B
FIGURE B8.27 Various time intervals before reaching the final pressure p_B within the vessel.

Eq. (B8.57). Therefore, the time interval before reaching the pressure p_B should be divided into two steps (see Fig. B8.27). In the first step, the above written Eq. (*c*) is still valid. For this step:

$$t_B' = 22.476 \ln \left(\frac{250}{27.825} \right) = 49.35 \text{ s}$$

For the second step the following differential equation holds [see Eq. (B8.56) and the Bendemann ellipse Eq. (B8.57)]:

$$dm = -\Psi_{s\,\text{max}} A_2 \frac{p}{\sqrt{RT_0}} \sqrt{1 - \left[\frac{p_{\text{atm}} - \beta_s p}{p(1 - \beta_s)} \right]^2} \, dt \qquad (d)$$

Then, combining Eqs. (*b*) and (*d*), the following is found:

$$dt = -22.476 \frac{dp}{p\sqrt{1 - \left[\dfrac{p_{\text{atm}} - \beta_s p}{p(1 - \beta_s)} \right]^2}} \qquad (e)$$

and after integration:

$$t_B'' = -22.476 \frac{1}{\sqrt{-a}} \left[\sin^{-1} \frac{-(b + 2ap_B)}{\sqrt{b^2 - 4ac}} - \sin^{-1} \frac{-(b + 2ap_{\text{lim}})}{\sqrt{b^2 - 4ac}} \right] \qquad (f)$$

where

$$a = \frac{1 - 2\beta_s}{(1 - \beta_s)^2} = -0.2544 \qquad (g)$$

$$b = \frac{2\beta_s p_{atm}}{(1 - \beta_s)^2} = 10,052 \text{ lb}_f/\text{ft}^2 \qquad (h)$$

$$c = -\left[\frac{p_{atm}}{1 - \beta_s}\right]^2 = -20,138,536 \text{ (lb}_f/\text{ft}^2)^2 \qquad (i)$$

After substituting items (g), (h), (i) into Eq. (f), the following time interval is found:

$$t_B'' = 7.66 \text{ s}$$

Therefore, the total evacuation time from initial pressure in the vessel, $p_0 = 250$ psia (17.24 bar) to pressure $p_B = 20$ psia (1.38 bar) is equal to

$$t_B = t_B' + t_B'' = 49.35 + 7.66 = 57.01 \text{ s}$$

For those who prefer to work with computers instead of solving differential equations, there is an option of solving this problem by using numerical analysis. Choosing a sufficiently small time step, and in each step balancing the system thermodynamically, while the outflow progresses (DO LOOP), the time of reaching the critical pressure ratio (or any pressure within the vessel) may be monitored by using appropriate WRITE statements.

STEADY TWO-PHASE FLOW

Introduction

A *phase* is simply one of the states of matter and can be either a gas, a liquid, or a solid. The general subject of two-phase flow includes gas-liquid, gas-solid, and solid-liquid flow.

The term *multicomponent* is used to describe flows in which the phases do not consist of the same chemical substance. In the petrochemical industries many processes involve the evaporation (and condensation) of binary ($n = 2$) and multi-component mixtures. Pure single-component, two-phase flows are those during evaporation and condensation of the same chemical substance. For example, steam-water flow is a single-component, two-phase flow, while air-water is a two-phase, two-component flow.

The main emphasis of the following presentation is on the two-phase flow of water.

Regimes of Gas-Liquid Flow

Description. Cocurrent, simultaneous flows of gases and liquids occur in numerous components of plant equipment such as steam generators, drain lines, and oil and natural gas pipelines.

Ever since the earliest visual observations of two-phase flow, it has been recognized that there are natural varieties of flow patterns. In addition to the random character of each flow configuration, two-phase flows are never fully developed. In fact, the gas phase expands due to the pressure drop along a pipe leading to a modification of the flow structure. The flow pattern depends also upon the geometry changes of a flow channel (bends, valves, etc.). Flow patterns will be classified according to pipe geometry and flow direction (upward, downward, cocurrent, countercurrent), and several shown in Refs. 16 and 17 are discussed in the following subsections.

Upward Cocurrent Flow in Vertical Pipes.   The main flow patterns encountered in a vertical pipe are shown in Fig. B8.28.[18] Bubbly flow is certainly the most widely known configuration, although at high velocity its milky appearance prevents it from being easily recognized. Bubbles are spherical only if their diameters do not exceed 1 mm; whereas beyond 1 mm their shape is variable. Roumy[18] distinguishes two bubbly flow patterns. In the *independent bubble configuration,* bubbles are spaced and do not interact with each other. On the other hand, in the *packed configuration,* bubbles are crowded together and strongly interact with each other.

Slug flow is composed of a series of gas plugs. The head of a gas plug is generally blunt, whereas its end is flat with a bubbly wake. A simple visual observation reveals that the liquid film which surrounds a gas plug moves downward with respect to the pipe wall.

Given a constant liquid flow rate, an increase of the gas flow rate leads to a lengthening and a breaking of the gas plugs. The flow pattern evolves toward an annular flow in a chaotic way. This transition configuration is called a *churn flow.*

Dispersed annular flow is characterized by a central gas core loaded with liquid droplets and flowing at a higher velocity than the liquid film which clings to the wall. Droplets are torn off from the crest of the waves which propagate on the surface of the liquid film. They diffuse in the gas core and can eventually impinge

onto the film surface. Hewitt and Roberts[19] evidenced the existence of a wispy annular flow where the liquid droplets gather into clouds within the central gas core (Fig. B8.29).

Finally, if the wall temperature is high enough to vaporize the film, the droplets will constitute a *mist flow.* Figure B8.30 shows the configurations taken by a liquid-vapor flow in a heated pipe as a function of the wall heat flux. The liquid enters the pipe at a constant flow rate and at a temperature lower than the saturation temperature. When the heat flux increases, the vapor appears closer and closer to

→ Increasing heat flux →
FIGURE B8.30 Convective boiling in a heated channel at a constant liquid flow rate. (—) Onset of nucleate boiling; (— — —) end of nucleate boiling; (—·—·—) Dryout; (---) limit of the superheated region. (*From Ref. 20.*)

the pipe inlet. The *local boiling length* is the extent of pipe where the bubbles are generated at the wall and condense in the liquid core, where the liquid temperature is still lower than the saturation temperature.

The usual way of presenting results of observations of flow patterns is to plot them on a *flow regime map*. A flow map is a two-dimensional representation of the flow pattern existence domains. The coordinate systems are different according to different authors and, so far, there is no agreement on the best coordinate systems. Selecting a series of flow maps is not easy, and no recommendation can be made since no method has proved entirely adequate so far.

Hewitt and Roberts' map (1969) is the most widely used chart for air-water and steam-water flows and is described in Refs. 16 and 17. The steam-water results of Bennett et al., are also well represented in the Hewitt and Roberts' diagram (see Refs. 16 and 17).

Downward Cocurrent Flows in Vertical Pipes.   So far the most comprehensive studies of downward cocurrent flow patterns are due to Oshinowo and Charles.[17] These authors distinguish six different flow configurations as shown in Fig. B8.31.

The downward bubbly flow structure is quite different from the upward bubbly flow configuration. In the latter case, bubbles are spread over the entire cross section, whereas in the downward flow, bubbles gather near the pipe axis. This coring effect is similar to the phenomenon observed in a flow of liquid loaded with solid particles whose density is smaller than the liquid density.

When the gas flow rate is increased, the liquid flow rate being held constant, the bubbles agglomerate into large gas pockets. The top of these gas plugs is dome-shaped, whereas the lower extremity is flat with a bubbly zone underneath. This slug flow is generally more stable than in the upward case.

The annular configuration can exhibit several aspects. For small liquid and gas flow rates, a liquid film flows down the wall (*falling film flow*). If the liquid flow rate is higher, bubbles are entrained within the film (*bubbly falling film*). When liquid and gas flow rates are increased a *churn flow* appears, which can evolve into a *dispersed annular flow* for very high gas flow rates.

Oshinowo and Charles proposed a flow map (described in Ref. 17) which was obtained from their own experimental data. They studied two-component mixtures
FIGURE B8.31   Downward cocurrent flow in a vertical pipe: air-water flow pattern: (*a*) bubbles; (*b*) slugs; (*c*) falling film; (*d*) bubbly falling film; (*e*) churn; (*f*) dispersed annular. (*From Ref. 21.*)

of air and different liquids flowing in a pipe 1 in (25.4 mm) in diameter at a pressure of around 25 psia (1.7 bar).

Cocurrent Flows in Horizontal and Inclined Pipes.   The number of possible flow patterns in a horizontal pipe is higher than in a vertical pipe. This is due to the effect of gravity, which tends to separate the phases and to create a horizontal stratification.

FIGURE B8.32   Flow patterns in a horizontal pipe: (*a*) bubbly flow; (*b*) plug flow; (*c*) stratified flow; (*d*) wavy flow; (*e*) slug flow; (*f*) annular flow. (*From Ref. 22.*)

Alves[22] proposed the classification shown in Fig. B8.32. In the *bubbly flow* configuration bubbles are moving in the upper part of the pipe. When the gas flow rate is increased, bubbles coalesce and a *plug flow* takes place. For low liquid and gas flow rates a *stratified flow* appears with a smooth interface. At higher gas rates waves propagate along the interface (*wavy flow*) and can reach the top wall of the pipe, giving rise to a *slug flow*. Finally, at high gas flow rates and low liquid flow rates an *annular flow* can exist, with a thicker film in the lower part of the pipe. These flow pattern names differ depending on the author. As an example, Taitel and Dukler[23] classed plug flows and slug flows under the same category (intermittent flow).

Figure B8.33 shows the evolution of a *vaporizing flow* in a horizontal pipe. The liquid enters the heated pipe with a low flow rate and at a temperature slightly lower than the saturation temperature. An important point concerns the upper part of the tube, which can dry out periodically and then suffer a sudden increase in wall temperature. If the wall temperature is high enough, the wall dries out completely, and the liquid droplets form a *mist flow.*

The earliest and the most durable of regime maps for two-phase gas-liquid flow in horizontal channels was proposed by Baker, as described in Ref. 24. It is commonly used specially in petroleum industries.

Goldmann[25] converted the Baker plot to a very informative representation of flow patterns for an adiabatic (no heat addition) steam-water system as shown in Fig. B8.34 for three different pressures.

Mandhane et al. (see Ref. 17), constructed a flow-regime map based on 5935 data points, 1178 of which concern air-water flows. Its coordinates are the superficial velocities j_f and j_g (volumetric flow rate of a given phase divided by the total cross-sectional area of pipe) calculated at the test section pressure and temperature.

The general trends of Mandhane's map were utilized by Taitel and Dukler.[23] They developed a theoretical approach for the prediction of transition between flow regimes. This approach also provides considerable insight into the mechanisms of the transitions. The generalized flow regime map for a case of horizontal pipes, proposed by Taitel and Dukler,[23,26] is presented in Fig. B8.35.
FIGURE B8.33 Evolution of flow pattern in a horizontal evaporator tube: (*a*) Liquid single-phase flow; (*b*) bubbly flow; (*c*) plug flow; (*d*) slug flow; (*e*) wavy flow; (*f*) annular flow. (*From Ref. 17.*)
FIGURE B8.34 Flow pattern of two-phase flow. (*From Ref. 25.*)

Mass flux $\dot{G} = \dot{m}/A$ conversion: 1 $lb_m/(ft^2 \cdot h) = 0.0488$ kg/(dm² · h). For pressure conversion to SI units see Table B8.1.

The five regimes considered are: *intermittent* (slug and plug), *stratified smooth, stratified wavy, dispersed bubble,* and *annular-annular dispersed* liquid flow. The condition of stratified flow is central to this analysis. The first step is to define boundaries of these flow regimes. On the generalized flow regime map the transition boundaries (lines *A, B,* and *D* in Fig. B8.35) between different flow regimes are found to be functions of h_f/D only (see Fig. B8.38). When the theory is solved in dimensionless form the following dimensionless groups emerge: *X, Y, T, F,* and *K.*

All dimensionless flow pattern transition criteria are functions of h_f/D, which in turn is a unique function of the dimensionless groups *X* and *Y*, as shown in Fig. B8.36. Thus the transition from stratified to intermittent and to annular-dispersed liquid is uniquely determined by three dimensionless groups *X, Y,* and *F.* Further, for any specified value of *Y*, the transition is uniquely determined by *X* and *F* and can be represented on a generalized two-dimensional map. For example, for horizontal flow ($Y = 0$) a series of values of *X* were selected, and the corresponding values of h_f/D were determined from Fig. B8.36. Then the value of *F* required to
FIGURE B8.35 Generalized flow regime map for horizontal two-phase flow. (*Taitel-Dukler, 1976.*)
FIGURE B8.36 Equilibrium liquid level as a function of the dimensionless groups X and Y. (*From Ref. 26.*)

satisfy the theoretical transition equation given in the references can be calculated. The curve describing the relation between X and F, which satisfies this theoretical transition equation for horizontal flow, is designated as boundary A in Fig. B8.35. The calculation, as above, may be repeated for inclined pipes with other values of Y specified, by using the corresponding Y-curve in Fig. B8.36.

It is suggested that when the equilibrium liquid level in the pipe is above the pipe centerline, intermittent flow will develop, and if $h_f/D < 0.5$, annular dispersed flow will result. Because transition takes place at constant value of $h_f/D = 0.5$, a specific value of X characterizes the change in regime for any value of Y (see Fig. B8.36). For horizontal pipes ($Y = 0$), this value is $X = 1.6$, and this is plotted in Fig. B8.35 as boundary B. It was observed during experiments that the h_f/D at transition will vary between 0.35 and 0.5. This band of values is shown by the two vertical lines marked B in Fig. B8.35. Visual observations show this transition between the intermittent and annular patterns to be a gradual one that is not well-defined.

For values of X on the right of boundaries A and B in Fig. B8.35, waves will tend to bridge the pipe, forming a liquid slug and an adjacent gas bubble. At high liquid rates and low gas rates, the equilibrium liquid level approaches the top of the pipe, as is apparent from Fig. B8.36. With such a fast-running liquid stream the

gas tends to mix with the liquid, and it is suggested that the transition to dispersed bubble flow takes place when the turbulent fluctuations are strong enough to overcome the buoyant forces tending to keep gas at the top of the pipe. The terms in theoretical transition equation are again dependent only on h_f/D and thus on X and Y. For any specific value of Y, a two-dimensional representation for this transition is possible, with X and T used as the dimensionless coordinates. It is possible to map this transition on Fig. B8.35 by using the common X abscissa and T as an ordinate, as shown by curve D calculated for $Y = 0$.

To find a flow regime for actually existing pipe flow conditions, the dimensional groups X, Y, T, F, and K are calculated from the following equations, and are compared with those values in Fig. (B8.35) which correspond to the appropriate boundary line.

Parameter X, the Lockhart-Martinelli parameter

$$X = \sqrt{\frac{(dp/dz)_f}{(dp/dz)_g}} \tag{B8.64}$$

where the quantities $(dp/dz)_f$ and $(dp/dz)_g$ are the frictional pressure drops of the liquid and gas that would be observed if these fluids were flowing alone in the pipe. The value of X can be calculated with the knowledge of flow rates, fluid properties, and tube diameter (consult the references).

Parameter Y, dimensionless pipe inclination parameter (inclination angle β is positive for downward flow). Y is zero for horizontal pipes and represents the relative forces acting on the liquid in the flow direction due to gravity and pressure drop.

$$Y = \frac{(\rho_f - \rho_g)\, g \sin \beta}{g_c (dp/dz)_g} \tag{B8.65}$$

Parameter T, dimensionless dispersed bubble flow parameter: transition between intermittent (slug/plug) and dispersed bubble regimes

$$T = \sqrt{\frac{g_c (dp/dz)_f}{(\rho_f - \rho_g) g \cos \beta}} \tag{B8.66}$$

Parameter F, transition between stratified and intermittent or annular-dispersed liquid regimes (Froude number modified by density ratio)

$$F = \sqrt{\frac{\rho_g}{\rho_f - \rho_g}} \frac{j_g}{\sqrt{Dg \cos \beta}} \tag{B8.67}$$

Parameter K, (Weber number) dimensionless wavy flow parameter: transition between stratified smooth and stratified wavy regimes (not shown in Fig. B8.35)

$$K = F \sqrt{\frac{D j_f}{v_f}} \tag{B8.68}$$

It is, of course, not necessary to use a flow regime map at all. Given any set of flow conditions (gas and liquid rates, pressure, pipe size, and pipe inclination angle:

positive for downward flow), the flow pattern that exists for that condition can be determined by comparing appropriate calculated parameters with corresponding values on the transition lines at evaluated h_f/D, by using hand or computerized calculations based on detailed theoretical equations presented in Refs. 23 and 26, with the help of Fig. B8.36 or its computerized representation.

Countercurrent Flow of Steam and Water in Horizontal and Inclined Pipes. Countercurrent flow of steam and water may exist only when a pipe does not run full. There are two very important areas in a plant design where this kind of flow is carefully studied:

1. Design of self-venting lines where the vapor is not carried down the drainpipe with the liquid, but can rise counter to the liquid flow, continuously venting the pipe
2. Initiation of a condensation-induced water hammer in horizontal or nearly horizontal pipes containing steam and subcooled water

The stratified countercurrent flow of a gaseous phase and a liquid is governed by the open channel flow criterion expressed as a liquid Froude number:

$$\mathrm{Fr} = \frac{j_f}{\sqrt{gD}} \tag{B8.69}$$

The stratified void fraction α in a circular pipe versus dimensionless vapor gap is presented in Fig. B8.37.

The region of condensation-induced water hammer in horizontal and nearly horizontal pipes experiencing the countercurrent flow of steam and subcooled water is bound by the *absolute stability limit* at the lower flow boundary and by the *pipe-full limit* at the upper flow boundary. Bjorge and Griffith presented a one-dimensional, stratified model that predicts initiation of a water hammer in those important cases.[27,28]

Designing self-venting lines is discussed later in this section, while the condensation-induced water hammer is described in the later section "Steam-Condensation-Induced Water Hammer."

Pressure Drop in Gas-Liquid Flow (Nonflashing Flow)

The evaluation of the two-phase (TP) pressure drop in an evaporating or condensing channel or in a geothermal pipeline involves integrating the local pressure gradients along the channel length. This local pressure gradient is composed of three terms: a frictional term, an accelerational term, and a static head term[16,17,29]:

$$\left(\frac{\Delta p}{\Delta L}\right)_{\mathrm{TP}} = \left(\frac{\Delta p_F}{\Delta L}\right)_{\mathrm{TP}} + \left(\frac{\Delta p_A}{\Delta L}\right)_{\mathrm{TP}} + \left(\frac{\Delta p_Z}{\Delta L}\right)_{\mathrm{TP}} \tag{B8.70}$$

Using the separated flow (separated phases) model, these three components are respectively given by:

$$\left(\frac{\Delta p_F}{\Delta L}\right)_{\mathrm{TP}} = \Phi_{\mathrm{LO}}^2 \left(\frac{\Delta p_F}{\Delta L}\right)_{\mathrm{LO}} \tag{B8.71}$$
FIGURE B8.37   Void fraction in a circular pipe versus dimensionless vapor gap.

where Φ^2_{LO} is known as the *two-phase frictional pressure drop multiplier,* and $(\Delta p_F/\Delta L)_{LO}$ is the *frictional pressure drop* calculated from the D'Arcy-Weisbach equation for the total flow when the fluid (liquid and steam) is entirely in the liquid phase, as described in the section "Steady Single-Phase Incompressible Flow in Piping":

$$\left(\frac{\Delta p_A}{\Delta L}\right)_{TP} = \frac{\dot{G}^2}{g_c} \frac{\Delta}{\Delta L} \left[\frac{x^2 v_g}{\alpha} + \frac{(1-x)^2 v_f}{1-\alpha}\right] \qquad (B8.72)$$

where $\dot{G}$ is the total mass flux, x is the quality, and α is the void fraction;

$$\left(\frac{\Delta p}{\Delta L}\right)_Z = \frac{g}{g_c} \sin\theta \left[\frac{\alpha}{v_g} + \frac{1-\alpha}{v_f}\right] \qquad (B8.73)$$

where θ is the angle of pipe inclination to the horizontal.

To evaluate the local pressure gradient, expressions are needed for the functions Φ^2_{LO} and α. A very large number of correlations have been proposed for these functions, and a summary of the better-known correlations is given in Ref. 16. Various studies agree that the most accurate correlations for Φ^2_{LO} are those by

Baroczy, Chisholm, and Lombardi. The most accurate void fraction correlations are those of Smith, Premoli, and Chisholm, with the latter having the added advantage of great simplicity. A void fraction is sometimes expressed in terms of the slip ratio S^* (ratio of the phase velocity of the vapor to that of the liquid):

$$S^* = \left(\frac{x}{1-x} \right) \left(\frac{\rho_g}{\rho_f} \right) \left(\frac{1-\alpha}{\alpha} \right) \tag{B8.74}$$

Baroczy's correlation is widely used in the United States.[30] This correlation may be considered an extension of that of Lockhart and Martinelli, and of Martinelli and Nelson.[29] Baroczy[31] used experimental data in adiabatic conditions where the acceleration pressure drop is zero (the acceleration pressure drop is important in a case of heated channels) and where the gravity pressure drop is either zero (horizontal lines) or could be neglected. This correlation is given in two sets of curves:

1. A plot of the two-phase multiplier Φ^2_{LO} as a function of the property index PI for a fixed mass flux of 10^6 $lb_m/(ft^2 \cdot h)$ [1356 kg/(m² · s)], as shown in Fig. B8.38, where:

$$PI = \frac{(\mu_f/\mu_g)^{0.2}}{\rho_f/\rho_g} \tag{B8.75}$$

2. Plots of a correction factor for mass velocity effects, Ω, as a function of the property index and mass flux, are shown in Fig. B8.39. This correction factor multiplies Φ^2_{LO} whenever $\dot{G}$ deviates from 10^6 $lb/(ft^2 \cdot h)$ [1356 kg/(m² · s)]. Baroczy's correction factor for mass velocity effects varies with mass flux in a rather peculiar manner. Since several investigators have observed changes in pressure-drop behavior characteristics with flow regime, these variations may be related to flow pattern changes.

Baroczy compared his correlation method with experimental data for water-air, water-steam, and other liquids including liquid metals, organic oils, and so forth over a wide range of conditions and found the agreement good.

Critical Gas-Liquid Flow ("Flashing" Flow)

General Remarks. Critical or mass-limiting flow is characteristic of compressible fluid systems. In two-phase flow, a maximum or critical flow rate is also observed. When fluid travels in a horizontal pipeline its pressure decreases until it reaches the pipe exit. If a liquid in the upstream vessel is near the boiling point, its pressure in the pipeline may drop below the saturation point, resulting in vapor formation (*flashing*). Therefore, two-phase flow may occur starting from a certain cross section in the line. There are cases where fluid entering the pipe may already be a liquid-vapor mixture. If the pressure in the downstream receiver is reduced sufficiently to cause the flow velocity at the pipe exit to equal that of the speed of sound at local fluid conditions, the mass flow rate reaches its maximum value, and the flow is said to be *choked*. The maximum flow rate at the choke point is called *critical flow rate*.

At the present, there is no general model or correlation for critical two-phase flow that is valid for a wide range of pipe lengths, pipe diameters, and upstream conditions including subcooled liquid. For these reasons, different models may be
FIGURE B8.38 Baroczy frictional pressure drop correlation for $\dot{G} = 1 \times 10^6$ lb$_m$/(ft$^2 \cdot$h); (1356 kg/(m$^2 \cdot$s)). (*From Ref. 31.*)

more appropriate for designing specific two-phase flow discharge systems. The most frequently used models and calculation procedures are described in the following subsections.

Fanno Model (Thermal Equilibrium, Homogeneous). All homogeneous-equilibrium models are based on three assumptions:

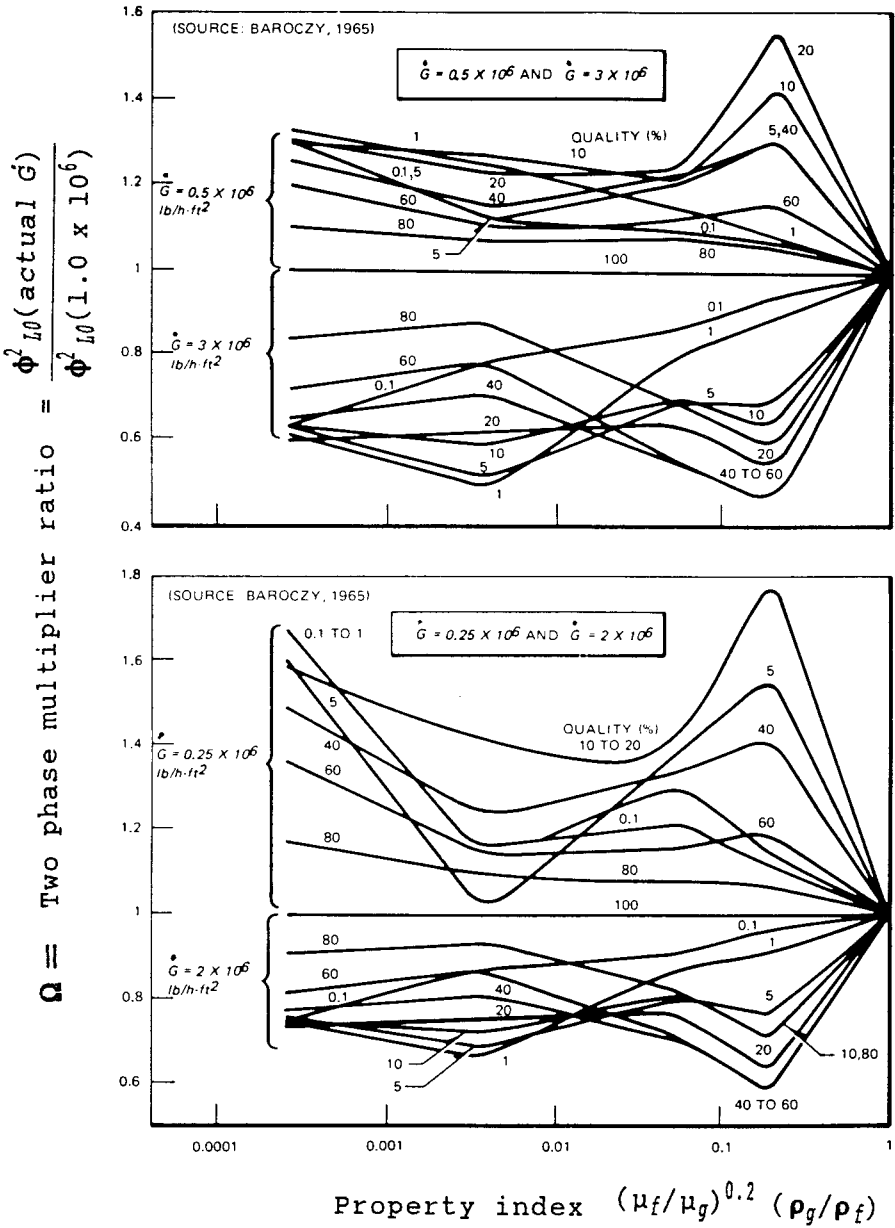
1. There is no slip between phases.
2. There is thermodynamic equilibrium between the liquid and vapor at all times.


FIGURE B8.39   Baroczy correction factor for mass velocity effects. (*From Ref. 31.*)

3. The specific volume is calculated from equation

$$v = v_f + x(v_g - v_f) \tag{B8.76}$$

Equation (B8.22) represents the Fanno line[10,32] for a single-phase compressible flow, as a locus of conditions in a pipe of constant diameter. Having fixed w_1 and h_1 at the starting point, the stagnation enthalpy h_0 can be calculated. This stagnation enthalpy is constant along the length L of the pipe.

For the two-phase (wet steam) region the following expressions hold

$$h = h_f + h_{fg} \tag{B8.77}$$

$$v = v_f + x v_{fg} \tag{B8.78}$$

$$s = s_f + x s_{fg} \tag{B8.79}$$

From Eqs. (B8.22), (B8.77), and (B8.78), the following is found[32]:

$$x^2 + 2x \left[\frac{v_f}{v_{fg}} + J g_c \left(\frac{A}{\dot{m}} \right)^2 \frac{h_{fg}}{v_{fg}^2} \right]_x + \frac{(v_f^2)_x - v_1^2 + 2 J g_c \left(\frac{A}{\dot{m}} \right)^2 [(h_f)_x - h_1]}{(v_{fg}^2)_x} = 0 \tag{B8.80}$$

Choosing a set of temperatures (or corresponding saturation pressures) below T_1, the appropriate values of h_f, h_g, v_f, v_g are calculated by using steam tables.[5] Then, solving Eq. (B8.80) for each pressure, the corresponding steam quality x is computed. Each intersection of corresponding x and p values represents the Fanno line point on the h-s diagram. The choked condition at the pipe exit is defined by maximum entropy:

$$\frac{ds}{dh} = 0 \tag{B8.81}$$

The detailed calculation procedures for finding the static pressure p_L at the distance L from the choked exit is the same as described in the subsection "Adiabatic, Constant-Area Flow with Friction."

Allen Model (Thermal Equilibrium, Homogeneous).   Neglecting potential energy (elevation term), Eq. (B8.11) applied to the one-dimensional, steady-state flow in a channel (no technical work), per unit mass, becomes

$$d \left(\frac{w^2}{2g_c} \right) = -v dp - d' w_f \tag{B8.82}$$

By using the differential form of the D'Arcy-Weisbach equation for work done against fluid friction

$$d' w_f = f \frac{w^2}{2g_c} \frac{dL}{D} \tag{B8.83}$$

and the differential form of the continuity equation (B8.21)

$$dw = \left(\frac{\dot{m}}{A}\right)dv \tag{B8.84}$$

the following result is found[33]:

$$vdp + \left(\frac{\dot{m}}{A}\right)^2 \left(\frac{vdv}{g_c} + \frac{fv^2}{2g_c D}dL\right) = 0 \tag{B8.85}$$

Dividing Eq. (B8.85) by v^2 and integrating between locations l and x along the pipe, it follows that

$$\left(\frac{\dot{m}}{A}\right)^2 = g_c \frac{\int_{p_1}^{p_x} -\frac{dp}{v}}{\ln\frac{v_x}{v_1} + \frac{fL}{2D}} \tag{B8.86}$$

A similar equation is presented in the paper by Benjamin-Miller.[34]
FIGURE B8.40 Function $(\dot{m}/A)^2$ versus pressure.

The function $(\dot{m}/A)^2$ has its maximum value at choked pressure $p_x = p_c$ as illustrated in Fig. B8.40. For a given pipe diameter and piping layout (equivalent length L) the choked pressure may be calculated by assuming a friction factor and evaluating the integral numerically by taking small pressure increments and summing the values $\Delta p/\bar{v}$, where $\bar{v}$ is the average specific volume within the chosen Δp limits.

To evaluate the average specific volume, the Benjamin-Miller method assumes isentropic expansion between pressures p_{x-1} and p_x, while the Allen method assumes isenthalpic expansion between those pressures. Allen suggests in his paper that the difference in specific volume, whether isenthalpic or isentropic expansion is used, will not be large.

Allen found a simple relationship between critical pressure, initial pressure, and the rate of flow:

$$p_c = \frac{\dot{m}}{A}C_A p_1 \tag{B8.87}$$

where

$$C_A = \left[\frac{1}{g_c} \left(\frac{h_{f_1} - h_{f_2}}{p_1 - p_2} \right) \left(\frac{2 v_{fg1}}{h_{fg1} + h_{fg2}} \right) \right]^{1/2} \qquad \text{(B8.88)}$$

In computing the constant C_A, the subscript 1 refers to saturation conditions at the source (say drain cooler exit) temperature, and the subscript 2 refers to saturation conditions an infinitely small amount below this temperature. Practically, a finite interval of one degree less than the temperature at drain cooler exit is recommended for use.

For a given stagnation enthalpy in the upstream source, and for a given mass flux $\dot{m}/A$, the corresponding pipe exit critical pressure may be found using Fig. B8.41.

In order to apply Eq. (B8.86) for finding the pressure at the outlet of the control valve, or at any distance L from choked pipe exit, the value p_x should be replaced by the calculated critical pressure p_c, and Eq. (B8.86) must be solved by trial for $p_1 = p_L$ [convergence on the lower limit of the integral in Eq. (B8.86)].

Allen succeeded in writing Eq. (B8.86) in terms of a single variable by expressing the specific volume of a mixture in terms of pressure. See Ref. 33 for more details.

Note: 1 lb$_m$/(ft$^2 \cdot$ s) = 4.88 kg/(m$^2 \cdot$ s)
For pressure and enthalpy conversions to SI units see Tables B8.1 and B8.3.
FIGURE B8.41   Pipe exit critical pressures for water-steam mixtures (*Allen Model.*)

Moody Model (Thermal Equilibrium, Nonhomogeneous).   Moody considers isentropic expansion of a homogeneous fluid in a converging nozzle (Fig. B8.25). The nozzle may be considered as a pipe of diameter D_2 and length $L = 0$.[35] The two-phase flow pattern at the exit is annular with no entrainment, but the exit velocities of each phase may differ, resulting in an exit slip ratio.

The Moody model is based on the same logic as described for the previous homogeneous models, the only difference being that average vapor velocity and

average liquid velocity are not equal (nonhomogeneous annular flow). Moody developed the following expression for $\dot{G}$:

$$\dot{G} = \sqrt{\frac{2Jg_c\left[h_0 - h_f - \frac{h_{fg}}{s_{fg}}(s_0 - s_f)\right]_2}{\left[\frac{S^*(s_g - s_0)v_f}{s_{fg}} + \frac{(s_0 - s_f)v_g}{s_{fg}}\right]^2_2 \left[\frac{s_0 - s_f}{s_{fg}} + \frac{s_g - s_0}{(S^*)^2 s_{fg}}\right]^2_2}} \tag{B8.89}$$

Equation (B8.89) shows that $\dot{G}$ is a function of S^* and p_2 when h_0 and s_0 are known (upstream stagnation properties). The following expression for slip ratio S^* at the maximum flow rate was found:

$$S^* = S^*_2 = \left(\frac{v_g}{v_f}\right)^{1/3}_2 \tag{B8.90}$$

which indicates that S^* is the function of p_2 only. Then, for known h_0 and s_0, a maximum (choke) value of $\dot{G}_c$ is derived from the relation:

$$\frac{d\dot{G}}{dp_2} = 0 \tag{B8.91}$$

The shape of the $\dot{G}(p_2)$ function is similar to that for homogeneous flow (Fig. B8.26). Exit properties for maximum steam/water discharges $\dot{G}_c$, associated with stagnation enthalpies h_0, are shown in Fig. B8.42.

Mass flux ($\dot{G} = \dot{m}/A$) conversion : 1 $lb_m/(ft^2 \cdot s) = 4.88$ kg/(m$^2 \cdot$ s)

FIGURE B8.43 (*Continued*)

The thermal parameters of the fluid at a distance L from the choked pipe exit are found in a similar way to what is described earlier in the section "Adiabatic, Constant-Area Flow with Friction." Computer solution of numerical integration of equations developed in Ref. 36 leads to graphs expressing the relation between the maximum (critical) two-phase discharge rate $\dot{G}_c$ from uniform pipes and the stagnation pressure p_0, the initial static pressure p_1, the fluid enthalpy h_1, and the pipe characteristics described by $\bar{f}\,L/D_H$. They are presented in Fig. B8.43 (taken from Ref. 29). Here $\bar{f}$ is the average D'Arcy-Weisbach friction factor calculated for the average liquid Reynolds number; L is the pipe length upstream from the choked exit; and $D_H = 4\,A/(\text{wetted perimeter})$ is a characteristic linear dimension (for flows in pipes of circular diameter it is equal to the pipe diameter).

References 35, 36, and 37 should be consulted for additional information concerning the development of the Moody Model.

Henry-Fauske Model (Nonequilibrium, Nonhomogeneous). The Henry-Fauske model[38] is of importance for choked two-phase flow through short pipes, nozzles, and orifices, where the fluid transit is short and thermodynamic equilibrium between phases cannot be reached. Since the phases have different densities, the pressure gradient will also tend to accelerate the lighter vapor phase more than the liquid. It is assumed in this model that at throat the actual fluid quality may be determined by introducing a nonequilibrium parameter N.

For a given stagnation condition of p_0 and x_0, the model predicts both the critical (choke) pressure and the flow rate. The theory is extended to subcooled inlet conditions. The calculated mass fluxes $\dot{G}_{\max}$ corresponding to initial stagnation conditions p_0, h_0, in the wet steam and subcooled liquid regions, are presented in Figs. B8.44 and B8.45 (based on Ref. 30). The figures indicate how the max flux $\dot{G}_{\max}$ increases with increased pressure p_0, holding the stagnation enthalpy at the same level [say 500 Btu/lb$_m$ (1163 kJ/kg)]. Steep stagnation pressure lines, especially those below 1100 psia (6.89 bar), in Fig. B8.44 indicate extreme sensitivity to the fluid enthalpy in determining the mass fluxes at low qualities, near the saturation line $x = 0$. Therefore, a very careful estimation of stagnation conditions ahead of a valve, as well as the computerized Henry-Fauske model are helpful in predicting reasonable values of mass fluxes in this wet-steam region. It is the responsibility of the designer to ensure that his or her evaluation yields conservative results.

For a specified inlet stagnation enthalpy h_0 and different stagnation pressures p_0, the values of $\dot{G}_{\max} = (\dot{m}/A)_{\max}$ and the corresponding choke pressures p_c can be found, as they are presented in a sample calculation (Table B8.16 and Fig. B8.46) performed by using a computer program.

The Henry-Fauske theory was developed for two-phase critical discharge of single-component mixture through convergent nozzles. Because the orifices (e.g., valve orifices) cannot be considered as nozzles, a discharge coefficient of 0.84, as recommended in Ref. 37, should be applied. More information on this subject may be found in Ref. 39.

Comparison of Results Generated by Different Models. As mentioned in the section "General Remarks," there is no general model for two-phase critical flow that is valid for all cases of interest. Each model is only applicable for a limited range of parameters. The number of critical flow models available may cause some apprehension when the task of selecting one is approached.

In order to facilitate the selection of an appropriate model for a given problem, some useful graphs are presented in this subsection. Figures B8.47 and B8.48 show the critical (choke) pressure versus stagnation enthalpy for the mass fluxes of 50

NOTE: 1 kg/(dm^2.s) = 0.01 kg/(m^2.s) = 20.48 lb$_m$/(ft^2.s)
For pressure, and enthalpy conversions to other units see TABLES B8.1 and B8.3.

lb$_m$/(ft$^2 \cdot$s) [244.12 kg/(m$^2 \cdot$s)] and 600 lb$_m$/(ft$^2 \cdot$s) [2929.46 kg/(m$^2 \cdot$s)]. The curves marked by *F, A, M,* and *H-F* represent the values corresponding to the following models respectively, Fanno, Allen, Moody, and Henry-Fauske. Figures B8.49 to B8.52[40] represent a comparison of critical flow rates predicted by various models and their relations to experimental data (also see Ref. 37 and 38 on this subject). The following conclusions can therefore be made:

1. A homogeneous equilibrium theory (Fanno model, Benjamin-Miller model, Allen model) may be used to predict critical flow rates from long pipes ($L/D \geq$ 40). This theory provides a lower bound to all presented experimental data. It is generally recognized, however, that this theory underestimates the choked mass flux at low pressures and qualities. As the pressures and qualities increase, the accuracy of the answer improves.[41]

2. The Moody model predicts flow rates higher than those observed for stagnation qualities above 0.01; thus being conservative, it is recommended for U.S. water-reactor licensing calculations (e.g., loss-of-coolant accident—LOCA). It should be explained here that the computer program RELAP4/MOD5[30] is a part of the Nuclear Regulatory Commission's (NRC) water reactor evaluation model

FIGURE B8.52 Discharge of saturated water through orifices, nozzles, and pipes. (*From Ref. 40.*)

(WREM). The critical flow model criterion of the WREM specifies use of the Henry-Fauske model in the subcooled region and the Moody critical flow model in the saturated region. To effect a smooth transition, therefore, the first point in the Moody critical flow tables has been placed in the last portion of the table for the Henry-Fauske critical flow model extended into the subcooled region. This limitation of the subcooled Henry-Fauske table should be realized during RELAP4 calculations.

3. The Henry-Fauske model is in reasonable agreement with short pipe ($L/D <$ 5) and nozzle data for qualities greater than 0.001. Below this limit, however, agreement is less satisfactory, and the model underestimates the flow of saturated water through orifices by about 50 percent.

Applications

Design Considerations. Very often, severe problems can occur if slug flow is present in the pipeline. A number of circumstances will lead to the generation of slug flow. For instance, if an oil-gas mixture flows along a pipe on the seabed and then rises to a platform level up a vertical pipe, the liquid may collect upstream of the bend until it reaches a given level, at which point it is swept up the vertical leg, giving rise to mechanical problems in the platform equipment. In power plants, a similar phenomenon may occur in a pocketed line. Also, slug flow causes pressure fluctuations in piping, which can upset process conditions and cause inconsistent instrument sensing.

Existence of two-phase flow in a pipeline may also cause more severe fluid transient problems than occur in a single-phase condition. Should a two-phase flow condition be unavoidable in the system operation, the impact of two-phase flow transient condition should be taken into consideration in system design and piping support evaluation.

Slug flow can be avoided in piping by (1) reducing line sizes to the minimum permitted by available pressure differentials to achieve a safe mass flow rate, as indicated in Fig. B8.34; (2) designing for parallel pipe runs that will permit increasing mass flux per pipe at low load conditions by removing one pipe from service; or (3) arranging the pipe configurations to protect against slug flow (for example, in a pocketed line where liquid might collect and slug flow develop).

Slug flow will not occur in gravity-flow lines when appropriate venting is provided. Figure B8.53(*a*) shows a sketch of a non-self-venting gravity drain from a tank where the drain runs full; hence it requires a separate vent line. Figure B8.53(*b*) shows the typical design of a self-venting gravity drain which does not require a vent, but which usually has a separate vent line to maintain continuous drainage during plant transients. A hard-tee connection (i.e., flow through the branch) at a low point can provide sufficient turbulence for more effective liquid carryover. A diameter adjustment coupled with gas injection can also alter a slug-flow pattern to bubble or dispersed flow. Gas addition, however, when used solely to avoid slug flows, can be expensive.

The design of the transmission and distribution network for large district heating systems often represents more than half of the total investment cost and therefore is of vital importance to the economics of the system.[42] However, it must represent an optimized balance between economics and reliability of supplying heat to customers. From the distribution point of view, the temperature level of hot water in the district heating system should be as high as possible. The flow rates of hot water will then be reduced, the pipe sizes minimized, the pumping cost reduced, and
FIGURE B8.53   Drain system requirements: (*a*) design of non-self-venting gravity drains; (*b*) design of self-venting gravity drains.

the heat exchangers in the subscriber's substation will be smaller. The required temperature of the domestic water sets the minimum-possible supply temperature at 160 to 180°F (70 to 80°C). Pressure level at all points in the transmission and distribution network must always be so high that dangerous flashing or creating steam pockets will be avoided. The lowest-possible pressure in the system is therefore determined by the maximum hot water temperature and the minimum static head within the network (highest elevation).

Sample Problems B8.9 and B8.10

Sample Problem B8.9 (Self-venting line).   To illustrate the design of a self-venting line, an example of calculating the diameter and minimum slope required to discharge 362,000 lb_m/h (164,200 kg/h) of 200°F (93.33°C) water (approximately 750 gpm) into a tank at ambient pressure is presented.

A properly designed drain line with gravity flow will be self-venting if the liquid Froude number (dimensionless parameter), Eq. (B8.69), is less than approximately 0.3[43]:

$$Fr = \frac{w_L}{\sqrt{gD}} \leq 0.3 \tag{a}$$

where g = 32.174 ft/s² (9.80665 m/s²) acceleration due to gravity
 D = inside pipe diameter, ft (m)
 w_L = velocity the liquid would have in the pipe flowing full with the given flow rate, ft/s (m/s)

$$w_L = \frac{(362{,}000 \text{ lb}_m/\text{h})\,(0.016637 \text{ ft}^3/\text{lb}_m)}{(3{,}600 \text{ s/h})\,(\pi D^2/4)}$$

$$w_L = \frac{2.131}{D^2} \qquad (b)$$

Substituting (b) into (a) yields:

$$0.3 \geq \frac{w_L}{\sqrt{gD}} \geq \frac{2.131}{D^2\sqrt{32.174D}}$$

or:

$D^{2.5} \geq 1.251$, and the diameter of the self-venting line should be

$D \geq 1.094$ ft $= 13.13$ in

Use 14-in Std. pipe; inside diameter $D = 13.25$ in

The minimum slope of a self-venting line may be calculated on the basis of an assumption of constant depth of water in the line. Assuming this depth to be $D/3$, the flow in a pipe may be considered as an open channel flow. The Chezy formula describes velocity in such a flow[1] as:

$$w = C_1\sqrt{r_h(SL)} \text{ ft/s} \qquad (c)$$

where (SL) = slope of the pipe (channel), ft/ft
  $r_h = A_L/O_H$ = hydraulic radius, ft (notice that for a full flow in pipe, $r_h = 0.25\,D$)
  A_L = cross-sectional area of liquid in the channel, ft^2
  O_H = wetted perimeter of the conduit (the portion of the perimeter where the wall is in contact with the fluid), ft
  C_1 = Chezy coefficient

The Chezy coefficient C_1 is described by the widely accepted Manning formula[1]:

$$C_1 = 1.486\,\frac{r_h^{1/6}}{n} \qquad (d)$$

where $n \approx 0.014$ is the Manning roughness factor for a metal conduit.

Formula (d), however, must be modified in conjunction with the SI units, to obtain, for an identical input, the same results for the minimum slope SL in both systems of units, the SI and British (the coefficient 1.486 becomes 1.000).

The calculation of the hydraulic radius is performed as follows (see Fig. B8.54 and use geometry formulas from Ref. 44, typical):

For liquid depth ratio $h/D = \frac{1}{3}$, the length of arc K-N-M subtended by θ

$$S_{K\text{-}N\text{-}M} = D\cos^{-1}\left(1 - \frac{h}{R_D}\right) = 1.2310D \text{ ft}$$
FIGURE B8.54   Cross-section geometry of a self-venting pipe.

the central angle in radians

$$\theta = \frac{S_{K-N-M}}{R_D} = \frac{(1.2310)D}{R_D} = (2)(1.2310) = 2.4619 \text{ rad}$$

segment area A_L

$$A_L = \tfrac{1}{2}(\theta - \sin\theta)R_D^2$$

$$A_L = \tfrac{1}{2}(2.4619 - 0.6285)R_D^2 = 0.9167 R_D^2 = 0.2794 \text{ ft}^2$$

hydraulic radius

$$r_h = \frac{A_L}{S_{K-N-M}} = \frac{0.9167 R_D^2}{(1.2310)(2)R_D} = 0.3723 R_D = 0.2055 \text{ ft}$$

Then, from (d), the Chezy coefficient is equal to:

$$C_1 = \frac{1.486}{0.014}(0.2055)^{1/6} = 81.54$$

The actual flow velocity of liquid in the self-venting line is found from the continuity equation

$$w = \frac{\dot{m}v}{A_L} = \frac{(362{,}000)(0.016637)}{(3600)(0.2794)} = 5.99 \text{ ft/s}$$

Solving the Chezy equation (c) for the slope SL yields

$$(SL) = \frac{w^2}{C_1^2 r_h} = \frac{(5.99)^2}{(81.54)^2(0.2055)} = 0.0263 \ \frac{\text{ft}}{\text{ft}} = 0.315 \ \frac{\text{in}}{\text{ft}} \left(26.25 \ \frac{\text{mm}}{\text{m}} \right)$$

Industrial experience[43] requires the minimum slope for a self-venting line to be not less than 0.5 in/ft (42 mm/m). Therefore, in the case of this problem, the minimum slope should be 0.5 in/ft (42 mm/m).

Sample Problem B8.10 (Fanno Model). Consider a refrigeration system filled with Freon-12. Boiling Freon at initial temperature $t_1 = 104°F$ (40°C) is being throttled in a capillary tube of 0.059 in (1.5 mm) internal diameter at the rate of 22.05 lb_m/hr (10 kg/h). Calculate the choke pressure and the velocity of the fluid at choked-line exit conditions. The properties of refrigerant R-12 are listed in Table B8.17.

Equations (B8.77) through (B8.80) are used to generate the following table. The procedure is explained by calculating results for a chosen Fanno line point at the temperature of 86°F (30°C) (one of those points in Table B8.18):

For saturated conditions at $t = 86°F$, from Table B8.17, the following is found:

$$p_{sat} = 108.04 \text{ psia}$$
$$v_f = 0.012396 \text{ ft}^3/\text{lb}_m$$
$$v_g = 0.37657 \text{ ft}^3/\text{lb}_m$$
$$h_f = 27.769 \text{ Btu/lb}_m$$
$$h_g = 85.821 \text{ Btu/lb}_m$$
$$s_f = 0.057301 \text{ Btu/(lb}_m \cdot °R)$$
$$s_g = 0.16368 \text{ Btu/(lb}_m \cdot °R)$$

In a similar way, for initial conditions (saturated *liquid* at $t_1 = 104°F$):

$$p_1 = 139.33 \text{ psia}$$
$$h_1 = 32.067 \text{ btu/lb}_m$$
$$v_1 = 0.012783 \text{ ft}^3/\text{lb}_m$$

Pipe cross-section area:

$$A = \frac{\pi}{4} \frac{(0.059)^2}{(12)^2} = 0.0000190 \text{ ft}^2$$

Mass flux:

$$\dot{G} = \frac{\dot{m}}{A} = \frac{22.05}{(3600)(0.0000190)} = 322.4 \ \frac{\text{lb}_m}{(\text{ft}^2 \cdot \text{s})}$$

Equation (B8.80) may be rewritten as:

$$x^2 + Bx + C = 0$$

* Inches of mercury below one atmosphere.
Temperature conversion: $t_C = (t_F - 32.0)/1.8$.
For pressure, specific volume, enthalpy, and entropy conversions to SI Units see Tables B8.1 through B8.4.

where

$$B = 2\left[\frac{v_f}{v_g - v_f} + \frac{(Jg_c)}{(\dot{G})^2} \frac{(h_g - h_f)}{(v_g - v_f)^2}\right]$$

$$= 2[0.03404 + 105.300] = 210.7$$

$$C = \frac{v_f^2 - v_1^2 + 2\left(\frac{Jg_c}{\dot{G}}\right)^2 (h_f - h_1)}{(v_g - v_f)^2}$$

$$= \frac{(0.012396)^2 - (0.012783)^2 - (2)(0.103394)}{(0.132623)}$$

$$= 0.155923$$

Then, the quality x is equal to

$$x = \frac{-B \mp \sqrt{B^2 - 4C}}{2} = 0.0740$$

and, from Eqs. (B8.77) to (B8.79):

$$h = h_f + x(h_s - h_g) = 32.06 \text{ Btu/lb}_m$$

$$v = v_f + x(v_s - v_g) = 0.03934 \text{ ft}^3/\text{lb}_m$$

$$s = s_f + x(s_s - s_g) = 0.06517 \text{ Btu/(lb}_m \cdot °\text{R)}$$

Similar procedures for other pressures (or temperatures) result in the tabulated values. Sample data in Table B8.18 shows that the maximum entropy is 0.06946 Btu/lb$_m$, the corresponding pressure (critical or choke pressure) is 17.94 psia (1.24 bar), and the corresponding temperature is $t_{exit} = -13°F (-25°C)$. Try to relate the above presented findings to the Fanno line model presented in Fig. B8.16.

The exit velocity of the fluid is calculated from the continuity equation applied to the pipe exit condition:

$$w_{exit} = c = v_{exit}\dot{G} = (0.760557)(322.4) = 245.362 \text{ ft/s (74 m/s)}$$

TRANSIENT FLOW ANALYSIS

General Background

Hydraulic transient problems in piping systems result from faulty plant design and also from faulty plant operating procedures as, for example, rapid changes in operational functioning of components such as pumps and valves. They may produce rapid momentum changes as the column of water in the system is suddenly stopped or started. Large momentum changes can subject system components to severe force transients, and these must be considered when designing the system to ensure its safe, reliable operation.

Hydraulic transient problems may result in the formation of vapor cavities when the system pressure is reduced to the saturation pressure at a certain fluid temperature. Vapor cavities can easily form in a piping system that has a wide elevation range, if permitted to drain after the system is shut down. This behavior is known as *column separation.* In a large cooling-water system, reclosure of water columns after separation can result in destructive water hammer loads if appropriate design consideration is not given to alleviate these effects.

Analysis of hydraulic transients should be performed for all major plant systems. In addition to the maximum and minimum design pressures for components and the forcing functions for pipe supports, the analysis will help provide appropriate procedures for system startup and shutdown and operator responses to power failure.

Transients that exhibit single-phase flow can be analyzed by one-dimensional wave theory. During a transient condition, pressure waves are generated throughout the system. In complex systems, these waves may be analyzed with the aid of a computer.

Newton's second law, the equation of motion, is a vector relation. Considering the x-direction, a useful working form of the momentum theorem may be written[11]:

$$\Sigma F_x = \frac{d}{dt}\left(\frac{m}{g_c}w_x\right) = \int_{cv} \frac{\partial}{\partial t}\left(\frac{\rho}{g_c}w_x\right)dV$$

$$+ \int \frac{\rho}{g_c}w_n w_x dA_{out} - \int \frac{\rho}{g_c}w_n w_x dA_{in} \qquad \text{(B8.92)}$$

where the left-hand side represents the algebraic sum of the x-forces acting on the system during the time interval dt. By using vector notation, the momentum theorem for a control volume may be represented by a single equation

$$\Sigma \bar{F} = \frac{\partial}{\partial t} \int_{cv} \frac{\rho}{g_c} \bar{w} dV + \int_{cs} \frac{\rho}{g_c} (\bar{w} \cdot \overline{dA}) \bar{w} \qquad \text{(B8.93)}$$

which is the fundamental principle in the dynamics of fluid motion. In words, the resultant force acting on a control volume (cv) of the pipe segment is equal to the time rate of increase of linear momentum within the control volume plus the net efflux of linear momentum across the control surface (cs) of the pipe segment boundary. The term $\Sigma \bar{F}$ in Equation (B8.93) is the algebraic sum of all forces exerted by the surroundings on the material instantaneously occupying the control volume. These include (1) *body forces* which are proportional either to the volume or mass of the body (e.g., forces of gravitational attraction) and (2) *surface forces* which are exerted at the control surface by the material outside of the control volume on the material inside the control volume (e.g., pressure acting on the control surface). It is generally advantageous to take surface normal to the velocity wherever it cuts across the flow.

The first partial derivative term in Eq. (B8.93) is the average time rate of increase of linear momentum ($m\bar{w}/g_c$) of the system during time Δt. In the limit as Δt approaches zero, it becomes $d/dt(m\bar{w}/g_c)$. In Ref. 29 this term is called the *wave force* F_{wi} on a bounded pipe i-th segment of length L_i. A *segment* (within a control volume) is always defined as a straight pipe between elbows, turns, or between an elbow and piping component or equipment. Fluid acceleration inside the pipe generates forces on all segments that are bounded at either end by an elbow, a turn, or a piping system component.

Immediately following a flow disturbance due to a sudden flow rate reduction (by a rapid control valve adjustment) or flow-rate increase (e.g., a pipe break), a compression or a decompression wave propagates into the fluid contained by the pipe. As the fluid pressure is increased or reduced, its density changes accordingly. The compression or decompression travels at sonic speed through all pipe segments, finally arriving at the vessel where a decompression or compression wave is reflected back toward the disturbance location (valve or a rupture). As compression or decompression waves move through the pipe, the pressure at one end of each segment exceeds the pressure at the other, resulting in net forces F_{wi}.

Successive wave transmissions and associated fluid acceleration forces decay as steady discharge is achieved, and this transient term in Eq. (B8.93) vanishes when steady flow is reached. Although the wave force F_{wi} vanishes at steady flow, the second term in Eq. (B8.93) in Ref. 29, called the *blowdown force,* survives on the discharging segment. This phenomenon will be discussed in more detail in the subsection "Pipe Rupture."

Note again, that when steady flow is reached, the wave force vanishes. During steady-state conditions, there is no unbalanced force in the segment. Also, note that a positive segment force acts along the pipe axis opposite to the direction of flow. Equation (B8.93) is valid for bounded pipe regardless of the bend angle at either end of the segment. Large computer programs have been developed to help predict forces generated during postulated hydraulic transients in piping systems.

Pipe Rupture

If a pipe break occurs, thrust and jet forces generated by fluid discharge can cause further damage to piping and other plant components unless adequate mechanical

restrains are employed. Discharging fluid creates a reaction thrust on the ruptured pipe itself and impingement loads on objects struck by the jet of fluid. Moreover, fluid acceleration inside the pipe generates forces on all segments that are bounded at either end by an elbow or turn. Although pipe thrust may basically be considered as a steady-state phenomenon, its initiation is accompanied by a violent transient following the sudden sonic decompression wave starting at the break location.

The mechanics of the steady pipe thrust problem are similar to those involved in rocket propulsion. The steady thrust can be computed as follows. If A, is the exit area (or the area of a break), p_0, is the exit-plane pressure, ρ_e is the density of the escaping fluid to the atmosphere at pressure p_{atm}, $\dot{m}$ is the escaping mass flow rate, and w_0 is the velocity of efflux, the momentum Equation (B8.92) leads to the following expression for the thrust[11]:

$$T = \frac{\dot{m}}{g_c} w_e + (p_e - p_{atm})A_e \ \text{lb}_f \tag{B8.94}$$

In a rocket jet engine with a converging-diverging nozzle there is a minimum throat area A_t characterized by the critical pressure ratio and the sonic velocity (Ma = 1). Provided the nozzle is so designed that its enlarged exit area behind the throat (as a Venturi tube) ensures expansion down to pressure $p_0 = p_{atm}$, prevailing in the external atmosphere, the exit velocity w, becomes supersonic, and the thrust of the engine reaches its maximum. This important conclusion is valid irrespective of the type of fluid considered, whether gaseous or liquid.

If the nozzle were a simple converging nozzle, as it could be considered in a pipe break, A_0 would equal A_t (throat area). After transformation of Eq. (B8.94) by using the *ideal gas* relations, as presented in section "Single-Phase Flow in Nozzles, Venturi Tubes, and Orifices," subsection "Steam and Gas Service," the following expression for a simple convergent nozzle maximum thrust is found[11]:

$$T_{conv} = A_t \left[2p_o \left(\frac{2}{k+1} \right)^{1/(k-1)} - p_{atm} \right] \tag{B8.95}$$

Then, for *superheated steam* ($k = 1.3$), the following ideal gas thrust may reach its maximum value

$$T = A_t(1.26p_0 - p_{atm}) \tag{B8.96}$$

and for *saturated steam* ($k = 1.1$)

$$T = A_t(1.23p_0 - p_{atm}) \tag{B8.97}$$

If *incompressible liquid* escapes from a vessel (or broken pipe), where stagnation pressure is p_0, its subsonic exit velocity is expressed by Eq. (B8.35) (with $z = 0$ and $p_2 = p_{atm}$). Then, by using this expression for w_0 in Eq. (B8.94), the steady thrust (reaction force) can be found from the following expression:

$$T = \frac{\dot{m}}{g_c} w_e = \frac{\rho}{g_c} A_e w_e^2 = \frac{\rho}{g_c} A_e \frac{2g_c(p_1 - p_{atm})}{\rho} = 2A_e(p_1 - p_{atm}) \tag{B8.98}$$

Thus, while the speed of efflux is inversely proportional to the density, the thrust in this case is independent of the density and depends only on the area of the break (orifice) and the gauge pressure ($p_1 - p_{atm}$).

As an example, consider a vessel containing cold water at 1050 psia (72.4 bar).

As a result of a postulated 12-in (0.3-m) pipe break, water is discharged into the atmosphere. As calculated by using Eq. (B8.98) this would produce an impressive steady thrust of 225,000 lb$_f$ (999,600 N), while the velocity of efflux, calculated from Eq. (B8.35), at its density of 62.5 lb$_m$/ft^3 (1020 kg/m^3), is equal to 388.1 ft/s (118.3 m/s).

If a *two-phase critical flow* escapes from a vessel or a broken pipe, one may expect somewhat different thrust characteristics. Various critical two-phase flow models, as discussed in the section "Critical Gas-Liquid Flow," provide the mass flux and thermodynamic parameters (choke pressure, steam quality) at the nozzle throat in terms of vessel stagnation properties and pipe fL/D. Moody[45] used his model (see subsection "Moody Model") for calculating critical blowdown from a 1050 psia (72.4 bar), typical for a boiling water reactor (BWR) vessel. He found that at $fL/D = 0$ (pipe break just where it is attached to a vessel), T/A_e for critical saturated water blowdown is 183,000 lb$_f$/ft^2 (8,762 kN/m^2), which is about half the value of thrust/area from Eq. (B8.98) for incompressible liquid blowdown. Furthermore, T/A_e for saturated steam is 182,000 lb$_f$/ft^2 (8,714 kN/m^2), which is closely predicted by Eq. (B8.97). Predicted thrust and impingement properties are shown to give reasonable agreement with available data. It is also clear that increased values fL/D (pipe break at a certain distance from the vessel) would reduce the thrust. (Compare with the Fanno model discussed in section "Critical Gas-Liquid Flow," subsection "Fanno Model.")

For more detailed discussion and numerical examples on this subject, see Refs. 29 and 45.

Typical Water Hammer Transients

Water hammer is a pressure wave, usually resulting from rapid changes in the flow rate in a pipe, which is characterized by the transformation of kinetic energy of moving fluid into pressure. Typical transients for a water-filled system include rapid valve closure, pump startup, or pump trip within the circulating water system, feedwater system, or service water system of a power plant, or the cooling water system of a process plant. The water hammer phenomena in a piping system also may result due to formation of vapor pockets at locations where the pressures are reduced to or below vapor pressure. This phenomenon is normally called *column separation.* The subsequent collapse of these vapor pockets may develop significant pressure spikes which should be taken into consideration in system design and analysis.

The basic water hammer equation is derived from equations of conservation of mass and momentum in a single pipeline. For low-flow velocities [much lower than the speed of sound in the fluid (Ma ≪ 1)] and for columns of fluid rejoined near a closed valve or a dead end (final flow velocity $w = 0$), the produced peak (maximum) pressure of inertia is estimated from the following equation (see Refs. 1 and 46):

$$\Delta p = \frac{\rho}{g_c} c \Delta w \qquad (B8.99)$$

where Δw is the relative closure velocity of the fluid before impact, ρ is the fluid density, and c is the sonic wave speed. Using the bulk modulus of elasticity of water $K = 0.3 \times 10^6$ psi (2.07 × 10^6 kPa) the speed of sound in water without any pipe wall effect is ~4700 ft/s (~1435 m/s). For a circular elastic steel pipe of diameter

d, in which the Young's modulus of elasticity for the wall material is $E = 30 \times 10^6$ psi (206×10^6 kPa), the wave speed is expressed by[1]:

$$c = \sqrt{\frac{g_c K / \rho}{1 + \frac{d}{e}\frac{K}{E}}} \tag{B8.100}$$

where *e* is pipe wall thickness. By using Eq. (B8.100) for cold water, the wave speed *c* varies from 4490 ft/s (1370 m/s) for $d/e = 10$ to 2360 ft/s (720 m/s) for $d/e = 300$. If the valve closure time is less than $t = 2L/c,$ where *L* is the length of a pipe from the valve to the upstream vessel, the action is called *rapid closure.* The term *slow closure* refers to times of closure greater than $2L/c.$ In the case of column separation or column rejoining (*reclosure*), large flow velocities are not necessary for significant peak pressures and segment forces. For example, for cold water with ~10 ft/s (~3 m/s) closure velocity in a 10 in pipe, a peak pressure of inertia of ~570 psi (~39 bar), as calculated from Eq. (B8.99), could produce a segment force as high as ~43,000 lb_f (~190 kN).

NUREG-0582[47] has identified a number of high-energy systems in nuclear power plants that have had a history of transient-related problems. It also discussed the major causes of transient problems which are attributable to events such as pump startup, stopping, or seizure; pump startup with inadvertently voided discharge lines; valve opening, closing, and instability; check-valve closure and delayed opening; water entrainment in steam lines; steam bubble collapse, and mixing of subcooled water and steam from interconnected systems; slug impact due to rapid condensation; and column separation and subsequent rejoining. Some of these transient events can be prevented by implementing appropriate operating procedures. However, there are other events that may occur during normal/upset, emergency, or faulted plant operating conditions. These flow transients in the piping system may cause significant dynamic loads and large reactions on the piping, piping supports, and connected equipment. These transient loads must be analyzed and incorporated into the pipe stress analysis and pipe support evaluation.

The service water system of a nuclear station illustrates the application. The system is designed to supply cooling water to remove heat from component heat exchangers throughout the station. Hydraulically, such a system is far more complex than a condenser circulating water system because there are numerous heat exchangers and considerable variations in piping elevation.

Figure B8.55 depicts the major components of a typical service water system in the case of a pressurized water reactor (PWR) unit; Fig. B8.56 shows the profile (vertical) of a portion of the system, including the control building air-conditioning water cooler (HVK) and emergency diesel engine cooling water (EGS) piping. Because of the high elevation of the HVK piping, a vapor gap will form on either side of the HVK heat exchanger when the service water pumps trip out. Also, because of the U-shaped piping configuration, a water column will be retained in the central portion of the HVK piping, as shown. After the pump has restarted, the vapor gap at the inlet piping may close rapidly—resulting in severe pressure and force transients—unless proper care is taken in the design and operation of the system.

Typical Steam Hammer Transients

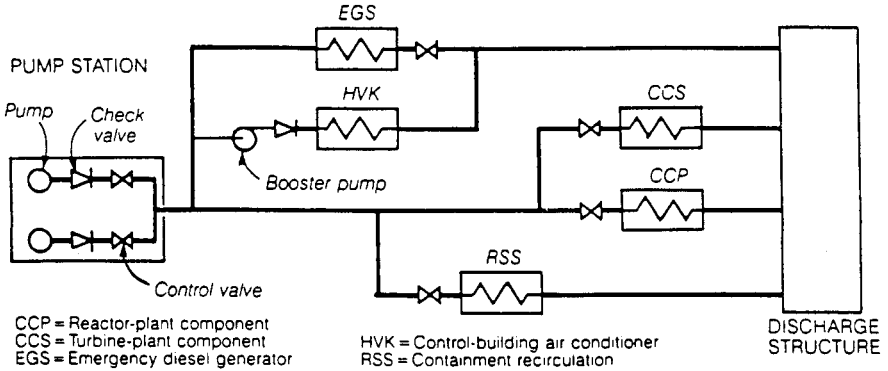
Steam hammer is defined as the pressure surge generated by transient flow of superheated or saturated steam in a steam line, but not as the collapse of steam


FIGURE B8.55   Major components of a service water system for a PWR-type nuclear power plant.

pockets which was described in the previous section. Usually the pressure spikes due to steam hammer are not as high as in water systems because of the large compressibility of steam.

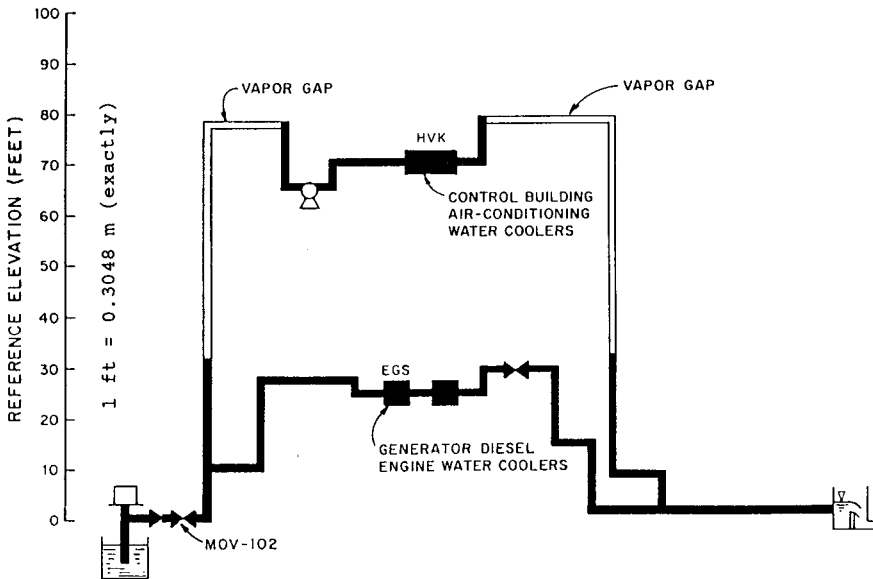
Typical applications of a steam hammer program to perform analysis of compressible flow include studies of the turbine generator main steam and bypass system, the safety relief valve blowdown, the reactor core isolation cooling system, the high-pressure coolant injection system, and so forth. The program could apply the method of characteristics with finite difference approximations for solutions of unsteady one-dimensional compressible fluid flows. The choking phenomena of


FIGURE B8.56   Partial service water system profile showing vapor gap.

steam flow are included in the program. In analyzing transients in a safety/relief-valve discharge system, the program has an option to handle the blowdown forces at the interface of steam discharging into the suppression pool.

Steam-Condensation-Induced Water Hammer

Several flow conditions may lead to severe condensation-induced water hammers, with steam and water counterflow events in a horizontal pipe being potentially the most severe. Water-cannon events (subcooled water with condensing steam in a vertical pipe) may occur if the right geometry and system conditions exist. Pressurized water entering a vertical steam-filled pipe can cause a severe transient event over a wide range of piping geometry conditions. Hot water entering a lower-pressure line is also a very common condition for many nuclear power plant piping systems, especially for those heater drain dump lines which lead to the condenser.

Condensation-induced water hammers of the steam and water counterflow type can occur in a horizontal pipe with a steam- and water-stratified environment. If the water is highly subcooled, violent condensation may occur. This rapid condensation process will generate a significant steam flow above the water surface. The shearing forces at the interface between the steam and the subcooled water can create enough turbulence to generate a water slug, which in turn will entrap an isolated steam pocket. Continued rapid condensation of the entrapped steam will accelerate the water slug into the void, causing a damaging water hammer. Two conditions must coexist in the system to initiate this condensation-induced water hammer, namely:

- A steam and subcooled water stratified flow exists in a significant length of a horizontal or near-horizontal pipe
- Substantial turbulence exists at the steam-water interface

Depending on the void fraction and subcooling in the two-phase flow environment, the magnitude of the pressure wave generated by steam condensation and bubble collapse can be devastating. These events should be prevented from occurring by all practical means (see Refs. 28, 29, 48).

In summary, the significant condensation-induced water hammer conditions are:

- Subcooled water with condensing steam in a vertical pipe
- Steam and water counterflow in a horizontal pipe
- Pressurized water entering a vertical steam-filled pipe
- Hot water entering a lower-pressure line

Practical Recommendations to Minimize Water Hammers

Protection Devices to Minimize Water Hammers. Various devices may be used to protect piping systems from damage by severe hydraulic transients. Check valves, standpipes, and accumulators prevent the occurrence of transients or reduce their effects.

Vacuum-breaker valves allow air to enter a piping system when a vacuum develops. Sometimes installed on heat exchangers, these relief valves may be located in the system where water-column separation may occur during transient conditions. Air in the system will significantly attenuate pressure spikes when water columns rejoin.

Check valves are sometimes used in service water systems to prevent column separation. Following a power loss, water in the high portion of a riser may drain out because of the large change in elevation, creating a vapor cavity. In this situation, a check valve may be installed at the bottom of the upstream riser to prevent water drainage and column separation.

A *standpipe* may be used in a cooling water system where relief of vacuum pressure is necessary. Serving as a simple surge tank, the standpipe admits water and possibly air into the system. This either eliminates column separation or reduces the severity of column reclosure because of air injection.

An *accumulator* of proper size may effectively eliminate column separation after a power failure. The device, a closed container partially filled with water topped with compressed air, is usually installed immediately downstream from a pump station along with a check valve. Following a power failure, the pump coasts down and the pump head decreases rapidly, causing the check valve to close. Compressed air in the accumulator will supply fluid flow pneumatically into the main line to minimize downsurge, and will provide a cushion on the return surge.

Field Tests for Hydraulic Transients.   Frequently, field tests for hydraulic transient loading are conducted to accomplish the following:

- Verify that system design is adequate
- Determine the best way to operate a system to avoid transients
- Discover scenarios of unanticipated transients
- Validate results obtained from analytical approaches

The first three functions are often included as part of the normal startup and checkout of a new system.

Field tests serve to measure key parameters related to hydraulic transients while operating a system in a manner that could produce plausible transient events. Validation of analytical results involves benchmarking the computation method for known operating parameters; or benchmarking, combined with checking of input variables such as pump characteristics and valve opening or closing time. In many cases, transients introduced by valve opening or closing and by pump trip or startup are overpredicted, and can be improved with the help of field test data.

System Design Considerations.   There are three ways to prevent or minimize fluid transients through effective system design: (1) general design practices that either reduce or eliminate a possible transient; (2) adding special systems to either control or prevent a transient; and (3) performing time-history analysis of loads, and designing a pipe support system to accommodate the transient loads.

General design practices should include:

- Designing all steam-line piping to provide continuous downward slopes with provisions for low-point drainage to preclude the formation of water pockets (upstream of a potentially isolable valve is considered to be a low point).
- Where allowed by system design function, providing slow-opening/closing valves
- Providing high-point vents or air-release valves in water-filled lines to allow system venting to eliminate the formation of air pockets
- Using vacuum breakers to minimize potential dynamic effects by providing an air cushion in fluid-carrying pipelines that could otherwise be under an occasional vacuum

Special systems that preclude or diminish the effects of fluid transients include:

- Loop-fill systems that continuously maintain a primary piping system in a filled and pressurized condition during operating modes when that system is on standby (e.g., fire-protection system and emergency core-cooling systems).
- Steam-line preheating systems that continuously maintain or allow gradual heatup of steam supply lines to reduce rapid steam condensation and the development of water slugs that generate substantial loads on the piping system.

The overall piping system stress qualification should consider as appropriate all loading conditions, including the dynamic effects of fluid transients. Piping codes prior to 1970 were rather vague in this regard; however, the more recent editions of ASME Section III of the Boiler and Pressure Vessel Code are quite specific and require this consideration. The forcing functions generated by manual or computer modeling are incorporated into the stress analyses which are used as the basis for designing a support system that can accept the loads and maintain them within the code-allowable limits for safe, continuous system operation.

Pump Net Positive Suction Head (NPSH) Transients

In dealing with net positive suction head problems, effort has been made to distinguish between NPSH required or NPSHR and NPSH available or NPSHA. The NPSHA is a function of pump design or pump requirement, while the NPSHA is a function of the pump system which must provide the required NPSH. The available NPSH must always exceed the required NPSH by a certain margin which must be positive even during transient conditions (see Ref. 49).

Large steam-electric power plants are equipped with several stages of low-pressure and high-pressure feedwater heating within the turbine cycle. There may be as many as three or four stages of low-pressure closed feedwater heaters situated between the condenser and the deaerator which supplies heated condensate to the feedwater pump. Under transient conditions when load change is sudden and large, a check valve in the steam extraction line from turbine to deaerator closes to avoid backflow and possible damage to turbine blading. Deaerator pressure at this moment decreases fairly rapidly, while colder water from the condensate system continues to enter the deaerator, and hot water continues to be withdrawn.

Turbine load rejection is a case of an even more severe transient. Immediately following a turbine load rejection from a maximum load, warm condensate will enter the deaerator initially. The temperature of the condensate, however, will eventually decay to a point exactly equal to the condenser hot-well temperature because the low-pressure heaters will no longer receive extraction steam from the turbine. It is this transient condition which should receive prime consideration in feedwater system design.

As extraction steam is cut off from the deaerator, pressure in the corresponding deaerator storage tank falls rapidly, as does the pressure at the pump suction. However, temperature and vapor pressure of water at the pump do not change until colder water from the tank has had a chance to travel down the pump suction piping. If actual pressure at the pump impeller falls below the vapor pressure there, cavitation will result. It is the production of these vapor pockets, or bubbles, and the consequent collapse as the head, or pressure, is developed in the impeller, that generates the cavitation which produces the noise, vibration, and the pitting attack of the impeller's surfaces. The measurable consequences of cavitation on a pump's

performance are a loss in flow and head resulting from voiding of vane passages, turbulence, and two-phase flow.

The design of fluid systems must clearly establish criteria that address steady-state and transient conditions from the view of system or component protection. Certain types and severity levels of transients can be accommodated by the pump but may not be tolerated by the system.

Short-term transients can be considered momentary events where the available NPSH falls below the required NPSH at a particular moment. These events will probably have no measurable effects on the pump mechanically and, because of their duration of fractions of a second to seconds, should not measurably affect performance which would be restored with restored suction conditions.

Transients which occur for periods that range from seconds to a few minutes will have a measurable impact on performance. Sustained suction conditions that are below minimum NPSH requirements will cause cavitation in the eye of the pump's suction impeller, which in turn will reduce flow and developed head. Long-term, low-NPSH transients, by design, must be avoided.

To protect the main feed pump against unwanted transient suction pressure decay and cavitation, the following steps can be considered by the plant designer:

1. Increasing static suction head by raising the deaerator or lowering the pumps. The absence of high structure in nuclear power plants creates a location problem for a deaerator.

2. Increasing deaerator storage capacity. A deaerator removes entrained oxygen from feedwater and provides a surge tank which reduces the possibility for rapid transients and provides approximately 5-min storage if a condensate pump fails.

3. Reducing pump suction pipe (downcomer) resident capacity by sizing the connecting piping as small as practical and routing it as directly as possible. Preliminary sizing of the downcomer should be based on a flow velocity of 10 ft/s (3 m/s).

4. Lowering deaerator pressure. In most fossil-fueled power plants, deaerators operate at either the fourth or fifth turbine extraction point in the eight-heater cycle which means at 80 or 160 psia (5.5 or 11 bar) respectively. Operating experience with these pressure levels is sufficient to justify the use of either.

5. Installing a booster feed pump. Auxiliary turbine-driven feed pumps require low-speed, low-head booster pumps (generally of single-stage design) ahead of the main feed pump. This booster pump is capable of handling the required capacity with the low NPSH required. A survey revealed that every power plant larger than 400 MW currently under construction uses auxiliary turbine drives for feed pumps and their boosters.

6. Injecting steam into deaerator (pegging).

7. Injecting cold water at a point sufficiently ahead of the pump suction nozzle to provide good mixing (deaerator bypass system).

While items (1) through (5) may be called preventive actions, items (6) and (7) are corrective actions.

In order to chose the base design for a particular plant, information on the magnitude of the NPSHA decay during the transient is needed. Theoretical background for computerized or hand calculations relating to these problems, as well as numerical examples, are presented in Refs. 50, 51, 52.

Pump NPSH transients have been modeled, photographed under test conditions,

and certain chronic transients have resulted in verifiable documented cases where NPSH conditions were the cause of pump problems. However, in spite of our sophistication and diligence in this area, over many decades NPSH transients and their impact remain a serious problem.

NPSH transients must be understood as well as the pump's capabilities to withstand such events; then margins can be applied initially in the design of the system.

CHAPTER B9
CEMENT MORTAR AND CONCRETE LININGS FOR PIPE

Richard E. Deremiah, P.E.
Project Manager
Price Brothers Company
Dayton, Ohio

INTRODUCTION

History

It has been known for over 100 years that portland cement mortar and concrete provide considerable protection to embedded ferrous materials against the corrosive effects of soil and water. The most common embedded ferrous material receiving this type of protection has been the steel bars in reinforced concrete. There are literally thousands of reinforced concrete bridges, buildings, parking garages, and other structures in service today. During the 1920s practical methods were developed to apply portland cement mortar linings to cast-iron and steel pipe in the manufacturing plant. In the 1930s a method for applying cement mortar linings to in-situ pipe was developed. Since that time, a significant amount of steel pipe, cast-iron pipe, and more recently, ductile iron pipe has been lined with portland cement mortar. Portland cement mortar linings have become the most common protective measure used for pipe in water and wastewater service. The concrete pressure pipe industry also took advantage of the protective properties of portland cement mortar and concrete during the development of reinforced concrete pressure pipe in the early 1900s and prestressed concrete pressure pipe in the early 1940s. Since the mid-1940s, portland cement mortar and concrete linings for concrete pressure pipe have proven highly successful, with almost all such pipe still remaining in active service. Portland cement mortar and concrete linings are very economical and provide superior corrosion protection.

Terminology and Definitions

Mortar   A mixture of portland cement, fine aggregate (sand), and water

Concrete	A mixture of portland cement, fine aggregate (sand), coarse aggregate (gravel), and water
Tuberculation	The formation of localized corrosion products scattered over the metal surface in the form of knoblike mounds
Passivation	The formation of a tightly adhering and protective chemical oxide film on the metal surface due to the presence of highly alkaline portland cement mortar or concrete
Vertical casting	A method of placing the concrete for a pipe involving the use of a steel inside form and outside form
Centrifugal casting	A method of placing a concrete or mortar lining by centrifugal force inside a revolving cylinder
Radial compaction	A vertical method of placing a pipe's concrete lining by the use of a special revolving packerhead
Pneumatic placement	A method of applying a mortar lining to a surface using compressed air equipment

Application

The interior of unprotected ferrous metal water pipelines can be attacked and damaged by corrosion, which in turn can lead to the formation of leaks, scale, or tuberculation or a combination of these defects. Leaks obviously compromise the structural integrity of the pipeline, resulting in the need for repair or replacement. The buildup of corrosion products in the form of scale or tuberculation can seriously degrade the flow characteristics of the pipeline. If the condition becomes severe enough, repair or replacement is required. For this reason, it is imperative that some form of protection be provided to the ferrous metal surface. Portland cement mortar and concrete protective linings have been found to be a highly effective and economical solution.

Reference Standards

Table B9.1 summarizes the commonly used industry standards which apply to portland cement mortar and concrete linings for pipe.

References

Table B9.2 lists American Water Works Association (AWWA) manuals that provide technical information and guidance for portland cement mortar- and concrete-lined pipe.

TABLE B9.1 Reference AWWA Standards for Cement Mortar and Concrete Linings for Pipe

Number	Title	Remarks
American National Standards Institute (ANSI)/ American Water Works Association (AWWA) C104/A21.4[1]	Standard for Cement-Mortar Lining for Ductile-Iron Pipe and Fittings for Water	For factory-applied mortar linings in ductile iron pipe
ANSI/AWWA C205[2]	Standard for Cement-Mortar Protective Lining and Coating for Steel Water Pipe-NPS 4 (DN 100) and Larger-Shop Applied	For factory-applied mortar linings in steel pipe
ANSI/AWWA C300[3]	Standard for Reinforced Concrete Pressure Pipe, Steel-Cylinder Type	For concrete and mortar linings in concrete pressure pipe
ANSI/AWWA C301[4]	Standard for Prestressed Concrete Pressure Pipe, Steel-Cylinder Type	For concrete and mortar linings in concrete pressure pipe
ANSI/AWWA C302[5]	Standard for Reinforced Concrete Pressure Pipe, Non-Cylinder Type	For concrete and mortar linings in concrete pressure pipe
ANSI/AWWA C303[6]	Standard for Concrete Pressure Pipe, Bar-Wrapped, Steel-Cylinder Type	For mortar linings in concrete pressure pipe
ANSI/AWWA C602[7]	Standard for Cement-Mortar Lining of Water Pipelines in Place-NPS 4 (DN 100) and Larger	For field-applied mortar linings in steel pipe, cast iron pipe, and ductile iron pipe

Corrosion-Preventative Properties of Portland Cement Mortar and Concrete for Lined or Encased Steel and Iron

Portland cement mortar or concrete linings protect steel and iron by three interrelated processes:

1. They form a barrier coating which works to prevent physical damage to the metal surface.

2. They passivate the metal surface. Hydrated portland cement is highly alkaline, with a pH of about 12.5. At that pH, a passivating oxide film forms and is maintained on the metal surface, preventing corrosion.

TABLE B9.2   Reference AWWA Manuals for Cement Mortar and Concrete Linings for Pipe

Title	Remarks
American Water Works Association Manual of Water Supply Practices ''M9—Concrete Pressure Pipe''[8]	Covers the four types of concrete pressure pipe and fittings

Potable water
Raw sewage
Treated sewage
Seawater
Power plant cooling water (both seawater and fresh water)

CONCRETE PRESSURE PIPE AND FITTINGS

Pipe

Pipe manufactured in accordance with the ANSI/AWWA C300,[3] C301,[4] and C302[5] standards is required to have high-strength structural concrete on the inside surfaces of the pipe which, in addition to enhancing the load-carrying capability, provides corrosion protection to the embedded reinforcing elements. All concrete is placed at the factory by vertical casting, centrifugal casting, or radial compaction methods.

Pipe manufactured in accordance with the ANSI/AWWA C303[6] standard is

required to have a mortar protective lining. The mortar is mixed using 1 part portland cement to 3 parts fine aggregate, with enough water added to obtain the necessary workability. The mortar lining is placed at the factory by the centrifugal casting method.

Fittings

The fabricated steel fittings for all four types of concrete pressure pipe (ANSI/ AWWA C300,[3] C301,[4] C302,[5] and C303[6]) receive a mortar lining. The mortar is mixed using 1 part portland cement to 3 parts fine aggregate, with enough water added to obtain the necessary workability. These mortar linings are placed at the factory by hand layup, pneumatic placement, or centrifugal casting methods.

Application methods and curing

Table B9.4 summarizes the lining application and curing methods allowed by the various concrete pressure pipe standards. This table also shows the limits on the ambient temperature and the mortar or concrete mix temperature during application of the lining.

Thickness

The thickness of the concrete or mortar linings for concrete pressure pipe vary by pipe diameter and pipe type but are at least 0.50 in (13 mm) thick. In the case of the AWWA C300,[3] C301,[4] and C302[5] pipe, the concrete core, in addition to providing corrosion protection to the steel cylinder or reinforcing mesh, provides resistance to external loads. This is why the thickness can vary with the design parameters. The mortar lining in the AWWA C303[6] type of pipe is primarily used to provide corrosion protection to the steel cylinder. Its thickness does not generally change with the design parameters. The mortar lining for fittings of all concrete pressure pipe types must be at least 0.375 in (9 mm) thick. The primary purpose of the mortar lining in fittings is to provide corrosion protection.

Joint Protection

As shown in Fig. B9.1, a small annular gap between the lining of adjoining pipe sections results after assembly of a concrete pressure pipe steel bell and spigot joint in the field. Depending on the nature of the water being transported and the protective coating applied to the joint rings by the pipe manufacturer, it may be
FIGURE B9.1   Mortaring of interior joint recess for prestressed concrete cylinder pipe.

necessary for the installing contractor to mortar this annular recess to protect the steel joint rings. The transmission of aggressive water such as raw sewage or seawater usually requires that the inside joint recess be filled with cement mortar after installation.

DUCTILE IRON PIPE AND FITTINGS

In most cases, ductile iron pipe and fittings are mortar-lined at the factory. Field application of a mortar lining is normally done on older, in-service pipe for rehabilitation purposes. Ductile iron pipe can be supplied with protective linings other than cement mortar lining. Some of the other protective linings may be more appropriate, depending upon the fluid being transported. For instance, ductile iron pipe transmitting raw sewage under gravity flow conditions might be lined with a protective material since sulfuric acid, which may form in the space above the flow, can severely attack portland cement mortar linings and ferrous pipe materials. For most nonaggressive raw water and potable water transmission situations, cement mortar linings are very economical and the most common means of protection.

Table B9.5 summarizes the mortar lining application methods, curing methods, and mix proportions used in the manufacturing plant and in the field for ductile

TABLE B9.5 Cement Mortar Lining Application, Curing, and Mix Proportions for Ductile Iron Pipe

		Applied at manufacturing plant	Applied in the field
Pipe	Application	Centrifugal casting or pneumatic placement	Mechanical placement and troweling
	Curing	Asphaltic seal coat, steam, or water	Water
	Mix pro-portions	1 part portland cement, not more than 2 parts fine aggregate, and sufficient water to achieve required workability	1 part portland cement to 1–1½ parts fine aggregate, and sufficient water to achieve required workability
Fittings	Application	Hand-placed or pneumatic placement	Hand-placed if not by mechanical placement and troweling
	Curing	Asphaltic seal coat, steam, or water	Water
	Mix pro-portions	1 part portland cement, not more than 2 parts fine aggregate, and sufficient water to achieve required workability	1 part portland cement to 1–1½ parts fine aggregate, and sufficient water to achieve required workability

TABLE B9.6   Factory-Applied Mortar Lining Thickness for Ductile Iron Pipe and Fittings

Pipe size range	Mortar lining thickness
NPS 3–NPS 12 (DN 75–DN 300)	0.0625 in (1.6 mm)
NPS 14–NPS 24 (DN 350–DN 600)	0.0938 in (2.4 mm)
NPS 30–NPS 64 (DN 750–DN 1600)	0.125 in (3.2 mm)

iron pipe and fittings. Table B9.6 summarizes the factory-applied mortar lining thickness requirements for ductile iron pipe and fittings. Linings with twice the thicknesses shown in Table B9.6 (known as double thickness) can be supplied for extra protection if requested by the purchaser. Table B9.7 shows the field-applied mortar lining thickness requirements for ductile iron pipe and fittings.

TABLE B9.7   Field-Applied Mortar Lining Thickness for Ductile Iron Pipe and Fittings

Pipe size range	Mortar lining thickness for old and new ductile iron
4–10 in (100–250 mm)	0.1875 in (4.8 mm)
11–23 in (280–580 mm)	0.25 in (6.4 mm)
24–36 in (600–900 mm)	0.3125 in (8 mm)
>36 in (900 mm)	0.3125 in (8 mm)

Joint Protection

As with the concrete pressure pipe joint, in the case of factory-applied mortar linings, a small annular gap between the lining of adjoining pipe sections results after assembly of a ductile iron bell and spigot joint in the field. Depending on the nature of the water being transported and the protective coating applied to the joint surfaces by the pipe manufacturer, it may be necessary for the installing contractor to mortar this annular recess to protect the joint. In the case of field-applied mortar lining, the lining is continuous across the joint, and no further work is needed at the joint.

STEEL PIPE AND FITTINGS

The decision regarding where to apply the mortar lining for steel pipe—at the manufacturing plant or in the field—is based on a number of factors including

TABLE B9.8 Cement Mortar Lining Application, Curing, and Mix Proportions for Steel Pipe and Fittings

		Applied at manufacturing plant	Applied in the field
Pipe	Application	Centrifugal casting	Mechanical placement and troweling
	Curing	Steam or water	Water
	Mix proportions	1 part portland cement, not more than 3 parts fine aggregate, and sufficient water to achieve required workability	1 part portland cement to 1–1½ parts fine aggregate, and sufficient water to achieve required workability
Fittings	Application	Hand-placed or pneumatic placement if not by centrifugal casting	Hand-placed if not by mechanical placement and troweling
	Curing	Steam or water	Water
	Mix proportions	1 part portland cement, not more than 3 parts fine aggregate, and sufficient water to achieve required workability	1 part portland cement to 1–1½ parts fine aggregate, and sufficient water to achieve required workability

manufacturer capabilities, pipe diameter, shipping and handling considerations, and field installation conditions. As with ductile iron pipe, steel pipe can be supplied with a range of linings, only one of which is cement mortar lining.

Table B9.8 summarizes the mortar lining application methods, curing methods, and mix proportions used in the manufacturing plant and in the field for lining steel pipe and fittings. Table B9.9 shows the factory-applied mortar lining thickness requirements for steel pipe and fittings. Table B9.10 shows the typical field-applied mortar lining thickness requirements for steel pipe and fittings.

TABLE B9.9 Factory-Applied Mortar Lining Thickness for Steel Pipe and Fittings

Pipe size range	Mortar lining thickness
4–10 in (100–250 mm)	0.25 in (6 mm)
11–23 in (280–580 mm)	0.3125 in (8 mm)
24–36 in (600–900 mm)	0.375 in (10 mm)
>36 in (900 mm)	0.50 in (13 mm)

TABLE B9.10 Field-Applied Mortar Lining Thickness for Steel Pipe and Fittings

Pipe size range	Mortar lining thickness for old steel	Mortar lining thickness for new steel
4–10 in (100–250 mm)	0.3125 in (8 mm)	0.25 in (6 mm)
11–23 in (280–580 mm)	0.375 in (10 mm)	0.3125 in (8 mm)
24–36 in (600–900 mm)	0.4375 in (11 mm)	0.375 in (10 mm)
>36 in (900 mm)	0.5625 in (14 mm)	0.50 in (13 mm)

Joint Protection

In the case of factory-applied mortar linings, it is necessary for the contractor to mortar the inside gap at the joints after installation. Field-welded joints, for instance, will have had the mortar lining held back a few inches at each end to avoid damage due to welding. Figure B9.2 illustrates this example showing a steel pipe lap-welded slip joint. The installing contractor must hand-place the mortar to these uncoated surfaces after welding. This mortar shall be mixed using 1 part portland cement to not more than 3 parts fine aggregate by weight. Use only enough water to obtain the required workability. In the case of field-applied mortar lining, the lining is continuous across the joint, and no further work is needed at the joint.
FIGURE B9.2 Mortaring of interior joint recess for field-welded lap joint steel pipe.

MISCELLANEOUS CONSIDERATIONS

Supplemental Protection for Concrete and Mortar Linings

There are some service conditions which can be aggressive to concrete and mortar linings. Two of the most common are:

- Raw sewage: In sewer lines that do not flow full, under certain conditions hydrogen sulfide gas can be generated by biological action in the flow area and then be discharged into the air space above the flow line. In the environment above the flow line, bacteria and moisture can convert this hydrogen sulfide gas to sulfuric acid, which will attack concrete and mortar linings.
- Soft water: Soft water (water with very low calcium carbonate hardness) may attack concrete and mortar linings by leaching minerals from the cement matrix.

If these conditions are expected to occur in the pipe, steps should be taken to protect the concrete or mortar lining or to use another lining that is resistant to these conditions. The pipe manufacturer should be consulted for specific recommendations and availability of supplemental protective measures.

Inspection and Repair

After pipe has left the factory, the mortar or concrete lining may be subject to minor shrinkage cracking, especially in low humidity conditions. The existence of this type of cracking usually does not indicate any structural distress. Once the pipe has been filled with water, the shrinkage process will reverse and minor cracks will close. All pipe and fittings should be carefully inspected upon their arrival on the jobsite. Damaged, loose, or severely cracked concrete or mortar lining should be noted at this time and evaluated for repair. The pipe manufacturer should be consulted for assistance in evaluation and for repair procedures.

Shipping and Handling

Care should always be exercised when lifting and handling concrete- or mortar-lined pipe. Wire rope lifting cables should never be placed through the pipe or fitting and allowed to bear directly against the lining. Any lifting device that bears against the concrete or mortar lining must be suitably padded to avoid damage.

CHAPTER B10
FUSION-BONDED EPOXY INTERNAL LININGS AND EXTERNAL COATINGS FOR PIPELINE CORROSION PROTECTION

J. Alan Kehr
Technical Marketing Manager
3M Company
Austin, Texas

INTRODUCTION

Corrosion is a global problem, consuming 3 to 4 percent of gross national product in the developed countries of the world.[1] Selecting economical and effective techniques for minimizing the effects of corrosion is a critical design decision in pipelines as well as in other technologies. Protecting pipeline systems from corrosion is essential to prevent leaks and consequent possible environmental disasters, fire and explosion, personal injury, service disruption, and costly maintenance. Protective measures are critical, yet they represent only a small fraction of the long-term overall cost of a pipeline system. The effectiveness of the corrosion-prevention system has a direct bearing on the design life of the pipeline and significantly influences operational costs such as general maintenance, pumping energy, and capacity upgrades.

This chapter reviews fusion-bonded epoxy (FBE) coatings, three-layer polyolefin coatings which utilize FBE as the primary corrosion coating, and FBE linings as solutions for mitigating external and internal pipeline corrosion.

Higher operating temperatures in modern pipeline systems and a host of hostile environmental conditions during transportation, installation, and use require a new generation of FBE-based world-class coatings to protect the pipe exterior.[2] The FBE primary coating controls the steel/coating interface where corrosion begins. Advanced field application technology provides comparable-quality same-system coatings for the girth weld.

Higher levels of hydrogen sulfide (H_2S), carbon dioxide (CO_2), salt water, and higher operating temperatures aggravate internal pipe corrosion. Corrosion-resistant alloys, inhibitors, and linings provide solutions for internal corrosion problems. FBEs have been formulated to operate in these very harsh service environments. These internal linings provide additional advantages besides corrosion prevention for the pipeline system. For example, they[3]:

- Improve fluid flow for higher throughput and reduced energy requirements
- Improve pipe inspection prior to installation
- Prevent corrosion during storage
- Facilitate pipeline cleaning and water disposal after hydrostatic testing

BACKGROUND, HISTORY, AND ADVANTAGES OF FBE LININGS AND COATINGS

Fusion-bonded epoxy is a one-part, heat-curable, thermosetting epoxy resin powder. The application of heat causes this material to melt and adhere to a metal substrate. The resulting coating contains no trapped solvents, exhibits excellent adhesion qualities, and provides a tough, smooth finish that is resistant to abrasion and chemicals. FBEs have been in use since 1960 to protect pipelines from corrosion. It is estimated that over 50,000 miles (80,000 kilometers) of FBE-coated pipelines are installed around the world.

FBE is the favored primary coating for three-layer polyolefin corrosion coatings. In this technology, it has been in use since 1979.

FBE is currently specified in the oil, gas, and water pipeline industries. It has been used as an internal lining in desalination plants in Australia and the Middle East, and on gas transmission pipelines.[5] It has been in use to protect downhole tubing for over 20 years.[14] More recently, it has been used in sour crude pipelines.[4]

In the water industry, FBE provides a thinner coating compared to concrete, enabling smaller pipe sizes and reduced bulk and weight during handling and installation of pipe. The smooth, hard coating provides reduced friction compared to uncoated or concrete-lined pipe. This results in more efficient flow, reduced energy costs, and lower installed pump or compressor investment. It has been used on valves, pumps, and fittings in water districts for both water and sewer systems in California for nearly 30 years. It is in use protecting brine-pit piping systems, solving erosion corrosion problems as well as general corrosion.[5] FBE has been used in high-sand-content seawater cooling pipework for 10 years and these installations are still in excellent condition. It has been applied to valves and pipework handling seawater for the U.S. Trident submarine program and has a 20-year history in the pump manufacturing industry, effectively protecting against cavitation and slurry damage. In the United Kingdom, FBE has protected drinking water pipework since 1978, with coatings on over 2,153,000 ft^2 (200,000 m^2) of piping.[6] Specific formulations meet the drinking-water requirements of many countries.

There are reports of 6 to 18 percent flow efficiency improvements in gas transportation when using FBE internally-lined pipe as opposed to bare steel pipe. Using the 6 percent figure on an 800-mile (1300-kilometer) NPS 30 (DN 750) pipeline with a discharge pressure of 960 psig (6600 kPa) and a compressor station every 80 miles (130 kilometers), the potential savings are over $4 million in compressor equipment cost, plus an annual energy savings of about $1 million.

TERMINOLOGY

Cathodic Disbondment.   Loss of coating adhesion around a holiday (hole in the coating) when the coated pipe is provided with cathodic protection. The phenomenon of cathodic disbondment happens with all organic coatings.[7]

Cathodic Protection.   When external pipeline corrosion takes place, there are anodic and cathodic areas on the surface. In the anodic areas (the corroding sites), current flows from the pipeline steel into the surrounding electrolyte (water in the soil). Where the current flows from the electrolyte to the pipeline, the area is cathodic and does not corrode. An external source of current flowing to the pipe will make it cathodic and will prevent corrosion. This method of corrosion prevention is called cathodic protection.[8,9]

Cathodic Shielding.   Cathodic shielding can take place when an electrically insulating barrier prevents current flow from reaching the pipe. An example is disbonded coating that allows water to come in contact with the pipe, but does not allow cathodic protection current to passivate the pipe surface. Current flow under the coating will depend on the resistance of the water there and, after a short distance, will be insufficient to protect the pipe from corrosion.[8]

Coating.   Application of FBE on the internal or external surface of a pipe or other metallic equipment. When applied on the internal surface, it is referred to as a *lining*, and, when applied to an external surface, it is called an *external coating*.

Cure Time.   The time required to complete the heat-induced crosslinking reaction to the point where the coating provides the acceptable level of performance.[10]

DGEBA.   Diglycidyl ether of bisphenol A, a widely used solid epoxy resin employed in the manufacture of fusion-bonded epoxy pipe coatings.[20]

FBE.   Fusion-bonded epoxy.

Fusion-Bonded Epoxy.   A one-part, heat-curable, thermosetting epoxy-resin powdered-coating material normally comprised of an epoxy and a curing agent, plus other materials to provide a tough, well-adhered coating. The powder is sprayed onto a hot pipe where it melts, flows, and cures.

Gel Time.   The time interval during which the coating material converts from a molten liquid to a solid.

Holiday.   A discontinuity, or hole, in the coating that allows an electric charge to pass at a specific voltage.[32]

Joint.   1. A length of pipe. 2. The welded area connecting two pieces of pipe (i.e., field joint).

Nested.   Rows of pipe that rest directly on each other in storage.

NSF.   National Sanitation Foundation (U.S. certification agency for potable drinking water systems).

Powder Coating.   See fusion-bonded epoxy.

Soil Stress.   Damage to a pipeline coating caused by wet/dry cycling of the soil and/or pipe movement caused by temperature change.

Stacked.   Rows of pipe placed on each other in storage, but with intervening layers of stripping (normally wood).

Stress-Corrosion Cracking.   In the presence of stress, corrosion cracks can initiate.[9] The incidence of failures on pipelines have been in cathodically protected areas of

disbonded coatings where liquids at a pH of 9 to 11 and carbonate/bicarbonate solutions have collected[11] between the coating and the surface of the steel.

Three-layer Coating.   External pipe coating composed of an epoxy primary corrosion-protection layer, a tie-layer of modified-polyolefin adhesive, and an overcoating of polyolefin.

TYPES OF ORGANIC PIPELINE PROTECTION LININGS AND COATINGS

Internal Linings

Internal pipeline linings are commonly divided into three categories: concrete, rubber, and plastics.

Concrete Linings.   There are several factors to consider beside the initial cost per unit area of coating application.[12] Of particular interest are the effects of the concrete liner on the pipe diameter, and its roughness. A concrete lining is thicker than FBE lining, and consequently the concrete-lined pipe has a smaller inside diameter than FBE-lined pipe (Refer to Chapter B9 for a detailed discussion of concrete-lined pipe.) Plastic linings generally reduce the diameter by 40 mils (1000 microns) or less. Thus, the use of plastic linings can result in utilizing a smaller pipe size while retaining the same throughput. Refer to Chapter B12 for details on plastic lining. Another major advantage of using plastic linings instead of concrete is the reduction of roughness.

Rubber Linings.   Refer to Chapter B11 for detailed discussion of rubber lined piping.

Plastic Linings.   Internal plastic linings have been used in oil well downhole tubulars for almost 50 years. See Table B10.1 for material comparisons.[13]

Phenolic resins, formed by the chemical reaction between phenol and formaldehyde, have the longest history.[14] They provide good performance at high service temperatures and high pressures. Phenolic-based linings have low permeability to water vapor, and good carbon dioxide, solvent, and abrasion resistance. Low impact resistance, low flexibility, and moderate caustic resistance limit their usage. They are gas-permeable and normally are not applied beyond 5 to 8 mils (125 to 200 microns) in thickness. Phenolic liquids must be layered in multiple coats to achieve the necessary thickness and to facilitate solvent removal.

Urethane linings have experienced some usage over the last few years because of improved abrasion resistance and flexibility. However, recent improvements in other systems, such as FBE, have limited urethane's growth in the marketplace.

Nylon powder linings provide good flexibility, abrasion, saltwater, and impact resistance, but suffer from limited temperature resistance, hydrogen sulfide sensitivity, and acid resistance.

Modified epoxy-phenolic lining systems provide improved flexibility and caustic resistance compared to phenolics but exhibit reduced operating temperature ranges and acid resistance. They also tend to be permeable to water.

TABLE B10.1   Types of Organic Internal Linings

Type	Advantages	Disadvantages	Upper temperature	Single coat	Type
Phenolic	• Low water vapor permeability • Good carbon dioxide, solvent, and abrasion resistance	• Low impact • Low flexibility • Moderate caustic resistance	392°F (200°C)	N	TS L
Urethane	• Good abrasion • Flexible • Smooth, resists paraffin build-up		220°F (105°C)	Y	TS L
Nylon	• Good abrasion • Flexible • Good salt-water resistance • Resists installation handling damage	• Low hydrogen sulfide and acid resistance	220°F (105°C)	Y	TP P
Epoxy-phenolic	• Improved flexibility and caustic resistance compared to phenolic • Resists depressurization	• Increased water-vapor permeability • Reduced acid resistance compared to phenolic	250°F (120°C)	N	TS L
Epoxy-novolac—FBE	• Improved flexibility and caustic resistance compared to phenolic • Resists depressurization	• Increased water-vapor permeability • Reduced acid resistance compared to phenolic	300°F (150°C)	Y	TS P
Epoxy—FBE	• Flexible • Good salt-water resistance • Resists installation handling damage	• Increased water-vapor permeability • Reduced acid resistance compared to phenolic	250°F (120°C)	Y	TS

Abbreviation definitions:

Single Coat: Y = yes, the coating can be applied in a single pass. For example, FBE coatings are frequently applied at a coating thickness of 25 mils (625 microns). N = No, materials like phenolics are applied in several layers of 25 to 50 microns (1 to 2 mils).

Type: TS = thermoset coating system (there is a chemical reaction which causes the coating to cure and take on final properties). TP = thermoplastic. L = liquid. P = powder.

FBEs show improved flexibility and are saltwater, carbon dioxide, and caustic resistant. Like modified epoxy-phenolic liquid systems, they are generally limited to an operating temperature of 250°F (120°C). New chemistry is improving the operating-temperature and chemical-resistance windows for FBE linings. For best performance, the thickness is normally 16 mils (400 microns) and above. The coating is applied in one operation; FBEs have no volatile organic compounds (VOCs). In many cases FBE coatings are displacing other lining types.

External Coating

There are a number of factors to consider when selecting an external pipeline coating.[15,16] These include:

- Physical and chemical stability
- Resistance to soil stress
- Adhesion and resistance to impact
- Resistance to cathodic disbonding

Types of External Pipe Coatings.   This subsection reviews the available external pipe coatings and their capabilities on the just-noted factors:

Polyethylene tapes usually consist of a primer followed by adhesive backed polyethylene tape spiral-wound around the pipe. Alternatives include two separate tape layers. Tape is often applied over the ditch over a wire-brush-cleaned surface. Tapes provide economy of materials but have poor resistance to installation damage. Tape-coated pipes are susceptible to soil stress and can insulate the pipe from cathodic protection[15] current, thus creating a corrosive environment. They are also vulnerable to corrosion at the weld seam and at the tape overlap.

Extruded polyethylene over mastic has good resistance to installation and handling damage, but can be affected by shrinkage and soil stress. Currently, it is available for only up to NPS 24 (DN 600) diameter pipe[17] because of application-process limitations.

Waxes and vinyl tapes require simple application technology and provide resistance to water permeation, but they are susceptible to damage due to cathodic disbondment and have a very limited operating temperature range.

Asphalt enamels also have the advantage of utilizing simple technology. However, they soften at higher operating temperatures and have poor resistance to moisture and soil stress.[17] Field studies have also shown that they have a tendency to cathodically shield the pipe,[15] which means that corrosion can take place even though the cathodic-protection system appears to be functioning normally. There is evidence that stress-corrosion cracking of the steel pipe can take place under enamel coatings.

Coal-tar enamels show good resistance to cathodic disbondment, which means moderate increases in cathodic-protection current over time. However, impact resistance[18] is poor, which leaves pipes vulnerable to handling damage and storage problems. Soil-stress resistance is poor,[17] resulting in potential coating loss during operation.

Three-layer polyolefins combine the good oxygen barrier properties of FBE with the good moisture-penetration resistance of polyolefin. The thick polyolefin layer also provides superior resistance to mechanical handling damage. Polypropylene has good high-temperature properties. There is a theoretical concern about cathodic shielding, but 20 years of satisfactory field performance belie that concern.

Fusion-bonded epoxy coatings have good chemical resistance, do not shield the pipe from cathodic protection, and there are no known cases of stress-corrosion cracking of FBE coated pipe. The coating is tough, but when installation damage occurs it is readily detected and repaired. Field application of FBE coating on girth welds provides the same protection as the plant-applied materials. Two-

TABLE B10.2 Types of External Pipe Coating Systems

Material	Advantages	Disadvantages	Temperature ±2°F (5°C)
Polyethylene tapes	Simple application in field.	Cathodic shielding—SCC†. Very poor resistance to soil stress.	95°F (35°C)
Extruded polyethylene	Good resistance to handling and installation damage. Self-healing adhesive.	Limited to NPS 24 (DN 600) or smaller pipe. Limited at elevated temperatures under soil stress.	105°F (40°C)
Wax/vinyl tapes	Simple technology. Low moisture permeation.	Very sensitive to temperature. Prone to cathodic disbondment.	85°F (30°C)
Asphalt enamels	Simple technology.	Poor resistance to moisture and soil stress. Very sensitive to temperature.	95°F (35°C)
Coal-tar enamels	Good corrosion resistance.	Low soil stress resistance. Properties sensitive to temperature.	120°F (50°C)
Fusion bond epoxy	Good corrosion resistance. Does not shield CP* systems. No evidence of SCC†.	Moisture absorption and permeation. Susceptible to cathodic disbondment.	175°F (80°C)
2-layer FBE	Good corrosion resistance. Good resistance to handling and installation damage.	Moisture absorption and permeation.	230°F (110°C)
3-layer polyethylene	Good corrosion resistance. Good resistance to handling and installation damage.	Cathodic shielding concern	175°F (80°C)
3-layer polypropylene	Good corrosion resistance. Good resistance to handling and installation damage.	Cathodic shielding concern	250°F+ (120°C+)

FIGURE B10.2 Progression of coating solutions for external pipeline corrosion mitigation for a major North American gas transmission company.[15]

layer FBE systems have recently entered the marketplace. They allow combining specific performance properties of the two layers to meet pipeline requirements. For example, the chemistry of the primary coating can be designed for minimal cathodic disbondment, and the topcoat can be designed to enhance impact resistance and high-temperature operating performance.

See Table B10.2 for more comparison information; also see Fig. B10.1 for cathodic protection current density requirements for coating types. See Fig. B10.2 for the coating-systems technology migration of a major Canadian gas-transmission company.[15]

FBE CHEMISTRY

During the development of coating and lining formulations and manufacturing processes, two key factors must be balanced:

- Requirements of the application plant that will apply the internal lining or external coating material
- Performance requirements of the end user, the owner of the pipeline system

If the world's best lining or coating cannot be applied efficiently, economically, and consistently, it has little value. The opposite is also true.[19]

To assist the ''understanding'' component of the selection process, this section provides a brief overview of fusion-bonded epoxy chemistry to illustrate the performance properties available and the tradeoffs required. It reviews raw materials used, and their effects on properties important to the applicator and the end user.

FBE Raw Materials

From a chemist's viewpoint, epoxies are exciting to work with because of the wide range of properties that can be derived from the selection of available materials. Materials selection and chemistry significantly affect product performance:

- Resins
- Curing agents or hardeners
- Catalysts and accelerators
- Fillers and pigments
- Additives

Resins. The term epoxy[20] comes from the three-member ring available for reaction (see Fig. B10.3). While there are several different types of epoxy resins, the two most frequently used in FBE linings and coatings are based on either diglycidyl ether of bisphenol A (DGEBA) or novolac chemistry. DGEBA resins provide excellent adherence, good mechanical and electrical properties, and good
FIGURE B10.3 Epoxy ring.

resistance to chemicals. Novolacs provide a highly crosslinked coating that means improved elevated temperature performance and chemical resistance with reduced flexibility.

To be useful in powder coatings, an epoxy resin must be of sufficient molecular weight to be a brittle solid at ambient temperature, but low enough in molecular weight to melt, flow, and wet out the substrate at application temperatures.

Curing Agents.   To achieve desired properties, the epoxy resin must react with a curing agent or hardener. Curing agents can be divided into three classifications:

- Bases
- Acids
- Catalytics

Basic curing agents include materials such as aromatic amines, aliphatic amines, amides, and dihydrazides. Acidic hardeners include organic anhydrides, organic acids, and phenolics. Catalytic hardeners cause the homopolymerization of the epoxy resin and include such materials as Lewis acids and tertiary amines.

Each curing system provides unique properties and is chosen carefully with requirements of both the pipeline owner and the applicator in mind. Crosslink density significantly affects flexibility and chemical resistance. Acidic cures typically result in materials with improved resistance to low pH environments. Conversely, basic cure coating systems are more resistant to high-pH, caustic environments. The selected curing agent should be latent at room temperature and highly reactive at application temperature.

Catalysts.   Catalysts, or accelerators, can be divided into two categories—Lewis acids and Lewis bases. Many of the curing agents previously listed will act as catalysts for other curing systems. Others include imidazoles, BF_3 complexes, quaternary ammonium compounds, inorganic metal salts, phenols, and sulfones.

Catalysts serve two functions. First, they direct the curing mechanism of the lining or coating system. For example, the final properties of an anhydride-cured FBE system catalyzed with a base, such as an amine, will be significantly different from the same system catalyzed with a metal salt. Second, they control the speed of the curing reaction. Selection of the catalyst system is critical to final performance properties.

Pigments and Fillers.   Normally pigments are employed to impart a specific color, but they can also be reactive. Fillers provide both functional and economic improvements to lining and coating systems. They can impart improved flow control, chemical resistance, and hot-water resistance, but usually at the expense of flexibility. Examples include carbonates, sulfates, and silicas frequently seen in paint formulations.

While optimization of these materials is critical to coating performance, the formulator is most often able to provide unique properties through the development and use of additives. These additives are used to control the melt and flow characteristics of the lining or coating, improve adhesion performance, water permeation, and handling characteristics of the powder material and resulting coating.

Three-Layer Systems

Three-layer external pipe-coating systems utilize FBE as the primary corrosion coating. Polyolefins possess good mechanical properties but have no polarity to
FIGURE B10.4   FBE is the primary corrosion coating for the three-layer pipe coating system and provides adhesion to the steel. The modified polyolefin tie-layer adhesive reacts with the epoxy to provide a bond. The topcoat provides a moisture barrier and impact resistance and adheres well to the tie layer.

"wet" and adhere to steel. Combining the "polar" epoxy with the "nonpolar" polyolefin combines the positive properties of both materials. An intermediate adhesive layer of modified polyolefin achieves the bonding of the epoxy to the polyolefin. This adhesive contains polar groups grafted onto the carbon-bond spine of the polyolefin. The polar groups react with the epoxy. The polyolefin is compatible and bonds to the unmodified topcoat of polyolefin. See Fig. B10.4.

CHOOSING A FUSION-BONDED EPOXY COATING OR LINING

Application Properties

Powder Handling Characteristics are critical and must be compatible with the application process, whether it is electrostatic spray, flocking, or fluidized bed. Key elements affecting these properties are particle size distribution, electrostatic charging susceptibility, and softening point of the powder.

Cure, gel, and flow characteristics must be designed to fit the applicator's plant, or, conversely, the plant must be designed to fit the application characteristics of the powder coating. Gel and cure times can normally be adjusted without adversely affecting the performance properties of the lining or coating.[21] A lengthy gel time may cause the coating to sag, and the cure time may be too long. Undercure results in an insufficiently crosslinked coating that is brittle, easily damaged, and has poor

chemical resistance. If the gel time is too short, there will be inadequate wet-out and flow, resulting in a rough coating with increased probability of holidays. Some powders cure quickly using the residual heat of the steel. Others take longer to cure and require postbaking.

Stability of the powder can affect costs from the standpoint of storage environmental control. While FBE curing systems are normally latent, a chemical reaction slowly occurs at room temperature. This chemical reaction is called *advancing*. If the powder advances too far before usage, lining and coating application and performance will suffer.[22]

Environmental Conditions and Field Performance

Internal Lining.   Proper selection of a lining system means balancing chemical resistance and flexibility characteristics of the lining so that it can perform satisfactorily in adverse chemical, pressure, and temperature environments, yet meet the installation requirements.[13]

Judicial selection means gathering the facts and systematically evaluating the lining choices. All coating formulations are compromises, having clear advantages and distinct limitations. The biggest tradeoffs are normally between flexibility,

TABLE B10.3   Autoclave Testing (Internal Lining Selection Depends on Environment)

Temperature	200°F (93°C)	200°F (93°C)	275°F (135°C)
Duration (hours)	16	24	24
Liquid phase	5% NaCl Brine	15% HCl	34% Brine 33% Kerosene 33% Toluene
Gas phase	5% CO_2 95% Methane	Air	25% CO_2 75% Methane
Discharge	Cool for 4 hours then rapidly release pressure	Force-cool to ambient, release pressure over 5-minute period	Release pressure over 5-minute period at test temperautre
Results			
Lining A	Use	Don't use	Don't use
Lining B	Use	Use	Don't use
Lining C	Use	Use	Use
Lining D	Use	Use	Use

Lining A: Bisphenol-A type epoxy with NSF listing for potable drinking water
Lining B: Modified bisphenol-A type epoxy for harsh environment
Lining C: Novolac epoxy
Lining D: Novolac epoxy designed for girth-weld field application. Requires no primer or post cure.

application speed, and chemical/temperature resistance. The key is to find the most flexible system that can be economically applied in the application plant that gives optimum performance in the required operating environment.

Temperature and pressure combine to degrade lining performance and survival. Most coatings are permeated to some degree by hydrogen sulfide and carbon dioxide, which can cause blistering when pressure is released. This can also lead to premature failure of the internal lining.[23]

While field experience data is the most useful basis for decision making, it is often not available. To solve this dilemma, chemical resistance tests, such as autoclave testing, can be used. For example, in Table B10.3, for a high or variable carbon dioxide content environment, Lining A, a Bisphenol-A type epoxy with certification for potable water use in the United States, will work well in mild environments and relatively low temperatures. However, for more aggressive environments, such as higher temperatures and high levels of CO_2 or H_2S, a highly crosslinked novolac epoxy such as Lining C will be required.

Table B10.4 also shows examples of the compromises that must be considered. These compromises include the amount of flexibility required for pipeline installation and the equipment and facilities availability in the applicator's plant. For example, Lining A is relatively easy to apply since it requires neither a postcure nor a priming station. It is suitable for installation in a terrain that requires field bending. Lining B requires more extensive application facilities when used in a high-CO_2 environment, since proper application includes both the use of a primer and a postcure to achieve optimum properties.

TABLE B10.4 Application and Handling Characteristics of Different Types of Lining (Internal Lining Selection Depends on the Environment, Required Handling Characteristics, and Application Characteristics of the Material)

Lining	Elongation %	Primer required	Post cure	Wire line*	NSF†	Test‡
Lining A	6	No	No	+	Yes	Water
Lining E	4	No	Yes	++	Yes	Hot water
Lining E	4	Yes	Yes	++	No	3% CO_2
Lining B	6	No	Yes	++	No	3% CO_2
Lining B	6	Yes	Yes	++	No	100% CO_2
Lining F	1.5	No	No	+++++	No	100% CO_2

Lining A: Bisphenol-A type epoxy with NSF listing for potable drinking water (See Table B10.3)
Lining E: Modified Bisphenol-A type epoxy with NSF listing for potable drinking water
Lining B: Modified Bisphenol-A type epoxy for harsh environment (See Table B10.3)
Lining F: Novolac epoxy designed for wire-line damage resistance
* Wire Line: For downhole tubing, equipment is moved via a cable, or wire line. Resistance to damage by the wire line is based on a 1-to-5 scale with +++++ being the best rating.
† NSF: National Sanitation Foundation. U.S. certification agency for potable drinking water systems.
‡ Testing: An increase in either the temperature or level of CO_2 creates a more hostile environment for internal linings.

Primers.   Phenolic based primers have been used for years with excellent performance. However, they have three significant drawbacks:

- Requirement of closely controlled cure before topcoat application
- Postcure
- Emissions from the volatile organic content of the formulations.

Water-based primer systems eliminate these problems and are suitable for less severe internal-pipe environments. One such system has been in use in brine and saltwater source-injection wells for over a year.[24]

FBE APPLICATION PROCESSES

Single-Layer Process

While the FBE application process is straightforward, attention to details is important. The steps are:

- Clean
- Apply primer or surface treatment (if specified)
- Heat
- Apply FBE
- Cure
- Cool
- Inspect

Cleaning.   For most applications, blast cleaning of the metal substrate surface using hardened steel grit to a near-white-metal blast according to NACE No.2/ SSPC-SP10,[25] free of visible contamination and no more than 5 percent staining is sufficient. For internal linings in severe environments such as downhole tubing, the pipe must first be thermally pickled at a temperature of 725°F (385°C) followed by a NACE No. 1/SSPC-SP 5 blast cleaning with hardened steel grit or suitable mineral abrasive.[13]

For external coatings, the blast-cleaned surface is often washed with a phosphoric acid cleaner to remove blast debris and contaminants, such as salt, from the substrate. A chromate treatment is sometimes used to remedy coating deficiencies or to allow a wider window for the pipe-coating application temperature.

Priming.   In highly corrosive internal-pipeline conditions with high pressure, high temperature, and carbon dioxide or hydrogen sulfide, a primer is required[26] for the lining. For both phenolic- and water-based systems, the primer is applied prior to the heating step. In the case of a phenolic primer, the preheat drives out the volatile organic solvents and causes a partial cure before FBE application. Control of the prime-cure step is important to coating system performance. If applied too hot or allowed to fully cure before application of the FBE, there will not be proper adhesion between the two.

Water-based primers require an application temperature lower than the boiling point of water. Flash rusting can be avoided by preheating the pipe to about

150°F (66°C) and/or using an oil-free, compressed-air drying step immediately after application. If induction coils are used for heating, the primer should be nearly dry before entering coil.

Heating. The pipe is then heated to the application temperature range specified by the coating material supplier—usually approximately 350°F (177°C) for internal linings; 400°F (204°C) for three-layer external coatings; and 450°F (232°C) for stand-alone FBE external coating.

Applying. Depending on the configuration of the component to be coated, all commonly used application techniques are applicable:

- Fluidized bed—the powder is aerated in a chamber via air flow; the hot component is dipped into the "fluidized" powder.
- Flocking—powder is sprayed onto the component via compressed air.
- Electrostatic spray—powder is sprayed onto the preheated component with compressed air. An electrostatic charge is imparted to increase powder-usage efficiency.

Curing. When some FBE systems are applied to sufficiently heavy-walled articles [usually ⅛ in (3.2 mm) wall thickness or heavier], the heat retention of the metal provides the thermal energy required to achieve cure—the thermosetting chemical reaction that provides the required properties of the coating or lining. In that case, facilities for postcure are not necessary. Systems utilizing a phenolic primer generally require a postcure heating step to complete the chemical reaction of the primer.

For water-based primer systems, postcure conditions are determined solely by the fusion-bonded epoxy. The temperature of the postcure step is determined by the lining system requirements and is usually in the same range as the application temperature. For metal that is likely to outgas, such as cast-iron, it is important to postcure at a temperature well below the application temperature. For example, the component may be lined at 400°F (204°C) and postcured at 350°F (177°C). In extreme cases, a preheating outgassing step may be needed—several hours at 660 to 725°F (350 to 385°C) before cooling to application temperature and applying the lining.

Cooling and Inspecting. Cooling is achieved either by spraying the outside and/or inside of the pipe with water or by simply allowing it to dissipate the heat in ambient air. Appearance, holiday inspection,[27,28] and thickness[29] checks usually follow.

Three-Layer Application

The plant application of three layers of external coating material is obviously more complicated than a single coating, but is not fundamentally different in approach. The goal is to get three layers which are well-adhered to each other and to the steel substrate. Time management is the key to the coating process. The adhesive needs to be applied while the epoxy still has free polar sites available to bond with

$$t_1 = \text{Gel Time of FBE (Sec)}$$
$$t_2 = \text{Cure Time of FBE (Sec)}$$
$$d_1 = \text{Forward Speed x } t_1$$
$$d_2 = \text{Forward Speed x } t_2$$
FIGURE B10.5 Effective time management during the application process is critical to coating performance.

the adhesive layer, but sufficient gel strength to maintain damage-free continuity (see t_1, the gel time, in Fig. B10.5).

The FBE must be cured by the time the water cooling reduces the pipe temperature below the point where the chemical reaction effectively stops. The overriding performance consideration is the full cure of the epoxy. It is the epoxy primary coating that is elemental to the long-term corrosion protection of the coating system.

QUALITY ASSURANCE

Quality assurance requires systems, processes, and monitoring to ensure successful production. Each coating system, internal lining, FBE external coating, or three-layer external coating has many similar requirements and a few unique unto itself. All require careful inspection of the in-bound pipe for determination of fitness for use and suitability for lining or coating. This includes detection of oil or salt contamination that can be spread during the cleaning process to affect otherwise coatable pipe. It also includes searching for metal defects that will be covered by the coating. One of the advantages of FBE linings or coatings is that they are relatively thin and readily show surface defects in the steel that may cause future problems.

All processes require careful attention to and monitoring of surface preparation and surface treatment or priming steps. The preheating system must bring the pipe to the proper uniform application temperature without contaminating the surface. Proper attention must be paid to the time management aspects of the application process to ensure adhesion to the steel and/or between primer and layers of the lining or coating system.[30]

For internal linings, final inspection is mainly visual, and blisters, sags, runs, or

drips are identified. Also, film thickness and holiday inspections are made. For severe service, the lining must be holiday-free.[13]

FBE external-coating inspections are extensive and include destructive tests as well as evaluation of the coating on the pipe.[31,32] Nondestructive tests include visual examination, anchor profile measurements, measurement of thickness, and holiday inspection. Destructive tests require cutting a ring sample and performing bend, cathodic disbondment, cross-sectional porosity, impact, interface contamination, thermal characteristics (differential calorimetry evaluation for cure), hot water immersion, and adhesion. A recent survey[33] showed that the tests most important to the pipeline owner companies were pipe-surface cleanliness, holiday detection, coating thickness, and pipe-surface anchor profile.

For three-layer external coating systems, there are provisions for many of the same tests as in the quality assurance testing for FBE,[34] such as cathodic disbondment. Most reliance beyond visual inspection and process control is based on a peel-adhesion test to ensure bonding between the coating layers and to the steel substrate.

JOINT SYSTEMS COATINGS AND LININGS

To ensure corrosion protection, it is essential to provide quality lining or coating on the girth welds and joints that is equal to that on the main pipe body. Girth welds require special systems because of the potential for heat damage to the lining by the welding process. Several systems are available for coating the girth-weld area. Coupling systems are also available that either eliminate the welding process or protect the internal lining from heat damage.

The ideal system allows the use of the same lining or coating on the girth welds as on the remainder of the pipe. The process[5] is essentially the same as the plant lining or coating process, except that it is done in the field. The rest of this section describes the various systems and processes available for protection of the joint area.

Internal FBE Lining

The development of primerless linings that do not require postcure, yet provide the required chemical, temperature, and pressure resistance properties, has been a significant improvement in the process. Robots are available to do the operations inside the pipe.

Cleaning.   The cutback area is left bare by the coating plant. Sand- or grit-blast the surface to white metal prior to welding.

Welding.   Weld, X-ray (if specified), and accept for lining.

Postweld cleaning.   Blast-clean to remove flux. All blast media must be removed before beginning the internal lining process.

Heating.   Use an induction coil placed on the pipe exterior to bring the weld area up to lining temperature—normally in the 450°F (232°C) range.

Lining.   Center the spray head of the application robot on the weld bead and apply the coating. Frequently, both the internal lining and external girth-weld coatings are applied at the same time.

Curing.   Select a properly formulated girth-weld FBE that will cure through the residual heat in the pipe.

Inspecting.   For final assurance, use robotic video-inspection equipment to check the quality of the coating.

Welded Internal Coupling Systems

Couplings are available to isolate the welded area of the pipe from the corrosive effects of long-term fluid transmission. An attachment system acts as a welding guide for joining the two sections of pipe and becomes an integral part of the weld. The coupling allows pigging for cleaning and inspection of the pipeline.
FIGURE B10.6   Welded internal coupling system. The coupling is internally coated with FBE and externally coated to include the o-rings.

The coupling (see Fig. B10.6) is inserted into the end of an internally lined pipe to the weld guide. The second internally lined pipe is slipped over the protruding half to the weld nubs. The center portion of the outer coupling circumference has a machined recess holding heat-resistant material and a steel band with the attached weld nubs. The heat-resistant material acts as an insulator to protect the lining on the inside of the coupling from weld-induced heat damage. O-rings isolate the weld from corrosive attack. The welding process unifies the two pipes and the coupling.
FIGURE B10.7   Weldless coupling system for internal and/or external FBE coating

Weldless Coupling System

This system consists of a coupling that slips over the outside of the coated pipeline (see Fig. B10.7). The coupling is machined with serrated grooves and is smaller than the outside of the line pipe to provide a compression fitting.

A two-part epoxy is applied to the inside of the coupling and to the outside of the lined pipe. It acts as a lubricant during the compression-fit installation and as a seal at the pipe ends, where it forms a bead to provide a continously lined internal pipe. Normally, the coupling is installed in one end of each pipe in the coating-plant yard. In the field, a hydraulic ram is used to join the two pieces of pipe together inside the coupling.

The system is available for pipe in the range of NPS 2 to 12 (DN 50 to 300). It has been used in highly corrosive applications including carbon-dioxide injection, brine-water disposal, and produced fluids of hydrogen sulfide and carbon dioxide containing oil, saltwater, and natural gas.[35]

HANDLING, SHIPPING, STORAGE, INSTALLATION, AND REPAIRS OF FBE LINED AND COATED PIPE AND FITTINGS

For protection of the piping material without regard to the lining or coating, follow the guidelines outlined in API Recommended Practices *RP 5L1 Recommended Practice for Railroad Transportation of Line Pipe and 5LW Recommended Practice for Transportation of Line Pipe on Barges and Marine Vessels.* See NACE RP0394-94 *Standard Recommended Practice: Application, Performance, and Quality Control of Plant-Applied, Fusion-Bonded Epoxy External Pipe Coating*[31] for guidelines for handling, storage, and shipping of coated pipe. For rigid internal linings,[13] steps must be taken to prevent pipe flexing during handling and transportation.

FBE coatings are tough and resistant to handling damage. However, any organic material caught between a rock and a hard place (e.g., steel) can be damaged, and care must be taken to properly handle, load, and transport the coated pipe in one example of good practice, NPS 42 (DN 1050) pipe was coated, loaded onto rail cars, shipped 3000 miles (4800 kilometers), unloaded, and stockpiled. It was later

strung along the right-of-way and welded—representing a total of nine handling operations on the coated pipe. Final electrical inspection detected less than 1.5 holidays per joint.[36]

Handling and Shipping

Handling Equipment. Do not use forklifts unless dunnage between layers of stacked pipe is at least ¾ in (19 mm) thicker than the forks. Use at least 2-in (50-mm) runners. Do not use with nested pipe. The top of the forks should be padded with at least ³⁄₁₆ in (5 mm) of dense rubber or polyurethane. Torn or worn pads may allow burrs or other protrusions to come in contact with the coating. To protect the lower level of pipe coating, the bottom of the forks should also be padded.

Overhead Loading Equipment. Both sides of the pipe hooks and the first 4 ft (1.3 m) of the cable attached to the pipe hooks must be padded with at least ⅛ in (3 mm) of rubber or urethane. Overhead equipment may be used with either stacked or nested pipe.[37]

Use of dunnage—to wood strips that support and separate the pipe—is important to ensure safe arrival of the load. Care is required in attaching chocks or padding to the dunnage. Nails should be positioned to avoid contact with the pipe coating. This can be accomplished by countersinking the nails ⅛ in (3 mm) or positioning to avoid pipe contact. Dense rubber padding may be used as an alternative to countersinking the nails, but nails or staples used to attach the padding must not come in contact with the pipe surface. Do not use carpet or excelsior-filled kraft paper, since nails can penetrate through this type of padding.[37]

Separators. Pipe that is loaded or stored should have full-encirclement separators located within 3 ft (0.9 m) of the pipe ends, and one or more at approximately equidistant intermediate locations.[31,38]

There are several suitable materials available for separators, including tight-weave polypropylene rope, dense rubber padding, and cardboard sleeves. Material selection and number of separators depends on the compression characteristics of the separator and the weight of the pipe. For example, with pipe weighing 300 lb per ft (450 kg per m), either eleven 3 in (7.6 cm) wide by 0.6 in (1.5 cm) thick dense rubber pads or seven 0.75 in (1.9 cm) diameter tight-weave polypropylene rope separators will provide adequate separation between nested pipes.[39]

Separators at the rear end of the pipe may fall off in transit. They should either be attached by tape or placed in front of the dunnage.

Hold-down strapping, used during shipping, should be either nonmetallic or steel banding with burr-free edges. Steel bands should be at least 1.5 in (38 mm) wide. Padding should not be used with steel bands, because it may compress and allow loosening of the load. Chains can cause damage to both the coating and the pipe. Heavy, dense rubber padding for chains should be used, but even that is not foolproof.[38]

Submerged arc-weld beads, in contact with adjacent pipe or dunnage, may damage the coating. Position the weld seam to avoid such contact. This does not apply to electric-resistance weld (ERW) pipe, which does not have an elevated weld seam.[39]

Storage

Stockpiling of Pipe.   The bottom row of pipe should be elevated off the ground on timber skids or earth berms covered with polyethylene, properly spaced and leveled to support the coated pipe without damage. The bottom row should be restrained to prevent joints from rolling. The racks should be level over their entire length, but a slight tilt of the pipe to permit drainage is desirable.

To prevent damage by bevel-shoulder gouging, place the pipe as parallel as possible. Position the weld seam, if present, toward the interstitial gap, not toward the adjacent pipe.[38] Do not intermix short joints with long joints. To avoid bevel-damage to the coating, store short joints on the top or at the end of the pipe stack.

Chalking of FBE—the formation of a light-colored powdery residue on the coating surface caused by exposure to sunlight and moisture—is normal and acceptable, as long as the thickness of the FBE remains above the specified minimum. Chalking protects the coating from further damage, but it can be removed by rain, which allows further chalking and eventual reduction in thickness. For long-term outdoor storage (over two years), protect the sunlight-exposed surfaces with a latex paint[40] or other suitable shading system.

Installation

Off-Loading.   Use only nylon slings, rope belts, or other padded equipment as detailed in the handling section.

Bending.   Bending-machine shoes, calipers, and stiff back should be padded with standard rubber inserts. Burrs and other protrusions around the shoe entry and exit points should be ground smooth.

Welding.   The factory-applied coating cutback is normally adequate to prevent burn damage to the coating. Drape a 20 in (0.5 m) strip of fire-retardant matting or cloth over the top and to each side of the weld to prevent spatter from burning through the coatings. Precautions should be taken to ensure adequate ventilation during welding.

Field-Cutting.   When field-cutting pipe, the epoxy will carbonize or char about 2 in (5 cm) from the cut. Emissions from the lining or coating are no more toxic than those given off during the welding procedure. However, precautions should be taken to ventilate the area, particularly during tie-ins where there is little air movement at the bottom of the trench.

Girth-Weld Coating.   See the section ''Joint Systems Coatings and Linings'' for details.

Holiday Detection.   Make sure that the holiday detector (jeeper) can be set at the proper voltage. A rule of thumb for voltage is 125 V/mil (5 volts per micron). For more precise voltage calculations use the equation[27]:

$$\text{Testing voltage, } V = 525\sqrt{T} \qquad (\text{B10.1})$$

where V = Peak voltage in volts
T = Minimum specified thickness in mils (1 mil = 25.4 microns)

* Standards are under development.

An effective electrical connection between the pipe and the holiday detector is required for proper functioning of the equipment. A direct connection to an exposed steel surface on the pipe provides the best connection. An alternative is to use a flexible ground wire, approximately 30 ft (9 m) long, connected to the ground terminal of the detector and trailed along the surface of the earth.

If the pipe lining or coating surface is dry, use a continuous direct-current (DC) voltage holiday detector. If moisture such as dew is present, use a pulse DC voltage holiday detector to prevent false indications of coating discontinuity.[27,40]

Repair.   Remove rust or dirt with a cloth or wire brush. Do not remove the FBE pipe lining or coating unless that becomes necessary to remove rust. If undercutting is present, pry or cut away the coating until reaching adhered coating before effecting repair. Roughen the adjacent coating surface with 80 to 120 grit sandpaper to improve adhesion.

For base areas of 1 in (25 mm) diameter or smaller and farther than 8 in (20 cm) from the end of the pipe (the weld-affected zone), use heat-melting sticks. For larger areas, use two-part liquid epoxy.[31,40]

Melt (Patch) Stick.   Using any noncontaminating heat source, heat the area to be repaired to approximately 350°F (177°C). Apply the heat in a manner that avoids charring or burning the FBE pipe coating. Continue to heat the cleaned area until the coating is hot enough to melt the patch stick. When the coating is hot enough, the stick will leave residue behind when drawn across the surface. While continuing to heat, apply the patch compound using a circular motion to achieve a smooth, neat-appearing patch having a thickness of no less than 50 mils (1270 microns). Do not apply by melting the stick and allowing it to drip onto the pipe. Allow the patch to cool before handling.

Two-Part Epoxy.   Thoroughly mix the separate parts of the coating repair system. Combine the correct ratio of the two parts and mix thoroughly. A uniform color indicates adequate mixing. Apply using a spatula, paint brush, or paint roller. Allow to harden before handling, or protect while wet with a piece of tape. Cure can be speeded by preheating the pipe before application or by using a torch to gently heat the patch after application.

REFERENCE CODES, STANDARDS, SPECIFICATIONS, AND REGULATIONS

Table B10.5 provides a list of various codes, standards, and specifications which are related to piping and FBE lining and coatings. The listed codes cover piping systems, some of which may be lined and/or coated using fusion-bonded epoxy to protect against corrosive flow medium and the environment. The user may seek technical guidance from technical specialists in this field. Manufacturers input and recommendations must be taken into consideration in selecting and specifying suitable lining and coating systems.

Also, the user, owner, designer, and others associated with FBE lining and coatings must ensure compliance with the applicable local, state, and federal regulations.

CHAPTER B11
RUBBER-LINED PIPING SYSTEMS

Richard Lewis
Executive Vice President
Blair Rubber Company

David Jentzsch
General Manager
Blair Rubber Company
Akron, Ohio

INTRODUCTION

This chapter is written to provide the reader with information about rubber-lined piping, including engineering applications and installation details. Rubber lining has been used for decades to protect metal pipe from corrosion. Rubber lining has also demonstrated its superiority in protecting piping against abrasion and is used extensively in abrasive service applications.

Rubber-lined piping has been used for all types of chemical environments (acids and basic solutions) that range from a pH of 1 to 14, and with temperatures ranging from 50 to 220°F (10 to 104°C). Applications include such numerous services as cationic/anionic water-treatment systems; piping in plants that manufacture chemicals, including those producing hydrochloric acid, phosphoric acid, chlorine, and titanium oxide; and slurry pipe lining for both corrosive and abrasive conditions, such as in power plant and mining operations. The mining applications include transport of copper, iron and uranium ore, and other rare minerals mined and piped to overland plants and to tailing or settling ponds.

Rubber linings form an impermeable barrier to many gases and liquids. They can only provide protection, however, if the pipe is properly fabricated and the type of rubber lining is suitable for the chemical service. Many types of rubber linings exist. The correct type of rubber lining must be matched with the appropriate service conditions. This selection is determined by the rubber lining manufacturer.

PIPE FABRICATION REQUIREMENTS

Metal Specifications

Pipe intended to be lined with rubber linings should be fabricated such that all joints can be continuously welded and ground smooth. Any special requirements specified by an engineering company or end user shall be agreed upon by all parties prior to pipe fabrication. An overview of these specifications is provided in the following subsections.

Material

The surfaces are to be free of galvanizing or other plating, oil, and grease. The surface must also be free of scale and other foreign material not readily removed by sandblasting or shotblast. Castings, when specified, are to be smooth and free of porosity, defects, sand or blow holes, and other imperfections.

Pipe is to be seam-welded or seamless steel pipe unless otherwise specified. Wall gauge is to be specified if not shown or called for on purchase orders or drawings.

Flanges shall be flat-faced, Class 150 forged steel slip-on, weld neck, or boiler plate. Raised face flanges shall not be used. Class 125 cast-iron flanges or cast-iron pipe are not recommended for use with rubber lining. If customers insist on using cast-iron pipe and flanges, they do so at their own risk. Cast-iron is porous, which results in the formation of minute air blisters between the rubber and the metal. These air blisters expand during the steam cure, causing rubber-to-metal bond failure. A defect in the lining that looks like a blister is known as a *blow*.

Flanges on opposite ends of pipe are to have their bolt holes in exact alignment, unless otherwise specified. Pipe ends at the flange face are to be continuously welded and ground smooth. Rough burrs are to be removed.

When cast-steel domes and fittings are specified, they shall be free from porosity, sand holes, and other foreign material.

TABLE B11.1   Typical Lengths for Straight Pipe
National pipe size NPS (DN)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10–42 (250–1050)
Maximum recommended length feet (meters)	6 (2)	10 (3)	20 (6)	30 (9)	40 (12)	40 (12)

General notes: "L" denotes maximum overall length

Pipe Fabrication Design Criteria

Unless otherwise specified, dimensions for pipe are end to end. For projecting fittings the dimensions are measured from the centerline to the outside surface facing of the fitting, nozzle, or flange. The tolerances shown below apply to overall pipe length dimensions, when such tolerances are specified on the drawings.

Straight Pipe NPS 24 (DN 600) or less   Plus or minus $\frac{1}{16}$ in (1.5 mm)
Straight Pipe over NPS 24 (DN 600)   Plus or minus $\frac{1}{8}$ in (3.2 mm)
Flange Gaskets   Plus or minus $\frac{1}{16}$ in (1.5 mm)

Tables B11.1 through B11.4 provide the maximum length dimensions in designing runs of pipe that will allow the rubber lining applicator to install the lining. The maximum length dimensions shown include flange length; however, pipe may or may not have flanged ends.

TABLE B11.2 Pipe with Standard 45° Elbow Limitations
Pipe size NPS (DN)	L_1 maximum in (mm)	L_2 maximum ft (mm)
2 (50)	2 (51)	6 (1829)
3 (80)	4 (102)	6 (1829)
4 (100)	5 (127)	8 (2438)

16 (400)	36 (914)	10 (3048)
18 (450)	36 (914)	10 (3048)
20 (500)	36 (914)	12 (3658)
24 (600)	48 (1219)	30 (9144)

Construction

The necessary bolts, nuts, and washers to complete any assembly are to be furnished by the pipe supplier or fabricator; unless otherwise specified.

The pipe is designed to allow the rubber lining applicator to perform the task of putting the rubber sheet stock on the inside of the pipe. Tables B11.1 through B11.4 show that the smallest pipe size which can be lined is NPS 2 (DN 50); however, NPS 1 nozzles can be lined per the following specifications:

1. Maximum length of nozzle is NPS 1 (DN 25)
2. Maximum thickness of rubber is ⅛ in (3 mm)
3. Maximum distance from end of pipe is 18 in (450 mm)
4. Nozzle is attached to a minimum of NPS 6 (DN 150) pipe

TABLE B11.4   Header Branch Limitations: Branches Near End of Fabricated Piece
IF BRANCH CONNS. ARE REQ. IN OPPOSITE DIRECTIONS OFF MAIN RUN
DIM. 'C' SHALL NOT EXCEED 3'-0'' (914 mm)

Header size (DN)	Max. length or dimension L_1 in (mm)	Max. length or dimension L_2 in (mm)
2 (50)	4 (102)	6 (152)
3 (80)	6 (152)	6 (152)
4 (100)	9 (229)	9 (229)
6 (150)	12 (305)	18 (457)
8 (200)	24 (610)	18 (457)
10 (250)	24 (610)	32 (813)
12 (300)	24 (610)	34 (864)
14 (350)	24 (610)	36 (914)
16 (400)	24 (610)	140 (1016)
18 (450)	36 (914)	48 (1219)
20 (500)	120 (3048)	48 (1219)
24 (600)	240 (6096)	48 (1219)

Welding

All welded pipe joints to be lined with rubber are to be continuous solid welds.
All welds to be lined with rubber must be smooth with no porosity, holes, high
spots, lumps, pockets, or undercuts. Grinding shall be used to remove sharp edges
or high spots.

Nozzles, pad flanges, or reinforcement plates shall be properly braced. Maximum
allowable tolerance for overall pipe length, including gaskets, is ⅛ in (3.2 mm).

Interior corners to be rubber lined are to have a minimum radius of ⅛ in (3.2 mm).

Weld splatter must be entirely removed.

All joints, when possible, shall be welded using backing rings on the inside. If

welding with backing rings is not possible, then all welds must penetrate to the inside diameter of the pipe; thus leaving the inside diameter smooth.

In all cases, the fabricator shall assume responsibility for the strength of welds. All sharp edges and corners shall be ground smooth and have a contoured surface.

Metal Preparation

All metal surfaces to be lined shall be blasted to a white metal finish. White metal blasting is the process of removing all foreign matter (such as rust, scale, and paint) by the use of abrasives propelled by using 100 psi (690 kPa) of air. The surface finish will become a metallic gray-white color, with a roughened anchor pattern providing a 1.5 to 3 mil (37.5 to 75 micron) profile. Other acceptable standards are provided by the Structural Steel Painting Council (SSPC) or National Association Corrosion Engineers (NACE).

Cementing

Primer shall be applied immediately after removal of dust and sandblasting to prevent rusting. Additional coats of primers and cements may need to be applied as specified by the lining manufacturer. Primers and cements are normally applied on the inside of pipe with a swab, spray, or roller. Sufficient drying time between cement coats is required.

LINING GUIDELINES

Sheets of rubber are unrolled and cut to the desired size and shape on a clean, heated table. Care shall be taken so that the tie gum (sticky) side of the lining is facing out for cementing (see Fig. B11.1). The edges can be cut with a skive (30
FIGURE B11.1   Cutting stock showing at 30° bevel for a close skive joint.

to 45° angle) to aid in forming the seam. For best results the plastic side of the lining, once removed, is cemented and applied to the substrate. When the lining requires preshrinking, it is unrolled on the table and allowed to shrink prior to being cut to the proper size.

Two styles may be used to make a seam; *a butt skive joint* without cap strips

FIGURE B11.2   Butt seam.

(Fig. B11.2) *and overlap* (open or closed skive, Fig. B11.3). Referring to the lining specification ensures the proper seam style is applied. The butt skive is shown, along with an overlap method with a closed skive. Open skives are used when the rubber is a *one-construction lining*. One-construction lining is made with one type of rubber. A closed skive procedure is used on a multiple construction lining to protect the underlying plies. *Multiple construction rubber linings* refer to linings
FIGURE B11.3   Closed skive overlap.

that have more than one type of rubber in the layers (Fig. B11.4). For example; a three-ply lining may have a tie gum which is bonded to the substrate; a middle layer of hard rubber to resist permeation of a particular chemical; and a cover lining which resists abrasion or another type of chemical. Multiple construction linings are designed using a tie gum placed on one side of the lining and may have other layers to provide greater chemical and temperature resistance.

Lining Procedure for Standard Flanged Pipe

A tube shall be formed with lining stock using longitudinal skived seams. This is accomplished by wrapping the lining stock around a mandrel, using a liner inside the tube, or any other method to facilitate the making of a tube (Fig. B11.5). The spliced tube's outside circumference is slightly smaller than the inside circumference of the pipe to be lined. When forming the tube, the seam is formed by using steady, firm, and overlapping strokes with a roller. When rolling, always work toward the edges. This forces all the air out from behind the overlapping layers of lining or
FIGURE B11.4   Multiple construction lining (3-ply shown).
FIGURE B11.5 Method of building tube.

along the butt skive (Fig. B11.6). The spliced tube's length is longer than the pipe's length (Fig. B11.7).

Twisted multifilament strings (called bleeder strings) are then applied lengthwise to permit proper air venting between pipe and lining. String made from synthetic yarns is not to be used. Stringing is done after cementing the pipe, and the individual strings are spaced equally around the circumference. Normally, four strings are
FIGURE B11.6 Rolling operation.
FIGURE B11.7 Finished tube.

used on pipe of sizes up to and including NPS 6 (DN 150). Larger-sized pipe normally requires the use of additional strings. The use of strings is optional with applicators.

The tube is enclosed in a liner and a tow rope is attached to it. The tube is then pulled into the pipe with a slow constant pull (Fig. B11.8). One of two methods is used to seal the liner against the inside surface of the pipe.
FIGURE B11.8 Pulling in tube.

Method 1. The liner is removed and the tube expanded against the pipe wall by using air pressure. A mechanical extension and flange arrangement is used to seal the pipe ends and a minimum of 100 psi (690 kPa) internal pressure is maintained in the expanded tube for at least 5 minutes. If any air blisters are found after the air pressure is removed, they are punctured, vented, and repaired with a 2 in (50 mm) patch. For a finished cross-sectional view see Fig. B11.9.
FIGURE B11.9   Longitudinal seam detail.

Method 2. After the liner is removed, an air bag or *balloon* is pulled through the pipe, with stops at intervals where it is alternately inflated and deflated. Next, the extension is removed, the excess stock flared over the flange face, and trimmed flush. A covering is then applied to the full face of the flange. The inside diameter (I.D.) of the flange stock is skived to slightly less than the I.D. of the lining and stitched firmly to the tube stock or folded out and onto the flange surface. When using hard rubber lining on flanges, it is important that the pipe installer/user understand that soft rubber gaskets are required over the face lining.

On pipe sizes larger than NPS 6 (DN 150), the flange stock is lapped onto the lining instead of the skive used on smaller sizes. This lapping technique makes a stronger joint and is the preferred method. Some customers may prefer not to have laps at the flanges because of abrasion considerations or requirements on full line capacity (see Fig. B11.10 and B11.11 for rubber lining of flange facings).

See Fig. B11.12 and B11.13 for suggested lining styles of lateral nozzles and side outlets. Notice how the rubber is lapped into the main-run length of pipe.
FIGURE B11.10   Flange face rubber lining.

TUBE STOCK SKIVED

TO FLANGE STOCK
FIGURE B11.11   Flange face rubber lining.
FIGURE B11.12   Rubber lining of nozzle or branch connection.
FIGURE B11.13   Rubber lining of lateral nozzle or branch connection.

Lining Procedure for Large-Diameter Pipes

Piping that is too large to safely line by inflating a tube, but large enough to allow personnel to enter, is lined in the same manner as tanks or ductwork. Bleeder strings are used at the applicators option, to facilitate the escape of gases during curing. The stock is flared over the flange face and trimmed or buffed flush after the cure.

Next, a covering is applied to the full face of flange. The I.D. of the flange stock is then skived to slightly less than the I.D. or lining and stitched firmly to the tube stock. On larger-sized pipe, the flange stock is lapped into the pipe lining instead of applying the skive technique used on smaller pipe or applying lining to flange first. The lined pipe is cured as specified by the lining manufacturer. The best cure results will be obtained by using a steam autoclave.

After curing, the ends of the pipe are buffed to remove any excess rubber. This provides a smooth fit during installation at the plant site.

Lining Procedure for Victaulic Pipe

The inside of pipe shall be lined in accordance with procedures used for standard flanged pipe.

When using ⅛ through ¼ in (3.2 through 6.4 mm) linings, the tube lining is extended over the end of the pipe and bent back into the recess on the outside of the pipe. A round of friction tape is then applied over the rubber on the outside diameter (O.D.) of the pipe end. After the pipe is cured, the tape is removed and
FIGURE B11.14   Rubber lining of grooved pipe.

the O.D. buffed flush with the O.D. of the metal (Fig. B11.14). Other styles of pipe joints have been designed. These styles must be designed to prevent crushing or tearing the rubber during installation and use. Soft (30–40A Duro) rubber lined flanges must never be squeezed more than one-third their thickness. Harder rubber linings can't be squeezed, and will require a soft rubber gasket on the flanges.

TABLE B11.5   Limitations on Weld Seams

Pipe size		Maximum number of weld seams	
NPS	DN	Longitudinal	Circumferential
3–6	80–150	1	1 [in 10 to 14 ft (3 to 4.25 m) length]
8–16	200–400	2 (180° apart)	2 [in 20 ft (6 m) length]

TABLE B11.6   Maximum Straight Lengths

Pipe size		Maximum straight length
NPS	DN	
2–3	50–80	14 ft (4.3 m)
4–8	100–200	24 ft (7.3 m)
8–42	200–1050	40 ft (12.20 m)

Table B11.5 lists the maximum number of longitudinal and circumferential weld seams in a given length of pipe.

Table B11.6 provides the maximum straight length of pipe for a given pipe size which can be lined with rubber. The maximum straight lengths of different size pipes that can be lined depends upon the capabilities of the rubber lining applicator. Straight lengths of pipe up to 60 ft (18.29 m) long have been successfully lined.

PROTECTING RUBBER-LINED PIPE

Many sources for potential problems await rubber lined piping during installation at job sites. A partial, but not all inclusive, list of those sources is as follows:

1. Ozone from welding: Ozone can and will cause severe cracking of natural rubber in linings, and the corrosion barrier may be breached permanently.

2. Portable generators, power relay stations, and electric motors are a potential source of ozone.

3. Fumes from generators, such as nitrous oxide, are detrimental to rubber linings.

4. Arcing from electrical equipment and hook-ups generate a corona (ozone) environment.

5. Oils and liquids of many types cause softening and deterioration of the rubber.

6. Problems may occur from any one or more of the above sources and can occur either inside or outside of the structure being erected. Suitable protection must be provided.

Some suggested means for protection are:

• Installation of rubber lining should be done as near the end of the construction phase as possible.

• Openings to rubber-lined equipment should be closed as much as possible to prevent attack from hazards such as those noted.

• The ends of rubber-lined pipe should be blanked off and kept that way until ready for use. Lining on flanged faces should be protected during shipment or storage by covering with plywood or other suitable material.

• All portable rubber-covered items should be covered up for protection.

• Each piece should be identified by stamping on a ground area in such a manner that numbers will remain visible. Stencil: ''Rubber Lined—Do Not Cut or Weld.''

- Additional protective measures are available from rubber lining manufacturer publications.

ASSEMBLY, TESTING, INSPECTIONS, AND MAINTENANCE

Assembly on the Job Site

Care shall be taken to ensure that the rubber lined flange is not damaged by being cut or crushed during assembly. The rubber lining on a flange must not be compressed more than one-third of its thickness, or the lining could tear away from the metal surface, causing a leak. Listed below are recommendations for gasketing and bolt tightening rubber lined pipe, flanges, and equipment:

- The gasket thickness should be equal to or slightly less than the rubber lining, but not less than ⅛ in (3.2 mm).
- The gasket hardness should be equal to or slightly less than the hardness of the rubber lining, but not greater than 60 (Shore A).
- The surface of the lining in contact with the gasket should be treated with a release coating which will allow disassembly without causing damage to the lining.
- All bolts should be initially tightened until they are snug. Then each bolt should be torqued down to 15 ft · lb (20.3 N · m) using standard cross pattern techniques.
- After 24 hours, bolts should be checked to ensure that 15 ft · lb (20.3 N · m) is maintained. After the line or equipment is put in service, someone should check to ensure that there are no leaks. If a leak is observed, the bolts should be tightened evenly and only enough to stop the leak.
- For high-pressure applications [greater than 300 psi (2070 kPa)], flanges may require a high-pressure design versus the typical flat-face design.
- The alignment of all flanges should have a tolerance of ¹⁄₃₂ in (0.79 mm).

Testing

The test procedure outlined in this subsection measures the ability of rubber to withstand the effect of liquids. It is designed for testing specimens of elastomeric vulcanizates cut from standard sheets (ASTM D3182). The lining manufacturer can supply these for the lining specified.

In view of the wide variations often present in service conditions, this test may not give direct correlation with service performance unless the actual vessel considered for lining is utilized. However, this test method yields data on which to base judgment as to expected service quality.

This provides a method for exposing test specimens to the influence of liquids under definite conditions of temperature and time. The resulting deterioration is determined by noting the changes of volume, weight, and hardness before and after immersion in the test liquid.

For purpose of the test, it is desirable to use the liquid with which the vulcanizate will come in contact in service. Several small spools can be lined for the purpose of the test with various rubber linings.

If desirable, laboratory testing can be performed as outlined in ASTM D471. The standard specimen shall be square having dimensions of 6 in × 6 in (150 mm × 150 mm). Thickness of sample shall be 0.125 in (3.2 mm). The lining manufacturer can supply the proper sheet for the lining specified.

Three sample specimen squares shall be prepared for each composition to be tested. Two shall be immersed and one retained for the original data.

If necessary, this procedure can continue for more immersion cycles or longer periods; 168 to 672 hours are normally sufficient to be predictive.

During immersion, records of temperature and concentration which vary from the normal operating conditions should be maintained.

The following information is recorded with samples and sent to the manufacturer of the lining for evaluation.

1. State that the test was conducted in accordance with this test procedure.

2. Date and temperature of place of test.

3. Dates of various periods of immersion.

4. Immersion liquid utilized.

5. Temperature of exposure.

6. Statement of condition of exposed specimens from visual and manual examination.

7. Results of immersed and nonimmersed specimens in accordance with the ASTM D471 test method.

8. Report hardness before and after immersion in compliance with ASTM D2240.

Obviously, unsuitability of lining would be swelling, deterioration, delamination, softening, or hardening. Some chemicals may exhibit one of the noted characteristics but still provide adequate service life. This is why the lining manufacturer must be consulted throughout the process.

Testing Under Process Conditions

Operating environments in many industries today are more corrosive, chemical compositions are more complex, concentrations are greater, and processing temperatures are higher than in the past. Thus, if a lining is being considered, it is often beneficial for the consumer to evaluate rubber-lined samples under actual process conditions. A proper evaluation following an appropriate period of exposure would include a percent weight change and volume change of the sample, a change in hardness and surface appearance, and the degree and rate of permeation which is extremely important to check. In some cases, a destructive permeation can occur without significant change in the weight, volume, hardness, or appearance of the lining.

Often the vapor phase of a chemical is overlooked when testing for a lining. In some conditions, rubber lining exposed to chemical vapors can be affected more severely than an immersed lining.

Among the tests and test methods that can be used for rubber linings are: chemical resistance (immersion), ASTM D 471; chemical resistance (test cell), ASTM D 3491; abrasion resistance, ASTM D 3389; adhesion, ASTM D 429; tensile-elongation, ASTM D 412; absorption, ASTM D 471; and hardness, ASTM D 2240.

TABLE B11.7   Service Condition Information Required

---

1. Process or operation: _____
   _____

2. Equipment involved: _____
   _____

3. What chemicals are present and what are their minimum, maximum and operating concentrations? (Also include any impurities or incidental materials present, even though in traces only.)
   _____
   _____

4. Temperature: minimum _____   maximum _____   operating _____

5. Are there any abrasive materials present and, if so, what is the:
   a. nature of abrasive material _____
   b. percent of solids _____
   c. degree of abrasion (What is present service life of equipment?) _____

6. Operating pressure (psi) _____ or vacuum (inches of mercury) _____

7. Is slight contamination or discoloration of solution objectionable? _____

8. Is equipment a welded fabrication or casting? (If alloy, advise type.) _____
   _____

9. Has this type of equipment been rubber lined before? If so, advise type of rubber lining and service life obtained. _____

10. Have there been rubber failures in this service? _____
    If so, were they:
    a. in the liquid or vapor phase? _____
    b. hardening or swelling failures? _____
    c. caused by abrasion? _____

11. Will the pipe lining be exhaust steam cured? _____
    _____

12. Will there be supplemental heating of the tank contents (inner coils, recirculation, through a heat exchanger or external coils around the pipe walls)? _____
    _____

13. Will the lining be exposed to any thermal shock? _____

14. What are the consequences if the pipe lining should fail? _____
    _____

Table B11.7 is a form devised to help the specifier gather the information necessary to make an informed decision.

Inspections

The general appearance when looking inside of the pipe shall be observed and noted. Seams and lining should not have any lumps, blisters, or looseness, or have any open seams. The following inspections and tests are performed:

Hardness.   The durometer hardness is checked in accordance with ASTM D 412. This checks the cured hardness against that specified by the rubber manufacturer.

This is done 24 hours after completion of cure to allow the rubber to achieve its optimum properties. While the hardness or durometer reading in the laboratory under the proper conditions can produce consistent results; its use in a pipe by different people at different times, pressures, and methods can result in appreciable variations. This is especially true when the instrument requires a flat surface to make an accurate reading. There may be a variance in durometer readings of ±10 Shore A or D when lining is pressure cured in an autoclave or in an open atmospheric steam; or ±15 for a chemical-cured lining.

Pinholes. To detect pinholes and otherwise determine a lining's integrity, a high-voltage holiday detector or spark tester is used. A spark tester consists of a wand to which an electrical voltage is applied. The wand is passed over the lining at a rate of approximately one foot per second. Where there is a pinhole or other form of discontinuity in the lining, the current will pass through the discontinuity to the underlying steel and set off an alarm. But the current emanating from the tip can also pass through the lining to the pipe, if excessive voltages are applied. Thus, a spark tester used by anyone other than an experienced inspector can severely damage a lining. Precautions must be taken when using a spark tester. The possibility of damage must be weighted against the benefits of its use as an inspection instrument. This test is usually performed only on large-diameter pipe, NPS 24 (DN 600) or larger, or on small diameter pipe, NPS 6–8 (DN 150–200). Special equipment is usually required to ensure that the spark tester can reach all areas inside the long lengths of the pipe. It is quite imperative that the spark voltage settings are proportioned to the thickness of the lining to be tested. The following range of voltages are recommended:

Lining Thickness	Minimum Voltage
⅛ in (3.2 mm)	6250–8500 volts minimum
³⁄₁₆ in (4.85 mm)	10,000–12,500 volts minimum
¼ in (6.4 mm)	12,500–15,000 volts minimum

Materials such as neoprene- and graphite-loaded linings require even lower voltage ranges; 7500 volts for ⅛ in (3.2 mm) and ³⁄₁₆ in (4.85 mm); and 10,000 volts maximum for a ¼ in (6.4 mm) thickness. Spark testing should be performed only when it is considered necessary. Frequent spark testing may lead to extensive repair work. Used linings generally have reduced electrical resistance, especially after several years of service. Where salts have saturated the surface, or the solution has penetrated the lining, spark testing becomes more sensitive. Cracked linings also have a loss of gauge in the cracked area. In these cases, spark testing must be done with extreme caution, with a very low voltage setting.

The spark-testing equipment must be kept constantly moving; otherwise it could burn through the lining and create pinhole leaks. A leak would be seen as a white or blue arc jumping from the spark tester wand through the lining to the metal. If a leak is detected, this area should be marked and repaired prior to curing.

Maintenance

Rubber-lined pipe can be a large investment for a company. Thus, proper care and maintenance are always recommended. An experienced applicator can offer many detailed suggestions. Some basic considerations of maintenance are: avoid impact, such as can occur from dropped tools; prevent exposure to sunlight and outdoor

weathering; and protect from sudden temperature changes, which may cause thermal stresses that result in cracking, especially in hard rubber linings.

LINING SELECTION CONSIDERATIONS

Thickness Selection

Lining thickness may vary from ⅛ to ¼ in (3 to 6 mm). In some very abrasive conditions, up to 1 in (25 mm) has been applied. Experience has proved that not only the rate of abrasion must be considered but temperature also. For temperatures greater than 140°F (60°C), ¼ in (6 mm) thick lining will provide better service. Table B11.8 shows the recommended maximum lining thicknesses for different pipe sizes.

The most commonly used and economical lining thickness is ¼ in (6 mm). It offers long life for a wide range of applications.

Material Selection

The most important factor in selecting the right lining material is specific *chemical resistance* that will be required. The manufacturer must be consulted early in the specification process to ensure the right lining for the application. This subsection describes the most common elastomers used in pipe lining.

TABLE B11.8 Recommended Maximum Lining Thicknesses

Pipe Size NPS (DN)	Lining thickness, inch (mm)				
	¼ (6.4)	⅜ (9.53)	½ (12.7)	¾ (19.1)	1 (25.4)
2 (50)	X				
3 (80)	X				
4 (100)	X				
6 (150)	X	X			
8 (200)	X	X	X		
10 (250)	X	X	X		
12 (300)	X	X	X	X	
14 (350)	X	X	X	X	
16 (400)	X	X	X	X	
18 (450)	X	X	X	X	
24 and larger (600 and larger)	X	X	X	X	X

The second most obvious consideration in rubber lining is *abrasion resistance*. Generally, the softer the rubber the more resistant it is to *impact abrasion*. The harder the rubber the more resistant it is to *sliding abrasion*. Natural rubber and some other linings can be compounded over a range of hardness. Often a compromise must be reached between abrasion resistance and chemical or solution permeation (attack). For example, a soft rubber would be more impact abrasion resistant, but a hard rubber may be needed for permeation or chemical resistance. The rubber manufacturer should be consulted in these situations.

Temperature resistance, another important factor, can also depend on the hardness of the rubber lining compound. Hard natural rubber is more temperature-resistant than soft natural rubber; but the temperature resistance of synthetic rubber is determined more by the type of polymer used, such as neoprene and butyl.

Soft elastomeric linings are often considered suitable for temperatures up to 150°F (66°C) and semi-hard or hard linings up to 180°F (82°C). Certain synthetic elastomers can be successfully used to temperatures of 220°F (104°C). The destructive effects of chemicals on linings at elevated temperatures is accelerated. Oxidation and diffusion are more rapid, so the overall life of the lining may be shorter. To enhance the life of linings at elevated temperatures, a thickness of ¼ in (6.4 mm) or more is commonly recommended.

Elastomeric sheet linings resist many chemicals and are considered suitable for the following, subject to both temperature and concentration factors:

- Most inorganic acids, such as hydrochloric, phosphoric, sulfuric, hydrofluoric, and hydrofluosilicic
- Many organic acids, including acetic, tannic, and gallic
- Inorganic salt solutions, including ferric chloride, zinc chloride, tin chloride, sodium cyanide, and ferrous sulfate
- Inorganic bases, such as sodium hydroxide, calcium hydroxide, and potassium hydroxide
- Plating solutions, including nickel, brass, tin, zinc, silver, and cadmium
- Bleach solutions, such as sodium hypochlorite, calcium hypochlorite, and chlorine

Table B11.9 lists some common chemicals and the general polymer used for a lining. The manufacturer of the lining shall be contacted for advice about the proper lining selection. In-service testing may be needed to confirm the suitability of the material selected.

Common Elastomers

A brief description of each of the most common elastomers, with its general chemical resistant properties, is provided in this subsection.

Natural rubber has been used as a protective covering almost since its discovery. It can be produced in many ways, to create soft elastic and resilient compounds, or as hard as an ebonite-type product. The high sulfur, semihard, or hard versions offer vastly different properties. The inherent saturation affected by the high sulfur level creates a lining which exhibits greater resistance to chemical attack and permeation; but is most prone to commodity contamination through leaching of sulfur compounds into the contents of a vessel. Thermal and mechanical shock offer substantial hazards when the hard stock is used; but by compounding, an acceptable

TABLE B11.9 Chemical Resistance of Various Linings

Corrosion Media	°F (°C) Max temp of	Percent Concentration (%)	Nat. Rubber soft	hard	Butyl	EPDM	Neop.	Nitrile	Hypalon	Urethanes
Abrasion	–	–	R				R			R
Acetic acid	140 (60)	100		R	R					
Ammonium sulfate	200 (93)	saturated		R	R		R			
Chlorine gas wet	175 (79)	saturated		R						
Copper cyanide	160 (71)	saturated	R	R

Phosphoric acid	140 (60)	85			R					
Sodium chlorite	190 (88)	saturated	R							
Sodium hypochlorite	150 (66)	15			R					
Sodium hydroxide	194 (90)	50			R	R				
Sodium sulfate	190 (88)	saturated	R	R	R					
Sulfuric acid	180 (82)	20			R					
Sulfuric acid	150 (66)	50							R	
Water—fresh	175 (79)			R		R				
Water—salt	175 (79)						R			
Water—mine tailings	120 (49)			R			R			R

R = Recommended for the corrosion medium shown. Additional service conditions, such as exposure to sunlight, must also be considered before a lining is selected.

level of flexibility can be achieved to tolerate these conditions. The harder the rubber lining the better it can withstand higher temperatures.

Natural rubber linings have been known to handle many acids, alkalies, and other corrosive materials; however, strong oxidizing agents such as chromic and nitric acids attack natural rubber with vigor. Another limitation of natural rubber is its inability to withstand hydrocarbons such as benzene, toluene, gasoline, etc.

Natural rubber hardness ranges from 30 to 100 durometer (Shore A) and can withstand temperatures up to 190°F (88°C).

Butyl has gained prominence since its birth for inner tubes, diaphragms, and similar products, because of its excellent low permeability to gases. Butyl has also found wide application in the electrical insulation field because of its inherently good electrical properties and exceptional resistance to deterioration by heat, ozone, and weathering. Another quality in its favor is its extremely low water absorption characteristic. Because butyl has a high degree of chemical saturation, it can be compounded to offer greater resistance to heat and many chemicals, especially the oxidizing acids. But like natural rubber, butyl offers little resistance to petroleum oil and solvents. Butyl linings generally range in the 50 to 70 (Shore A) hardness, and some can be used in high-temperature applications up to 260°F (127°C).

EPDM has excellent weather- and ozone-resistance that is vastly superior to any other comparably priced polymer. It possesses good heat resistance over a wide range with a temperature resistance of 200°F (93°C). Hardness for EPDM linings can range from 50 to 70 durometer (Shore A). EPDM offers good resistance to water, acetic acid, and weak solutions of chromic acid. However, it has been established that even at higher levels of hardness hydrochloric acid will penetrate EPDM and have a destructive effect on the steel without showing any adverse effect on the rubber. This shows that the permeation not only of water but of chemicals is critical in the selection of the lining.

Nitrile rubber linings have gained increasing acceptance based on their exceptional resistance to petroleum products such as solvents, oils, and greases. The temperature resistance is good up to 200°F (93°C). The hardness is moderate to hard, 50 to 90 durometer (Shore A).

Urethane is a unique polymer in that it can be sprayed on. Urethanes can be applied up to several inches thick and offer great sliding abrasion and hydrocarbon resistance, but they lack resistance to many chemicals. Urethanes range in hardness from 50 to 90 durometer (Shore A). The service temperature for urethane is 120°F (49°C).

Neoprene is available in many types and with a variety of uses, which has made it a household name. Neoprene can be compounded to withstand temperatures up to 200°F (93°C) and effectively resist chemical attack by moderate chemicals, such as sodium hydroxide and seawater. It is also known to be moderately oil resistant. Durometer hardness ranges typically between 50 and 70 (Shore A). Neoprene is attacked by strong oxidizing acids and ketones.

Hypalon is a highly versatile polymer, capable of being compounded for excellent resistance to heat, flame, ozone, weather, tear, and abrasion. It offers resistance to oil and grease. Hypalon, because of its resistance to the effects of chemical oxidation, has gained recognition in the handling of chromic acid (10%) and hydrogen peroxide (30%). Operating temperature can be as high as 200°F (93°C). Hardness can be from 50 to 60 durometer (Shore A).

The foregoing guidelines will be useful in selecting the best lining for the service; however, specification writing should only be done after consulting with the lining manufacturer and possibly even testing of various linings in the media.

SUMMARY

Elastomeric linings can effectively protect piping and other components from harshly corrosive and abrasive environments. Rubber lining technology continues to advance with the development of new polymers, application techniques, and equipment.

GLOSSARY

This glossary describes and explains terms related to the manufacture, preparation, application, and testing of rubber and elastomeric lining materials used in the protective linings industry. Many of the terms are used in the specification and application of corrosive and abrasive resistant materials. This glossary includes chemical names, abbreviations, identifications, and colloquial expressions.

Abrasion Resistance.   The resistance of a material to loss of surface particles due to frictional forces.

Acid Resistant.   The ability to resist the action of identified acids within specified limits of concentration and temperature.

Adhesion.   The state in which two surfaces are held together by interfacial forces which may consist of molecular forces or interlocking action, or both. Adhesion values for tank lining are often determined by the procedures described in ASTM D429-Test Methods for Rubber Property-Adhesion to Rigid Substrates.

Adhesion Failure.   The separation of two materials at the surface interface rather than within one of the materials itself.

Adhesive.   A substance capable of holding materials together by surface attachment.

Age Resistance.   The resistance to deterioration by oxygen, heat, light, ozone, alone or in combination, during storage or use.

Antioxidant.   Same as age resistor, a chemical compounding material used to retard deterioration caused by oxygen.

ASTM.   The abbreviation for the American Society for Testing and Materials.

Autoclave.   A pressure vessel used for the curing or vulcanization of rubber parts by means of steam under pressure.

Blasting.   Surface cleaning and preparation of substrate using abrasives such as airborne sand, grit, or shot.

Blemish.   A superficial mark or impression on the surface of green or cured rubber lining.

Blister.   A cavity or a sac deforming the surface of a material usually due to expansion of an entrapped liquid or gas. Permeation failures of tank linings in service are sometimes evidenced by blister formation.

Bond.   The union of materials by use of adhesives, usually used in relation to parts vulcanized after attaching or being assembled together.

Bromobutyl.   Used in a general sense to mean a bromobutyl tank lining construction. ASTM designation BIIR.

Butt Seam.   A seam made by placing the two pieces to be joined edge-to-edge.

Butt Splice.   A joint made in a rubber part before or after vulcanization by placing the two pieces to be joined edge-to-edge.

Butyl Rubber.   A copolymer of isobutylene and isoprene rubber; ASTM designation IIR; chlorobutyl or bromobutyl rubber is the common name for such materials used in lining.

Calender.   A machine equipped with two or more heavy, internally heated or cooled rolls, used for the continuous sheeting or plying up of rubber compounds.

Calender Blister.   Trapped air between calender plies of a multi-ply rubber buildup.

Cement.   A dispersion or solution of an elastomer or compound in a solvent for use as an adhesive or coating.

Chlorobutyl.   Used in a general sense to mean a chlorobutyl tank lining construction. ASTM designation CIIR.

Chlorosulfonated Polyethylene.   Generic name of an elastomeric material sold as Hypalon,*™ ASTM designation CSM.

Closed Skive.   A reverse angle cut along the edge of a rubber panel. This enables the installer to stitch down the cut edge so that the tie gum is protected from exposure to the commodity contained in a tank.

Cure.   Similar to cross-linking, while cure covers all types (sulfur, peroxide, radiation, etc.).

Delamination.   Separation or splitting, either between plies in laminated goods or occasionally within the homogeneous part itself.

Durometer.   An instrument for measuring the hardness of rubber and plastics. The ''A'' durometer scale is used for flexible materials and the ''D'' for rigids.

Durometer Hardness.   A value that indicates the indentation or resistance to indentation of the indentor point of a durometer. High values indicate harder materials. See ASTM D2280-Test Method for Rubber Property-Durometer Hardness.

EPDM.   ASTM abbreviation for a terpolymer of ethylene, propylene, and a diene with the residual unsaturated portion of the diene in the side chain.

Ebonite.   A term for hard rubber, made by vulcanization of rubber with high levels (greater than 30 parts) of sulfur, where the high hardness is due to the sulfur content.

Elastomer.   A polymeric material which, at room temperature, is capable of recovering substantially in shape and size after removal of a deforming force.

Elongation.   Extension produced by tensile stress, usually expressed as a percent of original unit length.

Face.   The commodity-contacting surface in tank lining construction.

Face Stock.   The commodity-contacting stock in a multi-component lining.

Fish Eye.   A thin elongated void in a calendered sheet. This slight cosmetic blemish does not affect the service life of the rubber lining.

Gasket.   A deformable material clamped between essentially stationary faces to prevent the escape of matter through an opening or joint.

Gauge (Gage).   Refers to a dimension, generally the thickness of a product, as measured by a gauge of some type.

Hardness.   The measured resistance to indentation of a material.

Heat Resistance.   The property or ability of rubber articles to resist the deteriorating effects of elevated temperatures.

Holiday. A small uncovered or noncoated area in a substrate; usually refers to pinholes in thin coatings of rubber sheeting.

I.D. or ID. Abbreviation for inside diameter.

Immersion Testing. Commonly used to determine the resistance of tank lining compounds to various chemicals. See ASTM D 471-Test Method for Rubber Property-Effect of Liquids.

Lap Seam. A seam made by extending the flat edge of one piece of material flat over the edge of a second piece of material.

Light Aging. Deterioration of compounds when exposed to light (direct or indirect, natural or man-made).

NACE. National Association Corrosion Engineers.

Natural Rubber. Rubber formed in a living plant or tree, usually referring to *Hevea brasiliensis.* ASTM designation NR.

NBR. ASTM designation for copolymers of acrylonitrile and butadiene.

Neoprene. Originally the trade name, now the generic name of polymers and copolymers based on chloroprene. ASTM designation CR.

Nerve. The elastic resistance of raw rubber or compounds to permanent deformation during processing. A nervy tank lining will be difficult to lay around tight bends or in corners because of spring back.

Nitrile Rubber. Copolymers of acrylonitrile and butadiene. Same as NBR or Buna-N.

O.D. and OD. Abbreviation for outside diameter.

Off Gauge. Not conforming to specified tolerance on thickness.

Open Seam. A seam in which edges do not meet, forming a void.

Optimum Cure. The time and temperature of cure necessary to develop the desired combination of properties. Several laboratory procedures are available to help determine this point.

Overlap Splice. The edge of a panel which overlaps the end of an adjoining panel. The splice can be open or closed.

Over lay. To add another layer of lining over an in-place tank lining construction. Typical over lays are cap strips and dome ends of tank cars.

Oxidation. The reaction of oxygen with a rubber product, usually accompanied by a change in feel, appearance of surface, or a change, usually adverse, in physical properties.

pH. The measure, on a logarithmic scale of 1 to 14, of the relative acidity or alkalinity of an aqueous solution. Neutral pH (pure water) is 7. Hydrochloric acid would be approximately 1 and sodium hydroxide approximately 13.

Plasticity. The tendency of a material to remain deformed after reduction of the deforming stress to or below its yield stress.

Ply Adhesion. The force required to separate two adjoining plies in a specified width of a rubber product.

Ply Separation. A condition which occurs due to a loss of adhesion between plies.

Polymer. A macromolecular material formed by the chemical combination of monomers having either the same or different chemical composition.

Polymer Chain.   The chain of elements that form the basis of the structure of a polymer. The elements may be all carbon atoms, carbon and oxygen, silicone, nitrogen, etc.

Pressure Cure.   Vulcanization under pressure.

Profile.   Surface profile is a measure of the roughness of a surface which results from abrasive blast cleaning. The height of the profile produced on the surface is measured from the bottom of the lowest valley to the top of the highest peak.

PSI.   The abbreviation for pound per square inch.

Qualification Inspection or Test.   The examination of samples from a typical production run of products to determine adherence to a given specification for approval to become a supplier.

Quality Conformance Inspection or Test.   The examination of samples from a production run of products to determine adherence to a given specification for acceptance of that production run.

Rate of Cure.   The relative time required to reach a predetermined state of vulcanization under specified conditions.

Recovery.   The degree to which a rubber product returns to its normal dimensions after being distorted.

Reversion.   The softening of vulcanized rubber when it is heated too long or exposed to elevated temperatures. It is a deterioration in physical properties. (Extreme reversion may result in tackiness.) This most commonly affects natural rubber linings.

Rubber.   An elastomer, generally implying natural rubber, but used loosely to mean any elastomer, vulcanized and unvulcanized. By definition, a material that is capable of recovering from large deformations quickly and forcibly.

Sand blast.   To clean with sand or steel grit in a high velocity stream of air.

Seam.   A line formed by joining material to form a single ply or layer. A splice.

Semihard Rubber.   A term used for hard rubber which when fully cured is flexible and can be bent without shattering.

Shelf Aging.   The natural deterioration of rubber articles kept in storage or "on the shelf" under normal atmospheric conditions. This slow deterioration is due primarily to oxygen and ozone attack.

Shelf Life.   An expression describing the time a material can be stored without losing any of its properties.

Shore Hardness.   A term denoting a hardness value derived from an instrument developed by The Shore Instrument & Mfg. Co., Inc.

Skive.   A cut made on an angle to the surface to produce a tapered or feathered edge.

Skive Butt Seam.   Two skived edges joined edge-to-edge to form a smooth surface.

Spark Tester.   A high-voltage test unit used to detect breaks or holes in a lining.

Specific Gravity.   The ratio of the mass of a unit volume of a material to that of the same volume of water at a specified temperature. Specific Gravity is:

$$\frac{\text{grams/cc of material}}{\text{grams/cc of water (1)}} \quad \text{or} \quad \frac{\text{pounds/ft}^3 \text{ of material}}{\text{pounds/ft}^3 \text{ of water (62.4)}}$$

Specific Volume. The reciprocal (1/Sp. Grav.) of specific gravity. Also expressed as the ratio between the volume of one pound of water and the volume of one pound of material.

SSPC. Abbreviation for Steel Structures Painting Council.

Static Spark. A high voltage of static electricity.

Steam Cure (Open). A method of vulcanizing rubber parts by exposing them directly to steam.

Stitching. A method of joining two pieces of uncured rubber compound together by means of a stitching roller, and a hand held tool comprised of a wheel with a narrow edge which is often serrated. It is commonly used to make tank lining splices.

Substrate. The surface on which a coating or lining is applied.

Surface Preparation. The preparation of a substrate prior to applying tank lining: welding, grinding, blasting, cleaning.

Swelling. An increase in volume or linear dimension of a specimen immersed in liquid or exposed to a vapor.

Tack. The property of a polymer, compound, or adhesive that causes two layers to stick together on application of mild pressure. Tacky polymers or compounds do not necessarily stick to other surfaces.

Tack Cement. A formulated rubber/cement mixture which can be rolled or brushed on surfaces which will hold the rubber panel in place until cure takes place. Normally considered a part of the adhesive system.

Tensile Strength. The maximum tensile stress applied during stretching of a specimen to rupture processed per unit area of the specimen, i.e., psi and mPa.

Tie Gum. An intermediate layer of rubber employed to promote bonding of two surfaces; usually a soft rubber compound.

Vapor Phase. Vapor above the liquid in a tank car or closed storage tank; often the most severe conditions for rubber tank lining.

Vulcanization. 1) An irreversible process during which a rubber compound, through a change in its chemical structure (cross-linking), becomes less plastic and more elastic. Elastic properties are conserved, improved, or extended over a greater range of temperature. 2) It often refers to the reaction of rubber specifically with sulfur, while ''curing'' covers other methods of cross-linking. Both terms are often used interchangeably.

Weathering. A surface deterioration of a rubber article during outdoor exposure.

White Metal Blast. To send or shot blast a steel substrate to a SSPC No. 5 finish, as specified by the Steel Structures Painting Council (NACE #1).

CHAPTER B12
PLASTIC-LINED PIPING FOR CORROSION RESISTANCE

Michael B. Ferg
Crane Resistoflex
Marion, NC

John M. Kalnins
Crane Resistoflex
Bay City, MI

INTRODUCTION

Plastic-lined piping and fittings consist of a metal housing lined with chemically resistant plastic. The combination of a chemical-resistant engineered plastic liner inside a relatively inexpensive but mechanically strong pipe or fitting housing allows for the safe and economical conveyance of corrosive and dangerous chemicals. For this reason, plastic-lined pipe finds widespread use in such industries as the chemical process, pulp and paper, and metal finishing industries. It is also the desired choice when product purity is of concern, particularly when metal corrosion by-products cannot be tolerated in the process fluid. Industries requiring such purity are pharmaceuticals, food, power generation, and electronics, to name a few. When service conditions are within the capabilities of a plastic-lined piping system, it is often an economical alternative to expensive alloy piping. The methods of lining vary, but all achieve the same goal: to ensure that the liner and housing expand and contract as one unit, even though plastic and metal have greatly differing rates of expansion and contraction.

History

Plastic-lined pipe was first manufactured in the early 1940s and sold commercially in 1948.[1] The first piping system was made by mechanically reducing or swaging a steel tube housing down onto an extruded polyvinylidene chloride (PVDC) resin liner. Initially, plastic-lined pipe was not widely accepted by the chemical processing industries because the PVDC liner could only be used for acids and caustics to a maximum service temperature of 175°F (79°C). As new high-performance resins and different manufacturing techniques were developed, plastic-lined pipe was taken more seriously as a cost-efficient method of fighting corrosion.

Thanks to high standards developed by the various manufacturers in the plastic-lined pipe industry and more than 50 years of success in very aggressive applications, plastic-lined pipe is a proven and accepted piping product wherever corrosive chemicals must be conveyed.

METHODS OF MANUFACTURE

The plastic-lined pipe industry uses both extrusion techniques for melt-extrudable type resins or sintering methods for processing polytetrafluoroethylene[2] (PTFE) powder resins into their final forms. Sintering can be defined as forming a coherent bonded mass by heating a powder without melting it. The following sections provides a brief description of the type of processing used by the various manufacturers of plastic-lined piping products.

Liner Manufacturing Processes for PTFE Liners

Although PTFE fluorocarbon resins are thermoplastic materials, they do not flow readily as do most thermoplastics. Instead when PTFE melts at 647°F (342°C), it changes from a white solid to a transparent rubbery gel. Because of the extremely high viscosity of the melted PTFE, special techniques have been developed for converting granular PTFE resins to finished products. The basics steps common to all of these techniques are

- Compaction of the granular resin at a relatively low temperature into a compressed form so that it can be handled
- Heating of the compacted resin above its melting temperature (commonly called sintering) so that the polymer particles can coalesce into a strong homogeneous structure
- Cooling of the sintered product at a controlled rate to room temperature to achieve the desired degree of crystallinity development

Voids caused by insufficient consolidation of PTFE resin particles during preforming may appear in the finished articles. With reference to a temperature, for example 73°F (23°C), PTFE-liner specific gravities below 2.11 indicate a high-void content. The minimum accepted standard specific gravity as defined in ASTM F 1545 for PTFE-lined pipe is 2.14. Although void content is determined largely by particle characteristics and preforming conditions, sintering conditions can also have an effect. Sintering at too high or too low a temperature can increase void content.[3,4]

A number of processes are used to produce PTFE pipe and fittings liners. These are described below:

Paste Extrusion: This is the original method of producing cold-formed tubing from PTFE resin. PTFE resin is mixed with a lubricant, such as naptha, and is compressed into a dense billet. The billet is loaded into an extrusion chamber and is extruded under great pressure through a die-and-core pin combination. The resultant shape is a tube with a tightly controlled inside and outside diameter. The tube is then heated to drive off the lubricant and then sintered in an oven in a controlled time-and-temperature cycle. The tube may be used as a pipe liner or as a liner for elbows.

Isostatic Molding: This method is analogous to powder-metal sintering, in that the PTFE resin is compressed in special precision molds under great pressure to form a near-net shape. For lined piping products, the shape is either a tube, which will be used as a pipe liner, or a fitting shape, which will be used as a fitting liner. Pipe liners must be produced using special molds that consist of precision-machined cylinders and mandrels. After the PTFE is compressed, it is sintered in an oven in a controlled time-and-temperature cycle. The PTFE liners shrink approximately 3 to 5 percent during the sintering process, so the manufacturer must compensate for this shrinkage in the mold design.

Ram Extrusion: Ram extrusion is a continuous process in which the specially formulated granular PTFE resin is first fed to the charging unit, compacted at room temperature, then heated above its melting point (commonly called sintering) and then cooled back to room temperature. The above sequence of events is carried out in a single piece of equipment (vertical or horizontal) rather than in several operations as is common with other PTFE-forming methods. Succeeding ram cycles cause the compacted resin charges to advance, step by step, through the heated extruder die where sintering takes place. The process allows for the continuous production of extruded PTFE tubing of very controlled wall thickness.[5]

Tape Wrapping: PTFE resin is compressed into a billet from which a continuous narrow thin tape is *skived,* resulting in a tape very nearly identical to pipe thread sealant (plumber's tape). This tape is then wound crossways around a long mandrel in many layers, building a thickness that will eventually be the liner thickness. The tape-wrapped mandrel is put into a sintering oven, and a time-temperature cycle sinters the PTFE into a continuous tube.

Thermoplastic Liner Manufacturing

The other widely used thermoplastic liners such as polypropylene (PP), polyvinylidene fluoride (PVDF), and perfluoroalkoxy (PFA) are melt processed and are either extruded in tube form for piping or injection or transfer-molded for fittings, spacers, and valves.

Pipe and Fitting Lining Techniques

Pipe Lining.   The key to successfully manufacturing lined pipe is to combine the plastic liner with a metal housing such that the two will expand and contract as one, particularly when subjected to thermal changes common to the chemical process industry. There are a number of methods for inserting the liner within the steel pipe, used by various manufacturers. Each has its benefit as well as its limitations. They are as follows:

The first patent for lined pipe was granted in 1962[6] for a process by which an oversized liner is first drawn through a sizing die directly into a flanged pipe housing. The liner is allowed to expand against the housing by heating the pipe and liner in an oven that is programmed to provide a carefully controlled time-and-temperature cycle. This method first induces stresses into the liner, then relaxes those same stresses in the oven. The result is a liner which is locked into the housing, providing thermal stability and vacuum resistance. A modified oven

cycle for pipe that can be field fabricated results in a moveable liner that exhibits the same thermal stability and vacuum characteristics as the locked-in liner.

Another method involves inserting an oversized plastic liner into an oversized steel tube and then mechanically reducing (swaging) the steel down onto the liner to lock it in place, thus imparting a compressive force on it. The interior of the steel tube is roughened (picked) for the thermoplastic liners and grooved for PTFE. The picking helps anchor the liner and the grooves create an internal venting system for the PTFE lined product.

This manufacturing technique literally grips the liner and facilitates the plastic and steel to act as a single unit during thermal cycles. The amount of compression imparted to the plastic liner is easily demonstrated by measuring the liner push-out resistance of a swaged spool versus that manufactured by other techniques.

The last method is by simply placing a loose liner into a steel pipe housing. Although this method may serve the function of having a liner within the pipe, practice has shown that such lined systems do not perform well under thermal cycle conditions and can lead to premature failures.

Lined Fittings and Valves. PTFE fitting liners may be isostatically molded one of two ways:

- Outside the housing in special molds, which allows for quality assurance checks on the liner after molding
- By using the actual fitting as the mold, which eliminates the need for special molds.

The thermoplastic liners such as PP, PVDF, FEP, (perfluoroethylene propylene) and PFA are lined by traditional extrusion, injection molding, or transfer-molding techniques. The casting or fabricated-steel fitting is fitted with an internal mold that creates an annular space between itself and the metal housing. The melted plastic is injected into the annular space to form the actual lining. Unlike pipe, the sealing plastic face is molded in place as the fitting is being lined. The result is a seamless plastic with uniform wall thickness.

Spacers. Thermoplastic spacers are used as transition pieces when mating plastic-lined pipe or fittings next to other types of pipe equipment such as alloy piping, tanks, or pumps. Their purpose is to provide a firm surface against which the plastic-lined pipe end forms a positive seal. The bore of the spacer is equal to the inside (ID) diameter of the plastic-lined pipe with which it is used. The spacer also protects the plastic-lined pipe end (flared face) from damage which may be caused by imperfections in the surface of the dissimilar material. Often a gasket is added between the spacer and the dissimilar material to assist in providing a good seal and to protect the surface of the spacer. Spacers are generally first injection molded into 0.5-in-(12.7 mm) thick panels, and then separate panels are pressure formed to each other to form a solid plastic block of a desired thickness. The solid plastic block can now be machined to create a specific spacer type. PTFE spacers are available in solid plastic form in a ring or full-face configuration, or with a steel or ductile-iron housing. Solid PTFE spacers are machined from sintered cylindrical billets. For extra mechanical strength, solid PTFE spacers made with glass-filled resins are also available.

When connecting lined pipe to an unlined flat-faced flange, use a minimum 0.5-in-(12.7 mm) thick plastic spacer of the same material as the plastic liner for NPS 1 (DN 25) through NPS 8 (DN 200) pipe sizes and at least a 0.75-in-(19 mm) thick

spacer for NPS 10 and 12 (DN 250 and 300) pipe. For installing butterfly valves, use tapered bore spacers with the larger bore adjacent to the valve side. Use blind spacers when blanking off lined pipe, fittings, or valves. For small-angle direction changes, use a tapered face spacer. If in doubt about the spacer material, one can always use a reinforced PTFE spacer, as it will handle all temperatures and all but a few chemical systems.

For a full listing of the types of spacers available, consult the manufacturer. Also, spacers may be used only in accordance with the applicable piping code requirements.

Finished Pipe Fabrication

Flange-end options for lined pipe are dependent on the type of method used to fit the liner into the steel housing. For lined pipe that is swaged, a threaded-chamfered flange or a threaded-chamfered stub end fitted with a rotatable flange is screwed onto the pipe end. Although threaded flanges can also be used with all other pipe housings, a rotatable flange is typically used on other fabrication methods, and the steel pipe end is then flared. Other pipe end options can include lap-joint stub ends with rotatable flanges, or welded flanges.

The plastic flared face is now simply made by heating the exposed plastic stub and then flaring or molding it against the flange or flared-steel pipe end. For swaged lined pipe, the steel housing is cut through to just where the plastic shows and the steel collar removed to expose the plastic-liner stub end. For flared pipe, a longer liner is inserted into the steel pipe housing and then cut to the desired length. For pipe lined with thermal-expansion methods, the pipe is already flanged, and enough liner extends beyond the flange ends to make the flares.

Quality Control

Each plastic-lined pipe and fitting is subjected to a 10,000-volt minimum electrostatic test prior to shipping so as to ensure that the liners do not contain any defects. A visible or audible spark that occurs at the probe when an electrical contact is made with the housing indicates the presence of a defect in the liner and is cause for rejection. A 425-psig (2930 kPa) hydrostatic test is an acceptable alternative to the electrostatic test. The sealing surface of the liner is also to be free of any defects that would impair sealing effectiveness. Other quality checks such as metal-and-plastic traceability, mil certs, length, liner type, and pipe size are noted to make sure that the part being shipped meets with the requirements as listed on the order. Special requirements such as on-site inspections, X-ray inspection of welds, and hydrostatic tests are also accommodated. All pressure-containing welds in the steel housings are made by welders certified to the ASME Boiler and Pressure Vessel Code, Section IX, and subject to the provisions therein.

LINER MATERIALS

Plastic lining materials fall into two main categories: fluorinated plastics and nonfluorinated plastics. Fluorinated plastics are either fully fluorinated, as in the case of polytetrafluoroethylene (PTFE), perfluoroalkoxy, and perfluoroethylenepropylene,

or partially fluorinated, as in the case of ethylenetetrafluoroethylene (ETFE) and polyvinylidenefluoride. It is the fluorine-carbon bonding of these materials that provides the outstanding resistance to chemical attack. In fact, the fully fluorinated plastics exhibit better chemical resistance than virtually any other material, including other metals, plastics, or composites. They also possess[7]

- High thermal stability
- Resistance to sunlight degradation
- Low smoke and flame characteristics
- Resistance to fungus and bacteria build-up

  They generally have

- Low permeability to most gases and liquids
- High purity in the virgin form
- Processibility, formability, and moldability
- Cold weather impact strength
- High abrasion resistance
- Low coefficients of friction
- Approval for food contact use

The nonfluorinated plastics, polypropylene (PP) and polyvinylidene chloride (PVDC), are more general purpose materials that provide good overall chemical resistance. They have lower temperature and chemical resistance than the fluoro-polymers and are generally less expensive.

Liner Types

Polytetrafluoroethylene (PTFE).   PTFE was originally developed by DuPont in 1938, and was first utilized as a hose and pipe liner in the 1950s. (DuPont markets PTFE under the Teflon tradename, but other manufacturers use their own trade names such as Fluon, Hostaflon, Algoflon, and Polyflon.) PTFE is fully fluorinated and thus virtually inert to most chemicals.

Fluorinated Ethylene Propylene (FEP).   FEP was introduced in 1960 as the first melt-processible resin that matched the chemical resistance of PTFE. FEP is marketed under the DuPont trade name of Teflon FEP, and by others such as Hostaflon and Algoflon. The temperature handling capability of FEP, however, is less than PTFE or PFA. It can be used from $-20°F$ ($-29°C$) to $300°F$ ($149°C$). With the advent of PFA in 1972, FEP found fewer applications in the lined-pipe industry. FEP lined piping is offered by a few manufacturers on special order. FEP is still widely used, however, in other product forms, including solid tubing, corrosion-resistant film, and cable and wire insulation.

Perfluoroalkoxy (PFA).   PFA is a chemically modified polymer of PTFE that exhibits the same chemical resistance and temperature-handling capabilities as PTFE. It was developed by DuPont in 1972 as a melt-processible high-temperature

fully fluorinated plastic. PFA is also marketed by DuPont under the trade name of Teflon PFA, and by others as Hostaflon PFA and Neoflon. Although the cost of PFA resin compared to PTFE is appreciably higher, it still finds utility as both a pipe and fitting liner. PFA has found broader acceptance in other related product forms, including corrosion-resistant plastic-lined pumps, valves, and solid plastic tubing. As with PTFE, PFA can be used in cryogenic services when the housings and flanges are stainless steel. PFA costs 3 to 4 times that of PTFE.

Ethylenetetrafluoroethylene (ETFE).   ETFE is a partially fluorinated plastic copolymer of ethylene and PTFE and is marketed by DuPont under the trade name Tefzel. Other tradenames are Hostaflon ET, Aflon COP and Neoflon. ETFE exhibits better chemical resistance and temperature-handling capability than any other plastics except PTFE, PFA, and FEP. ETFE is offered as a liner for both pipe and fittings, and has a service-temperature range of −20°F (−29°C) to 300°F (149°C). ETFE can be specified for lower service temperatures in conjunction with stainless steel housings. For the chemical resistance of ETFE to various chemicals, please see Table B12.1. ETFE has about the same cost as PFA.

Polyvinylidene Fluoride (PVDF).[8]   Homopolymer PVDF is a partially fluorinated polymer that is marketed by Elf Atochem North America and Ausimont under the names KYNAR and Hylar, respectively. Other manufacturer's, tradenames are Solef, Neoflon, and KF. Elf Atochem also markets a copolymer of polyvinylidene fluoride and hexafluoropropylene (PVDF/HFP) under the tradename of KYNAR Flex. PVDF exhibits excellent chemical resistance to many chemicals and has a service-temperature range of −20°F (−29°C)(regardless of housing material) to 275°F (135°C). Homopolymer PVDF is widely used for piping conveying halogenated compounds but should not be used in any service where the pH is above 11. The PVDF/HFP copolymer has a higher mole percent fluorine and, as a result, can tolerate solutions of pH up to near 13. For the chemical resistance of PVDF to various chemicals, please see Table B12.1. PVDF also cannot tolerate esters, ketones, or aldehydes.

Polypropylene (PP).   Polypropylene is a good general purpose lining material that exhibits good chemical resistance to a wide variety of chemicals in the temperature range of 0°F (−18°C) (regardless of housing material) to 225°F (107°C). PP is generally used to convey inorganic acids such as hydrochloric and sulfuric as well as caustics such as sodium hydroxide. PP is readily attacked by free chlorine and should not be used in this service or other services where free chlorine may be generated in an upset condition. Chlorinated hydrocarbons can cause swelling and softening at elevated temperatures. Another sometimes observed attack is thermal oxidative degradation of PP, as caused by 93% and greater sulfuric acid concentrations. For the chemical resistance of PP to various chemicals, please see Table B12.1.

Polyvinylidene Chloride (PVDC).   PVDC has the lowest temperature limit of the standard lining materials and is known by the trade name SARAN. Its use as a lining was discontinued at the end of 1996. PVDC found widespread use in the water treatment and pulp and paper industries, as it had particularly good chemical resistance towards chlorine. Although the service temperature range for PVDC is 0°F to 175°F (−18°C to 79°C), it required special handling when the shipping, handling, and storage temperatures dropped to below 40°F (4°C). For the chemical resistance of PVDC to various chemicals, please see Table B12.1.

TABLE B12.1 Chemical Resistance of Liner Material

Liners made from PTFE and PFA are resistant to the following chemicals to 450°F (232°C).
Liners made from FEP are resistant to the following chemicals to 300°F (149°C).

Liner material maximum-use temperature (°F)				
Chemical	ETFE	PVDF	PP	PVDC
Acetic acid (glacial)	230	NR	70	125
Acetone (10%)	150	75	120	75
Ammonia (dry gas)	300	NR	140	—
Ammonia aqua (30%)	230	175	150	—
Amyl acetate	250	125	NR	125
Benzene	212	170	NR	75
Bromine liquid	150	150	NR	NR
Chlorine liquid	212	200	NR	NR
Chlorine gas	212	175	NR	75
Chlorine dioxide (15%)	250	150	NR	125
Chlorosulfonic acid	75	NR	NR	NR
Cyclohexane	300	275	NR	125
Diethylamine	230	70	120	NR
Ethyl acrylate	212	70	NR	—
Formaldehyde (37%)	230	120	140	125
Formic acid	275	250	140	150
Hydrochloric acid (10%)	300	275	185	175
Hydrochloric acid (20%)	300	275	175	175
Hydrochloric acid (36%)	300	275	150	—
Hydrofluoric acid (35%)	275	250	200	175
Hydrofluoric acid (100%)	230	212	70	NR
Hydrogen peroxide (30%)	250	212	70	125
Hydrogen peroxide (90%)	150	75	70	125
Methyl ethyl ketone	230	NR	70	NR
Methylene chloride	212	70	70	NR
Nitric acid (10%)	212	225	150	150
Nitric acid (50%)	150	120	70	125
Nitric acid (90%)	NR	NR	NR	NR
Phenol	212	120	140	75
Phosgene (gas or liquid)	212	120	NR	—
Phosphoric acid	275	250	225	125
Propyl alcohol	212	120	140	150
Sodium hydroxide (10%)	230	NR	225	150
Sodium hydroxide (50%)	230	NR	225	75
Sodium hypochlorite	300	125	150	125
Sulfuric acid (30%)	300	230	200	75
Sulfuric acid (50%)	300	230	125	NR
Sulfuric acid (93%)	300	200	NR	NR
Sulfuric acid (98%)	200	120	NR	NR
Sulfuric acid—fuming	120	NR	NR	NR
Toluene	250	170	NR	75
Trisodium phosphate	275	275	150	150

To convert from °F to °C, subtract 32 and multiply by 5/9.

Polyethylene (PE).   Polyethylene is not truly used by the plastic-lined pipe industry as such but is offered as a retrofit liner as a low cost option for refurbishing already installed carbon steel piping. The polyethylene liner is drawn into the steel pipe in a buckled form and then expanded out to the steel shell with heat and or pressure. Polyethylene has <180°F (82°C) temperature capability but has reasonable chemical resistance.

Selection Criteria

The piping-design engineer should specify the most economical liner material that is suitable for the given service conditions. The specifier must know the major and minor chemical(s) to be piped, as well as the concentration and operating temperature, in order to select the proper liner. By consulting published data for chemical resistance of plastics, the end user can choose an appropriate liner material. See Table B12.1. All lined-piping manufacturers publish chemical resistance charts for their plastic-lined piping products. Other factors, such as vacuum-handling capability, liner thickness, and reputation of the manufacturer, often influence purchasing decisions.

Liner Identification

Liners are color coded per the standards set by the APFA (American Pipe and Fittings Association) to allow for easy identification by the end user. See Table B12.2 for colors used.

TABLE B12.2   Polymer Standard Specifications*

Lining material—resin type	Standard resin specification	Allowable resin classification	Standard liner color	Maximum filler material (by weight)
Polypropylene	ASTM D 4101	Type I and II	Orange	<30% glass fiber
Poly (vinylidene chloride) (PVDC)	ASTM D 729		Gray	<20% glass fiber
Poly (vinylidene fluoride) (PVDF)	ASTM D 3222		Black	
Poly (vinylidene fluoride) Copolymer (PVDF)	ASTM D 5575		Black	
Polytetrafluoroethylene (PTFE)	ASTM D 1457 ASTM D 4894 ASTM D 4895		White	
Perfluoro (ethylene-propylene) Copolymer (FEP)	ASTM D 2116	Type III	Green	
Perfluoro (alkoxyalkane) Copolymer (PFA)	ASTM D 3307	Type II	Natural	
Ethylyene tetrafluoroethylene copolymer (ETFE)	ASTM D 3159	Type I	Natural	

* A maximum of 1% by weight of additives or colorants, or both, is permissible. Colorants, if used, shall be identified in the manufacturer's specification.

Clean reworked resins may be used, provided all mechanical property requirements are maintained. Only virgin PTFE resin may be used.

DESIGN CONSIDERATIONS

Installed Cost Comparisons

Specification of a corrosion-resistant piping system is a complex assignment, if for no other reason than the large number of available materials that vary both in cost and performance. The materials-selection phase usually yields a number of piping candidates that will perform adequately from a technical standpoint. Then a choice is made from the candidates on an economic basis. Three types of cost comparisons are common:

Material cost

Initial installed cost

Long-term life-cycle cost.

Many specifiers limit their economic analysis to materials costs only because they are relatively simple to estimate. Yet this approach poses a very real danger because it ignores what is often well over half of the true required investment for a piping system, that is, the in-place cost of the system, including fabrication and installation costs.

Many types of corrosion-resistant piping have relatively high material costs because they are supplied from the manufacturer in the form of prefabricated components. This, however, makes these materials relatively less expensive to install. Conversely, many piping systems with low material costs often require the additional expense of fabrication at the job site prior to installation.

A widely used formatted study[9] presents a comparison of initial installed costs for a broad variety of corrosion-resistant piping systems. It provides the engineer with a screening tool to help narrow the field of candidates for a piping project so that a final detailed economic study can be made on the specific piping arrangement under consideration. Factors considered in the study are: type of piping used, material costs, complexity of the piping system, fabrication and erection techniques, and labor rates and productivity in installation. Table B12.3 summarizes the installed cost ratios from the most recent publication for a NPS 2 (DN 50) complex piping system. The report list cost ratios are for NPS 2, 4, and 6 (DN 50, 100, and 150) piping layouts for both straight-run and complex arrangements.

A plastic-lined metallic piping system offers clear advantages over both metal and solid-plastic piping systems. Compared to a piping system consisting of corrosion-resistant metal, plastic-lined pipe provides equal or better resistance to chemical attack, depending on liner material. When comparing the installed cost of a flanged plastic-lined metallic piping system to a welded metallic piping system, the plastic lined system is often lower. See Table 12.3. This is especially true when comparing plastic-lined pipe to metal systems of higher alloy materials.

Compared to a plastic system made from the same material as the plastic liner, plastic-lined pipe provides higher service capabilities as well as higher mechanical strength. Plastic-lined piping systems are also available in a wider range of line sizes, with a broader selection of fittings, when compared to solid thermoplastic or thermosetting systems.

Plastic-lined pipe is not only used where chemical attack is a concern, it is also used where media contact with metal is detrimental, as in the case of ultra-pure chemicals and deionized water used in various processes in the electronics industry.

TABLE B12.3

Installed cost ratio (carbon steel as 1.00) of plastic-lined piping and other selected piping materials. Cost ratios based on a shop-fabricated complex system NPS 2 (DN 50) and 400 ft (102 m).

PIPING MATERIAL COST RATIOS			
PVC (sch 80)	0.56	PTFE-lined FRP	3.20
CPVC (sch 80)	0.63	Monel (Sch 40)	3.24
		Alloy 20 (Sch 40)	3.32
Carbon steel (Sch. 40)	1.00	Nickel (Sch 10)	3.34
304L S.S. (Sch. 10)	1.13	Hastelloy C-276 (Sch 10)	3.52
Rubber-lined steel (Sch 40)	1.16		
316L S.S. (Sch. 10)	1.20	PTFE-lined 304L SS (Sch 10)	4.12
304L S.S. (Sch. 40)	1.31	Nickel (Sch 40)	4.27
316L S.S. (Sch. 40)	1.45	Titanium (Sch 10)	4.46
		Hastelloy C-276 (Sch 40)	4.46
FRP/vinyl ester	1.78		
FRP/epoxy	1.86	Hastelloy B (Sch 40)	5.71
FRP/polyester	1.86	Zirconium (Sch 10)	5.95
Polypropylene lined steel (Sch 40)	1.90		
Saran lined steel (Sch 40)	1.91	Zirconium (Sch 40)	7.04
PVDF-lined steel (Sch 40)	2.47		
Alloy 20 (Sch. 10)	2.60		
Monel (Sch 10)	2.61		
Glass-lined steel (Sch 40)	2.69		
PVDF (Sch 80)	2.71		
PTFE-lined steel (Sch 40)	2.94		
Titanium (Sch 10)	2.99		
FEP-lined steel (Sch 40)	2.99		

Available Pipe Sizes

Corrosion-resistant lined pipe is widely available in NPS 1 to 12 (DN 25 to 300), with larger diameters up to NPS 24 (DN 600) available, but with limited liner-material selections. Except as otherwise noted, this discussion will focus on sizes NPS 1 to 12 (DN 25 to 300). Straight sections of pipe are available as standard and custom-length pipe spools. Standard spool lengths are 20 ft (6m), with 40-ft (12m) sections available when flange minimization is desired. A complete selection of plastic-lined metal fittings is available to include elbows, tees, reducing tees, instrument tees, crosses, 45-degree laterals, concentric and eccentric reducers, reducing flanges, and blind flanges. For examples of lined-pipe and fittings, see Figs. B12.1 and B12.2.

Metallurgy and Pressure Capabilities

Plastic-lined pipe and fittings are available in cast iron, ductile-iron and steel housings, and ANSI or ASME Class 125, 150, and 300 ratings respectively. The pressure-temperature ratings for ASME B16.5 Class 300 housings are down-rated to account for the safe-working pressure limit of the flared plastic. The pressure and temperature ratings for these housings are as listed in Fig. B12.3.

FIGURE B12.1 Small photo of lined pipe flanged end. (*Courtesy of Crane Resistoflex*)

Plastic-lined piping systems are rated for ASME Class 150 service. ASME Class 300 flanged systems are available, but they do not carry the true ASME Class 300 rating. This is because the sealing pressure required to meet ASME Class 300 requirements are beyond the mechanical capabilities of the plastic flared faces. Consult the manufacturer's literature for pressure and temperature limitations.

Temperature Limitation

All plastic-lined piping systems have a minimum- and maximum-use temperature that must not be exceeded. These use-temperature limits are derived from the various resin manufacturer's testing and are found in Table B12.4. These temperature limitations are always well below the melt temperature of the liner material. In the cases of PTFE, PFA, and FEP, the maximum-use temperatures apply to virtually all chemicals. In fact only a few chemicals attack these plastics, namely, molten alkali metals, elemental fluorine, and chlorine trifluoride, all at high pressures and temperatures above 500°F (260°C).

FIGURE B12.2 Concentric reducer, elbow, and tee. (*Courtesy of Crane Resistoflex*)

In the case of all other plastic-lining materials, resin manufacturers have gathered test data that indicates above which temperature limit various chemicals will either swell, react with, or degrade the lining materials. These temperatures are referred to as *rated* temperatures for use with particular chemicals. Below these recommended
FIGURE B12.3   Working pressures for ASME Class 150 and 300 plastic-lined pipe and fitting. (*Courtesy of Crane Resistoflex*)

limits, the chemical media will not swell, react with, or degrade the liner, and thus the liners can be safely specified for use. Just as there are high temperature limits, liners should not be used below the recommended minimum operating temperatures, as plastics can become brittle and be subject to mechanical rather than chemical failure.

Where a plastic-lining material is rated for less than its overall maximum use temperature, the end user must make certain that the rated temperature will not be exceeded. These situations can occur as a result of upset conditions, unusual ambient conditions, and unplanned exothermic reactions. If the possibility exists that the rated temperature could be exceeded, the end user should specify a different plastic-liner material with a sufficiently high-temperature rating for that chemical service.

TABLE B12.4   Temperature Specifications

Material	Temperature range, °F (°C)
PTFE	−20 to 500 (−29 to 260)
PFA	−20 to 500 (−29 to 260)
FEP	−20 to 300 (−29 to 149)
ETFE	−20 to 300 (−29 to 149)
PVDF*	−20 to 275 (−29 to 135)
PP	0 to 225 (−18 to 107)
PVDC	0 to 175 (−18 to 79)

* Homopolymer and copolymer

Vacuum Capabilities

Vacuum-rating capability in lined-piping products depends on liner thickness, liner-manufacturing process, and pipe-lining process. Typically, most manufacturer's NPS 1 to 8 (DN 25 to 200) material is rated for full vacuum at the liner material's maximum-use temperature. The vacuum capability of different manufacturers NPS 10 and 12 (DN150 and 300) lined piping varies from just-pressure service (no vacuum) to full vacuum capability. Since there is no industry standard for vacuum ratings, it is critical that the end-user consult the manufacturer's literature when considering lined pipe for vacuum service or services which may experience vacuum.

An added precaution regarding vacuum ratings: Piping not rated or designed for vacuum service when installed in vacuum service can lead to liner collapse and failure.

The unplanned or upset condition that induces vacuum can cause failure in nonvacuum-rated piping. Block valves, positive displacement pumps, unexpected rapid cooling, and other conditions can produce inadvertent vacuum conditions in process lines. The design engineer should decide if these scenarios are likely and select lined piping with the appropriate vacuum-handling capability.

Dimensional Compatibility with Other Flanged Systems

Finished lined pipe spools and fittings are measured from plastic-sealing face to plastic-sealing face. Plastic-lined fittings conform to the nominal overall length and center-to-face dimensions as specified in ASME B16.1, Standard for Cast Iron Flanges and Flanged Fittings; ASME B16.42 Standard for Ductile Iron Pipe Flanges and Flanged Fittings; or ASME B16.5 Standard for Flanges and Flanged Fittings. However, it is always a good idea to check with the manufacturer for the applicable dimensions, as some special shapes and systems may have other dimensions.

Joining Techniques

Traditionally, plastic-lined pipe, elbows, branched fittings, reducers, and instrument connections have the plastic liner flared over the flange in order to make connections that seal without exposing the metal housing to the service media. Sealing is accomplished by flaring or molding the liner material out over the metal flange face to form a *formed or flared in place* gasket-sealing surface. See Figs. B12.1 and B12.2. The purpose of this design is to ensure that the service media contacts only the plastic and never the metal. Flanges conform to ASME Class 150 or Class 300 ratings. For pipe spools and fabricated fittings, many types of flanges are available, including lap-joint rotating, slip-on, socket weld, welding neck, and threaded. In the case of a cast fitting, the flange is integral to the casting. The plastic-flared face serves as its own gasket and therefore a gasket is not required. When mating plastic-lined components to other nonlined components, such as carbon steel or alloy piping, fittings, valves, pumps, or vessels, it is recommended that a plastic spacer be used as a transition piece. See Fig. B12.4. However, flanged connections are a potential source of leaks, and new technologies now allow for their significant reductions. See the later section on Flange Reduction Techniques.

Permeation and Venting

Permeation is the migration of small amounts of flow media through the liner wall, in the absence of cracks or continuous voids. It is the product of two functions: the diffusion between molecular chains, and solubility of the permeant in the polymer. If the permeant is as polar as the polymer, or has similar chemically functional groups, it will be more soluble in the polymer.[10] All plastics are subject to permeation, with some plastics exhibiting higher permeation rates than others.[11]

Permeation data relative to chemical handling are very limited because there is no universal laboratory protocol for measuring permeation that generates data applicable to all situations. Care must be exercised in extrapolating the thin-film data frequently found in the literature to the liners used in chemical-process equipment and piping.[12] In general, all other things being equal, pressure and temperature predominantly will drive permeation from a process perspective, and liner thickness and polymer crystallinity from a material viewpoint. Insulation has been determined to help decrease the thermal gradient across the liner and hence decrease the magnitude of permeation.

ASTM F1545 requires components lined with PTFE, FEP, and PFA to be vented (venting is not required for other liner materials) to prevent permeant vapors from collecting between the PTFE liner and the pipe housing. Depending on the manufacturer, venting is achieved by directing the permeant vapors to the pipe ends behind the plastic flare faces, and out at the flanges (Fig. B12.5), or out vent holes drilled through the pipe housing, back from the flanges. All PTFE-lined fittings regardless of manufacturer contain vent holes in the housing. Testing shows that both methods

Connections of plastic-lined pipe to other types of piping

NOTE: Extreme care must be used to avoid bending of plastic flange. A special ring gasket is required around the O.D. of the flared plastic face of the plastic-lined pipe.

Plastic-lined pipe to flanged metal pipe, valves, fittings and pumps
NOTE: No flat gasket required if flange face is smooth and non-fragile. However, most alloy piping uses raised face flanges, and therefore, a gasket should be used.

FIGURE B12.4   Recommended installation of plastic-lined pipe to carbon-steel, alloy and non-metallic piping systems. (*Courtesy of Crane Resistoflex*)

adequately vent permeant vapors in piping lined with PTFE. For piping that will be insulated, the vent hole or flange face must not be blocked. Vent extensions or vented flange covers are available for pipe and fittings that can be insulated.

Another situation associated with permeation is the tendency of some permeants

to form corrosive acids at the interface of the vent because of atmospheric humidity. These acids can attack the area where the vent is located. In systems where permeants are known to corrode the area of the vent location, vents located on the pipe housing can be fitted with a half-coupling with a replaceable sacrificial nipple. This nipple can be periodically replaced.

All other things being equal, a thick liner will reduce the permeation rate when compared to a thin liner. Liner thickness varies by manufacturer, ranging from .100-in (2.5 mm) to .130-in (3.3mm) in NPS 1 (DN 25), to .200-in (5 mm) to .425-in (10.8 mm) in NPS 12 (DN 300). Table B12.5 lists the ranges of PTFE liner thickness that are available. Specific thickness data is shown in each manufacturer's literature.

FIGURE B12.4 (*Continued*) (*Courtesy of Crane Resistoflex*)
Pressure Drop Calculations[13,14]

In order to calculate pressure drop through lined pipe, the variables of importance regarding the lined pipe are the true inside diameter and the friction factor. The true ID can usually be determined from the metal pipe and liner thickness data in the manufacturer's literature. The friction factor, which is necessary to calculate the pressure drop using the Darcy equation, can be obtained if the Reynolds number and roughness factors are known. Moody diagrams contain many curves for roughness factors. See Fig. B12.6. For lined pipe, use the curve labeled smooth pipes to arrive at the friction factor. It should be noted that flow rates in plastic-lined piping have been kept less than 12 ft/sec (3.7 m/sec), which in turn limit the pressure drop of the system. It has been also suggested to keep gas velocities in lined piping to less than 35 ft/sec (10.7 m/sec). Typical pressure-drop curves for PP, PVDF, and PTFE are shown in (Fig. B12.7).

Abrasion Considerations

In general, plastic-lined piping is not the first choice to solve problems associated with abrasion. Some slurries, however, due to their aggressive chemical nature,
FIGURE B12.5 Swaged pipe and PTFE venting collar system. (*Courtesy of Crane Resistoflex*)

TABLE B12.5 Published PTFE-Liner Thickness Versus Pipe Size

Pipe size NPS (DN)	PTFE-Liner thickness range inches (mm)
1 (25)	0.125 (3.2) − .138 (3.5)
1.5 (40)	0.125 (3.2) − .150 (3.8)
2 (50)	0.125 (3.2) − .160 (4.1)
3 (80)	0.125 (3.2) − .185 (4.7)
4 (100)	0.125 (3.2) − .187 (4.7)
6 (150)	0.145 (3.7) − .275 (7.0)
8 (200)	0.150 (3.8) − 0.315 (8.0)
10 (250)	0.190 (4.8) − 0.325 (8.2)
12 (300)	0.200 (5.1) − 0.425 (10.8)

VALUES OF (vd) FOR WATER AT 60° F (VELOCITY IN FT./SEC. X DIAMETER IN INCHES)

require lined pipe. In these cases, it is advisable to design the system so as to minimize the slurry velocity (less than 2 to 4 ft/sec or 0.6 to 1.2 m/s), and the number of changes in direction. Some have found that installing a tee in the place of a 90-degree elbow can minimize liner wear by having the material wear on itself. Other factors such as solids loading, particulate size, and particulate hardness also determine the amount of abrasion that will result from piping a slurry. Since slurries can erode the plastic liner to the point of failure, and the time required to do so depends on many variables, there is no accurate way to predict lined-pipe service life in a slurry situation. If practical, it is advisable to install a test piece

in the actual service to determine if lined pipe will be suitable in a given slurry service.

Nonstandard Fittings Configurations

When faced with the need for a plastic-lined component that does not conform to ASME B16.5, B16.42, or B16.1 dimensional requirements, the end user should consider rotationally lined piping products. Components can be rotationally lined with ETFE or polypropylene.

Rotational lining is a process that is not dependent on the fitting or component geometry for a satisfactory lining job. Therefore, an unlimited number of custom fittings, such as two-and three-branch instrument tees, manifolds, reducing elbows, branch elbows, and other complex configurations can be lined with a thick seamless, mechanically bonded liner. See Fig. B12.8.

FIGURE B12.8 Rotationally lined custom fittings. (*Courtesy of Crane Resistoflex*)

Powder resin is placed inside the housing, and the flanges are capped with special tooling. The housing is bolted to a spindle that rotates on two axes simultaneously. The spindle rotates in an oven that is heated to the resin's melt temperature, and the resin coats the interior evenly. After the fitting is allowed to cool, the tooling is removed, the flares finished, and the components are hydrostatically or electrostatically tested.

Underground Installations

Direct burial of unprotected plastic-lined steel pipe is not recommended without additional surface preparation. Various systems are available for this purpose, including tar coating and wrapping with a pressure-sensitive PVC tape. The tape should be wrapped with at least a ½-in (12.7 mm) overlay down and back the length of the pipe.

The user should recognize that all manufacturers of flanged plastic-lined piping systems recommend that the flange bolts be checked for tightness on an annual basis. Consequently, for obvious reasons, this is difficult to do if the pipe is buried. However, the flangeless technology option as described later in this chapter does allow for plastic-lined pipe to be considered for burial because of the virtual elimination of flanged connections.

If the pipe is to be buried, proper trench preparation is a must. This is to include depth, width, foundation, bedding, backfill, and earth cover. Backfill should only be done with clean sand containing no rocks or foreign material that could point load onto the pipe surface. Refer to ASTM D2321 for typical guidelines.

INSTALLATION AND MAINTENANCE PRACTICES

Shipping and Handling

Plastic-lined pipe and fittings are shipped with protective end covers made of wood or plastic and are designed to prevent damage to the plastic flared faces. The covers should be left on the pipe and fittings until just before installation time. Plastic caps are also used on plain (not flanged) pipe that is to be fabricated in the field. When moving pipe and fittings with a forklift, never put the forks inside a pipe or fitting, as permanent damage to the plastic liner will likely occur. Either secure the fittings to a pallet, or use a sling arrangement to move lined piping products with a forklift.

Installation

The installation of plastic-lined pipe is similar to that of flanged carbon-steel pipe, but some special precautions must be employed.[15,16,17] The flared plastic ends must be protected until the pipe or fitting is installed.

Bolt Torques. Bolts should be tightened to the manufacturer's published recommended torque values. If lubricants other than those listed by the manufacturer are to be used, a new torque value should be determined or calculated. Lubricants such as copper-based antiseize and nickel-based never-seize have nut factors[18] similar to that of fluoropolymer-coated bolts. Bolting or stud material should be ASTM A193 Grade B7, and nuts should be ASTM A194 Grade 2H. The reason for this is that it is possible to have bolt stress in the 50–70,000-psi (345–483,000 kPa) range which can be above the yield strength of low-and medium-grade bolting materials. The bolt must be able to stretch in its elastic zone in order to properly function at the flanged connection. If a bolt stress exceeds the material yield strength, the bolt will be deformed and result in decreased load being applied to the plastic gasket surface. A calibrated torque wrench should be used to avoid excess torque, which

can also permanently damage the plastic flare faces. Bolt threads should be clean and lubricated. Bolting should be tightened in a *star* pattern to ensure even tightening of the flanges. When the initial torque value has been reached for all bolts on the flange connection, continue tightening, using the star pattern, until the bolt torques are at 80 percent of maximum torque value recommended by the manufacturer. After the first thermal cycle, all bolts should be checked and retorqued if necessary. This practice should also be followed on an annual basis and more frequently if the process has frequent thermal cycle swings. Fluoropolymer-coated bolts and nuts are typically used with PTFE-lined stainless-steel piping as many stainless-steel bolting materials are of low- to medium-strength quality.

Gaskets and Spacers. Gaskets are not required for connections of lined pipe to other lined pipe, because the plastic liner is flared out over the face of the flange and serves as its own gasket. Gaskets are recommended, however, when bolting lined pipe up to an unlined raised-face flange or glass-lined or graphite equipment. (Please note that the gasket material must be compatible with the service media.) Again, the emphasis is on protecting the plastic flare face. Special gaskets or spacers may be required when bolting up to dissimilar materials. See Fig. B12.4.

Shop and Field Fabrication. Plastic-lined pipe can be fabricated either in the shop or in the field. Shop fabrication, being the most economical method, is recommended when equipment arrangement is firm and detailed piping drawings are available. In the shop, pipe is cut to exact length, flanges are attached, and the liner ends molded or flared. Each item can be *piece marked* to conform to piping drawings that show the location of each piece for field identification.

Field fabrication should be used when equipment locations and piping lengths may not be firm at the time the pipe is purchased. Procedures for field flaring are specified by each manufacturer.

A compromise is available that allows shop fabrication when equipment arrangement is not firm. The line is completely fabricated in the shop, with the exception of the closure piece, which is supplied for field fabrication to exact length.

Support Requirements. The following are additional items that need to be considered when installing plastic-lined piping:

- Hanger spacing for plastic-lined piping is essentially the same as recommended for carbon steel piping.
- Special attention should be given to the steel wall thickness (Schedule 40, 30, or 20) because this variable will determine the free span.
- Supports such as spring-loaded hangers, clevis-type hangers with adjustable rods, guided support shoes, adjustable pipe stanchions, and pipe-roll support may be considered and should allow freedom of movement resulting from temperature changes.
- In addition, for plastic-lined pipe, it is recommended that each spool be supported near the flange connection for maximum protection against excessive deflection.
- Additional support is recommended where flow changes direction and in areas of high load concentrations such as clusters of valves or fittings.

Thermal Expansion and Contraction. Consideration for thermal expansion must be given to the system and allowances made for expansion and contraction. Where deemed necessary by the engineer or designer, a stress analysis should be done in

order to avoid overstressing of piping, fittings, and gasket faces.[19] Thermal expansion can be compensated for by using expansion loops or expansion joints.

Welding.   Never weld on plastic-lined pipe or use it as ground for electric welders, as the heat generated could severely damage the liner. Do not flame-cut plastic-lined pipe.

Paint.   Lined piping products are generally shipped with a protective primer on the external metallic housing, which is applied at the factory. In many cases, this primer is suitable for compatible topcoats, or it can be sandblasted off for application of paint by the end user. When sandblasting, the end caps protecting the molded or flared plastic face must not be removed, and sandblasting should be directed away from the these plastic pipe ends. If the pipe is to be vented with holes on the pipe or fitting housing, the vent holes must be cleared of any debris so that paint will not plug them. An alternative to the end user applying paint in the field is to have primer, midcoat, and final coat applied at the factory. Special paint capabilities vary by manufacturer due to local emissions limits on the volatile organic content of different paints. The end user should forward all available information regarding the paint, including the end user's internal paint specifications, paint data sheets, and paint-material-safety data sheets. Special paint application by lined pipe manufacturers will generally result in an additional charge to the end user.

Heat Tracing.   Handling materials that have high freezing points or high viscosity often requires the use of a pipe tracing system. Four systems that have been successfully used in tracing plastic-lined pipe are:

- Hot water
- Heat-transfer fluids such as Dowtherm
- Electrical resistance
- Steam

Any heat-tracing system used with plastic-lined pipe must be applied in accordance with the manufacturer's written recommendation.

Among the factors to be considered in the selection of tracing methods are the temperature rating of the plastic liner for the intended chemical, service, climate, length of heating season, temperature range to be maintained, length of tracer run, initial costs, operating costs, and need for future expansion

Steam tracing of polypropylene-lined pipe is not recommended, because it requires much more care in design and maintenance. However, the tracing of PVDF, FEP, PFA, and PTFE-lined pipe with steam may be done successfully, keeping in mind the maximum temperature limitations for these liners.

Tracing lined pipe with electrical heating tape has been successful in many applications, particularly those in which continuous heating is not needed. Such tracing is available in strip or cable form. In electrical tracing systems, it is especially important that the temperature-controller sensing device be placed in direct contact with the heating strip or cable to ensure that the maximum operating temperature of the pipe lining is not exceeded. As with the fluid tracing systems, flanges, fittings, valves, et cetera, should be protected from excessive heat losses. Refer to manufacturer's literature for specific recommendations.

As with both steam and electrical systems, it is important that standoff strips or heat transfer cement be used to prevent direct contact and hence hot spots on the

pipe. Some installers have found that taping electrical heat tape to the pipe with 2-in-(50.8 mm) wide aluminum tape helps spread the heat.

Hot water and heat-transfer fluids are generally preferred when there is a need for closer control of operating temperatures or to hold them within the temperature limitations of plastic liners. The choice of heat-transfer fluids will depend on the temperature range.

Jacketed-Lined Pipe. Straight-pipe sections are also available with an exterior jacket made from pipe that is typically one size larger than the lined pipe. The jacket is contained with pipe caps the same size as the jacket that are bored out to fit the O.D. of the lined pipe. Inlet and outlet ports are generally half-couplings welded to the jacket. All jacket fabrication and welding on the pipe is done prior to lining of the pipe spool. The heating fluid can be water, steam, or heat transfer fluid. Fittings are generally not jacketed, but separate clamp-on jackets over the standard fitting housings are commercially available.

Insulation. The techniques used in insulating steel pipe can also be used with plastic-lined steel pipe. But, care should be exercised to ensure the integrity of the venting system. For PTFE lined pipe and fittings that are vented via small vent holes, the end-user must specify that vent couplings be welded over the vent holes prior to lining. The end-user then threads a pipe nipple into the vent coupling. The nipple must be long enough to extend beyond the insulation to prevent the blockage of the venting system.

Grounding. Grounding of piping systems is required if a possibility exists for spark generation through the buildup of a static electrical charge.[20] This typically occurs when nonconductive fluids such as xylene, toluene, or hexane are piped in plastic-lined piping. Although metallic or alloy systems may be better suited for this kind of fluid, lined pipe is selected if product purity is of concern or the process fluid has intermittent corrosive contaminants present. Several techniques are used by the chemical process industry to ensure that adequate grounding is achieved. First, it is important toassure that the metallic pipe shell is properly grounded. Two techniques are used to assure continuity to a ground connection. One is to carefully weld stud bolts to the pipe shell and electrically connect separate spools with braided-wire cable. The other is simply to use the flange bolts as an electrical connection[21]. These two techniques simply ensure that a path to ground is assured. However, the process fluid that has potential to build a static charge is on the inside of the piping, and therefore any charge buildup here must be dissipated. This is typically accomplished by inserting a grounding paddle (exotic metal such as hastelloy or tantalum) between flange connections. The handle of the paddle is then connected via a braided cable to the grounded pipe shell such that bleedoff of any internally generated charges can occur. Some European manufacturers offer carbon-filled PTFE-lined piping systems in which the liner resistivity is such that electrical charge dissipation can occur through the liner to the grounded steel shell. Ultimately, the design of the exterior/interior grounding system is the responsibility of the end-user.

Corrosion Allowance

Metals generally corrode due to electrochemical reactions, which gradually return the metal from a higher energy level (alloy) to a lower energy level (element or ore). In most cases this ongoing process can only be slowed by specifying a metal wall thickness that will deliver a predictable length of useful service life.

Plastics on the other hand, do not corrode. Instead, they are susceptible to attack from solvation, where the media reacts with the plastic, causing swelling or cracking, and failure. A plastic is either completely resistant to a chemical at a given temperature, or it will react with a chemical at, or above, a certain temperature. This process is usually rapid but can be avoided by following lined-pipe manufacturer's guidelines for their various liner material's resistance to different chemicals. When these guidelines are followed, and the system is installed and maintained in accordance with the manufacturer's guidelines, a plastic-lined piping system will provide a long, reliable service life.

Field Hydrotest

Test the integrity of the installation per the applicable section of ASME B31 Piping Code, using a hydrostatic test. Sometimes it is more practical to *hydrotest* in sections, using spectacle blind flanges to block off portions of the piping. If a flange leak occurs during hydrotest, and that flange has been properly torqued, do not tighten further. Instead, the bolts on the opposite side of the leak should be loosened one-half turn, and the bolts on the leaking side should be tightened one-half turn.

If the leak continues, remove the bolts and inspect the flare faces for indications of damage. Do not remove the bolts if the system temperature is more than 30°F (17°C) above ambient temperature, or flare distortion may occur. Slight scratches or dents that do not exceed 20 percent of the liner thickness can be repaired by hand with sandpaper or emery cloth. Repeat the torquing process to 80 percent of final torque. If necessary, the bolts can be tightened to the maximum torque published in the manufacturer's literature. Exceeding this torque, however, may cause permanent damage to the plastic flare faces. Because of the nature of plastic-lined piping, it should not be assumed that the first hydrotest will always be successful. Installers and users should be prepared for the possible additional time and expense of retorquing that may be necessary for a successful hydrotest.

Maintenance Considerations

Maintenance requirements vary by application. A system that sees mostly ambient temperature may require little maintenance, such as a periodic spot check of bolt torques. A system that undergoes frequent thermal cycles may require a preventive maintenance program that entails a higher frequency of spot checks.

Field Fabrication of Lined Pipe

Field fabrication of pipe spools allows end users and authorized lined-pipe distributors to fabricate lined-pipe spools locally, a factor which expedites turnaround times when compared to factory-made finished pipe spools. Straight pieces of lined pipe without flanges are stored at the end user's or distributor's shop until a requirement for a pipe spool arises.

Using special field-fabrication tooling supplied by the manufacturer, the end user or distributor can fabricate custom-length flanged pipe spools. The tooling and procedures are not interchangeable for use on products from different manufacturers. Flange options for field-fabricated pipe spools vary by manufacturer. Consult manufacturers for field fabrication instructions.

FLANGE REDUCTION TECHNIQUES

Flanged connections have long been recognized as a potential leak source, and new technologies now allow for their significant reductions. This has been brought about in part by the realization that flanged connections are a significant contributor to fugitive emissions, which are regulated by the 1990 Clean Air Act amendments. Among these is a new butt-fusion—welded flangeless connection of the plastic liner,[22] extra long lengths of pipe spools up to 40 ft (12 m), and single and multiple bent pipe spools.[23,24] See Fig. B12.9.

A new and patented flangeless joining technique was formally introduced in 1995, which can virtually eliminate over 90 percent of the flange connections of a plastic-lined piping system. As a base, it utilizes the well known technology of butt-fusion-welding that is widely used by the solid-plastic pipe industry. In order to provide overall mechanical continuity, a low-profile steel mechanical coupling is

FIGURE B12.9 Illustration showing the flange-reduction possibilities of precision-bent plastic-lined pipe as compared with traditional flanged piping (*Courtesy of Crane Resistoflex*).
FIGURE B12.10 Sectioned view of a butt-fusion-welded polypropylene plastic liner connected with a mechanical coupling. (*Courtesy of Crane Resistoflex*)

engaged over the butt-fusion weld. See Fig B12.10. Other couplings and devices are available, but the user should determine which meet the code requirements of the applicable section of ASME B31, Pressure Piping Code.

The process is accomplished by butt-fusion welding two adjacent plastic-liner stub ends together to form a strong, leak-free joint. A special low-profile mechanical coupling is then installed over the welded connection to add structural integrity that is equivalent to a welded system. Coupling installation is accomplished with a hydraulic tool designed to seat the two swage rings positioned over the coupling sleeve. This technology allows the user to eliminate almost all flange connections for carbon-steel piping lined with polypropylene, polyvinylidene fluoride, perfluoroalkoxy and PTFE. A PFA- and PTFE-lined stainless steel option is available. Fittings are a low-profile construction with longer centerline to face dimensions so that the mechanical coupling can be slipped over the butt-fusion-welded joint prior to locking the coupling into place. Although the purchase price of the flangeless system may be initially more expensive, the user should look at the total life-cycle cost before making a final piping selection.[25]

The standard spool length for the plastic-lined pipe industry is 20 ft (6 m). Customers that now wish to further reduce the number of flange connections can also purchase 40 ft-(12m) long spools in NPS 1.5 (DN 40) through NPS 6 (DN 150) pipe sizes. These spools are an excellent complement when the flangeless system is being installed.

Lined pipe manufacturers also offer bent-lined-piping systems that can eliminate 50 to 70 percent of flange connections in a 20 ft-(6m) piping run with straight sections and elbows. Bends are done on a 3D pipe diameter bend radius to prevent collapse of the plastic liner. Available sizes are NPS 1 to 4 (DN 25 to 100) in both carbon-steel and stainless-steel pipe housings. Bent-pipe systems conform to the same ASTM F1545 testing requirements as conventional lined pipe. Although bent-
FIGURE B12.11   High integrity flange connection. (*Courtesy of Crane Resistoflex*)

pipe spools offer many obvious advantages, they require special manufacturing techniques and are generally made at the factory. Replacement spools are seldom stored on site and do require extra lead time for delivery. Consequently, it is a good idea to have a stock of replacement fittings nearby if an emergency replacement is required. Bent pipe can either be flanged or flangeless.

Modified Flange Connections

Where flange connections are necessary, there is a modified leakless flange connection that utilizes a dual-sealing action. The dual-sealing action is achieved through the use of belleville washers located behind the plastic flare and secondary sealing rings, also known as *load bearing rings* See Fig B12.11. When the user tightens the flange bolts, the belleville washers deflect enough to impart the necessary sealing pressure on the PTFE flare faces. Due to the interaction of the load-bearing ring and the belleville washers, the sealing pressure is optimized and not exceeded, even though this system calls for almost quadruple the bolt torque values of a standard lined-pipe connection. The result is a leakproof flange connection that allows practically zero emissions and is Factory Mutual Approved.

APPLICABLE INDUSTRY STANDARDS

Requirements for the materials, workmanship, dimensions, design, fabrication, working pressures and temperatures, test methods, qualification requirements, and markings are set forth in ASTM F 1545. This is the specification for metal pipe and fittings lined with PTFE, PFA, FEP, ETFE, PVDF, PVDC, and PP. ASTM F 1545 is the consolidation of the following six separate (but related) specifications:

ASTM F 423 Standard Specification for Polytetrafluoroethylene (PTFE) Plastic-Lined Ferrous Metal Pipe, Fittings and Flanges

ASTM F 491 Standard Specification for Poly (Vinylidene Fluoride) (PVDF) Plastic-Lined Ferrous Metal Pipe and Fittings

ASTM F 492 Standard Specification for Propylene and Polypropylene (PP) Plastic-Lined Ferrous Metal Pipe and Fittings

ASTM F 546 Standard Specification for Perfluoro (Ethylene-Propylene) Copolymer (FEP) Plastic-Lined Ferrous Metal Pipe and Fittings

ASTM F 599 Standard Specification for Poly (Vinylidene Chloride) (PVDC) Plastic-Lined Ferrous Metal Pipe and Fittings

ASTM F 781 Standard Specification for Perfluoro (Alkoxyalkane) Copolymer (PFA) Plastic-Lined Ferrous Metal Pipe and Fittings

ASTM F 1545 lists requirements for materials of construction, qualification testing, and inspection requirements for plastic-lined piping as follows:

ASTM F1545 Requirements for Plastic-Lining Materials

Plastic-lining materials shall be made from a resin that conforms to the appropriate specifications as shown in Table B12.2.

ASTM F1545 Requirements for Lining-Material Mechanical Properties

For liner materials, the minimum tensile strength and minimum elongation at break when tested in accordance with the specifications shown in Table B12.2 shall conform to Table B12.6. Note that these are minimum requirements. Lined-piping manufacturers use various formulations of resins that may exceed the minimum values shown.

TABLE B12.6 Polymer Mechanical Properties

Lining material—resin type	Minimum tensile strength at break, psi (MPa)	Minimum elongation at break, %
Polypropylene (PP) Type I	4000 (27.6)*	10*
Polypropylene (PP) Type II	3000 (20.7)*	10*
Polypropylene (PP) 30% Glass Filled	2500 (17.3)*	2*
Poly (vinylidene chloride) (PVDC)	1500 (10.3)*	2*
Poly (vinylidene fluoride (PVDF)	4500 (31.0)	10
Poly (vinylidene fluoride) copolymer (PVDF)	4000 (27.6)	300
Polytetrafluoroethylene (PTFE)	3000 (20.7)	250
Perfluoro (ethylene-propylene) Copolymer (FEP)	3000 (20.7)	250
Perfluoro (alkoxyalkane) copolymer (PFA)	3800 (26.2)	300
Ethylyene tetrafluoroethylene copolymer (ETFE)	6500 (44.8)	275

* Minimum tensile strength and elongation at yield.

TABLE B12.7 Approved Ferrous-Metal Flange and Fitting Material Standards (ASTM)

ASTM F1545 Requirements for Ferrous-Metal Pipes, Flanges, and Fittings Materials

The mechanical properties of the ferrous metal pipes, flanges, and fittings shall conform to the appropriate specifications listed in Table B12.7, except as they are influenced by accepted methods of processing in the industry (for example, Van Stone flaring, bending, swaging, welding, and threading).

ASTM F1545 Requirements for Inspection Testing

ASTM F1545 provides for a final proof test of finished components prior to shipping. Each pipe spool and fitting, prior to shipment, shall be either hydrostatically or electrostatically tested in accordance with the following:

Hydrostatic Test.   The internal test pressure shall be 425 psig (2930 kPa) for Class 150 and Class 300 components. Reach full test pressure within one minute and hold for a total of three minutes. Observe the pressure gage throughout the test for evidence of leakage, which shall be cause for rejection.

Electrostatic Test.   Conduct the test with a nondestructive high-voltage tester at a minimum output voltage of 10 kV. A visible or audible spark, or both, that occurs at the probe when electrical contact is made with the housing because of a defect in the liner shall be cause for rejection.

TABLE B12.8 Test Temperatures, °F (°C)

PTFE	PFA	FEP	ETFE	PVDF	PP	PVDC
500 ± 5	500 ± 5	300 ± 5	300 ± 5	275 ± 5	225 ± 5	175 ± 5
(260 ± 3)	(260 ± 3)	(149 ± 3)	(149 ± 3)	(135 ± 3)	(107 ± 3)	(79 ± 3)

ASTM F1545 Requirements for Qualification Testing

ASTM F1545 also requires each lined-pipe manufacturer to perform qualification testing on representative pipe and fittings in each liner material being offered for sale. This is not meant to be an inspection test for customer orders but a verification that the methods and materials used by each manufacturer will result in a product that is capable of satisfactory performance in conditions found in a chemical plant environment. The representative pieces must pass the hydrostatic or electrostatic test following each of the tests in order to be in compliance with the specification for specific test designs. Refer to ASTM F1545.

High and Low-Temperature Aging Test. This test is to determine the ability of the lined component's to withstand extended exposure to the liner material's maximum and minimum temperature. Test temperatures for the high-temperature test are shown in Table B12.8, and the low-test temperature is 0°F (−18°C).

Steam-Cold–Water Cycling Test. This test is to determine the lined components ability to withstand rapid, repeated, and extreme temperature cycling. A representative pipe spool is blind flanged and then filled with steam at the pressure listed in Table B12.9. When the temperature stabilizes, the steam is shut off, and the pipe spool is filled with ambient water until the outside metal temperature reaches 122°F (50°C). This procedure is repeated for 100 cycles. At the completion of the test, the liner shall exhibit no buckling or cracking.

Vacuum Testing. ASTM 1545 does not require that lined-pipe manufacturers offer vacuum-rated piping products, but if manufacturers make claims of vacuum-handling capability, they must perform vacuum testing per ASTM F1545.

The above qualification tests, again, are not production-inspection tests but are designed to establish baseline levels of quality and performance for products that are regularly installed in the most demanding chemical services. Reputable plastic-lined piping manufacturers will provide certificates of compliance to ASTM F 1545 upon request.

TABLE B12.9 Steam Test Pressures, psig (kPa)

PTFE	PFA	FEP	ETFE	PVDF	PP	PVDC
125 ± 5	125 ± 5	50 ± 3	50 ± 3	30 ± 2	4 ± 1	*
(862 ± 35)	(862 ± 35)	(345 ± 21)	(345 ± 21)	(207 ± 15)	(28 ± 7)	*

* The thermocycling test for PVDC-lined pipe and fittings should be run using water at 175 ± 5°F (79 + 3°C)

PROJECT SPECIFICATIONS

A piping specification is used by the process engineer to develop piping and instrumentation drawings by the designer to lay out the piping run and product-detailed drawings by the purchasing agent for procurement and by the field engineer to ensure proper installation.[26] Thus the specification must include: the maximum pressure and temperature ratings; a list of flow media; the complete description of pipe, fittings, valves-and other piping items; and installation details. To be certain that a complete specification is achieved, the following procedure has proven useful:

1. The process engineer specifies maximum operating pressure and temperature and the flow media. An *initial piping index* can be useful in supplying this information. At this point it is necessary to ascertain that all possible media are included, that the operating conditions (pressure, temperature, and vacuum) are not minimized or exaggerated, and that the size range is all inclusive and accurate.

2. Completely describe all pipe and components. Reference the applicable ASTM standards to which all material and tests must conform. Include the size range required. Note the limitations of individual components—e.g., does a valve, hose, expansion joint, or sight glass have a pressure or temperature rating lower than that of the specification?

3. To assist the designer in laying out the pipe and in preparing detailed drawings, provide information giving the maximum and minimum lengths available, the methods of making branch connections, and the connections to dissimilar piping materials. Include instructions regarding the use of reducing tees, instrument tees, gaskets, and spacers.

Most frequently, piping components fail because their design capabilities have been exceeded. Know what is required of the components you specify and do not expect more from them than what they have been designed for. Reliable manufacturers of plastic-lined piping will not recommend the use of their products for services and conditions not previously tested.

INSPECTION AND SERVICE LIFE ANALYSIS

Currently there is an increased interest and more activity focused on improving existing mechanical-integrity standards that will continue to improve the overall mechanical integrity of process piping in the process industry.[27] The objective here is to eliminate piping and equipment-related incidents caused by leaks and failures that result in unscheduled maintenance, downtime, and asset losses. This can be approached by analysis of existing piping systems, the historical-type failure modes, and the expected service life. A repeat pattern of failures or a prioritized listing can help the maintenance department implement a plan for reduction and elimination of reccurring patterns. A key to any good maintenance program is the proper documentation of when a piping system was installed and any maintenance replacements that may have occurred. This is particularly important in today's mobile employment environment, as the personnel that originally installed the piping may not be at the same location several years into the future.

Plastic-lined piping also does not lend itself to traditional methods of inspection common in metal or alloy systems. The difficulties lie with lined pipe itself, as there

is no *corrosion rate* basis that can be applied, such as a steady loss of thickness, until failure occurs. Rather, the action of the corrosive, if it has any effect, will alter the structure of the plastic at varying rates. When such changes in properties occur, this can lead to the eventual mechanical failure of the plastic liner. The determinant of suitability then becomes the rate at which the property changes occur. Performance variability is due to the type of plastic used, grade, quality, manufacturing process, and the service condition.

The following procedures have been employed to minimize and identify piping problems:

1. Ultrasonic techniques have proven useful in locating liner collapse. Decreased flow or pressure drop may also preclude liner collapse due to vacuum or permeation.
2. Visual inspection is a time-tested method.
3. Excessive external corrosion or that around a vent port on fluoropolymer-lined piping may indicate a liner leak.
4. Destructive testing of spools taken from service of known length of time in a documented environment.
5. Excessive loading due to thermal stresses may result in flange leaks. Make sure that the piping has been properly supported. The Manufacturers Standardization Society (MSS) Standard Practice SP-69, Pipe Hangers and Supports-Selection and Application, provides good references for supports and hangers.
6. Excessive fluid loading such as water hammer or the thermal expansion of hydraulically full piping can cause liner failure. Other loads can be in the form of rapid decreases in temperature via the introduction of a liquified gas.
7. Infrared can be used in locating leaks if corrosion and or oxidation reactions are taking place. Inspection must be done at night, and the capabilities are dependent on the degree of access to the piping system.

For particularly aggressive chemical services, it may be advisable to install several test spools that can be removed at predetermined time intervals to ascertain the overall pipe condition. The user may elect to re-install them or perform destructive tests for determination of liner properties. Current practices vary from company to company and site to site. Issues of internal versus external inspection can depend on the severity of service. Generally the approach is to replace it when it fails.

Plastic-lined piping is a durable product, but it should be recognized that it does not last forever. Although, cases have been reported where service life has exceeded 25 years, 10 to 15 years is typical, particularly in aggressive services. However this range can be decreased with high-temperature operation or high numbers of thermal cycles.

AUXILIARY PRODUCTS

There is a variety of auxiliary lined products compatible with lined pipe and fittings. These products include PTFE-lined hose, PTFE expansion joints, lined valves, dip pipes and spargers, sight-flow indicators, and strainers. These items are offered by most lined-pipe manufacturers to supplement their standard lined-pipe offering. Other equipment such as lined pumps, vessels, valves, flowmeters, and other lined components are available from a wide variety of manufacturers, enabling the end

user to design and install a complete corrosion-resistant plastic-lined system with no metal-wetted parts.

INTRODUCTION

History of Double Containment Piping

Up until the 1970s, dual arrangements of piping systems utilizing a carrier pipe with a secondary piping providing containment for purposes of environmental protection or safety were limited to highly specialized applications. These involved rare applications in the nuclear, gas, or chemical processing industry, where highly toxic or lethal chemicals or fluids were transported. The use of an outer jacket to maintain a positive seal around a primary carrier piping system and protect the primary piping was rarely encountered.

In the 1970s, several large U.S. electronics manufacturers began placing their underground, and in some cases aboveground, hazardous chemical piping systems piping within an outer jacket for the sole purpose of preventing leakages from getting into the ground water supply. Part of the reason for doing so was due to inadequate performance on the part of ordinary single-walled piping components intended to handle these chemicals. Leakages from joints, failures of piping materials due to poor manufacture or installation practices, inappropriate material selection, and soil corrosion were some of the contributing factors. Thus began the modern day practice of placing underground piping systems within a secondary containment piping system for the sole purpose of protecting the local environment.

Unfortunately, many of these early systems met with complications that resulted in less-than-successful performance. The first attempts at dual arrangements met with frequent failure. This was primarily due to systems being designed with combinations of piping components whose geometries were not readily compatible. Also, there were technical issues that arose that had not been addressed in the design. This had to do with structural concerns (supporting and centering the inner system), differential thermal expansion issues, penetration sealing issues, and many others. Additionally, many of these systems were installed with poor fabrication techniques, resulting in installations that lacked inherent stability and were thus readily subject to premature failure. The lack of design consideration and installation deficiencies resulted in failures that manifested themselves in predictable ways. These included the separation of split outer pipe and split outer fittings, coupled with failed inner welds, thereby leading to a double failure. Other means of failure included premature failure of inner and outer pipes due to fatigue, excess strain, and many other reasons.

In certain individual states of the United States of America, such as California, there was a movement toward implementing secondary containment piping systems in gasoline and petroleum stations. The first known application of this was a service station in Torrance, Calif., in 1981, under the watchful eye of local fire officials and other environmental officials. Soon thereafter, other gasoline stations throughout California were implementing double containment piping systems with integral leak detection.

During this same time frame, the federal government of the United States was studying ways to protect against the failure of underground storage tanks and piping transportation systems. This resulted in revisions to the Resource Conservation and Recovery Act (RCRA) of 1976, which were enacted in 1984. Signed into law as the Hazardous and Solid Waste Amendments of 1984 (U.S. Public Law 98-616, signed Nov. 8, 1984), it extended and strengthened the Solid Waste Disposal Act, as originally amended by the Resource Conservation and Recovery Act of 1976. The amendments contained strict requirements and provisions for underground storage tank and piping systems.

For systems containing a hazardous waste [hazardous according to the EPA as defined in the Code of Federal Regulations (CFR), Title 40, part 241], hazardous substance [also according to §40CFR261], or petroleum-based substance with 10 percent or more of its volume underground (including piping), the regulations contained strict provisions. For hazardous waste the regulations [according to §40CFR264] required secondary containment and leak detection for all underground systems. They also required the same for aboveground systems unless they were visually inspected for leaks on a daily basis. For hazardous substance the regulations [according to §40CFR280] similarly required all undergound systems and aboveground systems not visually inspected on a daily basis to have secondary containment and leak detection as well.

For petroleum substances, the regulations [according to §40CFR280] gave the user a choice of providing secondary containment with leak detection or to use corrosion-resistant materials with frequent monitoring and tightness testing (petroleum-based products only). An alternative for petroleum piping applications involved the use of ordinary carbon steel (e.g., A-53 or A-106, Grade B) with some form of coating and cathodic protection added. In the case of the so-called hazardous chemicals, aboveground systems were regulated as well, unless the systems were to be inspected on a daily basis. The regulations applied to both new systems and existing systems. Existing systems were subjected to a retrofit requirement according to a time table, with the oldest systems being required to be replaced first. Thus,

all existing systems in the United States installed prior to December 1988 were scheduled to be replaced within a 10-year time frame from the commencement of the regulations, by December 1998, if they were not already in compliance. It is important to note that there are many aspects to the U.S. regulations (e.g., minimum volume requirements, regulated substances, leak detection requirements and options, etc.), and that the requirements and degree of enforcement vary according to each individual state. Other countries beyond the United States are currently considering the development of similar regulations and are expected eventually to adopt them by the early twenty-first century.

The 1984 amendments passed in the United States provide a framework by which individual states, territories, and possessions of the United States are mandated to draft state legislation, with their laws being at least as stringent as the U.S. federal law. Enforcement is required at the individual state level, with the federal Environmental Protection Agency overseeing each state program. Prior to the federal laws being adopted in the United States, some of the individual states where ground water contamination has been a particularly bad problem have adopted similar laws, prior to the federal government requiring them to do so (e.g., California, New York, parts of Texas, and others). In certain parts of Europe and Canada, local, officials have in some cases required double containment piping for hazardous chemical systems on a limited basis.

Overview of Double Containment Piping Systems

To provide secondary containment for piping systems, there are design considerations to be considered that are beyond those that apply to tanks. Whether the system is a pressure transfer pipe or a drain, waste, and vent system will have a significant impact on the design, layout, material selection, wall thicknesses, leak detection method chosen, and other aspects to be considered. Additionally, a system may be a relatively straight piping run, it may consist primarily of fittings, or it may have parts that are both straight in sections and fitting intensive in others. Further, whether a system is intended for burial or whether it is intended for aboveground use also have a significant impact on its design. Space limitations are an important consideration as well. A piping system that is intended for tight pipe-rack work, or is to be located near other buried structures, will have different installation requirements and different requirements for material selection, wall thicknesses, pressure ratings, et cetera, in comparison to a system that does not have space constraints.

In terms of material selections for the inner and outer pipes, there are a number of factors that have an effect on what should be selected. For primary piping components, the chief consideration in making its material selection has to do with the ability of the material to withstand the corrosive effects of the inner fluid. The same basic techniques and criteria used for selecting materials for single-walled piping systems must be used for primary piping in a double containment system. However, the interaction of the inner and outer systems, how they are tied together; the preferred joining method, and how joining affects system installation; the compatibility between the secondary system and its joining method, and how joining affects system installation; the compatibility between the secondary system and its joining methods all factor into the considerations for selecting the combination of materials to be used.

For secondary containment piping components, the considerations for choosing the material to be used must include risk analysis. The risk analysis used must take

into account the anticipated frequency and duration that it is reasonably expected that the outer material may be in contact with the contained fluid. It also involves weighing the possibility of failure against the sensitivity of the external environment and the relative extent of damage that a *double failure* might cause. Since there may be only infrequent (or no) contact with the corrosive fluid in a properly designed system, and the time of contact once an event occurs may be short in duration, a less expensive material may be an appropriate choice for some applications. However, for many applications the risk created by even the remotest chance of a double failure might be too great even to take a chance on using a less corrosion-resistant material.

Leak detection in a double containment piping system usually consists of some means of monitoring the status of the annular space that exists in the system. Detection methods that are used typically measure the presence of a fluid or some change in physical state. Other methods can be used (i.e., flow measurement), but the most effective means is to monitor the status of the system's annular space to detect for a change from a status quo.

The proper design of any piping system must include all the forms of analysis that are normally applied to single walled systems (e.g. stress analysis, structural analysis, burial analysis, etc). However, the design of double containment piping systems adds several new twists to the already complex nature of piping design. This includes such novel items as the fluid dynamic requirements for draining or flushing the annulus, or the added mechanical complexities that result from the interaction of the separate, interacting inner and outer piping systems.

When one considers the interaction of an inner and outer pipe system, and the resulting stresses and reactions thereof, the analysis often becomes complex. In fact, most piping design stress computer codes are not capable of accurately modeling this situation. Structural analysis of double containment piping systems is also inherently complex, as one has to deal first with the structural supporting requirements of the inner system and then also deal with the support (or burial) of the complex assembly, which tends to be a more rigid assembly than a comparable single-walled pipe. In underground situations, for instance, the structural design for a combined system is governed by the burial situation, yet the structural design of the inner piping is according to aboveground single-wall pipe standards. In fact, the inner pipe can often be thought of as a single-walled pipe that is supported within a circular pipe rack.

The most important individual principle to consider when designing double containment piping systems is that the basic principles of piping design remain unchanged. The systems must first be designed according to the ordinary rules, codes, and considerations of single-pipe design. Then all the complexities of one pipe system interacting within another must be considered as well.

There are a vast number of material and system configurations to consider on any given project. However, this aspect of double containment piping may be viewed in a positive way. The vast number of choices presents a designer with an opportunity to provide a solution for every application. A suitable design can be achieved in every case. The final choice of material and system configuration usually is determined by price and code criteria, and to a certain extent, by personal preference.

A complete double containment piping system is one that is engineered, designed, installed, started up, and operated successfully. To engineer a double containment piping system fully typically involves much more than simply procuring preengineered components. The term *preengineered* is a widely used marketing term that usually refers to products that are sold as prefabricated components, which are in some cases available in standard sizes and materials. This term is often misused,

as a surprising number of preengineered systems available from even the largest sources have been conceptualized and sold with little to no engineering having been performed on the system components. However, double containment piping systems by their nature usually have at least some unique requirements, necessitating a custom design to some extent. Thus designers must use good judgement when procuring preengineered components as part of their system.

Any two combinations of materials can be effectively combined for a given double containment piping application. However, there are many aspects involved to make this possible. Materials must be properly selected for the given application. System components must be procured; it must be known early on in a project whether they are commercially available in the sizes and pressure ratings required. They must also be available in the time frame required by the project. A system must always be engineered with sufficient detail, giving consideration to all applicable factors. All regulations governed by the local jurisdiction and appropriate design code rules must be satisfied. Ultimately, whoever is to take responsibility for the design and operation of the facility must be satisfied that the design is a safe and workable solution.

Overview of Leak Detection Systems

While a double containment system can be designed without a leak detection or monitoring system, the effectiveness of a system is considerably lessened without it. There are many methods available to provide sensing of the annulus that exists between primary and secondary systems. These methods are divided into two basic categories: automatic sensing systems and nonautomatic sensing systems.

Continuous Sensing Systems. Continuous sensing systems normally involve a sensing mechanism and an automatic alarm device. The most sophisticated form of sensing consists of continuous-line leak detection. Continuous-line leak detection is a technology designed to give relatively precise locating abilities for the determination of the location of leaks. For piping systems, this is a very important feature, although it also adds significantly to the initial cost of a system. There are two types of technologies; conductive (resistance)-based systems and those that are based on the measurement of impedance, commonly referred to as TDR-based systems (TDR is a common abbreviation for time-domain reflectometry). Both technologies are effective, although there are subtle differences between the two.

Other forms of continuous sensing are based on some form of point probes. These include liquid level sensing, pressure sensing, moisture sensing, pH sensing, conductivity (resistivity sensing), vapor detection, ultrasonic sensing, movement sensing, and many others. The various forms of sensing may also be combined for added effectiveness. The advantage of point probe systems is in the ability to customize the system, but an inherent disadvantage is the lack of ability to locate a leak with precision.

Noncontinuous Sensing Systems. Noncontinuous leak-sensing systems consist of visual detection systems, manual detection, inventory monitoring (tanks), and soil and vapor monitoring. Soil and vapor monitoring may also be used on a continuous basis, although it is not very common to do so. Visual detection can be designed easily into aboveground systems, but for underground systems they must be placed in manholes or sumps. Two forms of underground visual monitoring are very inexpensive and can be facilitated readily by having the secondary system flow open

at the end of the pipe system, or by designing low point sumps with risers to the ground surface. Manual detection is normally facilitated by installing drip legs with valves in aboveground systems and with either low point sumps with risers to the ground surface in underground systems, or by positioning drip legs with valves in manholes. Manual systems can be a very cost effective and efficient method of leak detection and usually are a good idea to have as a backup or redundant method when other methods are employed. Inventory monitoring is a practical method for tank systems, but for piping systems it becomes more costly and complex, as a material balance must be performed. Noncontinuous systems are for the most part nonspecific in terms of locating leaks, unless a system is designed with very frequent locations for visual or manual monitoring.

Applicable Design Codes

Double containment piping systems must be designed, fabricated, inspected, and tested to applicable codes and regulations. Since by far, the majority of double containment piping systems are for drainage applications, plumbing codes play a particularly important role in double containment piping. Many nonpressure drainage piping systems are governed by local and/or national plumbing codes. Examples of these are the UPC (Uniform Plumbing Code), which is written by IAPMO (International Association of Plumbing and Mechanical Officials) and endorsed by the PHCC (Plumbing-Heating-Cooling Contractors), and additionally the IPC (International Plumbing Code), which is written by BOCA and ICBO. The most important requirement that these plumbing codes cover pertains to the carrier pipe fittings. Typically they should be approved by the respective code, such as the UPC or the IPC, according to the authorities having local jurisdiction.

Other nonpressure systems are often considered by local authorities having jurisdiction as *process* systems, and may thus be out of the jurisdiction of local plumbing codes. In many of these systems, there are no design standards that may govern the design. Thus it is up to the individual designer to use good judgment and to be sure that they at the very least meet or exceed applicable environmental standards.

In the United States and Canada, process piping systems are subject to the rules of the ANSI/ASME B31.3 Process Piping Code, including double containment piping systems. The ANSI/ASME B31.3 Code is a subset of the ANSI/ASME B31 Pressure Piping Code, which is described in more detail in Section 1.5.6, Piping Design Codes. The ANSI/ASME B31.3 Code references various applicable product manufacturing standards, performance standards, and material specifications that are to be used as a part of a double containment piping system. The Code covers all the rules necessary to complete a double containment piping system. However, the ultimate responsibility of interpreting and applying the ANSI/ASME B31.3 Code, in order to arrive at a completed double containment piping system that is safe and reliable, rests with each individual owner or owner-appointed representative.

In order for the ASME/ANSI B31.3 Code to apply to a double containment pipe system, most piping has to operate at a pressure of greater than 15 psi (1 bar), or contain a vacuum. However, the Code may still apply to a system having a positive internal pressure less than 15 psi (1 bar) if the fluid being conveyed meets certain requirements in terms of flammability or toxicity, which would apply to many chemicals commonly used in a double containment piping system. The ASME/ANSI B31.3 Code does provide all the information a designer needs to know to design a double containment piping system. However, it is up to the individual

designer to interpret the Code as to how it instructs one to do so. There are no specific references to a double containment piping system or secondary containment piping component in the Code. There are specific references to the testing and inspection of outer jacketing, however.

In Europe, the European Parliament has adopted the Pressure Equipment Directive (PED) which will affect process piping and will go into effect on Nov. 29, 1999. The PED requires that piping systems comply with "essential safety requirements" as a function of the fluid service. One possible outcome presently being studied by the European Parliament and the ASME is to have piping systems meet these essential safety requirements by having piping systems comply with the ASME B31.3 Process Piping Code. Not enough is known at the time of this writing to determine the feasibility of whether the PED will ultimately reference the B31.3 Code.

DOUBLE CONTAINMENT PIPING COMPONENTS

Straight Piping Sections

Figure B13.1 illustrates required dimensional information needed for a typical layout for straight piping sections for both nonmetallic and metallic piping material–based
FIGURE B13.1 Typical layout details for a straight pipe section of double containment piping. *(From* "Handbook of Double Containment Piping Systems," *C. Ziu, McGraw-Hill, New York, 1995.)*
FIGURE B13.2 Example of factory prefabricated 20-ft lengths of piping showing support spacing based on 5-ft spacing between supports for piping intended for staggered joining (top) and simultaneous joining (bottom). *(Orion Fittings, Inc., Kansas City, KS)*

systems, as may be used, for instance, in portions of double walled piping system on any project, each unique section of straight piping should have all details clearly indicated, except for highly fitting intensive projects where only short lengths of straight pipe exist.

Details that must be shown for a typical straight pipe section, or specified clearly, include: the materials of construction, with reference to the appropriate ASTM, DIN or AISI specifications; all inside and outside diameter sizes (including the annular space); wall thicknesses; applicable tolerances; location (spacing) and type of internal and external supports and leak detection cable (if applicable); and references to detail drawings of internal and external supports. A section of piping can be considered unique if any of these variables vary in any way. Both side and cross-sectional typical views should be shown. For intensive projects where separate spool drawings are to be prepared for each and every spool length of pipe, there is no need for typical straight pipe–section details on drawings. Figure B13.2, Fig. B13.3 and Fig. B13.4 show support-spacing options for various 20-ft, 10-ft and 5-ft sections of double containment piping.
FIGURE B13.3 Example of factory prefabricated 10-ft lengths of piping showing support spacing based on 5-ft spacing between supports for piping intended for staggered joining (top) and simultaneous joining (bottom). *(Orion Fittings, Inc., Kansas City, KS)*

Termination and Initiation Component Design

There are several options for terminating a double containment zone, thereby making a transition from double containment piping to ordinary single-wall piping. The most simple option is to keep the annulus open ended where it is permissible. For most applications, end closures are required. Examples of some typical end closures are provided in Figs. B13.5 through B13.8.

Closure Rings and Insert Rings. One of the more common termination arrangements for metallic systems that has been used extensively in jacketed pipe applications is the closure ring. Closure rings also find application as a termination device in double containment pip-

ing systems. Examples of closure rings are provided in Figs. B13.9 and B13.10. A closure ring is a concept similar to the internal anchor-baffle (see Fig. B13.12 and Fig. B13.13), except that an internal anchor-baffle is welded to the inner and outer pipes on both sides; a closure ring is welded only on one side to the secondary containment piping. A closure ring may be used on thermoplastic piping, as it is weldable, although the resulting secondary containment pressure rating (pressure capability of the annulus) may be substantially less than that of the primary piping. A variation of the closure ring is an insert ring (collar), which may be used in systems that use solvent cementing (PVC, CPVC, ABS) or adhesive bonding (all RTRP materials).

Anchoring Components and Methods for Primary Pipe

It is occasionally necessary to restrain a piping system at a given point by securely anchoring it at that point. This may be for such reasons as controlling vibration; controlling, directing, and limiting the amount of thermal expansion in a pipe; and

SECTION Z–Z

Ziu,* "Handbook of Double Containment Piping Systems," *McGraw-Hill, 1995.)*

other reasons. Since it is required in single-walled piping practice, anchoring is thus required for primary piping in double containment piping for the same reasons for its use in single-walled piping.

External-Anchoring Components and Methods.　A primary pipe in a double containment system may either be anchored externally (external to the annulus) or internally (internal to the annulus). An external arrangement involves interruption

of the secondary-containment feature, and is also referred to as a double termination arrangement. Since termination arrangements are a natural point of interconnection, the systems are restrained in place. Further, since they may be bolted together via a flange, the flanges may be secured to a building part, resulting in a completely rigid arrangement. The same effect can be achieved if an outer pipe is anchored at points away from the flange on both sides and sufficient intermediate guiding is provided.

The main drawback with this type of arrangement is that this area is no longer secondarily contained. Some other means of secondary containment must be added. If secondary containment is required to be provided, then possible solutions for aboveground systems include either a dike structure to be constructed around it, or a protective flange cover provided. An example of a protective flange cover for a double termination arrangement via flange is illustrated in Fig. B13.11. Another option in some aboveground applications is to leave the flange arrangement single contained and provide daily visual inspection at this point. In underground systems,

the arrangement will require either placement within a concrete sump or manhole, or the provision of a protective flange cover.

Internal-Anchoring Components and Methods.   There are options for anchoring the primary piping that eliminate the need to interrupt the containment casing. A variety of internal methods exist, some of which are fabricated, and others that involve specialized fittings.

A basic fabricated version, termed an *internal-baffle* arrangement, is illustrated in Fig. B13.12 and Fig. B13.13. This method is a variation of the termination closure

ring described earlier. It is suitable in metallic systems where the metal can be directly welded to the baffle.

A variation of the internal-baffle for use in systems that use a metallic primary piping and a nonmetallic outer system is illustrated in Fig. B13.14. This type, like the version shown in Figure B13.13, may have the baffle extend radially in order to allow it to be directly attached or secured to an external structure. These arrangements are suitable in aboveground applications; in underground applications the
FIGURE B13.14   Internal anchoring method for metallic primary, nonmetallic secondary containment piping arrangements.

flanges would have to be directly buried and may therefore require extra protection (i.e., coating and cathodic protection of the bolts, in addition to protective shrink-wrap covers, etc.).

A structural design of a homogeneous internal-anchor component (perhaps more appropriately termed an *internal termination anchoring fitting,* as it effectively terminates double containment at its point of use) is presented in Figs. B13.14 and B13.16. Figure B13.15 illustrates a solid annulus version, while Fig. B13.16 illustrates a version that is designed to allow annular flow (and maximize the flow through the component).
FIGURE B13.15 An example of a homogeneous internal anchor coupling having a solid annulus for compartmentalization purposes. *(U.S. Patents #5,141,261 and 4,930,544)*

Any homogeneous-material internal-anchoring component is generally considered to possess single containment in its center portions. Therefore, these components may require additional secondary containment around their exterior (i.e., a concrete sump, dike, etc.) to satisfy secondary containment requirements.

Figure B13.17 illustrates another type of patented internal-anchor fitting, designed to enable the primary piping to be anchored while minimizing stresses on the component itself, lessening the chance of failure as compared to the homogeneous versions, yet maintaining 100 percent secondary containment and also allowing any combination of materials.

The fitting shown in Fig. B13.17 allows for drainage of leaks through the annulus.

Alternatively, it may be provided with specialized *annular plugs* or seals to prevent flow. One would desire to prevent annular flow when designing a system in a compartmentalized fashion or when using these fittings as termination fittings.

Anchored Systems Using Anchored Fittings

One of the more common ways to anchor double containment piping systems is to anchor each and every fitting internally by the use of collar inserts or welded in place plate supports. This method has been used extensively for many years in jacketed process piping systems using metallic materials. However, the method has been popularized in recent years in double containment systems due to the highly successful commercial introduction of a patented system available from the Fibercast Co. (Sand Springs, Okla.) trademarked as the DualCast System. Examples of this type of system are shown for metallic systems and for the DualCast system in Figs. B13.18 and B13.19, respectively. An example of a patent pending system using conical internal anchors in thermoplastic socket-based drainage systems is shown in Fig. B13.20.

In this type of system it is important to anchor every outlet of every fitting. In other words, branch fittings require anchoring on all three sides and elbows on both sides. In doing so, the straight piping running between fittings are thereby anchored as well, although the straight pipes must still be adequately guided axially between consecutive fittings, except for very short runs.

Interstitial Supports

Various types of interstitial supports (also referred to as centralizers, among other names) are shown in Figs. B13.21 through B13.26.

Pressure Fittings

LAYOUT OF DOUBLE CONTAINMENT PIPING SYSTEMS

A double containment piping system is only partially designed once its piping and components have been sized and their pressure ratings established. The layout of the system must then be determined, taking into account all the requirements of the application. These include: flexibility requirements, installation requirements, inspection, examination and testing requirements, leak detection–system requirements, and others. It also involves the detailed design of interconnecting parts, design and placement of centering devices (interstitial supports), and double containment fitting details. Space issues are of the utmost importance, as potential interferences may exist between inner and outer components. This includes interferences that may result from differential movements that occur when inner and outer systems are subjected to different amounts of thermal expansion, which may be undesirable. The allowable space can have a profound effect on the fabrication and installation of a system.

System layout is interrelated to all other aspects of system design by virtue of performance criteria. For instance, the final pressure rating of a primary pipe system will be directly affected by the layout and the resulting frictional losses that are calculated. Each layout choice will also result in unique stress levels developed in the system components, based on design temperatures and pressures. The distribution of these stresses will also change upon each change in layout detail. Layout choices will have an effect on other aspects of system design as well (i.e., structural, heat transfer, fluid dynamics, etc.). In each design, the layout process involves first selecting a layout and then determining its suitability for the given design conditions. Often this involves computing stresses or performing some other analysis to determine if the chosen layout will result in a safely working system over its design life; if it is determined that the system may fail under the layout that has been selected, aspects of the layout must be changed and a new analysis performed. By its very nature, the layout process involves trial and error on the part of the engineering design team.

There are two layout issues to which the first time designer and customer of a double containment piping system must pay special attention at the start of a project. The first concerns the overall size of double containment piping and its components. By its nature, the overall diameter sizes are much greater than their corresponding single-walled primary piping systems. While this aspect of double containment piping sounds obvious, it often is a source of surprise and frustration for facility owners and piping designers. This aspect of double-containment piping is a limiting factor, particularly when a system is being installed as a retrofit into an existing facility, or a specified slope has to be met.

A second major item of importance has to do with allowing sufficient clearance for primary fittings to be installed or fabricated within secondary containment fittings; in other words, providing adequate clearance between the two components or, stated differently, proving adequate internal clearance. This item is important for all systems, but it is highly important for those requiring an internally flexible design and layout.

It is difficult to present specific criteria for all layout details that may be encountered in a system design. There are an infinite set of conditions that may be encountered; no two piping systems are ever completely alike. However, considerations for many of the common aspects of double containment piping system layout can be described.

The layout selected will have an effect on the overall system performance. The overall layout of any system, consisting of each individual detail acting together to form a complete system, must always be analyzed as to its suitability by a competent professional to achieve a safe, working system.

Pressure Piping Systems

Pressure piping systems include both aboveground and underground systems that operate at 15 psig (1.1 bar) or greater internal pressure, or operate at vacuum conditions (below 0 psig). Secondary containment portions of these systems may also be pressure rated to the same extent as the primary, but not in all cases. The choice is normally up to the designer, although code requirements may dictate whether it is required. Systems that operate under vacuum conditions (less than 0 psig, 14.7 psia, 1 bar absolute) are also classified as pressure piping systems even if they will never be subjected to a positive internal pressure.

The layout of a pressure piping system is far from an exact science and is not taught in schools. Most competent designers develop their techniques from experience and from working with other designers. The ASME B31 Pressure Piping Codes state many useful layout concepts based upon allowing adequate space and minimizing the stresses of pressure piping systems. To minimize stresses in a system layout, as described in the ASME Codes, one must provide a system whose stresses are well balanced during operation. A system whose stresses are evenly balanced will result in a system where detrimental stresses will not occur during operation. These criteria, which set a worldwide accepted basis for determining the layout of a pressure piping system, also provides the designer with guidance to determine if a system can have a restrained or flexible layout.

Nonpressure Double Containment Piping Layout Considerations

Nonpressure systems include both aboveground and underground systems whose primary systems operate at a pressure between 0 and 15 psig (bar). The major type of nonpressure system is the gravity flow chemical drain waste and vent (DWV) system, which is designed to drain chemical waste by means of gravity to sewers, treatment or holding tanks, or a treatment facility. The secondary, containment portions of these systems are typically designed to the same performance specs as the primary system (i.e., to a pressure rating of 10 ft of head, or 0.3 bar). In some instances, the secondary containment jackets of these systems may be designed in an open-ended fashion, whereby the secondary containment jacket flows open ended over a tank or treatment pond. When a system is allowed to be designed in such a manner, the pressure rating of the secondary containment at most will accommodate any head buildup due to developed back pressures. The secondary, containment design normally is the choice of the designer, although Code or regulatory requirements may dictate what is required.

While many underground waste systems are of the gravity-fed, nonpressure type, some double containment waste-piping transfer lines can be pressurized due to the distance they must convey the fluids, or due to a lack of slope. Also, in some systems where a substantial change in elevation exists (> 33 ft, 10 m), the line may have to be reclassified as a pressure system, as some of its components will be subject to greater than 15 psi (1.1 bar). In many projects, the site does not allow for much change in elevation. Since elevation changes will be limited, the system may have

both nonpressure and pressure characteristics. The usual design in such applications involves the nonpressure line (lines) draining into a sump, whereby the fluid is then moved within a force main by the use of a sump pump.

Underground piping may include pressure transfer lines that are routed underground at the choice of the owner. This may be due to reasons of surface aesthetics, unavailable surface space due to surface restrictions, the existence of underground tanks, or to control-piping temperatures-safety concerns. In the case of petroleum marketing outlets, piping is placed underground for all four reasons. Some aspects of underground layout apply to nonpressure lines and pressure lines. General layout considerations for underground pressure and nonpressure piping double containment systems are discussed here.

Many aspects of nonpressure waste piping and other non-ASME Code underground piping layout practices are defined in many localities by building or fire codes. There are also many well-defined layout practices that have been developed by various professional disciplines and their organizations (e.g., American Society of Civil Engineers, American Water Works Association, American Society of Plumbing Engineers, etc.). However, most competent designers involved in nonpressure piping and underground pressure piping applications gain their layout knowledge from working on actual projects and by following the practical methods of other accomplished designers.

Designers of nonpressure chemical DWV systems (e.g. from laboratories) should be aware of the differences between a plumbing code [e.g. IPC (BOCA/ICBO), UBC (IAPMO), CSA, etc.] and a design code (e.g. ANSI/ASME B31.3, 31.9). Design codes cover the mechanical design integrity of the components and system, whereas a plumbing code typically does not. Though a design code may not be required for certain systems by local jurisdiction, designers should consider applying such codes to verify the mechanical integrity of the system.

Chemical Waste DWV Piping Systems, Acid Waste DWV Piping Systems, and Chemical Sewers

Chemical waste piping systems include those that serve as drain, waste, and vent piping for chemicals of all types. These types of systems are commonly referred to as *acid waste DWV systems* by plumbing engineers. Although the name implies that they are specific to the disposal of acids, they may be designed to convey acids, bases, organic chemicals, chlorinated solvents, or inorganic chemicals of all types. The name is designated as acid-waste piping because acids are among the most commonly encountered chemicals in laboratory and plating applications whereby such chemicals are commonly discharged into the waste piping after they have served their purpose. The plumbing and sanitary engineering profession has historically designated this piping with its specific label to distinguish it from other sanitary drain, waste, and vent lines in building services.

Chemical-waste materials should not be discharged into a regular sewer system without first being neutralized or treated in some fashion. Many chemical waste piping systems are designed to allow fluid to discharge into a neutralization basin or treatment pond, where the chemicals are treated. The neutralized or treated product is then allowed to be discharged into the sewer system or waterways once the effluent is within prescribed purity limits.

Layout considerations for these systems include such items as determination of diameter sizes (capacity of the piping), slope determination, determination of component style, and venting requirements. Other system selection factors (such

as material selection) can, in certain locations, be based on fire-related considerations such as flame and smoke spread ratings of the materials, and adherence to U.L. (Underwriter Laboratories) and F.M. (Factory Mutual) standards. Whenever a layout is to be determined for nonpressure waste systems or other type of underground system, the authority having local jurisdiction must be contacted as to what codes, standards, and permits apply.

Whereas the design and layout of most sanitary drain, waste, and vent and other plumbing-related piping is governed by strict building codes, chemical, waste piping systems are not regulated in all areas. The reason that it may not be covered in certain local building codes is that in many municipalities it is classified as process piping. Process piping is ordinarily not covered by the general building codes. However, an aboveground system may be still subject to fire code regulations, depending on the locality where it is to be installed. Although there may not be strict coverage under building codes, the design and layout of such systems should still follow the well-defined engineering practices of ordinary DWV piping. This includes sizing practices, slope determination, provision of proper venting, and other principles of design and layout.

One aspect of chemical waste piping design that tends to be common among systems of this type is that most systems have at least part, if not all, of the system buried directly under a building slab or behind walls or between floors, which usually means very limited access to the piping system. If there is a leak detected, portions of the building usually have to be excavated to get at the pipes. It also means a disruption of ongoing activities within the building and could result in lost revenue in the event of a repair. Therefore, the selection of material for the secondary containment pipe becomes critical in this situation. The fluid will have a tendency to remain in the annulus for a fairly long period of time, at least until a repair operation can be scheduled. For these reasons, there is added incentive to use homogeneous inner and outer materials.

Floor Drains and Other Fixture Outlets.   The purpose of a chemical or acid waste drainage system is to collect waste from laboratory sinks, fume hoods, and floor drains. However, other applications exist for aboveground drain systems to allow drainage of fluids from process equipment, rinse-down areas, potential spill areas around tanks and vessels, and other areas in order to transport the waste to a remote treatment area. These lab sinks, fume hoods, and floor drains are the points of introduction of the waste fluids.

Typical diameters for outlet primary piping from fixtures range from NPS 1½ (DN 40) diameter to NPS 4 (DN 100) diameter. These outlet pipes must be equipped with secondary containment piping ranging in sizes from NPS 3 to 8 (DN 80 to 200) diameter sizes, respective of the aforementioned primary pipes. Outlets from floor drains are usually NPS 2 (DN 50) in diameter to a maximum of NPS 6 (DN 150).

Figure B13.59 details an ideal configuration for fixture outlets that must be equipped with secondary containment. In this example, the secondary containment jacket is shown as being directly welded (or bonded) to the underside of the sink, basin, or tank. This is possible only in systems involving homogeneous or highly compatible materials. It is something that is highly encouraged in the layout of such systems as it will lead to a transition involving high integrity. A reason why this is important is that it allows the transition from single containment to double containment to be made above the level of the first primary pipe joint. In contrast, Fig. B13.60 illustrates a transition from single containment to double containment where the transition is made below the level of the first joint. Either transition is acceptable if it occurs aboveground in an area considered to provide adequate

secondary containment. If the transition occurs underground it is critical that it be made above the level of the first joint. Otherwise, a concrete sump equipped with a leak detection probe may have to be constructed around the area to prevent the possibility of leakage to the surrounding soil.

Floor drains also have many specific concerns that need to be addressed. The same transition concerns expressed in the previous paragraph apply. However, there are a number of additional concerns in comparison to fixture outlets. Figure
FIGURE B13.61   Illustration of three types of double containment floor drains: (a) polypropylene *(Orion Fittings, Inc.);* (b) stainless steel *(J.R. Smith);* (c) epoxy or vinyl ester RTRP. *(Fibercast).*

B13.61 illustrates examples of typical double containment floor drains. These floor drains should be provided with a flashing in order to collect any leaks safely that occur where the brim is sealed into the floor, something that can be expected to occur eventually in many floor drains. There should be perforations provided in their basins that allow collected fluids that leak around the brim to drain into the primary portion of the drain, which will allow fluids to flow down their respective primary pipe outlets. It is important that fluid never be purposely introduced into the annulus of double containment piping because a leak would then be sensed and repair procedures may be initiated, though not needed. Thus, collected leaks around a brim are discharged into the primary portion of the drain.

In Fig. B13.61, the transition from single containment to double containment is made by attaching the secondary containment pipe directly to the underside of each drain's drip pan-flashing by using a weld or bond. This is often desirable for floor drains, as they typically are directly imbedded in concrete flooring. This is readily possible if the drain, the primary pipe, and the secondary containment pipe are constructed of homogeneous materials; if it is not possible (i.e., in hybrid material systems), then in most jurisdictions in the United States, a concrete sump has to be constructed around the area with some form of monitoring applied.

Use of Traps.   Floor drains and fixtures need to be provided with traps at their outlets in chemical systems where there is a possibility of backup of gases from the system through the fixtures or drains.

The most common type of trap in a chemical DWV system is the P-trap. A typical double-containment P-trap is illustrated in Fig. B13.62. A requirement of
FIGURE B13.62 Typical double containment P-trap where the system uses metallic or thermoplastic butt welding/fusion pattern pressure fittings as the basis to fabricate a non-plumbing-code approved drainage system.

P-trap design is that a minimum of a 2-in (50 mm) water seal be provided in the design. In a trap equipped with secondary containment, the annulus will always have the same theoretical seal dimension as the primary pipe, plus a small amount equal to the sum of the annulus available at the bottom of the bottom elbow and the wall thickness of the primary elbow. (One should note that the annulus is meant to remain normally empty, thus the seal dimension of the secondary pipe is described only in theoretical terms.) An alternative arrangement is illustrated in Fig. B13.63, where single-walled components are housed inside a secondary containment sump.

Another feature of traps that must be considered is whether or not the primary P-trap needs to be provided with a cleanout at its low point. Cleanouts are often provided at the bottom of traps in ordinary plumbing systems to allow the drain
FIGURE B13.63 Fabricated double containment P-trap incorporating a cleanout, where the system uses metallic or thermoplastic butt welding/fusion pattern pressure fittings as the basis to fabricate a non-plumbing-code approved drainage system.

SOCKET PIPE PLUG
FIGURE B13.64   Alternative arrangement for P-traps involving carrier components housed inside a specialized secondary containment tank-like structure.

to be unclogged of collected aggregates, hardened foam, etcetra. Therefore, if the trap requires a cleanout to be provided, then a specialized arrangement is required. Figure B13.64 illustrates an arrangement where the primary part of the trap has cleanout capability; the secondary containment portion is provided with a removable access cover that is further equipped with a digital liquid-sensing probe. An arrangement of this type would need to be placed inside a sump that can safely house such an arrangement and allow the safe collection of fluids when they spill. Care should be taken when opening a cleanout in this configuration, as the hazardous chemicals will likely be present in the bottom of the P-trap. The maintenance worker-contractor should be equipped with the proper safety clothing, masks, and protective eyewear.

Underground Horizontal Headers.   Most systems involve one or more vertical waste stacks that collect waste from horizontal branches and floor drains and discharge waste vertically into a common header installed under the building. Each stack normally connects to a header through either a 90°-long sweep elbow, or through a long-turn-tee-wye (45° lateral with a 1/8th bend). Floor drains that are used to collect emergency spills are typically connected to an underground P-trap that is in turn connected to the header at the exit of the trap. Underground headers usually connect outside the building to an underground main, are fed into a common sump or basin, or are drained into a neutralization tank.

A typical underground header system used at a laboratory-type facility is illustrated in Fig. B13.65 and shown in the accompanying photograph of the same system, Fig. B13.66. The layout of the system is typical of a two-story laboratory building that collects wastes from various fixtures, floor drains, and vertical waste stacks. Underground header systems should have orthographic plan view drawings prepared, similar to that shown. An overall plan view showing all headers should be prepared, as well as individual drawings for each header. The individual headers should include details of all connections, including fitting types, location, and method of attachment (type of weld or bond).
END VIEW   PLAN VIEW
SIDE VIEW

FIGURE B13.65   A typical underground lab-waste header subassembly in a gravity-waste application.

An alternative design for underground headers that fall within a building's limits is to place a single-walled header within a lined or coated open trench. This can be done on all or a portion of an underground header that is within a building's limits. Fig. B13.67 is an example of single-walled underground headers contained within a coated, open trench. In this example, perpendicular double containment pipes are terminated upon entry to the common trench, whereby multiple pipes are secondarily contained by the associated common open trench. Shown in Fig.

FIGURE B13.66   Photograph of the header illustrated in Fig. B13.65.
FIGURE B13.67 An example of single-wall underground chemical waste headers housed inside of a coated secondary containment concrete trench in a chemical weapons testing and research facility for the U.S. Army Corps. of Engineers. *(Poole & Kent Co.). (From* "Handbook of Double Containment Piping Systems," *C. Ziu, McGraw-Hill, New York, 1995.)*

B13.68 is the structure designed to support the different pipes. While not indicated in the drawing, stainless steel or fiberglass pultruded grating is placed over the trench to prevent a worker's falling into the open trench.

In this example, there are also underground side headers feeding into the trench, each of which is individually double contained before it enters the common trench. When more than one header can run parallel to others it becomes economical to place them inside a common trench. Designers must consult with the authority having local jurisdiction to determine if a common means of secondary containment can be used for more than one primary pipe. Also, while open trenches are readily suitable inside a building, they lose some of their appeal outside a building. Outside building limits, rainwater will readily enter an open trench, which means that rainwater flow will have to be monitored and diverted to a waste treatment facility when contamination is detected. This can mean a very large increase in capacity for the waste treatment facility, making the use of open trenches less desirable outside a building's limits.

Underground Horizontal Mains. When an underground header exits a building's limits, horizontal waste piping either continues as an underground main or ties in via branch connection to a main. Mains may collect wastes from one or more headers, possibly multiple headers from more than one building. An underground main typically carries waste to a remote site where it is processed, stored, or discharged into an industrial sewer. The main may either be a gravity-fed drain pipe, or it might operate as a pressure force main. The decision whether to move the chemical waste fluids by either gravity or pressure depends on the present and future capacity needs, the distance to be traveled, and available slope.

Several drawings are needed to depict the layout of the underground mains accurately. The overall schematic of the mains, including their relation to buildings and other surface structures, should be shown on a plan-view drawing, which should show all pipes, including branch connections and changes in direction of the piping. The location of fittings, manholes, and other major details should also be indicated. Any horizontal change in elevation should be shown by preparing a profile view drawing, indicating all changes in elevation of the pipe (or pipes) and the surface geography. The elevations should be indicated at various points along the drawing in order to determine burial depths, locations of manholes, and other details accurately. Whenever feasible, a combined drawing should be prepared so that it is easy to coordinate location and elevation. Both drawings should be drawn to scale in order to assist in preparing accurate takeoffs and estimates of project costs.

In addition to these drawings, detail drawings should be prepared for all unique aspects of underground mains. At least one typical detail drawing needs to be prepared for each unique section. A section is considered unique if there is any change in size, diameter (including annular space), wall thickness, materials of construction of the primary or secondary containment piping, type and spacing of interstitial supporting devices, or type of welds (bonds). If any of these variables changes, then a separate detail drawing needs to be prepared.

A typical drawing illustrating a combination plan view and profile view of an underground gravity-fed double containment main is shown in Fig. B13.69.

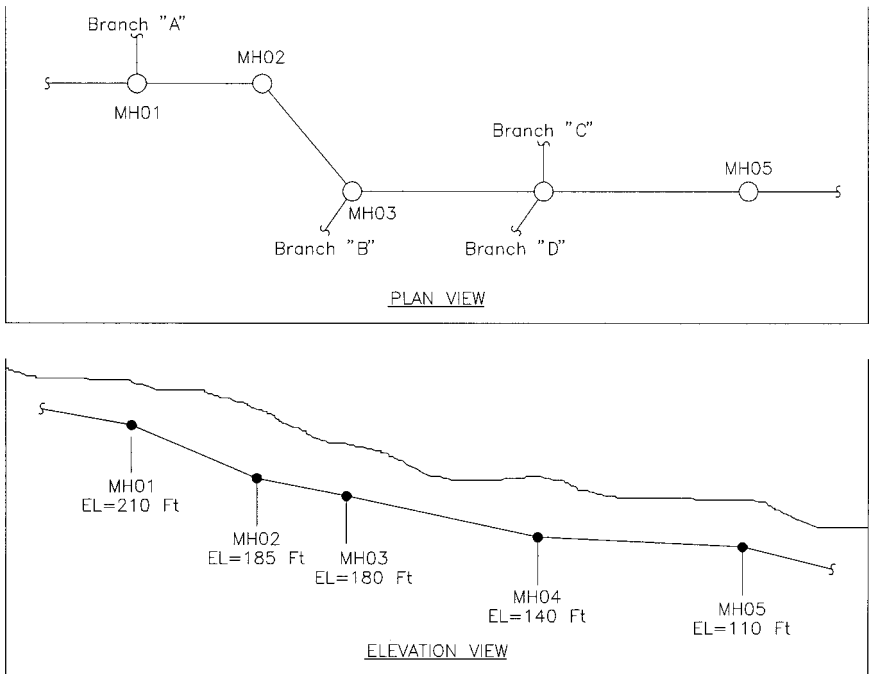
Gradient of Internally Supported Headers to Prevent Pocketing. If primary pipes are intermittently supported by means of internal centering supports (centralizers), they must not contain sag pockets in order to drain freely. To eliminate pockets, each downstream internal centralizing support must be lower than its upstream neighbor by an amount that depends on the sag of the pipe between them. A
FIGURE B13.68 A structural supporting system used to support the pipes shown in Fig. B13.67. *(Source: Poole and Kent Co.)*


FIGURE B13.69 A typical combined plan- and profile-view drawing for an underground gravity-flow chemical sewer.

practical average gradient of internal support elevations to meet this requirement may be found by using the following equation B13.1.

$$G = \frac{4y}{L} \qquad (B13.1)$$

where G = gradient, in/ft
$\qquad L$ = span, ft
$\qquad y$ = deflection, in

The difference in elevation between a downstream internal centering support and its upstream neighbor must be four times the theoretical deflection of the pipe between them to establish the grade. It has been suggested as a conservative measure to use twice the theoretical mid-span deflection when determining the slope of the double containment pipe. If so, the elevation difference between successive supports would be eight times the theoretical mid-span. The elevation of the internal supports is equal to the invert of the secondary containment pipe.

Use of a Common Sump with Discharge into Pressure Force Mains. In the plan and profile view of Fig. B13.69, the elevation changes by more than 100 feet. What happens if a change in elevation is not available to allow the piping to experience
FIGURE B13.70   A typical common sump system with a pressurized discharge header.

the minimum change in elevation required to sustain the minimum required slope? The normal procedure in this instance is to drain all horizontal underground headers into a common sump and then pump the fluids involved by use of a sump pump through a pressure-force main. When this method is used, the underground header should be designed as a pressure pipe, according to all the rules of design for pressure pipes described throughout this book.

An example of a system of this type is illustrated in the plan view shown in Fig. B13.70. When such a design is used, the sump may have to be provided with an integral liner and the interstitial space monitored for leaks, as it is in effect an underground storage tank. Local authorities having jurisdiction vary in their interpretation of this type of arrangement; thus, it is important to consult with them on any given project.

Underground Fitting-in-Manhole Arrangements

In nonpressure and pressure systems that are installed underground, it is common to avoid direct burial of double-containment fittings. Most direct burial of double containment fittings is limited to bends and elbows. The direct burial of branch fittings is often avoided due to the difficulty in installing these fittings underground, leak detection concerns, and other reasons. Where there is a substantial amount of thermal expansion and contraction expected, the installation of double containment fittings underground of all types is usually avoided.

A common design approach for underground system (pressure and nonpressure) layout of fittings is to place single-walled fitting connections inside secondary con-
FIGURE B13.71a   Plan details for manhole MH01 from Fig. B13.69.

tainment manholes. In most situations, it becomes more economical to terminate secondary-containment piping in the entry to a secondary containment manhole, thereby making use of single-walled fittings. Manholes, if constructed of lined or protected concrete, effectively serve as a means of secondary containment. Any secondary containment piping penetrations can be made watertight by the use of mechanical seals, by welding secondary containment piping to manholes (if a compatible lining material is used), or by using a waterstop with grouting applied

FRONT ELEVATION VIEW
FIGURE B13.71b   Front elevation details for MH01 from Fig. B13.69.
FIGURE B13.72   An example of a valve contained inside a secondary containment open sump.

around the outer pipe circumference. Grouting can also be applied on the inside, outside, or both.

If manholes are designed to be readily accessible, primary piping fittings can be joined by using flanges. This greatly aids in the installation of such items, and makes maintenance easier. In addition, expansion joints can be incorporated in the layout, being positioned between the fittings and the pipe flanges. This can serve as a means of alleviating thermal expansion in the straight pipe sections (if the primary piping is designed in an unrestrained manner) and serves as a means of isolating fittings and complex fitting arrangements. As examples of possible designs, details of underground fitting manhole arrangements, for manhole MH01 that is referenced in Fig. B13.69, is shown in Fig. B13.71. An example of a valve in a secondary containment manhole is shown in Fig. B13.72.

When using a lined or coated concrete structure as a means of secondary containment, it is necessary to incorporate some means of leak detection in such structures. This is due to the fact that single-walled fittings in such structures, or their flange connections, may be a source of leaks. Furthermore, double containment pipes that have a non-open-ended annulus at the entry to such structures may also have some means of leak detection added to the straight pipe sections as well.

As an alternative design, the arrangement shown in Fig. B13.73 may be used. In the alternative arrangement, the fitting area that is positioned in the manhole is part of an uninterrupted double
FIGURE B13.73   A plan view of a manhole detail whereby the piping components housed within feature continuous double containment.

containment piping zone. The arrangement may be positioned as such to allow for easier installation of the fitting or fittings, incorporation of leak detection connections, future easy access, etcetera. When this type of arrangement is used, a manhole does not always have to be lined or coated, nor does it have to be provided with its own leak detection.

Thermal Expansion Layout

Using Internally Flexible Systems for Handling Differential Thermal Expansion. When adequate room to prevent contact due to differential expansion and contraction between primary and secondary containment elbows does not exist, the diameter of secondary containment elbows may be increased to allow primary elbows sufficient room to flex. In systems that have a significant amount of thermal expansion, expansion loops, offsets, or additional changes of direction might be required to achieve the desired level of flexibility. Alternatively, expansion joints may be added into the inner or outer pipe sections. Most nonmetallic materials have a linear coefficient of thermal expansion that is far greater than that of metals; additionally, they are subject to early failure due to creep-strain accumulation when they are designed in a restrained fashion. RTRP materials do not yield, and as such, they must be laid out with sufficient flexibility to avoid premature failure. However, due to the design of certain components and the high strength of machine-made RTRP components, it is usually best to lay out machine-made RTRP systems as restrained systems. This section discusses the different unrestrained possibilities for accommodating differential thermal expansion in these systems.

Expansion Joints in Double Containment Systems. Expansion joints may be used in principle on both primary and secondary containment piping systems. They may be used in both primary, and secondary containment portions of nonstrained systems. However, there are many limitations to their use. If expansion joints are to be used as part of a primary, piping system, ready access to the expansion joint must also be included in the design. This means provision of a tank or access device as a component of the secondary containment system. In underground systems, the use of expansion joints for compensation of primary pipes is limited to manholes or where a trench is used as a means of secondary containment. On the other hand, expansion joints may be readily applied to secondary containment pipes in aboveground, nonrestrained systems to compensate for differential thermal expansion. This is true regardless of which pipe is experiencing the larger temperature change.

Use of Directional Changes (Elbows) to Accommodate Expansion of Double Containment Pipe Straight Sections. The natural changes of direction (elbows) that exist in any system can be used to accommodate thermal expansion and contraction. Additional changes of direction may also be added to the layout to increase the amount of flexibility inherent in a system. By doing so, stresses will be minimized and the distribution of stresses will be better balanced. Directional changes, like loops and offsets, can be positioned in a horizontal or vertical configuration. Like the two-elbow offset, they also can be rotated at any angle. An elbow used in this fashion is sometimes referred to as freely floating.
FIGURE B13.74 A patented subassembly of a double containment system incorporating "internal-flexibility" by means of specialized elements that maximize flexibility of the carrier components and minimize stresses and the resulting strains on the subassembly components. The commercially licensed arrangement for thermoplastic systems is sold under the trade name Rionflex™. *(U.S. Patents: 5,482,088, 5,715,587, 5,690,148, 5,452,922, 5,901,753; 5,862,834, 5,197,518; others may apply; further patents pending; Orion Fittings, Inc.)*

Figure B13.74 illustrates the important aspects of a patented directional change assembly designed to accommodate large-magnitude differential expansion and contraction in a double containment piping system.

Two major design considerations are involved when using an elbow to accommodate thermal expansion and contraction. The first involves whether or not an inner elbow will come in contact with its associated outer elbow due to differential movements of the two systems. If they do contact each other, substantial stresses may develop in both primary and secondary containment components, which may lead to a premature double failure. To determine if this is possible, and thus if sufficient space exists, a dimensional analysis must be conducted.

A second major design issue involves the closest point of lateral restraint from the inner or outer elbow. Each elbow that requires movement must have its closest points of lateral restraint on each side far enough away so that adequate flexibility is provided to the elbow. The closest point that will provide lateral restraint to a primary-pipe elbow is where inner and outer components come in contact with each other whenever they are allowed to do so. If a system is designed such that inner and outer component contact is prevented through adequate annular space, the interstitial support that is closest to the elbow on each side will become the point of closest lateral restraint in most applications. There are interstitial supports that do not function as points of lateral restraint in horizontally positioned systems,
FIGURE B13.75 A patented double containment expansion loop subassembly incorporating "internal-flexibility" by means of specialized elements that maximize flexibility of the carrier components and minimize stresses and the resulting strains on the subassembly components. The commercially licensed arrangement for thermoplastic systems is sold under the trade name Rionflex™. *(U.S. Patents: 5,482,088, 5,715,587, 5,690,148, 5,452,922, 5,901,753; 5,862,834, 5,197,518; others may apply; further patents pending; Orion Fittings, Inc.)*

which is referred to as a flexibility support. An example is illustrated in Fig. B13.25 and Fig. B13.26.

The analysis of aboveground secondary containment elbows may be treated similarly to the way that aboveground single-wall-piping elbows are. However, the added rigidity that interstitial supports provide, in terms of adding resistance to bending, must be included in any design. If a system is permanently and rigidly interconnected with frequency (i.e., a simultaneously fused system or a restrained-fitting RTRP system), there will be greatly added resistance to bending for the secondary containment elbows. Underground, direct-buried piping is substantially restrained from moving in most cases.

Expansion Loop Design for Double Containment Pipes.   Where other methods are not suitable, expansion loops offer an alternative method to compensate for thermal expansion and contraction. Loops may be positioned vertically or horizontally and may vary in configuration. They may be used in horizontal or vertical piping sections. One conventional approach for calculating the size of an expansion loop in a single-walled pipe is by using the guided-cantilever-beam theory. This approach assumes that piping demonstrates substantial elasticity and assumes limited piping rotation of the ends of each straight run. It also assumes that the loop consists of two cantilever beams, each with one end fixed and concentrated loads applied at their free ends. Figure B13.75 shows a standard four-elbow 90°-expansion loop in a double containment piping system. Figure B13.76 illustrates an expansion loop assembly involving four 45° elbows.

Expansion Offset Design for Double Containment Piping.   An expansion offset assembly is very similar to an expansion loop. The design requires the same general rules applied to expansion loop design sizing. Expansion offsets can also be positioned in either a horizontal or vertical configuration. The conventional method for calculating the size of expansion offsets in a single-walled pipe is by the use of the guided-cantilever-beam theory. This approach assumes that the piping demonstrates substantial elasticity and assumes the ends of the pipe are restrained against rotation. It also assumes that a pipe offset behaves as a cantilever beam, with one end fixed
FIGURE B13.76 Variation of the patented expansion loop subassembly shown in Figure B13.77 whereby 45° elbows are used in place of 90° elbows to minimize horizontal laying width. This type of arrangement is often preferred for gravity-drain systems. The commercially licensed arrangement for thermoplastic systems is sold under the trade name Rionflex™. *(U.S. Patents: 5,482,088, 5,715,587, 5,690,148, 5,452,922, 5,901,753; 5,862,834, 5,197,518; others may apply; further patents pending; Orion Fittings, Inc.)*

and a concentrated load applied at its free end. Figure B13.77 illustrates an example of an expansion offset in a double containment piping system.

Installation-Related Layout Issues for Nonpressure and Pressure Piping Systems

Types of Secondary Closures and Their Locations.   Secondary closures consist of closures that are used to seal gaps remaining in a secondary containment piping system assembled using a staggered joining sequence in order to complete a contain-
FIGURE B13.77 An example of a Z-bend offset subassembly of a double containment system incorporating "internal-flexibility" by means of specialized elements that maximize flexibility of the carrier components and minimize stresses and the resulting strains on the subassembly components. FIGURE B13.78a   Illustration of a gap in a double-containment pipe. *(Source: Guardian division of Eslon Thermoplastics, Inc.)*

ment casing. Many secondary closure methods exist; however, they may be divided into two basic types: end-type closures (terminations) and midline closures.

End closures are described earlier in this chapter; midline-type secondary closures are discussed here. Midline closures are required whenever a gap exists either in a straight pipe section or in a secondary containment fitting. They are applicable mainly to systems where staggered welding is used as the sequence for joining and whenever sections are prefabricated. A gap in straight pipe section of a secondary containment pipe requiring a midline secondary closure is illustrated in Fig. B13.78. This type of gap exists for systems that use a staggered joining sequence.

There are a many options to complete containment casings where such a gap
FIGURE B13.78b   Shown here is the tubular slip-coupling after it is telescoped into position and welded on both ends to close the gap. *(Guardian Division of Eslon Thermoplastics, Inc.)*

CLAM—SHELL COUPLING
FIGURE B13.79   Cross-sectional view of an assembled clam-shell coupling.

exists in straight pipe sections. Four basic welded (bonded) types include: (1) split-pipe sections or *clam-shell* couplings, (2) weld wraps, (3) sheet wraps, and (4) slip couplings. These four types are illustrated in their as-installed condition, designed to close a midline gap, in Figs. B13.79 through B13.82. Figure B13.83 is a photograph of a slip coupling being installed into an 8-in (200 mm) nominal-diameter secondary containment polyolefin pipe.

When secondary fittings are manufactured in two halves as clam-shell fittings, they can also serve as the point of closure in the jacket in lieu of, or in-addition to, having gaps in the straight pipe sections. Examples of fiberglass clam-shell fittings are shown in Fig. B13.84.

Simultaneous Fusion

An alternative sequence of constructing a double containment piping assembly is termed *simultaneous fusion* and pertains only to systems composed of thermoplastic piping inner and outer components. Simultaneous fusion is most readily applied to heat-element-based butt-fusion-based thermoplastic systems due to the ability to

WELD—WRAP
7" DIA TUBING x .187
WALL THICKNESS

3" PIPE

6" PIPE
FIGURE B13.80   Cross-sectional view of a weld-wrap assembly.
FIGURE B13.81   Cross-sectional view of an assembled sheet wrap.

combine primary and secondary containment pipe sizes that are relatively close in diameter. The method can also be applied to small-diameter heat-element-based socket-fusion systems and solvent-cement-based socket systems. However, the necessary tools are not readily available, and if they were, it would be difficult to get them.

The object of any simultaneous fusion system is to prepare both primary and secondary containment components so that they are permanently fixed to each other and can thus be joined to a mating set of components. In some systems, simultaneous fusion can be used to join 100 percent of all components involved in the piping system. It can also be selectively used for situations where staggered welding is the primary method, in lieu of using secondary closures. Simultaneous fusion can substantially reduce overall labor involved on a project, unless primary piping joints leak upon initial pressure test. However, the inspection of primary welds is substantially limited, and the method is best suited for applications where a flexible (unrestrained) layout is not required. A simultaneously welded system will typically result in a structurally more rigid assembly.

Simultaneous fusion is more easily applied to systems that have identical primary and secondary containment materials. If a heat-element butt-fusion-based system is used, the materials should have a welding temperature range that overlaps and specific welding pressures that are nearly the same.

The procedure for simultaneous fusion is illustrated in Figs. B13.85a through
FIGURE B13.82   Cross-sectional view of an assembled slip-coupling.

FIGURE B13.83 A tubular slip-coupling is bonded to the secondary containment coupling using hot-air welding in a thermoplastic double containment piping system. *(Grewe Plastics)*

B13.85l. The single most important consideration in performing simultaneous fusion is that the components should be prefabricated so that they align on the same plane at their ends; the alignment must occur within very close tolerances ($< 5\%$ of diameter). The standards according to DIN, and accepted worldwide, requires that thermoplastic butt-fusion pipes be aligned to within 10 percent of their wall thicknesses in terms of their diametrical alignment. Therefore, the use of thick-walled pipes (SDR 17.6 or thicker) as the material of the primary pipes for primary pipes 8-in nominal diameter (approximately 200 mm ISO 161/1 outside diameter) and below is highly recommended.

Secondary Containment of Valves in Double Containment Piping Systems

Valves present unique layout concerns for double containment piping systems. By their nature, they are designed to be operating mechanical devices. Their operation can be either by manual or some automatic means (i.e., pneumatic or electrical operation). Either way, they require a considerable degree of access for either operation or maintenance purposes. Various valve types commonly encountered in chemical piping are discussed in this section, along with their associated layout alternatives.

Wherever possible, valve use should be maintained outside zones of pressurized secondary containment. By maintaining valves and other high-maintenance-operating mechanical items outside zones of secondary containment, added system complexity may be avoided. Whenever a valve must be added to a primary pipe system that is required to have pressurized secondary containment, there will be added expense. The added expense arises from the need to contain the valve in such a manner so as to enable ready access to its secondary containment housing, yet maintain its containment in a pressure-tight manner between times when access is required. Since valves are common sources of leaks and vapor emissions, additional and frequent maintenance of a double containment piping system will be required due to the increase in detected leaks. Thus it is much simpler and more cost effective to maintain a primary-pipe-system valve outside a zone of pressurized secondary containment.

Valves may still be secondarily contained; they just cannot be easily and inexpensively housed and still meet the necessary requirements. A common way to provide containment for such a valve is by the use of a lined or coated concrete dike, berm, or building floor in an aboveground application and by the use of a lined or coated concrete sump or accessible manhole in an underground application.

Valves may also be required as part of the secondary containment piping system (i.e., vent and drain valves, leak-detection and instrumentation isolation valves, etc.). These valves are usually small diameter (< 2 in, 63 mm) and of the quarter-turn (on-off) variety. They are usually not required to be contained; however, as part of an underground system, they must be positioned inside a concrete housing (which does not normally have to be lined) in order to be accessed and operated and to prevent their being directly buried.

Multiple Primary Pipe and Common Secondary Containment Pipe Systems

Multiple primary pipe systems (housed within a common secondary containment pipe) present additional layout complications beyond the ordinary complications discussed in this chapter for a single-walled pipe within a single secondary containment pipe. Many of the complications arise from the increased importance of the orientation of the primary pipes within the common secondary containment pipe. In such systems, the following factors have to be well thought out: (1) secondary containment sections must be initiated; (2) primary pipes have to follow bends; (3) in some systems they pick up branches along the way; and (4) secondary containment sections are eventually terminated. Throughout a system of this type, the pipes must maintain their relative positions within the cross-sectional plane.

Multiple pipe systems by their nature require additional detailed drawings to be prepared, as compared to single primary piping double containment systems. This is due to the fact that there are many more details to consider in order to create a successfully installed system. The details should include enough information

to determine the method and spacing of supporting devices, termination and initiation arrangements and parts, welds (bonds) at each of these areas, and any other instructions the fabricator might need. The additional costs of fabrication, engineering, and capital costs of enlarged secondary containment pipes make multiple-pipe systems more expensive than running a series of individually contained primary pipes, in many situations. They also tend to be difficult to repair or modify. Therefore, secondary containment of multiple pipes should only be considered where space is limited. Common secondary containment of underground multiple pipes may be better accomplished with the use of lined tunnels (manways or walkways) or lined trenches. An example of a common secondary containment trench designed to house multiple primary pipes is shown in Fig. B13.67.

Rotation in Multiple Primary Pipe and Common Secondary Containment Pipe Systems. An issue that arises in the design and layout of multiple primary pipe systems is called *rotation*. In rotation of multiple primary pipe systems, the pipes change their relative orientation in the cross section of the bundle after a change in direction. This will occur whenever a vertical pipe directional change occurs, followed by a perpendicular change in direction. This is illustrated in Fig. B13.86. If each of the four lines is followed, it can be noticed that they all change orientation.
FIGURE B13.86   Example of "rotation" in a multiple carrier pipe system. Note that the relative orientation of "a" through "d" change after undergoing two changes of directions. *(Reprinted with permission from* Chemical Engineering, *Sept. 1991, Copyright 1991, by McGraw-Hill, Inc. with all rights reserved).*
FIGURE B13.87   Rotation in multiple pipe systems can be corrected by the addition of an additional elbow in some circumstances. Note how the overall orientation of (a) through (d) remain the same after the addition of the third elbow. *(Reprinted with permission from* Chemical Engineering, *Sept. 1991, Copyright 1991, by McGraw-Hill, Inc. with all rights reserved).*

Rotation in and of itself is not a bad situation. However, it can be an undesirable feature if the carrier pipes are to maintain their original positions, due to equipment connections, maintaining positions for branch connections, et cetera. To prevent rotation, a third elbow can be added into the system, as illustrated in Fig. B13.87.

LEAK DETECTION METHODS
AND REQUIREMENTS

Overview of Leak Detection

Leak detection is one of the most important aspects of double containment piping and double-walled tank systems. Without an effective and reliable means to sense that a leak has occurred, the additional protection otherwise added by means of providing secondary containment may be compromised. Once a fluid leaks into an annulus of a pipe or the interstice of a tank, there is no longer any means to contain the leaked fluid secondarily; only a primary means of containment exists at that

point, that is, unless tertiary containment has been incorporated into a system design (e.g., placing the double-walled pipe or tank into a tertiary concrete structure).

Left undetected, a fluid may have a chance to corrode through its secondary containment casing, or may find its way through defects in the containment to the surrounding environment. It is important that a leak be detected as early as possible so that any chance of fluid escaping to the surrounding environment is minimized. A system whose leaks are detected early can be repaired right away and quickly returned to its original safe working condition.

Both single-walled and double containment piping systems may be monitored for leaks by a wide variety of methods. There are likewise numerous methods to detect leaks that originate from single-walled or double-walled tanks and vessels. Both double containment piping and any associated tanks and vessels can be equipped with automatic sensing mechanisms to continuously monitor and activate an alarm as soon as system upset occurs. Alternatively, manual and visual leak detection methods may be incorporated by adding the necessary components into the design of a system. In addition to interstitial monitoring, there are both internal methods and external methods that exist to monitor for leaks, although most of these methods work best for tanks (as opposed to pipes). More than one method of leak detection may be used as a means of redundancy.

The successful implementation of any leak detection system is related to many different aspects of the design and installation of a piping and associated tank system. On any given project, it is essential that leak detection be considered from the conceptual phase of the project. By doing so, any needed design details or installation procedures may be taken into account from the start and carefully coordinated. When a project follows this practice, costly design changes and construction delays or problems can be avoided. The best overall result is achieved when leak-detection decisions are considered from the very start of a project.

Leak Detection Cable Systems

Continuous line-leak–sensing and locating systems, commonly referred to as *leak detection cable,* have been installed in many double-containment piping systems. The appeal of leak detection cable is that approximate locations of leaks can be sensed early after a leak occurs. Several types exist, each based upon the continuous measurement of an energy source, thereby monitoring for changes in the energy source behavior. The two most common methods include: (1) conductance (resistance) -based cable systems, whereby the conductance (resistance) of an electrical signal is continuously measured; and (2) impedance-based systems, also referred to as TDR (time-domain-reflectometry) systems, whereby the impedance of an energy pulse wavelength is continuously monitored against a set pattern to detect changes. Each has subtle differences and capabilities; both are capable of performing their desired functions, namely, determining the approximate location of a leak and alarming a user as to its existence.

In one type of conductance-based cable, which is intended to sense conductive fluids, an electrical current is short circuited when a fluid bridges a gap between sensor and signal wires. Resistance monitoring is a straight-forward concept that applies Ohm's law to determine the location of a short. It is a method that can immediately sense small leaks, even over relatively long lengths of cable. Thus it has relatively sensitive reporting capabilities and is a well-proved technology. Unless condensation is eliminated or controlled, versions of conductivity-based cable which

is designed to detect conductive fluids will report false leak signals due to its sensitivity.

Impedance-based (TDR) leak-detection cable technology is based on the measurement of the impedance of an energy pulse and is similar in concept to radar technology. It has the subtle advantage of locating multiple leaks if a prior leak is of small magnitude and confined to a local area. Impedance-based systems compare favorably with conductance-based systems, although impedance methods lack some of the precision inherent in resistance-based methods. This is particularly true if a leak occurs at the far end of a long length of cable.

Thus, both types of cable technologies have subtle differences that could prove useful for a given design condition. For instance, it was mentioned that conductance-based cables have the ability to detect very small leaks (some are capable of signaling a leak with < 0.25 in of cable length wetted, when fully immersed), thereby aiding in early detection of a leak. The ability to detect a leak early can help to limit the total quantity of a leak (release). Accordingly, the amount of work to repair a piping system could be kept to a smaller scope. If a leak were to remain undetected for a longer time, there is greater potential for more work to be involved in the repair of the system.

A unique feature of TDR-based technology is the ability to detect multiple leaks. This feature is interesting, but there are limited applications where it is of benefit. To continue to operate a double containment piping system once a leak has been detected is a somewhat self-defeating practice for the concept of double containment. Good operating practices suggest that a system be immediately repaired upon the detection of a leak. In fact, RCRA requirements in the United States would not allow a user to continue to operate a regulated system once an initial leak has been detected.

In order for a TDR-based cable to detect a second leak once the first has occurred, the system must map over the first leak. When this occurs, the cable sensing system is subject to a signal-attenuation effect, which will lead to a reduced sensitivity. Figure B13.88 graphically shows this effect, based upon a first leak at 150 ft down a TDR cable's length. The sensitivity of the TDR cable, as measured by an amount of wetted cable required to create an alarm condition, depends on the magnitude of the mapped-over leak, as shown in Fig. B13.88. However, it also depends on the distance of the first leak from the source of the signal. Sensitivity values will improve for TDR-based sensor cables exposed to fluids at less than the effective range; alternatively stated, this also means that sensitivity will lessen as cables are exposed to fluids at greater than the effective range.

Leaks that occur in a near-simultaneous manner could be detected using mapping-over techniques in a TDR-based system. However, it is very rare for multiple leaks to occur simultaneously once hydrostatic testing has been concluded. The time when multiple leaks may be reasonably expected to occur is during an initial primary-pipe hydrostatic test. Thus, having a cable of this type in place during initial pressure testing might be desirable. However, cable systems are not recommended to be installed prior to, or during, a hydrostatic-pressure test, according to manufacturers of both resistance-based and TDR-based sensing cables. Pull cable should always be installed first and left in place during pressure testing. Only upon completion of all testing should actual cable be installed. Thus, the ability to detect multiple leaks is of little real benefit.

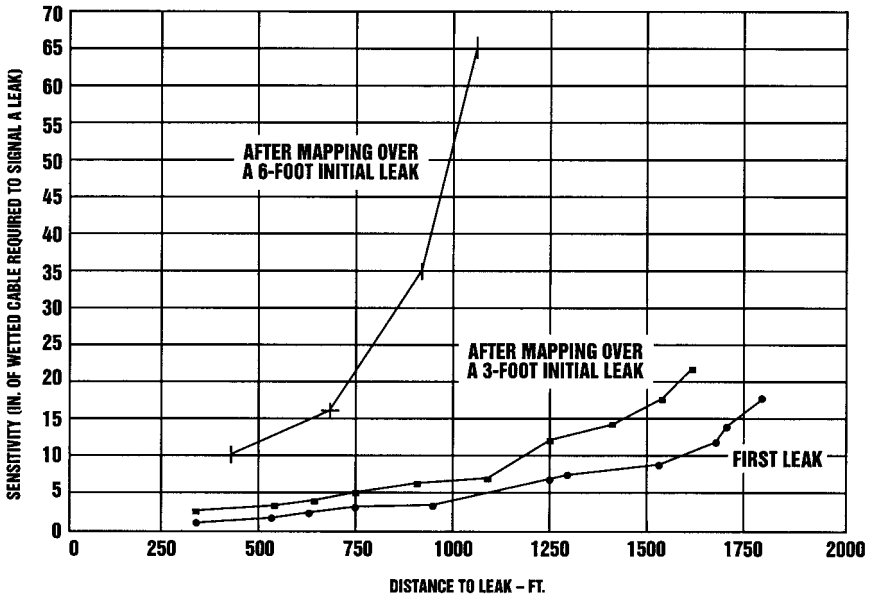
Another difference between the two cable technologies involves their sensitivity in detecting a first leak, in relation to their overall length. For resistance-based systems, sensitivity is nearly constant over the full length of a cable, even for very long lengths (> 1000 ft). Sensitivities of TDR-based cables do vary according to


FIGURE B13.88   Response of a typical TDR-based cable to a second leak, based upon a first leak that occurs 150 ft away. Data is shown for a leak that spreads 3 ft, and for one that spreads 6 ft. First leak data is shown for comparison. *(Source: Based on test data supplied by Raychem Corp.)*

length, however. The farther down the length of cable, the greater the wetted length of cable required to create an alarm condition, due to signal attenuation. For a long pipeline (>1000 ft), this effect can be significant, as illustrated by Fig. B13.89.

Both resistance-based and TDR-based cable sensing systems claim an accuracy in detecting leak location to within plus or minus 1 percent of the total cable length, or 5 ft, whichever is greater. Accuracy of leak location is functionally different from cable sensitivity. In assessing the performance capability of a leak detection cable system, one needs to consider both the claimed accuracy and the sensitivity of the cable to obtain a complete picture.

Installation of leak detection cable requires carefully planned coordination with other aspects of the piping system installation or associated tanks. It also requires that close inspection and control practices be followed during an installation. These functions can either be provided by outside inspectors or by the installers of the cable systems, provided they receive adequate training. Each detail must be carefully considered, both in the engineering design and during the installation process. Detailed requirements should be clearly described in project plans and specifications.

Leak Detection Cable System Component Detail.   There are many individual components that collectively make up a continuous sensing cable system. The exact design of components varies by manufacturer, and not all systems require the same type of components. For instance, some cable manufacturers do not use connectors to install straight lengths of cable. Instead, they use continuous cable spliced together
FIGURE B13.89 Sensitivity of a typical TDR-based cable based on the length down the cable where a leak occurs. *(Source: Based on test data supplied by Raychem Corp.)*

at the ends. Examples of a variety of cable constructions are illustrated in Fig. B13.90 and Fig. B13.91.

The major components that may be encountered in any leak-detection cable system, aside from the alarm panel, consist of: (1) cable, (2) jumper cable, (3) jumper feedthrough fitting, (4) feedthrough assembly, (5) branch connector, and (6) termination device. All cable systems utilize cable, jumper cable, and some type of jumper feedthrough fitting. However, the actual design of the components varies considerably from manufacturer to manufacturer.

Probe Monitoring Systems

Leak detection may be effectively pro-vided by dividing a double containment piping system's annulus into separate, isolated leak detection compartments. Each compartment may then be moni-tored with some form of probe measur-ing device. The types of probes typically used include: (1) liquid level sensing, (2) moisture detection, (3) vapor detection, (4) conductivity and resistivity, (5) pH measurement, (6) pressure sensing, (7) flow measurement (primary piping), (8) density measurement, (9) wavelengths (light, radar, and sonar), (10) motion de-tection, and (11) others. While providing compartments in an annulus may be
FIGURE B13.90a Example of the construc-tion of a typical conductance-based leak-detec-tion cable, which is specific to conductive fluids. *(Source: Raychem Corp.)*
Sensing cables are specifically designed to detect either aqueous or hydrocarbon-based liquids. A unique branching connector lets locating systems follow complex, branching pipelines.

FIGURE B13.90b   Example of the construction of a typical conductance-based leak-detection cable that is specific to nonconductive fluids. *(Source: Raychem Corp.)*

the most efficient means of incorporating a point probe–based detection system, it is not the only approach. Point-probe systems may also be used in a system designed with a continuous annulus, although the ability to locate a leak reasonably is significantly less.

Normally, probes are housed within a branch outlet, or reducing-branch outlet, which is provided in the secondary containment pipe. Examples of possible arrangements are shown in Figs. B13.92 and B13.93. Such arrangements often function as a means to house a probe, in addition to functioning as a combination low-point drain (high-point vent) and manual detection point. Normally, probe systems are
FIGURE B13.91a   Example of the construction of a TDR-based cable designed to detect corrosive chemicals. *(Source: Midwesco)*

FIGURE B13.91b   Example of the construction of a TDR-based cable designed to detect hydrocarbons. *(Source: Midwesco)*

more readily applied to aboveground systems. In underground systems, probes can be attached at manhole locations using the branch arrangement illustrated in Fig. B13.93, immediately after piping-manhole penetration.

Liquid Level Sensing. Detection of a fixed level of liquid is among the simplest probe systems to design and implement in a double containment piping system. A liquid level system will function in a very reliable manner to detect leaks. However, it will not distinguish between water (including groundwater or condensate) and service fluids. In this type

FIGURE B13.91c Example of the construction of a TDR-based cable designed to detect water and hydrocarbon fluids in addition to steam and hot water up to 400°F. *(Source: Midwesco)*

of system it is important to have a pressure-tight annulus and to eliminate condensation by providing a moisture-free inert gas in the annulus (both items are important for most methods of sensing leaks). A liquid level detection system can be implemented by installing a liquid level measuring device in a vertically positioned dropleg branch, as shown in Figs. B13.92 and B13.93, or in low-point sumps such as those shown in Figs. B13.94 through B13.97.

A liquid level probe (or probes) may be connected to an alarm panel that signals an alarm when a specified level of liquid is detected. The system is good for establishing a leak in a certain zone of an annulus. It will not allow the source of a leak to be specifically identified within a leak zone, however. Also, it is not designed to detect small leaks quickly caused by a spraying but will rapidly respond to major leaks. A liquid level sensing system may be coupled with other types of probes to distinguish between types of fluids, resulting in a very effective overall approach to detecting leaks.

Moisture Detection. Moisture probes are useful for detecting the presence of groundwater or service fluids that have a high water content. There is a wide variety of types of probes available; the sensitivities of available probes vary widely. The

FIGURE B13.92 Illustration of a downward-positioned probe attachment for a horizontally mounted liquid-level sensor future attachment.
FIGURE B13.93   Illustration of a probe attachment in a manhole location.

wide range of moisture probe styles available allows a system designer to select a customized system designed for a specific application.

A moisture probe system can be implemented by installing a moisture measuring device in a vertically positioned drop-leg branch. A branch for a probe of this type need not be at the 6 o'clock position of an annulus. Most sensitive probes can be positioned at the 12 o'clock position of an annulus, since they detect fine vapors.

A moisture probe (or probes) may be connected to an alarm panel that signals

when a change in moisture content of the annular space is detected. Such a system is good for verifying that a leak of a primary service fluid has occurred in a certain zone of the annulus. It will not allow the position of a leak to be specifically located within a leak zone. However, it can be good for detecting small leaks if the probe used is highly sensitive.

Vapor Detection.   Vapor detection systems are very similar to moisture detection systems, except that vapor probes detect volatile chemicals other than water. This type of probe is normally designed to detect fluids that have high vapor pressures, including organic chemicals, halogens, and other chemicals that are relatively volatile. There are many types of vapor probes available with varying values of sensitivity. The type of organic chemical being carried in a primary piping system will determine the type of probe that should be selected for any given application. The sensitivity of the probe to be selected is based upon the type of leak to be detected (e.g., small leak versus major leak), although most vapor probes tend to be highly sensitive compared to other forms of leak detection. When an earlier response is desired, a probe that has a greater sensitivity is desirable.

Conductivity (Resistivity) Measurement.   The conductivity or resistivity of an annular space can be measured to detect whether a leak has occurred. This type of probe measurement system is most effectively used in conjunction with a liquid level or pressure sensing system as a means of classifying the type of fluid being sensed. In such an arrangement, liquid-level or pressure monitoring may be used as the primary system to detect the presence of fluids. The conductivity (resistivity) probe will then help to distinguish between water from groundwater or condensation and the service fluid (which must be of the conductive type), based on a change in conductivity. Conductive fluids include such fluids as acids, bases, salts, other organic chemicals, and a host of polar and semipolar organic solvents. Conductivity probes have also been used as the sole means of detection for double containment piping systems.

Conductivity probe systems can be incorporated into a double containment pipe annulus by installing a conductivity measuring device in a vertically positioned drop-leg branch or low point sump. The probe (or probes) may then be connected

to a computer or recording device to record the conductivity continually, or may be directly connected to an audio alarm. Monitoring conductivity is good for identifying the fluid that has leaked but can also be used as the sole means to sense for leaks. Conductivity probes can detect small leaks in addition to major leaks. In a very general sense, leak detection cable is a form of conductivity (resistivity) probe. This is not the primary purpose of leak detection cable, but it has been used in this manner. Therefore, a short section of leak detection cable could theoretically be used as part of a point sensing approach.

pH Probes.   A pH measurement probe functions in much the same way as a conductivity (resistivity) measurement system. However, pH measurement is limited to detection of acids or bases as only this type of chemical can be measured in terms of pH. Since pH measuring devices are mostly designed to function in a wetted capacity, they normally are used as a secondary means of detection, in combination with some other type of probe. A pH probe system can be implemented by installing a pH measuring device in a vertically positioned drop-leg branch or low point sump. The probe (or probes) may be connected to an alarm panel that signals when a change in pH is detected. The system is good for classifying whether a leak of a primary service fluid has occurred in a certain annular zone by reporting its pH value. It will not allow a leak's location to be specifically identified within a given leak zone. It is best used in conjunction with some other leak detection method.

Flow Measurement.   A change in flow of primary piping may be related to the possibility that a leak has occurred. The means for accomplishing flow monitoring is to place a flow measuring device at the beginning and end of the piping system. If the flow of the primary pipe changes by more than a set amount, an alarm can be sounded. This method is good for detecting large leaks. However, it may not detect a fine spraying of fluid, such as would initially occur in a ductile material that is subject to stress cracking (e. g., polypropylene). Flow measurement can be very effective when used in conjunction with other methods.

Pressure Sensing.   The pressure of an annular space can be measured to determine changes in pressure. A pressure change can be used to determine whether primary or secondary containment has been breached, making it a very useful form of monitoring. The value and sign of the pressure change depend on the relative pressures of the annular space, the primary (core) pipe, and the pressure of the surrounding local atmosphere. For pressurized primary piping systems, a failure of the primary piping systems can be detected by a pressure rise in its annular space (assuming the annular space is maintained under a lower pressure than its primary pipe). In pressure piping systems where a positive pressure is maintained in its annular space, at an intermediate pressure between the primary pressure and the external environment, a drop in annular pressure will reflect a failure (breach) of the secondary containment system.

For drainage systems that maintain an annular space under a positive pressure, a pressure drop can signal a leak in the primary piping. However, a pressure drop in this type of system could also mean that the secondary containment has been breached. Therefore, a further investigation has to be made, unless a separate probe is added to provide additional information as to the origin of the leak.

Gas that is maintained under a low pressure tends to find its way out of threads, valve seals, et cetera over a period of time. Therefore, some loss of gas could occasionally be expected from secondary containment threaded joints, and resulting

false (low-point) alarms triggered. This must be taken into account in operational training procedures so that false alarms do not lead to a leak detection system's being ignored.

The pressure of a primary piping system can also be monitored. A substantial drop in primary piping pressure will often mean that a leak has occurred somewhere over its length. This type of approach is useful for detecting large leaks.

The pressure of a double-walled tank's interstitial space can also be measured to determine if changes in pressure of a contained gas or liquid (e.g., brine) occur. The value and sign of the pressure change depend on the relative pressures of the interstitial space, the primary tank, and the pressure of the external atmosphere. Most double-walled tanks are for low-pressure service. Therefore, it may be difficult to distinguish between a breach of primary or a secondary containment of a double-walled tank in most applications.

Manual/Visual Monitoring Methods

Noncontinuous sensing of double containment piping systems includes those methods that do not involve the incorporation of any type of continuous measuring device, or instrument, to the secondary containment piping system. The three main categories of noncontinuous sensing include manual detection, visual detection, and periodic annular pressure monitoring.

Manual detection typically is accomplished by adding valves to a secondary containment piping system at various low points in its annulus. The low-point valves can be occasionally opened to detect the presence of fluids. Such valves are normally positioned on drip legs, usually at each low point and other intermediate points of the double-containment piping system annulus.

Manual leak-detection methods are only effective when used as part of a regular inspection program where the system is routinely inspected. Manual systems serve as a very effective secondary means of leak detection, used in conjunction with any other method or methods. It is usually a built-in feature to most well-designed systems, where appropriate low-point drains are provided.

Visual Detection Methods.   Visual detection may be provided in a number of ways. It can be provided for the entire secondary containment piping system or any partial portion. Visual leak detection can be provided by using a transparent material (borosilicate glass, clear PVC, etc.) as the outside piping (and fittings where applicable). A more practical application involves flanging in a short section of clear piping, or providing clear piping or sight glass as part of a secondary containment drip-leg branch. Visual containment can also be provided where an open-ended secondary containment piping system is used, by observing the end of the pipe for fluid leakage. Visual detection is most effectively applied as part of a regular inspection program where the system is routinely inspected. Visual leak detection systems also serve as a very effective secondary means of leak detection, used in combination with any other method.

Periodic Pressure Monitoring.   The pressure of an annulus can be occasionally monitored to detect if a leak has occurred. To do so, a pressure gauge (instead of a transducer) must be provided in an annulus in at least one position. A typical connection for providing a pressure gauge in an annulus is illustrated in Fig. B13.98.

It may be desirable for some installations to maintain an inert gas under pressure and monitor the pressure of the gas. In applications involving pressure-rated primary
FIGURE B13.98   Illustration of a pressure tap in a secondary-containment pipe for attachment of a pressure gauge.

piping, the annulus does not have to be maintained under a fixed pressure. A rise in pressure will signify that a breach of primary containment has occurred. However, it is not possible to detect a breach of secondary containment in such a system, unless a fixed pressure is maintained in the annulus.

Condensation Effects in Annuli

If air that is warm and relatively humid is introduced into the annulus of a double containment piping system prior to final closure, moisture will condense when the system is subjected to a colder temperature. This often occurs when a system is constructed during the summer season and later subjected to cold winter operating temperatures.

Condensation is a common concern among designers and owners-to-be of double containment piping systems, and for very good reasons. The principal concern rests with the fact that a leak detection system may interpret this action as a false alarm. It does depend to some extent on the sensitivity of the leak detection system selected. However, no leak detection method is immune to this effect, including visual and manual means. Frequent false alarms may subsequently lead to ignoring actual alarms on the part of plant operations personnel, a very dangerous practice, and one that is self-defeating to the system. Also, metal materials could be subjected to various corrosion effects produced by the water (galvanic, pitting, microbiologically induced corrosion, etc.). Therefore, there are many reasons to avoid the possibility of condensation in an annulus.

The solution to the condensation dilemma is a simple and inexpensive one. Replace the original air with a dry or inert atmosphere. Alternatively, a vacuum may be pulled into the annular space, if inner and outer pipe components are mechanically strong enough to withstand vacuum conditions. It has been assumed by many that this is a very involved and expensive activity. However, if an annulus is designed in a leak-tight manner and has been provided with adequate high-point vents and drains, this task will actually be one of the least expensive aspects of the

Notes:
1. Table assumes nitrogen to be completely dry at atmosphere pressure and 70°F, and assumes 100% mixing.
2. In many applications, a dew point of $-20°F$ is lower than is necessary. A higher design dew point will require less nitrogen.
3. This table assumes 100% mixing, which yields results that are highly conservative. Actual practice should consume less nitrogen.

entire project. Table B13.1 shows that, for a majority of systems, it takes a relatively small amount of nitrogen to decrease the moisture content of a system to the equivalent of the saturation level (dew point) at $-20°F$, a level at which no condensation could be expected in most applications. Since bottled nitrogen currently (1994) costs approximately $0.14–0.15 (U.S.) per cubic ft when supplied in bottles that hold the gas at 2200 psi (150 bar), the cost for nitrogen will typically be less than $1000.00 (U.S.). The data assume 100 percent mixing in all cases, which is an extremely conservative assumption.

The discussion in the preceding paragraph is valid for systems where the annular space is closed in a leak-tight manner. However, in a system that terminates in an open end (including at a manhole entry), natural draft circulation will occur due to temperature differences between the gas in the annulus and the outside ambient air. This means that moist air eventually will return to the annular space through this process. The answer to this dilemma is that the atmosphere should be replaced initially, and then periodically recharged with the same dry gas to displace the moist air that periodically returns. The period of time for replacing the air will depend on the specifics of the climate, the season of the year, and the layout of the system. Another alternative is to install an air line at the beginning of the annulus from a source that continuously puts out relatively dry air at a pressure slightly higher than atmospheric, thereby continually displacing the volume of air in the system. This would most likely be an overly conservative and expensive approach for most systems, but an alternative none the less. In general, close-ended systems are preferable to open-ended systems so recharging can be minimized.

CHAPTER B14
PRESSURE AND LEAK TESTING

INTRODUCTION

Robert B. Adams

President and CEO
EST Group, Inc.
Harleysville, Pennsylvania

Pressure testing is required by most piping codes to verify that a new, modified, or repaired piping system is capable of safely withstanding its rated pressure and is leak tight. Compliance to piping codes may be mandated by regulatory and enforcement agencies, insurance carriers, or the terms of the contract for the construction of the system. Pressure testing, whether or not legally required, serves the useful purpose of protecting workers and the public.

Pressure testing may also be used to establish a pressure rating for a component or special system for which it is not possible to establish a safe rating by calculation. A prototype of the component or system is subjected to a gradually increasing pressure until measurable yielding first occurs or, alternatively, to the point of rupture. Then by using derating factors specified in the code, or the standard, appropriate to the component or system, it is possible to establish a design pressure rating from the experimental data.

PIPING CODES

There are a great many codes and standards relating to piping systems. Refer to Chap. A4 for a comprehensive listing and overview of codes and standards for piping systems, covering many different applications. Two codes of major importance for pressure and leak testing are the ASME B31 (previously called ANSI B31) Pressure Piping Code and the ASME Boiler and Pressure Vessel Code. While these two codes are applicable to many piping systems, other codes or standards may have to be met as required by the authorities, insurance companies, or the owner of the system. Examples might be AWWA standards for water transmission and distribution system piping.

The ASME B31 Pressure Piping Code has several sections. They are

- ASME B31.1 for Power Piping
- ASME B31.2 for Fuel Gas Piping
- ASME B31.3 for Process Piping
- ASME B31.4 for Liquid Transportation Systems for Hydrocarbons, Liquid Petroleum Gas, Anhydrous Ammonia, and Alcohols

B.651

- ASME B31.5 for Refrigeration Piping
- ASME B31.8 for Gas Transmission and Distribution Piping Systems
- ASME B31.9 for Building Services Piping
- ANSI/ASME B31.11 for Slurry Transportation Piping Systems

The ASME Boiler and Pressure Vessel Code also has several sections which contain pressure and leak testing requirements for piping systems, pressure vessels, and other pressure retaining items. These are

- Section I for Power Boilers
- Section III for Nuclear Power Plant Components
- Section V for Non Destructive Examination
- Section VIII for Pressure Vessels
- Section X for Fiberglass Reinforced Plastic Pressure Vessels
- Section XI for In Service Inspection of Nuclear Power Plant Components

There is great similarity with respect to the requirements and procedures for testing among the many codes. Various leak-testing methods, planning, preparation, execution, documentation, and acceptance standards for pressure testing will be discussed in this chapter. Equipment, useful for pressure testing, will also be included in the discussion. The material that follows should not be considered a substitute for a complete knowledge or careful study of the particular code requirement that must be used to test a particular piping system.

LEAK-TESTING METHODS

There are many different methods for pressure and leak testing in the field. Seven of these are

1. Hydrostatic testing, which uses water or another liquid under pressure
2. Pneumatic or gaseous-fluid testing, which uses air or another gas under pressure
3. A combination of pneumatic and hydrostatic testing, where low pressure air is first used to detect leaks
4. Initial service testing, which involves a leakage inspection when the system is first put into operation
5. Vacuum testing, which uses negative pressure to check for the existence of a leak
6. Static head testing, which is normally done for drain piping with water left in a standpipe for a set period of time
7. Halogen and helium leak detection

Hydrostatic Leak Testing

Hydrostatic testing is the preferred leak-testing method and perhaps the most often used. The most important reason for this is the relative safety of hydrostatic testing compared to pneumatic testing. Water is a much safer fluid test medium than air

because it is nearly incompressible. Therefore, the amount of work required to compress water to a given pressure in a piping system is substantially less than the work required to compress air, or any other gas, to the same pressure. The work of compression is stored in the fluid as a potential energy, which could be released suddenly in the event of a failure during a pressure test. A calculation of the potential energy of air compressed to a pressure of 1000 psig (6900 kPa) compared to the potential energy of the same final volume of water at 1000 psig (6900 kPa) shows a ratio of over 2500 to 1. Therefore, the potential damage to surrounding equipment and personnel resulting from a failure during a pressure test is far more serious when using a gaseous test medium. That is not to say that there is no danger at all in a hydrostatic leak test. There can be substantial danger in a hydrostatic test due to air trapped in the piping. Even if all air is vented from the piping before pressurizing, workers are well advised to conduct any high-pressure test with safety in mind.

Hydrostatic testing may not be practical if during normal operation, the piping system cannot tolerate traces of water or its residue. An example would be a cryogenic system, which operates at a subfreezing temperature for water. The time required for removal of all traces of water prior to placing the system into operation could impede the startup process. Another example would be piping for a liquid sodium system. Traces of water left in the pipe would react violently with the liquid sodium. If another convenient-to-use liquid is not available, it may be more practical to use pneumatic testing.

Another disadvantage of hydrostatic testing may be the cost of disposal of the water if it has become environmentally contaminated from residue in the piping. In addition, it takes more time to fill and empty the system. Furthermore, if the system normally operates with a gaseous medium, the piping may not be strong enough to support the weight of a liquid test medium without additional temporary supports.

Inspection for leaks is a visual examination of all joints for signs of water. The leak-detecting capability of a hydrostatic test is not as good as a pneumatic test and is far less sensitive than a properly conducted halide or helium leak test. A hydrostatic test is sufficiently sensitive if the system normally operates with a liquid. However, if the system normally operates with a gaseous medium and slight leakage of this medium is unacceptable, a hydrostatic test may not be sufficiently sensitive to detect a slight gas leak. The reason for this is that the surface tension of water can act as a barrier to a leakage path that has a very small dimension. A gaseous-fluid test medium will leak through a small space that water will not pass through because of the surface tension of water. If it is sufficient that a system designed to operate a gaseous process is bubble tight, pneumatic testing is appropriate. However, if the leakage requirement is more stringent than bubble tight, halide or helium leak testing would be required. In either case the gaseous test is only more sensitive than the hydrostatic test if the system is completely dry at the time of the test.

Pneumatic Leak Testing

The fluid normally used for a pneumatic test is compressed air, or nitrogen if the source is bottled gas. Nitrogen should not be used in a closed area if the possibility exists that the escaping nitrogen could displace the air in the confined space. Persons have been known to become unconscious under such circumstances before realizing they were short of oxygen.

Because of the greater danger of injury with a gaseous test medium, the pressure that may be used for visual examination for leaks is lower for some piping codes than is the case for a hydrostatic test. For example, for pneumatic tests, ASME B31.1 permits the pressure to be reduced to the lower of 100 psig (690 kPa) or the design pressure during the examination for leakage. If the pressure required by the code is quite high, persons may be barred from the test area and sonic listening devices used to search for leaks. However, normally inspection for a leak is done with a soapy-water mixture that is applied to the joints and which produces bubbles when air is escaping. The applicable code may specify that pneumatic testing can only be done with the approval of the owner of the system (for example, ASME B31.1 section 137.5.1 and B31.3 section 345.5.1).

Combination Pneumatic and Hydrostatic Testing

A low air pressure, most often 25 psig, (175 kPa) is first used to see if there are major leaks. This low pressure reduces the danger of personal injury but still enables major leaks to be quickly located. Repairs, if needed, can then be done before the hydrostatic test. This method can be very effective in saving time, particularly if it takes a long time to fill a system with water only to find leaks on the first try. If leaks are found in a hydrostatic test, it will take longer to remove the water and dry the piping sufficiently to make repairs.

Hydrostatic-pneumatic leak testing is different from the two-step test in the preceding paragraph. In this case the pressure test is conducted with a combination of air and water. For example, a pressure vessel designed to contain a process liquid with a vapor phase or air above the liquid may have been designed to support the weight of liquid to a certain maximum-expected height of liquid. If the vessel was not designed to support the weight when completely filled with liquid, it would be possible to test this vessel only if it was partially filled with process fluid to a level duplicating the effect of the maximum-expected level.

Initial Service Leak Testing

This category of testing is limited by the codes to certain situations. For example, ASME B31.3 limits the use of this technique to category D fluid service. Category D fluid services are defined as nonhazardous to humans and must operate below 150 psi (1035 kPa) and at temperatures between −20 and 366°F (−29 and 185°C). ASME Code B31.1, section 137.7.1, does not allow initial service testing of boiler external piping. However, that same section of ASME B31.1 permits initial service testing of other piping systems if other types of leak testing are not practical. Initial service testing is also applicable to inspection of nuclear power plant components by Section XI of the ASME Boiler and Pressure Vessel Code.

As indicated, this test is usually run when the system is first put into operation. The system is gradually raised to normal operating pressure as required in ASME B31.1 or design pressure as required in ASME B31.3. It is then maintained at that pressure while an examination for leaks is conducted.

Vacuum Leak Testing

Vacuum leak testing is an effective way to determine whether or not there is a leak anywhere in the system. This is normally done by drawing a vacuum on the

system and trapping the vacuum within the system. A leak is indicated if the trapped vacuum rises toward atmospheric pressure. A manufacturer of components quite often uses this type of leak test as a production leak test.

However, it is very difficult to determine the location or locations of a leak if one exists. Smoke generators have been used to determine the piping location where smoke is drawn into the piping. This is very difficult to utilize unless the leak is sufficiently great to draw all or most of the smoke into the pipe. If there is substantially more smoke generated than can be drawn into the pipe, the smoke that dissipates into the surrounding air can easily hide the leak location.

Obviously, this method is not suitable for testing the piping at or above the operating pressure unless the piping is to be operated at a vacuum.

Static-Head Leak Testing

This test method is sometimes called a drop test because a drop in the water level in the open standpipe, added to the system to create the required pressure, is an indication of a leak. Once the system and standpipe is filled with water, the standpipe level is measured and noted. After a required hold period, the height is rechecked and any decrease in level and the hold period are recorded. Any leak location is determined by visual inspection.

Halogen and Helium Leak Testing

These test methods use a tracer gas to identify leakage location and leakage quantity. In the case of halogen leak detection, the system is charged with halogen gas. A halogen detector probe is used to sense leakage of the tracer gas from any exposed joint. The halogen leak detector, or sniffer, consists of a tubular probe which sucks a mixture of leaking halogen gas and air into an instrument sensitive to small amounts of halogen gas. This instrument employs a diode to sense the presence of halogen gas. The leaking halogen gas is passed over a heated platinum element (the anode). The heated element ionizes the halogen gas. The ions flow to a collector plate (the cathode). Current proportional to ion formation rate, and thus to leakage flow rate, is indicated by a meter. The halogen detector probe is calibrated using an orifice that passes a known leakage flow. The detector probe is passed over the orifice at the same rate that will be used to examine the system for leakage. The preferred tracer gas is refrigerant 12, but refrigerants 11, 21, 22, 114, or methylene chloride may be used. Halogens should not be used with austenitic stainless steels.

Helium leak testing may also be done in the sniffer mode, as explained above for halogens. However, in addition, helium leak testing may be performed using two other methods that are more sensitive in detecting leakage. These are the tracer mode and the hood or closed system mode. In the tracer mode a vacuum is drawn on the system, and helium is sprayed onto the outside of joints to be inspected for leakage. The system vacuum draws helium through any leaking joint and delivers it to a helium mass spectrometer. In the hood mode, the system to be tested is surrounded by concentrated helium.

The hood mode of helium leak testing is the most sensitive method for detecting leaks and the only method accepted by ASME Code Section V as quantitative. Manufacturers of components requiring a hermetic seal will use the hood method of helium leak detection as a production leak test. In these cases, the component may be surrounded by helium in a chamber. A connection to the component is made

to a helium leak detector, which attempts to draw the internals of the component to a vacuum close to absolute zero. Any leakage of helium from the surrounding chamber into the component will de drawn into the helium leak detector by the vacuum it is producing. The helium leak detector contains a mass spectrometer configured to sense the presence of helium molecules. This closed-system testing method is capable of sensing leaks as small as 1×10^{-10} cc/sec (6.1×10^{-12} cubic in/sec), standard atmospheric air equivalent. The closed-system method is not appropriate to measuring a large leak that would flood the detector and render it useless for further measurement until every helium molecule could be withdrawn from the detector.

The closed-system method is not appropriate to a piping system in the field because of the large volumes. Also it does not show the location of the leak or leaks. Finally, the sensitivity of leak detection, using the closed system, is many orders of magnitude greater than normally required. The helium sniffer is the least sensitive method and is subject to false indications if helium from a large leak at one location in the system diffuses to other locations. A large leak can also flood the detector, temporarily rendering it useless until all the helium is removed from the mass spectrometer. The helium pressure used in all these methods is normally one or two atmospheres, which is sufficient to detect the presence of very small leaks. The low pressure also serves to reduce the amount of helium required for the test. Helium leak testing is rarely, if ever, used to demonstrate that the system can safely withstand the design pressure rating.

Helium leak detectors will not be successful in finding leaks unless the component or piping system is completely dry. Liquid contained in a small leakage path, due to capillary action, may seal the leak because of the low pressure of the helium and the surface tension of the liquid. Therefore great care is required to use this approach under completely dry conditions. Otherwise this system may be even less sensitive in detecting a leak than a high-pressure hydrostatic test. Furthermore, the helium leak detector is easily contaminated by oils and other compounds and rendered inaccurate. Field conditions are normally not free of the possibility for contamination of the leak detector.

Sensitivities of Leak-Testing Methods and Acceptance Standards

The order in which the various leak-testing methods indicate leak tightness, from least sensitive to most sensitive, are

1. Hydrostatic leak testing with visual observation
2. Pneumatic testing with visual observation of bubbles in soapy mixture
3. Gas lake testing
4. Helium-mass spectrometer sniffer
5. Halogen-diode sniffer
6. Helium-mass-spectrometer tracer technique
7. Helium-mass-spectrometer hood method

The gas lake method is similar to pneumatic testing, but instead of using a soapy mixture to detect leakage, all the pneumatic leakage is collected and passed through a water trap to permit a quantitative measurement of total leakage. Obviously the gas lake method is practical only with certain piping or vessel configurations that make it simple to conduct all the leakage to one location.

Pneumatic bubble testing should provide for a sensitivity of at least 10^{-3} std cc/sec (6.1×10^{-5} cu in/sec). Pneumatic testing is at least 57 times more sensitive than hydrostatic testing at the same pressure because of the ratio of viscosities. This ratio can be even larger when considering the barrier effects of surface tension in a hydrostatic test.

The maximum acceptable leak rate standards in ASME Code Section V for tracer gas methods are

1. Helium sniffer maximum acceptable leak rate of 1×10^{-4} std cc/sec (6.1×10^{-6} std cu in/sec)
2. Halogen sniffer maximum acceptable leak rate of 1×10^{-4} std cc/sec (6.1×10^{-6} std cu in/sec)
3. Helium-tracer-probe maximum acceptable leak rate of 1×10^{-5} std cc/sec (6.1×10^{-7} std cu in/sec)
4. Helium-hood-method maximum acceptable leak rate of 1×10^{-6} std cc/sec (6.1×10^{-8} std cu in/sec)

The maximum sensitivity of the helium-hood method can be increased in special cases from 10^{-10} std cc/sec (6.1×10^{-12} std cu in/sec) to 10^{-14} std cc/sec (6.1×10^{-16} std cu in/sec). This is done by allowing the leakage to accumulate in a known volume before a measurement of the leakage is made.

SELECTION OF A TEST METHOD AND FLUID TEST MEDIUM

The test method and fluid test medium to be used are most often known at the early stage of design of the piping system. The piping system contract will usually specify the applicable codes. Even if the applicable codes are not spelled out, the piping designers will know which codes will apply, based upon the piping system application and the jurisdiction. The codes in turn specify the allowable pressure and leak-testing methods. The designers will almost always know from experience which of the various testing methods permitted by the applicable code will be employed by the contractor. Based on this knowledge, the piping-system designers will provide the means required for running the tests, such as properly located connections for filling, venting, pressurizing, and measuring the test pressure of the system. They may even provide for additional temporary supports for the weight of a liquid test medium if the piping is for a gaseous-process medium.

They will also consider how portions of the system that are not to be tested may be isolated from the portions under test. This is usually done with isolating valves and flange blinds. In some cases field tests need to be conducted on subassemblies of process piping or equipment. In those cases the piping or vessels may have openings for later connection to the final system. If there are open ends of the piping or open connections to a vessel that must be sealed during the pressure test, hydrostatic test plugs may be more economically employed for this purpose than temporarily sealing these openings by welding. Cross-sectional views of hydrostatic test plugs, shown in Fig. B14.1 and B14.2, are discussed in greater detail in the later section titled Hydrostatic Test Plugs. The advance knowledge of a requirement for hydrostatic test plugs can be especially important for plug sizes larger than NPS 12 (DN300). Larger test plugs usually require longer delivery times.

The chosen leak-testing method must be compatible with the piping-system requirements, in addition to meeting the code or standards requirements. Additionally the fluid test medium must be selected. These two choices are essential in establishing the test equipment required to fill or evacuate the piping, set and regulate the test pressure, and detect leaks by other than visual means. In addition, these two choices establish whether temporary additional supports may be required to support the weight of the test fluid medium. This entire test-related equipment must be arranged for far enough in advance to be available and in place prior to the starting date for the leak test.

Hydrostatic testing is most often preferred over pneumatic testing because of safety considerations. Water is the preferred fluid medium for hydrostatic testing. In addition to its relatively incompressible nature, it is also the safest fluid because it is nontoxic and nonflammable and it remains in liquid form down to atmospheric pressure unless heated above the boiling point. Water is readily and economically available. ASME B31.1, section 137.4.3, specifies water as the test fluid for hydrostatic tests unless otherwise specified. ASME B31.3, section 345.4.1, also specifies water as the test fluid for hydrostatic test unless there is the possibility of freezing or damage from adverse effects of water on the piping or the process for which the piping system is designed. This section provides for other uses of other nontoxic liquids as long as the flash point exceeds 120°F (49°C). If hydrostatic testing is being considered for a system that was designed for use of a gaseous medium as the process fluid, it must first be determined that the piping system will support the weight of the test liquid or that the piping can be safely supported during the hydrostatic test.

There are some cases where water cannot be employed as a fluid test medium. Traces of water left in the piping may react adversely with the process; for example, in piping for liquid sodium or a cryogenic process. If the test is to be run at temperature conditions which would make freezing likely, antifreeze may be added to the water as long as the antifreeze is not harmful to the piping or the process and the disposal of large amounts of antifreeze is not environmentally unacceptable. If water cannot be employed as the fluid test medium and another liquid is not practical, or if it is not practical to support the weight of a test liquid with piping supports, a pneumatic test may be the next best choice.

Testing of Piping Additions, Modifications, or Repairs

There is a lesser known technique for testing piping modifications or additions to older systems that can save considerable effort by testing only the new, modified, or repaired joints without the need for filling the entire piping system. This involves using a special device, called a flange test plug, shown in the cross-sectional view of Fig. B14.3, that will test only the weld between a weld-neck or slip-on flange and pipe. A modification of the flange test plug of Fig. B14.3 can be used to help make the weld between a weld-neck flange and a pipe in addition to also testing the weld. The modification adds a center port to sense any pressure in the pipe behind the plug and lengthens the plug to prevent seal damage from the heat of the weld. This device, called a flange weld plug, aligns the parts to be welded, provides for any gas purging requirements during the welding, and warns or protects the welder against any unexpected increase in pressure back in the pipe. Finally a special dumbbell test plug, shown in Fig. B14.4, may also be used to test only a single weld. The flange test plug, flange weld plug, and special dumbbell plugs are explained in greater detail in the later section titled Hydrostatic Test Plugs Suited
FIGURE B14.3 Flange test plug and flange weld plug. (*Courtesy of Expansion Seal Technologies, Harleysville, PA.*)

to Testing a Single Weld. All these devices save considerable time and money in testing plant expansions or modifications because it takes only moments to fill the small space surrounding the weld to be tested with the fluid test medium. There is also a substantial cost saving in the reduced amount of contaminated test liquid to be disposed of. It is always best to consider such options at the design stage because of the delivery time required for these special devices.

Test Pressures

The selected test method and fluid test medium, together with the applicable code, will also establish the rules to be followed in calculating the required test pressure. In most cases a pressure greater than the design pressure rating is applied for a short duration, say at least 10 minutes. The magnitude of this initial test pressure is often at least 1.5 times the design pressure rating for a hydrostatic test. However, it may be different, depending upon which code is applicable and whether the test is hydrostatic or pneumatic. Furthermore, the test pressure must never exceed a pressure that would cause yielding, or the maximum allowable test pressure of some component exposed to the test. In the case of ASME B31, section 137.1.4, and the Boiler and Pressure Vessel Codes, the maximum test pressure must not exceed 90 percent of yield for any component exposed to the test. The test pressure is needed to demonstrate that the system can safely withstand the rated pressure. Following this period of greater than design pressure, it is often permissible to reduce the pressure to a lower value for examination of leaks. The examination pressure is maintained for the length of time necessary to conduct a thorough

TABLE B14.1   Test and Examination Pressures

Code	Test type	Test pressure minimum	Test pressure maximum	Test pressure hold time	Examination pressure
ASME B31.1	Hydrostatic[1]	1.5 times design	Max allowable test pressure any component or 90 percent of yield	10 minutes	Design pressure
ASME B31.1	Pneumatic	1.2 times design	1.5 times design or max allowable test pressure any component	10 minutes	Lower of 100 psig or design pressure
ASME B31.1	Initial service	Normal operating pressure	Normal operating pressure	10 minutes or time to complete leak examination	Normal operating pressure
ASME B31.3	Hydrostatic	1.5 times design[2]	Not to exceed yield stress	Time to complete leak examination but at least 10 minutes	1.5 times design
ASME B31.3	Pneumatic	1.1 times design	1.1 times design plus the lesser of 50 psi or 10 percent of test pressure	10 minutes	Design pressure
ASME B31.3	Initial service[3]	Design pressure	Design pressure	Time to complete leak examination	Design pressure
ASME I	Hydrostatic	1.5 times max allowable working pressure[4]	Not to exceed 90 percent yield stress	Not specified, typically 1 hr	Max allowable working pressure[4]
ASME III Division 1 Subsection NB	Hydrostatic	1.25 times system design pressure[5]	Not to exceed stress limits of design section NB-3226 or maximum test pressure of any system component[5]	10 minutes	Greater of design pressure or .75 times test pressure
ASME III Division 1 Subsection NB	Pneumatic	1.2 times system design pressure[6]	Not to exceed stress limits of design section NB-3226 or maximum test pressure of any system component	10 minutes	Greater of design pressure or .75 times test pressure

TABLE B14.1 Test and Examination Pressures (*Continued*)

Code	Test type	Test pressure minimum	Test pressure maximum	Test pressure hold time	Examination pressure
ASME III Division 1 Subsection NC	Hydrostatic	1.5 times system design pressure	If minimum test pressure exceeded by 6 percent establish limit by the lower of analysis of all test loadings or maximum test pressure of any component	10 minutes or 15 minutes per inch of design minimum wall thickness for pumps and valves	Greater of design pressure or .75 times test pressure
ASME III Division 1 Subsection NC	Pneumatic	1.25 times system design pressure	If minimum test pressure exceeded by 6 percent establish limit by the lower of analysis of all test loadings or maximum test pressure of any component	10 minutes	Greater of design pressure or .75 times test pressure
ASME III Division 1 Subsection ND	Hydrostatic	1.5 times system design pressure for completed components, 1.25 times system design pressure for piping systems	If minimum test pressure exceeded by 6 percent establish limit by the lower of analysis of all test loadings or maximum test pressure of any component	10 minutes	Greater of design pressure or .75 times test pressure
ASME III Division 1 Subsection ND	Pneumatic	1.25 times system design pressure	If minimum test pressure exceeded by 6 percent establish limit by the lower of analysis of all test loadings or maximum test pressure of any component	10 minutes	Greater of design pressure or .75 times test pressure

Notes:

1. Boiler external piping must be hydrostatic tested in accordance with PG-99 of ASME Code Section I.

2. ASME B31.3 hydrostatic pressure must be raised above 1.5 times design pressure in proportion to yield strength at test temperature divided by strength at design temperature but not to exceed yield strength at test temperature. Where a vessel is involved whose design pressure is less than the piping and where vessel cannot be isolated, the piping and vessel can be tested together at vessel test pressure provided vessel test pressure is not less than 77 percent of piping test pressure.

3. ASME B31.3 initial service testing permitted only for piping in category D service.

4. ASME Code Section I hydrostatic test pressure at temperature of at least 70°F (21°C) and examination pressure at temperature less than 120°F (49°C). For a forced-flow steam generator with pressure parts designed for different pressure levels, the test pressure should be at least 1.5 times the maximum allowable working pressure at the superheater outlet but not less than 1.25 times the maximum allowable working pressure of any part of the boiler.

5. ASME Code Section III, Division 1, subsection NB, test pressure limits defined in section NB3226; also components containing brazed joints and valves to be tested at 1.5 times system-design pressure prior to installation.

6. ASME Code Section III, Division 1, subsection NB, pneumatic test pressure for components partially filled with water shall not be less than 1.25 times system-design pressure.

inspection for leakage. Again the examination pressure depends upon the particular code and the selected method of testing. Table B14.1 gives test and examination pressures for some of the ASME B31 and Boiler and Pressure Vessel codes.

The test pressure for each test is calculated by multiplying the code requirements for the leak-test method by the design pressure of the weakest component or line within the test boundary. An exception to this occurs when the design rating is given for a higher temperature than the temperature at which the pressure and leak test will be conducted. In this case the test pressure must be increased by an amount reflecting the decrease in strength of the material between the test temperature and the operating temperature unless that would exceed code limitations regarding the maximum test pressure. Another exception occurs in ASME B31.3, where a vessel cannot be isolated from the system, and the allowable vessel pressure is less than calculated test pressure for the piping. In such a case it is acceptable to hydrostatic test the piping at the maximum allowable vessel–test pressure provided the owner approves and the reduced test pressure is at least 77 percent of the calculated test pressure per ASME B31.3, section 345.4.3.

PRESSURE TESTING PROCEDURES

The field engineer, responsible for the implementation of the field test program, must first be familiar with the testing provisions of the code or standards that are part of the contract. This person must assure coordination between the test supervisor, QA/QC, the contractor, and owner. The person responsible for the testing should begin preparation for the testing phase far enough ahead of piping system completion so that all the equipment needed to conduct the test is ready to be used and all preparations are completed before testing is scheduled to begin.

Preparation of Test-Package Documentation

A P&ID (piping and instrumentation diagram) marked with information concerning the pressure test, the piping isometrics, a valve line-up sheet, a test cover sheet, and a test data sheet make up the package of test documentation.

The P&ID should be marked with the scope of the leak test, showing boundary valves and test blind locations to isolate connections of the piping to the parts of the system which do not need to be pressure tested. If hydrostatic test plugs are required to seal any pipe or vessel openings, that requirement should be noted. The valve line-up sheet shown in Fig. B14.5 should be completed, showing the valve positions required for the test. Also identify any valves which must have the internals removed or must be blocked in position. Test blinds may be fabricated in accordance with the data given in Table B14.2. The ASME B31 codes do not require retesting of a flanged joint once the blinds are removed.

Determine the required test pressure by reviewing the P&ID drawings to obtain the lowest line index and lowest design pressure rating within the boundary of the test. Two checks are required for proper test pressure.

First, review the design documents and vendor information to ensure that the test pressure will not overpressurize any equipment or piping component within the pressure test boundary. In addition, verify that there will be no possibility of brittle fracture at the test pressure and temperature.

Second, determine the head loss between the lowest part of the piping and the gauge location. The head loss in psig is equal to the difference in elevation in feet

multiplied by 0.4327 psig/ft (9.7 kPa/m) for water as the test fluid. This will establish the required gauge readings during the test to avoid overpressure at the lowest point in the system. Determine also the pressures that the lowest parts of the system will experience.

The test cover sheet contains an identifying number for the test, test date, test pressure, fluid test-medium description, and all release and acceptance signatures. Test release authorizations depend upon the project. They may include the welding field engineer, instrumentation field engineer, mechanical field engineer, hanger field engineer, quality control inspector, superintendent, third party representative, and client representative. The piping or hanger field engineer will have to verify that the lines are supported to handle the hydraulic loads. The client may also walk down the package before the test can be performed.

The pressure-test data sheet of Fig. B14.6 is used to record the data taken during the test. It also contains provision for the sign-off required by the field engineer and the code inspector, if applicable, as is the case with boiler external piping (BEP).

TABLE B14.2 Test Blind Dimensions

Test blind fabrication data

A = Blind plate diameter
B = Paddle handle width
C = Handle height
D = Blind thickness
t = Required blind thickness
d = Nominal diameter of pipe
P = Line design pressure (psig)
S = allowable material stress
	General notes:
	
	1. Plate material types
	  A-36, S = 12,600 PSI
	  A-285 GR. C, S = 18,350 PSI
	  A-570 GR. 36, S = 16,300 PSI
	
	$t = d\sqrt{\dfrac{3}{16} \times \dfrac{P}{S}}$

Note: This will provide a safety factor of 1.7 of yield. These same values may be used for A36 plate, however, the safety factor will be reduced to 1.4

Test blind thickness schedule A285 Grade C

Pipe size	Test pressure			t, Test blind thickness						
	A	B	C	100	300	500	700	1000	1500	2000

A = Blind diameter
B = Grip width
C = Height from center of paddle to top of grip

Preparation

As the piping system nears completion, a check list should be made of items still requiring completion before testing can begin. This list must be pursued by the person(s) responsible for running the test until all remaining items are completed. Otherwise, it could be discovered that the system is not ready to be tested only when testing is ready to begin. Reviewing P&ID drawings is the best way to develop

this checklist. A comparison of the P&ID drawings and the piping isometrics must be made to determine if there are any discrepancies. Review all valve types, flow directions, branch tie-ins, and any material changes. Recheck all in-line components to verify they can withstand the required test pressure.

After the crosscheck is complete conduct a physical inspection of the piping system using the P&IDs and piping isometrics. Typically systems are inspected for

- Completed and torqued flanges with no missing bolts or gaskets
- All gravity supports installed
- Proper pipe routing
- Correct valve type and orientation
- Vents and drains installed to allow proper filling and draining

- Proper material type verified using color codes or markings, and heat numbers recorded if required by the codes
- All required piping stress relief, weld examinations, and welding documentation completed and acceptable

Before the test is to be run, make certain, by reviewing the piping against the P&ID and valve line-up sheet, that

- All equipment not to be tested is disconnected from the test or isolated by closed valves or testing blinds
- Tagging and lockout of any valves used to isolate the test boundaries is in place to protect both the testing personnel and any others who may be on site
- All nonboundary valves in the test boundary are in the open position
- Expansion joints, if any, have required restraints to protect against damage from the test pressure
- All springs have travel stops to protect against the weight of the test medium
- All test equipment is checked and all test connections are tight

For gas systems, additional gravity supports may be required temporarily to support the weight of the test liquid.

Since requirements vary from project to project, the person responsible for the test will need to make a specific checklist of items for each project before testing can begin.

Hydrostatic Testing Preparation

All joints, including welds and flanges, of the portions of the system to be tested are left uninsulated and exposed for examination during the test. Some insulation may be installed on the straight runs or previously tested piping. If the system is to include jacketed piping, the leak tests should be run before any jacketing is installed.

A sample hydrostatic-test setup is shown in Fig. B14.7. A flow water pump is substituted for the pressurizing water pump during the filling of the piping. The water source should provide clean chloride-free water. The system is filled from the bottom to facilitate the venting of all air in the portion of the piping system under test. For sloped piping systems, filling should be done against the slope. Vents must be located at all high points in the piping and should be open during the filling stage. Once it is determined the system is completely liquid filled the vents may be closed and a pressurizing water pump connected to the system in place of the flow pump. The pressurizing pump must have a capacity greater than the allowable leakage of the system. Leakage at the packing glands of valves and pumps is permissible by the codes and is necessary to preserve the life of the packing. However, if this leakage is so great that the test pressure cannot be controlled by being trapped, there will be a problem in running the test. It is not very practical to turn the pressurizing pump on and off to maintain the pressure close to the required level. One solution is to temporarily tighten all the packings to a greater compression than is normally used during regular operation of the system. It may also be necessary to tighten flanges, screwed connections, and other mechanical or gland-type joints to eliminate leakage.

SAMPLE HYDROSTATIC TEST SETUP
FIGURE B14.7   Hydrostatic test setup.

Calibrated relief valves should be installed as close as possible to the filling connection and to the low point of the system. The relief valves have two purposes. First they protect against an accidental overpressure during the pressurization process. To accomplish this they must have sufficient relief capacity to pass the full flow of the pressurizing pump (or filling pump if it is also used for pressurizing). Second they protect against an increase in pressure during the test that might result from an ambient temperature increase. The relief valve should be set to prevent the system pressure from exceeding

- The maximum allowable pressure of the lowest rated component in the test boundary
- The maximum allowable seat or backseat pressure of boundary valves
- The maximum allowable set pressures for gagged system-relief valves
- The maximum allowable pressures established by the applicable code or project specification

It is very important to eliminate all trapped air from the piping before pressurizing the piping. Trapped air poses at least three problems in hydrostatic tests. First, the danger of injury is greater if there is a failure with trapped air in the system. Second, if the air is trapped at a piping joint that is leaking, there may not be visible evidence of a water leak. Third, the presence of trapped air will lengthen the time required to pressurize the system. This last effect may be used as an indication of the presence of trapped air. It is also possible to test for trapped air in a piping system by tapping the pipe. A hollow sound indicates the presence of trapped air.

On the other hand there is a potential danger posed by a completely liquid-filled piping system. Normally pressure is trapped in the piping system after the pressurizing pump has raised it to the test level. With a trapped system, an overpressure condition can occur with an increase in ambient temperature. This is most likely to occur if the system is pressurized and trapped early in the day. Later in the day as the temperature increases the system pressure will rise unless controlled. This is because the thermal coefficient of expansion of water is an order of magnitude greater than that of the piping system metal. As the ambient temperature increases, the thermal expansion of the water is greater than that of the piping by at least an order of magnitude. Thus with an ambient temperature increase, the water is compressed by the piping, with a consequent increase in the water pressure that can be dramatic because of the relative incompressibility of water. Because of the potential dangers posed by this phenomenon, the ASME B31.1, section 137.2.6, and ASME B31.3, section 345.2.1, cite precautions to be taken against pressure rise during testing. This is usually done with a pressure-relief valve set as indicated above. Another means of preventing a thermally induced overpressure is not to leave the test unattended. The gauges must be continually monitored and pressure bled off at the vents as needed.

Information concerning the test gauges should be recorded on the test data sheet. Calibration of the test gauges should be performed prior to the start of the test against a master gauge or deadweight tester whose own calibration is traceable to the U. S. National Institute of Standards and Technology (NIST) standards. If the gauge employed is an analog device, the test pressure should ideally occur at midscale but never below 25 percent of full scale. A 1 percent of full scale accuracy device is generally acceptable. If the gauge is a digital gauge it may be used anywhere within the range that the accuracy is specified. This is because the accuracy of a digital gauge is generally a fixed percentage of the reading rather than full-scale reading. After the test is concluded, and the pressure reduced to zero, the zero reading of the gauge should be verified. If the gauge fails to repeat the zero reading by a significant amount, the test reading is not to be trusted.

Conducting the Pressure and Leak Test

Pressurization of the system should be done slowly and in stages only after all trapped air has been eliminated. Visual checks for leakage should be made during the pressurization process. If the system pressure for the examination of leakage is different than the maximum test pressure, the system should be held at the maximum test pressure for the prescribed period before it is reduced to the examination pressure. When examining the system for leakage, any condensation should be wiped away from the system parts to provide a clear and unmistakable view of leakage.

If there are any joints that cannot be visualized during the leak test and it is decided to use a trapped pressure for indication of leakage at the hidden joint, be

aware of the following: First, there cannot be any significant leakage elsewhere in the system. Any leaking flanges or packings must be tightened to shut off their leakage. Any leaking joints must be repaired. The shutoff valves and blinds employed to isolate the system boundaries, including the valve to the pressure source, must be leak tight. If all the trapped air has been eliminated from the portion of the system under test, the trapped pressure will increase and decrease substantially as the ambient temperature increases and decreases. This occurs, as explained before, because of the greater thermal coefficient of expansion of the water as compared to the pipe material. A calculation using published values for the linear thermal coefficient and the bulk modulus of water estimates that the pressure will change approximately 40 psi/°F (497 kPa/°C). Any trapped air would reduce the magnitude of this effect. In order for the trapped-pressure test to successfully indicate a leak, the ambient temperature must remain reasonably constant. There is also another temperature-related effect to be aware of. When the piping is first pressurized, the liquid is heated by the compression. This heating immediately increases the liquid temperature above its surroundings. As heat transfer takes place to the surroundings there will be an exponential decline in liquid temperature and pressure. This effect can be recognized by its exponential nature. On the other hand a leak could be expected to cause a decrease in pressure at an approximate constant rate.

Normally the piping system, with the exception of possible leakage at pump or valve packings, should not show any visible sign of leakage. This is a requirement of ASME B31.1. Any sign of leakage at a permanent joint would be cause for repair to eliminate the leakage. However, in certain applications some leakage may be permitted if the consequences of small leakage amounts are not significant. This would have to be by permission of the owner or expressed in the piping system contract.

Draining the System

After the leakage test is completed the system may be drained. The piping may be drained and left to air dry or have hot air blown through it to dry it. Alternatively it may be left filled to prevent rust from forming until the system is put into operation. If the system is left filled after testing there should be warning tags on the valves to advise anyone of the wet layup condition. In draining the system, the following precautions should be observed:

- First make sure all system vents are open.
- Vents on tank-pressure vessels should be open and functional to avoid damage during draining.
- The rate of drainage should not exceed the allowable rate of the building or temporary drainage system.
- Disposal of test liquids containing surface preservatives or other water additives must meet local and project environmental requirements.
- Make certain that temporary piping and instrument connections are relieved of pressure before being disconnected.
- Make sure downstream pressure is relieved in systems containing check valves if the valves were not gagged open.

Cold Weather Testing

Hydrostatic testing with water should not be performed when there is chance for freezing. If the temperature is at or below 40°F, it is still possible to use water if one of the following options is employed to prevent freezing:

• Steam the line.
• Run warm water through the pipe.
• Use electric heat tracing on the line.
• Add antifreeze to the water.

The next to the last option may be a safety hazard and should be avoided unless the piping insulation is completed except for the area around the joints that need to be observed during the test. The last option may not be allowed because of environmental concerns about using and disposing of large amounts of antifreeze. Another liquid with a lower freezing point might also be considered.

Extra care should be used in draining systems in cold weather to ensure there are no remaining pockets of water that may freeze.

Pneumatic Testing

When hydrostatic testing cannot be employed, pneumatic testing may be employed with the approval of the owner of the system. Pneumatic testing may be performed with a gas as the only fluid or with a combination liquid and gas. The latter is called hydropneumatic testing and requires a smaller volume of gas, which reduces the danger associated with the test. However, the persons performing the examination for leakage must know whether each joint is exposed internally to the liquid test medium or the gaseous test medium. This is necessary because in the former case the examiner will look for signs of liquid escape whereas in the latter a soapy mixture must be applied to the joint to reveal signs of leakage.

A combination of pneumatic and hydrostatic testing may also be employed. The system is first tested with low pressure air, usually 25 psig (175 kPa), for major leaks. After any leaks are repaired, the system is hydrostaticly tested at the pressure required by the specified code.

Typically pneumatic tests are conducted with filtered, oil-free air, nitrogen, carbon dioxide, or other suitable nonflammable and nontoxic gas. Test temperatures are typically ambient. In pneumatic testing it is especially important to know that there will be no parts of the system under test that could have brittle failure at the test temperature.

Compressors or gas bottles with regulators may be used as the pressure source. The pressure source must have a capacity in excess of the expected leakage of the system. If the pressure cannot be regulated at the test-pressure levels, it must be trapped in the system. In this case the leakage must be reduced for the test by tightening flanges and packings so that the test pressure may be maintained. Again, a trapped gas system is subject to pressure changes due to variations in ambient temperature, but this change is much less than that for water. If the gas is presumed to behave as a perfect gas, the percentage change of the absolute pressure of the test gas would be the same as the percentage change of the absolute temperature of the gas. Assuming the test is run at 100 psig (670 kPa) and 65°F (18°C), a trapped pressure with no leakage would change 1 psi (6.9 kPa) for a 4.6°F (2.5°C) change in its temperature.

The following safety precautions must be taken when conducting pneumatic testing to reduce the possibility of injury due to rupture in the system or test equipment:

- Correctly sized and calibrated relief valves are installed.

- All persons in the area of the test are notified that the test will be performed.

- All unnecessary personnel are removed from the test area.

- The immediate test area is blocked off or roped off with warning signs so that no one can unknowingly enter the test area.

- The connecting line between the pressure source and the system must be capable of withstanding at least the test pressure and preferably the source maximum pressure.

- It is preferable to double regulate a bottled-pressure source so that if one regulator fails, the source is still regulated below the bottle pressure.

- A properly calibrated test gauge is installed in the system to monitor the pressure buildup.

- If leakage is discovered, the system must be vented before repairs or adjustments are made.

- Always check the test equipment before applying pressure.

During pneumatic testing, the test gauge(s) is normally installed at a remote location from the system undergoing the test. The pressure must be increased gradually to the test pressure and held for a period, usually 10 minutes. Before the examination for leakage is started, the pressure may be reduced to the design pressure, or even as low as 100 psig (690 kPa) for ASME B31.1 per section 137.5.5 if that is lower than design pressure.

A sonic detector may be used for detecting leakage at a safe distance from the system under test if it is considered unacceptable for personnel to be close to the piping under test. Otherwise, a leak detector solution may be applied to joints to see if bubbles develop at the joint, indicating a leak. Acceptable leak detector solutions include:

- A solution of liquid soap and water

- Linseed oil

- Any commercially available leak detection solution

If verification of a leak rate is required, flowmeters or totalizing meters may be used to monitor the test. These may be placed between the pressure source and the piping system.

After the test is completed, the pressure in the system is relieved. Exercise the following precautions when releasing the pressure:

- Make sure any residual downstream pressure is relieved in systems containing check valves that were not gagged open.

- Make sure temporary piping and instrumentation is relieved of pressure prior to disconnecting them from the system.

- Gases should be vented to the atmosphere outside any building

HYDROSTATIC TEST PLUGS

The region of the piping system that must be pressure tested can be isolated from other piping by valves or test blinds. However, in those cases where systems that need to be tested have open-ended pipes or open connections to pressure vessels, another means may be used to seal these openings. Such openings may be sealed temporarily by welding them closed. Alternatively, hydrostatic test plugs are also used to seal the open ends of pipe or pipe connections to vessels if required for a hydraulic test. They have the advantage of eliminating the time to weld a closure and the additional time to cut off the welded closure and repair the pipe end. They may also be used over and over again.

Although these plugs have been described as *hydrostatic* they can also be used with gases. However, the greater danger associated with using these plugs for testing with gas requires stricter adherence to safety rules to avoid any possibility of personal injury should failure occur. Some manufacturers of hydrostatic test plugs recommend the use of safety gags when testing with air. Safety gags are devices that are assembled over the pipe and secured by clamping them around the pipe. At the same time a cable or chain link extending from the safety gag is also secured to the test plug to prevent it from doing any damage should the plug be expelled from the pipe.

There are hydrostatic test plugs that seal against the inside diameter of a pipe or tube as well as those that seal against the outside diameter. Figure B14.1 illustrates the internal or ID (inside diameter) test plug and Fig. B14.2 illustrates the external or OD (outside diameter) test plug. Each cross-section view, and a view showing the installation of the test plug to the pipe. Both the ID test plug and the OD test plug have a seal, made of elastomeric material, which is expanded or contracted, respectively, to seal against the pipe. The plugs also have a positive gripping means to prevent expulsion from the pipe when pressure is applied. In addition, these plugs provide a center port for either filling the pipe with the fluid test medium or venting trapped air. This port may also be used as a connection for gauging the test pressure.

Inside-Diameter Hydrostatic Test Plugs

In the case of the ID test plug of Fig. B14.1, the hex nut on the center shaft is tightened to force the segmented grippers to slide up the conical support surface and expand outward in a radial direction. The gripper segments are constrained to contact the conical support surface by the gripper-retaining spring. The grippers have rows of sharp edges, which contact the inside diameter of the pipe. Once these sharp edges have been forced to contact the pipe, further tightening of the hex nut axially compresses the seal to expand the seal outwardly in a radial direction until the seal is also compressed against the pipe inside diameter. The seal is made of an elastomeric material, which can deform against the pipe surface to create a leak-tight seal. The best designs of hydrostatic test plugs for the inside diameters of pipes can seal at any pressure up to the limit of a pressure that will rupture a pipe of any wall thickness and strength. For example NPS 12 (DN300) inside-diameter plugs of the design of Fig. B14.1 have been tested at pressures as high as 12,000 psig (82,800 kPa) without failure. In this particular case the test fixture rather than the test plug limited the pressure. Smaller plugs have been tested to over 20,000 psi (138,000 kPa). ID test plugs can be made in sizes up to NPS 42 (DN1050). Larger sizes are possible, but the cost increases substantially.

Outside-Diameter Hydrostatic Test Plugs

The outside-diameter test plug of Fig. B14.2 works in the following manner: By rotating the insert piece it is advanced deeper into the body. The movement of the insert displaces the gripper segments toward the narrower end of the conical section of the body thus forcing the grippers inward in a radial direction against the pipe. When the gripper segments contact the pipe, the O-ring contained in the wedge-shaped annular seal also contacts the pipe but only with light contact force. Notice that, in the view illustrating the situation before pressure is applied, that the inside diameter of the wedge-shaped seal does not contact the pipe when the grippers first touch the pipe. From this point, if the pressure is admitted to the pipe, the pressure force will try to move the body away from the pipe end, but at the same time, this slight relative movement acts to further tighten the grippers against the pipe. Simultaneously, the pressure force acting on the wedge-shaped annular seal forces the seal to move away from contact with the narrow end of the grippers and deeper into the body cone. This movement continues until the inside diameter of the wedge-shaped seal is forced into contact with the outside diameter of the pipe. When the inner-diameter surface of the wedge-shaped seal touches the pipe, the O-ring is completely trapped in its groove. Because of this, very large pressures can be experienced without concern that the O-ring will extrude past the O-ring groove regardless of tolerances in the pipe outside diameter.

An advantage of the outside-diameter test plug shown in Fig. B14.2 is that a single plug for one pipe size may be used on any wall schedule. In comparison, a different inside-diameter test plug is most often required for each wall schedule. However, this advantage over an ID test plug is somewhat offset by the greater cost for the outside-diameter test plug.

The outside-diameter test plug of this design has another advantage over the inside-diameter test plug. Hand tightening will generally secure the gripper segments against the pipe, as in the case of a good inside-diameter test-plug design. However, as we have seen above, hand tightening is also sufficient to enable a leak-tight seal for the OD test plug whereas the ID test plug requires tightening with a wrench to make the seal leak tight.

The outside-diameter plug is also capable of having a larger center port for greater filling capacity if needed. Because of this feature, two OD test plugs with a hose connected between them can be effectively used as a jumper to temporarily repair a broken pipe.

Outside-diameter hydrostatic test plugs in this design are available in sizes up to NPS 4 (DN 100) for line pressures up to 10,000 psi (69,000 kPa) for the smallest plug, down to 5000 psi (34,500 kPA) for the largest. Outside-diameter plugs can be made for larger diameters, but the weight and cost become greater than desirable for most applications unless the pressure requirements are considerably lower.

Factors to Consider in Selecting a Hydrostatic Test Plug

A number of different designs of inside-diameter test plugs are available from different manufacturers. Some very inexpensive versions are made without grippers. Plugs, without grippers, rely on the friction force of the seal against the pipe to prevent expulsion of the plug by pressure. Test plugs without grippers are limited to lower pressures and even with lower pressure are unreliable, particularly when the inside surface of the pipe may be slippery. A slippery condition may result from moisture, oils, grease, loose material on the inside of the pipe, or a smooth coating applied to the pipe. The manufacturers pressure ratings for test plugs without

grippers apply only for clean dry uncoated pipe and proper tightening. The actual pressure that test plugs without grippers can withstand in slippery conditions is drastically reduced. This is because the friction coefficient between the seal and a slippery pipe may be as much as one or two orders of magnitude lower. It is always safer, regardless of pressure, to use a hydrostatic test plug that has a positive gripping means in addition to the seal. Well-designed grippers eliminate any effect from lubricants that can easily be displaced. However, grippers cannot entirely overcome the bad effects of loose material or smooth and hard surface coatings.

There are only a few outer-diameter hydrostatic test plug designs that are commercially available. In choosing a hydrostatic test plug for pressure testing, whether it be an inside-diameter or outside-diameter plug, the selected plug must at the minimum meet the required pressure rating. In addition, there are a number of very important factors to consider beyond just the initial cost alone. For safety considerations, it is very important to use a design that has at a minimum the following features:

• The test plug should remain firmly in the pipe at any pressure even though it was only hand tightened.

Some plugs must be tightened to a specific torque to prevent expulsion from the pipe at rated pressure or even pressures below the rating. Often the user does not have a torque wrench and therefore has no way of knowing when he has tightened the test plug in accordance with instructions. Other manufacturers do not give a tightening torque but instruct the user to tighten the plug enough to make the grippers completely and firmly contact the pipe. Such an instruction does not provide the user with any means of knowing when he has tightened the plug sufficiently to meet the requirements of the instruction. This is an extremely important safety issue for a first-time user or someone who might have been distracted before tightening the plug completely and never completed the job before pressure was applied. If the user has inadvertently forgotten to tighten the plug securely or simply didn't have the experience to do it properly, the danger is that the plug will eject from the pipe when pressure is applied, unless it is of a design that has the following construction features:

The segmented grippers must grip the pipe completely along their length before the seal is compressed. Designs which employ the grippers to compress the seal cannot have the grippers contact the pipe before the seal does. If the seal contacts the pipe before the grippers, it is possible to have a perfect *pop gun* when pressure is applied.

In addition, a single support cone for the segmented grippers is required to obtain the hand-tightening gripping capability. With the single cone, the entire axial length of the gripper is always in contact with the pipe inside diameter. Furthermore, the applied pressure must be able to displace the cone without interference from the seal in a direction that will force the grippers outward, along their entire length, with a greater force as the pressure increases. Grippers that are supported at either end by separated twin-cone surfaces will experience loosening at one end as the pressure increases. Furthermore, if twin-cone supports are utilized in a design where the grippers are also used to compress the seal, only the gripper end that loosens with pressure will contact the pipe, except at very high-tightening torque. Therefore, at some high pressure, which depends on how tight the plug has been installed, the gripper, supported by twin cones, will start to loose its grip.

• The test plug should remain firmly gripped in the pipe even at pressures up to those which cause bursting of the pipe.

A dual cone support for the grippers cannot accomplish the above objective because, as pressure is applied, the displacement of the plug expands the gripper segments outward at one end of the grippers and allows the grippers to retract away from the pipe inside diameter at the other cone support. In such a design, increased pressure does not cause increased gripper force along the entire axial length of the gripper.

Another design feature necessary to accomplish this objective requires that the compression of the seal and expansion of the grippers must be independent of each other. Designs that use the grippers to compress the seal cannot accomplish this objective.

In the case of OD test plugs it is not always practical to meet this objective. This is because it is expensive and cumbersome to make the OD test-plug body large enough to withstand the combination of the gripper and pressure loading.

• The seal should never contact the pipe during installation or removal.

Some test-plug designs incorporate seals that interfere with the pipe even before installation and tightening. Sharp edges on the open end of the pipe can damage a seal that is already larger than the pipe before installation. In addition, if the seal interferes with the pipe during installation, a large force is required to push the plug into the pipe. Alternatively, some users of plugs that have seal interference lubricate the seal to make it easier to install the plug. A test-plug design which has a seal that initially interferes with the pipe is also less tolerant of a wide range of pipe tolerances. A preferred inside-diameter test-plug design always has a seal that is smaller than the pipe inside diameter when the plug is being installed and removed.

• A test-plug design should never employ a fixed O-ring to seal the plug against the pipe.

First, a fixed O-ring would have to interfere with the pipe before it was installed in order to work at all. Second, having pipe and tube tolerances means that the O-ring interference will vary, depending on the tolerance. In the worst cases, the O-ring will have major interference with the largest pipe and be difficult to install. On the other extreme, with the smallest pipe, the O-ring will have little interference. Furthermore, with the smallest pipe, there will be a large gap between the plug parts and the pipe, allowing the O-ring to extrude into this gap under high pressure and fail. O-ring manufacturers recommend that the gap between the male and female parts be limited to a few thousandths of an inch for the highest pressure ratings to avoid extrusion of the O-ring out of its groove, and consequent failure.

• Any test plug should be able to function with only two gripper segments.

This is very important for cases where the pipe has a very out-of-round condition. In such a case it is likely that only two of the gripper segments will contact the pipe when pressure is first admitted.

• The test plug should be easily removable from the pipe after pressure is bled off.

Some gripper designs provide close to a locking angle, and, because of this, a severe impact is required to loosen them from the pipe after the test. In other cases the seal becomes wedged in the small space between the pipe and the test-plug parts, making it very difficult to remove the plug after the pressure is removed. This can be particularly true of test plugs that use low-durometer seals. However, some test-plug designs will work only if the seal is made from a low-durometer elastomer.

Care in the Use of Hydrostatic Test Plugs

Safety demands care in using any device to seal the open end of a pipe in order to run a pressure test. First verify that the pressure rating of the plug is greater than the test pressure to be used for the test. Next, the user must inspect the pipe end. It should be verified that the pipe diameter is within the range of dimensions that the plug is designed for. For example, if the plug seals against the inside diameter, that is the dimension that must be checked. Also, the surface against which the seal engages must be sufficiently free of defects for the seal to work. Finally, check the surface against which the grippers engage. This surface should be clean and dry. The pipe should not have a smooth and hard coating. Furthermore, there must not be any loose scale on this surface. If the grippers engage a loose surface scale as opposed to the pipe itself, the bond between the scale and pipe may break when pressure is applied, allowing the plug to slip.

Next examine the plug itself. It must be in good working condition. If there are signs of tearing of any of the gripper teeth they should be replaced. Also check that there is freedom of movement between the grippers and the supporting conical surfaces. Low friction between these two surfaces is essential to safe operation of the test plug. Sometimes users will find that a test plug was not cleaned and dried after the last use. If there are any signs of sticking, these parts should be cleaned and lubricated. Examine the hex nut and the threads on the shaft(s). They must be free of any damage or wear, and the hex nut must turn freely.

When installing the plug into the pipe always be sure to follow the manufacturer's recommended installation instructions. Always clean and properly store a test plug after each use.

HYDROSTATIC TEST PLUGS SUITED TO TESTING A SINGLE WELD

In those cases where a piping job is a repair, modification, or expansion of an existing system, it is very desirable not to have to fill and pressurize the entire piping system just to check the new welded joints. A device called a flange test plug shown in Fig. B14.3 can test a single weld between the pipe and a weld-neck flange or slip-on flange. Figure B14.3 shows cross-sectioned drawings of the plug before installation and the plug installed in piping. The flange test plug is inserted into the pipe after the weld is completed and bolted to the weld-neck flange. It is very important that the seal and mating parts are small enough to fit past any weld projection during the insertion and removal of the test plug. The seal, located behind the weld, is expanded in a radial direction to seal against the pipe by compressing the seal axially. The axial compression is accomplished by tightening the hex nut on the center shaft in order to squeeze the seal between the back washer and front washer. Flange test plugs larger than NPS 8 (DN200) have multiple shafts, which must all be tightened evenly to compress the seal.

Once the plug is installed, the fluid test medium can be admitted to the space between the flange and the seal against the pipe through ports located in the flange face. These ports also permit venting of the trapped gases for all positions but vertical up. In the latter case the trapped gas may be vented by temporarily relaxing the seal. Once the space surrounding the weld is completely filled with the test medium, it may be pressurized and the exposed weld joint visually examined for any signs of leakage. It is also possible to run a trapped pressure test with such a device. However, the same temperature effects as discussed before must be taken into account.
FIGURE B14.8a Special high lift flange test plug. (*Courtesy of Expansion Seal Technologies, Harleysville, PA.*)
FIGURE B14.8b Special high lift flange test plug being installed. (*Courtesy of Expansion Seal Technologies, Harleysville, PA.*)

The flange test plug can substantially reduce the testing time and cost in a plant expansion or modification. In addition, if the test fluid is contaminated by residue in the piping, it is necessary only to dispose of a small amount of fluid test medium in an environmentally safe manner, as compared to filling the entire piping system. This capability also overcomes the argument sometimes advanced that a single weld should be subjected to a radiographic examination rather then be pressure tested as the code requires. This argument for taking a different approach than the code requires has often been made because of the inconvenience and cost of filling and pressurizing the entire system.

There have been some flange test plug applications where the opening in the weld-neck flange is smaller than the pipe on the other side of the weld. For example, this may occur when the flange rating is considerably higher than that for the pipe. There have also been applications for hydrostatic test plugs where these must fit through a narrow entrance and then seal against a larger diameter. Both of these applications can be accommodated with the special high lift design shown in Fig. B14.8a. Figure B14.8b shows a photograph of a 24 inch (DN 600) special high lift flange test plug being installed in a west coast refinery. Figure B14.8a shows cross-section views before and after the plug has been installed and adjusted so that the seal contacts the pipe. After the flange test plug has been inserted into the piping and the flanges have been bolted together, the hex nuts at the flange end are tightened gradually in sequence. Initially, during the tightening process, the segmented supports are urged to ride up the adjoining conical surface and expand outward in a radial direction. Once these segmented supporting surfaces expand to a diameter slightly less than the internal diameter of the pipe, further radial

expansion of the segmented supports is prevented because the bottom washer engages the end of the cone. From this point, further tightening compresses the cone-shaped part against the seal to compress the seal axially and expand it outward until it seals against the pipe. The result is shown in Fig. B14.8a, identified as ''Flange test plug installed in pipe,'' and shows that the segmented pieces now act as back-up supports for the seal. The testing fluid medium may be admitted through one of the fill ports in the flange while the other serves to vent air from the space between the expanded seal and the flange. Once the liquid fill has been completed and is pressurized, any bending of the exposed portions of the seal due to pressure is resisted by the segmented supports. The use of this design has enabled a NPS 24 (DN 600) flange test plug to fit through an opening that was ⅞ in (22.23 mm) smaller than the diameter of the pipe against which the seal worked. In this application, the test pressure was over 2250 psi (15,525 kPa). Upon completion of the pressure test, the hex nuts are loosened, permitting both the seal and the seal-support segments to retract to their original size before installation. Removal of the flange bolts will now permit the flange test plug to be withdrawn through the smaller opening of the weld-neck flange.

A variation of the design of Fig. B14.3, called the flange-weld plug, may be used to align the weld-neck flange to the pipe and complete the weld prior to testing the weld. The fill ports may be used for inert-gas purging on the inside of the pipe during welding. The flange weld plug, unlike the flange test plug, has a center port for sensing pressure buildup back in the piping. If pressure were to build up behind the flange weld plug before the weld was completed, a dangerous condition wherein the plug might be ejected could occur. Gauges connected to the sensing port are used to warn the welder of any impending problem.

A safer design than the flange weld plug would be to use grippers in conjunction with the seal, as shown in the dumbbell plug of Fig. B14.4. This plug, unlike the hydrostatic test plug, utilizes twin cones supporting the gripper segments to resist movement of the plug in either direction due to unbalanced pressure forces. In case of an unexpected pressure buildup behind the seal, the grippers would function to prevent the plug from being ejected before the weld was completed. However, because of the twin-cone construction, the assembly must first be tightened to the rated torque before pressure is admitted in order to be certain the plug will not move. A single cone gripper would be an improvement.

Flange test plugs and flange weld plugs are available in sizes from NPS 1 to 36 (DN 25 to 900) and with flange ratings up to class 600. Higher ratings and sizes are possible.

FREEZE PLUGS

Thomas J. Bowling, P.E.

Manager
Pipe Repairs, Inc.
Alvin, Texas

Cryogenic freezing is a cost-effective technique for solidifying liquid in a pipe to form a pressure-resistant plug so that maintenance and pressure testing can be performed without shutting down the whole system. This technique for creating a

freeze plug has been used for over 30 years in process plants, cross-country pipelines, and nuclear submarines. Most applications are on water, although other liquids may be frozen effectively. Plugs as large as NPS 48 (DN 1200) have been used. Beyond this size, this method of isolation is not economical. Typical applications are

1. Piping repair
2. Valve replacement
3. Leakage and pressure testing
4. Secondary protection on water lines during nuclear fuel changes

The formation of a freeze plug is typically accomplished by circulating liquid nitrogen in a stainless, aluminum, or fiberglass jacket surrounding the pipe. See Fig. B14.9a, showing a typical installation for creating a freeze plug. The nitrogen inlet is located in the center of the jacket behind a centrally located thermocouple. There are two nitrogen vents as well as a drain connection shown. Also, shown in Fig. B14.9b, is an end view where the actual freeze plug can be seen. The liquid nitrogen extracts heat from the freeze-jacket walls, pipe walls, and the liquid within the pipe. The heat absorbed by the liquid nitrogen evaporates some of the nitrogen, and this heat is carried away from the jacket by the nitrogen-gas exhaust from the jacket. The nitrogen gas leaving the freeze jacket must be conducted away from any confined space where personnel are present. Nitrogen is heavier than air, and it is surprisingly easy to produce low-oxygen levels that can lead to asphyxiation. A few breaths of concentrated nitrogen can cause a loss of muscle function. Immediate
FIGURE B14.9a Typical installation for creating a freeze plug. (*Team, Inc., Alvin, TX*)

FIGURE B14.9b   End view in which actual freeze plug can be seen. (*Team, Inc., Alvin, TX*)

cardio-pulmonary resuscitation is required to restore oxygen to the lungs and allow recovery.

The time required to form a freeze plug and the amount of liquid nitrogen required for a particular application may be estimated in advance using *Freeze Stop Tables* provided by the manufacturer of the freeze plug system. See Table B14.3 for an example. Several factors in addition to pipe size influence the amount of nitrogen needed. They are: starting liquid temperature, liquid convection currents and flow in a connected pipe, high ambient temperature and winds, flow in the pipe if any, and radiation from the sun or surroundings.

The primary indication of plug formation is the temperature of the pipe within the freeze jacket. For water, the temperature should be in the range of 0 to $-20°F$ (-18 to $-29°C$). The secondary indication of success is a uniform band of frost formed completely around the pipe adjacent to the jacket. However, if a liner or process liquid sludge insulates the inside of the pipe, both may be false indications.

Because the liquid expands upon freezing, once the freeze plug isolates a volume of liquid, further freezing of liquid will serve to compress the remaining trapped liquid. The pressure in the trapped liquid can rise to a dangerous level unless relieved by opening a valve, cracking a flange, or other controllable means. On the other hand, as the temperature of the freeze plug drops below the freezing point, microcracks will form in the ice because the ice shrinks faster than the pipe. However, as soon as liquid enters the microcracks it will freeze and seal them.

The best way to test a freeze plug is to create a pressure difference across the plug, and monitor the pressure in the region trapped by the freeze plug for a change

TABLE B14.3 Liquid Nitrogen Requirements for Freeze Stop

Pipe diameter	Column I X		Column II ----------X		Column III X		Volume per hour to hold

that would indicate a leak. Freeze plugs have been tested to very high pressures. Generally the pipe will fail before the failure of a fully formed plug. This is due to the high strength of the bond between the ice and the pipe. However, in the interest of safety, any test pressure must be safely below any expected minimum value of brittle failure.

The liquid must wet the pipe to obtain a strong joint between the freeze plug and the pipe. Additionally, the plug strength increases with plug length. However, freeze jackets longer than three pipe diameters should not be employed due to the possibility of forming a double plug. A double plug can cause failure of the pipe within the jacket because of the very high pressure that is produced between two plugs that are close to each other.

In order to form a freeze plug that seals, the pipe must be full of liquid. An air bubble in the top of the pipe makes it impossible to form a freeze plug across the entire pipe diameter. Hydrocarbons with light ends that gas when depressurized can prevent the formation of a complete plug.

Also, hydrocarbon-based liquids, unlike water, do not have a specific freezing point temperature. Instead, they have a freeze range and become solid through a gradual increase in viscosity. Generally, if there is a question about the freeze point and characteristics of a fluid, a test sample may be frozen and evaluated.

The liquid should be stationary at the time of the freeze. There is a critical flow rate and pipe diameter above which it is impossible to achieve a fully closed plug. The critical flow rate is determined by several factors in addition to pipe size. These are pipe orientation, pipe material and thickness, pipe diameter, inlet fluid temperature, fluid freezing temperature, pressure-head-creating flow, and flow rate. Generally it is not possible to freeze plugs under flowing liquid conditions unless the pipe is small and the flow and water temperatures are both low.

It is sometimes difficult to know if there is flow in the line during a freeze unless there is an obvious leak. Undetected flow is probably the most common cause for an unsuccessful freeze. If freezing is taking longer than expected it may be possible to prove that this is due to flow in the pipe. Measuring the pipe wall temperature on both sides of the freeze plug does this. A difference in wall temperature on either side may indicate flow in a direction toward the lower temperature. Convection currents will delay the formation of a freeze plug and can sometimes prevent it from forming completely. Eddy currents generated in a branch line by flow in a main line can also interfere with the formation of a freeze plug in the branch line. Therefore it is best to locate a plug in a branch line as far away as possible from a flowing main line.

The pipe will contract in the longitudinal direction while the freeze plug is formed. This contraction will induce stress in any restrained section of pipe. The amount of contraction can easily be calculated to determine if resulting stresses will be too high to be safe. The freeze plug should not be located in any pipe fittings, valves, or other operating components. Although it is not recommended to locate freeze plugs at a pipe weld, freeze plugs have been successfully installed at pipe welds after adequate inspection and evaluation of the weld. The freeze area on the pipe should be inspected visually and nondestructively before a freeze. If significant flaws are detected, another section of the pipe should be chosen.

Once the freeze plug has been successfully formed and tested, the downstream side of the plug may be drained to remove the remaining liquid. It is best to maintain the freeze operation for another 15 to 30 minutes before opening the pipe and making repairs or changes. The freeze must continue to be monitored while piping revisions or repairs are made. This is done by watching the temperatures at the ends of the freeze jackets and making adjustments to the nitrogen flow to maintain

the freeze plug until all work on the pipe is completed. No hammering or impact loads should be applied to the piping during a freeze. If it is necessary to unbolt a flange it should be *hot bolted* before freezing. Hot bolting consists of removing the studs and nuts one at a time and cleaning and lubricating them or replacing them with new studs and nuts. Pressure surges should also be avoided during the freeze.

When the required work on the piping is complete, and the revisions or repairs have been tested, the plug(s) may be thawed. The thawing must be done so that the plug does not move and cause damage to the piping. The pipe should be completely liquid filled on both sides of the plug and the pressure equalized across the plug(s) during the thawing operation. These two actions reduce the ability of the plug to move during thawing. The liquid nitrogen must be drained from the freeze jacket(s) and the jacket(s) removed from the pipe to allow the plug(s) to thaw naturally. There is risk involved in warming the pipe from the outside to speed up the thawing. External heating of the pipe at the freeze-plug location could melt the interface between the plug and pipe wall, allowing the plug to move. This is most dangerous if the pipe is vertical, as the buoyancy of the plug would cause it to move upwards.

INTRODUCTION

General Description

Water-distribution systems that serve populated areas and industrial complexes, including offices and light and heavy industry, are classified broadly as being of the loop, gridiron, or tree types. Figure C1.1 describes these three types. Within the broad concept, there may be a combining of all three types used as the building blocks for the overall system.

In the *loop system,* large feeder mains that surround areas many city blocks square serve smaller cross-feed lines connected at each end into the main loop. See Fig. C1.1a.

In the *gridiron (or grid) system,* the piping is laid out in checkerboard fashion, with piping usually decreasing in size as the distance increases from the source of supply. See Fig. C1.1b.

In the *tree system,* there is a single trunk main, reducing in size with increasing distance from its source of supply; branch lines are supplied from the trunk. See Fig. C1.1c.

The grid and loop systems provide better reliability because of their multiple paths. Grid and loop systems are often backed up with feeder pipes leading directly from the pumping station to remote distribution centers serving to bolster the supply to meet increased demands with growth of population.

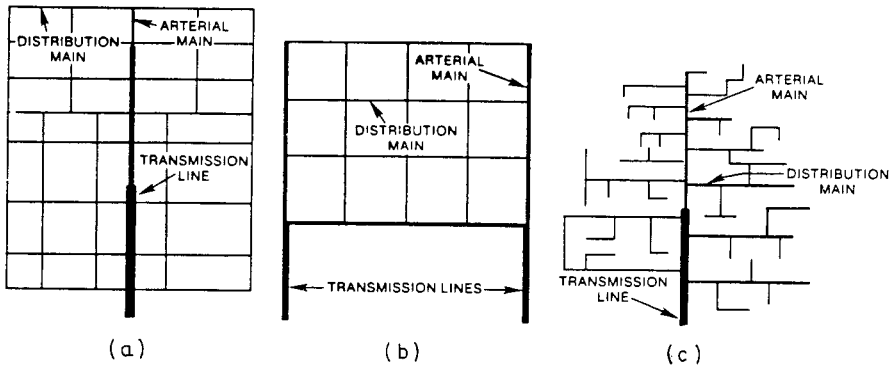
Water distribution systems are made up of pipes, valves, and pumps through which water is moved from the source to homes, offices, and industries that consume the water. The distribution system may include facilities to store treated and un-


FIGURE C1.1   (*a*) Loop system, (*b*) grid system, (*c*) tree system.

treated water for use during periods when demand is greater than the source can supply and when special service requirements must be satisfied.

The distribution systems are subject to the requirements of local ordinances and state laws and health regulations. Two important requirements of any water distribution system are that it supply each user with a sufficient volume of water at adequate pressure; and for treated water systems, that the quality of the water be maintained by the treatment facility and distribution system.

Types of Water Piping Systems

There are four general types of piping systems in water distribution utilities: transmission lines, in-plant piping systems, distribution mains, and service lines. *Transmission lines* carry water from a source of supply to the distribution system. *Distribution mains* are the pipelines that carry water from transmission lines and distribute it throughout a service area, e.g., a community or industrial complex. *Service lines* are small diameter pipes that run from the distribution mains to the user.

The prime objective of a distribution network is to supply a sufficient quantity of water to all parts of the system, at pressures adequate for the requirements of the users at all times and under all conditions of their demands, including sufficient flow and pressure for fire-fighting purposes. Therefore, the selection of pipe sizes, material, geometry, and configuration in distribution networks is influenced more by the necessity of maintaining adequate water pressure than by the economics of pumping costs.

The common industrial or power applications of water systems are condenser-circulating water and service cooling-water systems. A condenser uses circulating water to condense steam exhausted from the plant's turbines. In a large steam-power plant this requires a considerable amount of water to be continuously circulated. Consequently, since the circulating water directly affects the plant's efficiency and reliability, an efficient, reliable, and economical circulating water system is required.

Service water systems provide cooling water to a plant's components, heat exchangers, and other services required by the plant. Due to current environmental regulations, recirculation-type systems in which the same water is used repeatedly must be applied in most cases. Means of cooling the water is provided in the form

of cooling towers, spray ponds, or cooling ponds. Initial fill and makeup water, to compensate for evaporation, leakage, and blowdown, has to be provided from a river, lake, sea, or other large natural body of water. Some service water systems and, in nuclear plants, emergency service water systems may be once-through-type systems.

A siphon system is one in which the siphon principle is employed to carry the water through elevated parts of the system, such as the condenser, in order to reduce the pumping power required. These elevated portions of the water system operate under a partial vacuum. A pressure system is one in which the water flows under a positive head throughout. This system is generally used with recirculating systems, such as with cooling tower installations.

Vertical pumps set in an intake basin are usually the most suitable for circulating water and service water applications. The complexity of the intake structure is naturally affected by the number of pumps necessary for the system. Reliability points to the use of at least two pumps. The design criteria for the plant will dictate the final choice, whether it will be two pumps at two-thirds capacity each, or one-half capacity each, or some other number of pumps and load distribution. The capacity selection is the subject of a careful analysis, taking into account site space and hydraulic conditions, water requirement, variation of pumping head, the best efficiency range of the pumps, and the costs of various layouts and options.

The intake chambers for vertical pumps require careful design for good pump operation. The design must bring about a uniform and undistributed flow of water to the pump without whirl. Most pump manufacturers and Hydraulic Institute have design suggestions for intake chambers for their particular pumps. There are no standard solutions to vertical-pump intake problems, so each vertical-pump installation should be studied individually.

Booster pumps may be required to ensure pressure to most distant higher elevation points without overpressurizing the lowest components. Horizontal pumps are generally suited for this application.

The intake piping to the suction of horizontal pumps should be designed so as to avoid air pockets. Also, the water-flow velocity should be made uniform over the suction inlet area by placing bends as far as possible from the pump inlet.

Discharge Structure. On the discharge end of once-through cooling water systems, an underwater (or sealed) discharge must be provided to prevent entry of air into the piping, which would otherwise break the siphon action at the condenser. For complex systems an extensive load analysis is performed to establish a seal elevation that is adequate for all operating conditions. Refer to the section on hydraulic grade lines. One means of providing this seal is through the use of a seal well, that is, a basin with a water level controlled by an overflow weir. The seal-well water level regulates the height of the siphon recovery, and it is the final elevation to which the system circulating pump delivers the water.

Beyond the seal well, the discharge into the river or other body of water must be done in such a way that the discharge velocity is dissipated without washing away banks, tearing up the bottom, undermining the discharge piping, or permitting uncontrolled recirculation to the intake.

These systems require attention to problems such as air binding and water hammer, as discussed in this chapter.

A concern about maintaining reliability in plants utilizing raw water for cooling is the accumulation of microbiological growth and sediment accumulation (silting). A critical concern in nuclear plants is keeping piping and components free of clogging or bacterial attack. Strong prevention and maintenance programs are the norms for important systems.

The design of high-temperature, high-pressure piping such as boiler feedwater (FW) systems require considerable experience and study. Refer to Chap. B2. Besides those typical hydraulic problems inherent in lower pressure, lower temperature systems, concern for flashing cavitation and the problems associated with handling two-phase flow and large-system transients are encountered. Refer to Chap. B8 and App. E9.

Velocities ranging from 10 to 25 ft/sec (3 to 7.6 m/sec) in high-pressure and high-temperature water systems are normal, as the fluid is usually high-quality, low-solids water. Piping material can range from carbon steel, such as ASTM A106 on the low-temperature end, to carbon, molybdenum and chrome, and molybdenum alloy steels such as ASTM A335 after the high-pressure heater temperature above 750°F (399°C). FW piping is usually seamless and employs welded joints. Flanged connections, where required, must use a temperature-resistant gasket. Refer to Chap. A7.

Network Analysis of Distribution Systems

The complexity of the analysis required for a well-designed water-distribution system is comparable to that of utility electric power networks. There are several procedures that may be used for the analysis of flow in complex piping networks, such as the Hardy-Cross method. All such methods involve the solution of a flow problem considering head losses of a complex distribution network resulting in extremely tedious and time-consuming trial and error calculations. With the development of state-of-the-art computer hardware and software, complex network problems involving hundreds of branches can be solved in a relatively short time. Illustrative Example C1.1 presents a sample problem using the Hardy-Cross method of flow-network solution.

Illustrative Example C1.1

1. Make a skeleton drawing of the network. Indicate by appropriate arrows the points of constant flow input or output, constant head input or output (see Fig. C1.2).

2. Number all loops in the system in arbitrary sequence. Do not include "loops around loops." For example, in Fig. C1.3 there are two loops, not three. The large loop (*abcdefg*) is not numbered. The two basic loops (*abfg* and *bcdef*) are numbered.

3. Number each line. A line has two ends. An end may be a point at which water is drawn from or added to the system, one at which pipe characteristics
FIGURE C1.2
FIGURE C1.3
FIGURE C1.4
FIGURE C1.5

change, or a tee joint. For example, in Fig. C1.4, the point x is the meeting of three lines, not two; point y is the meeting of two lines where an NPS 8 (DN 200) pipe joins a NPS 10 (DN 250) pipe; point z is simply a bend in the single pipe and is not the end of any line, although it could have been specified as one, if desired. Figure C1.4 shows the complete numbering of the system shown in Fig. C1.2. Note that each line is numbered once and only once, even though it may be in more than one loop. Also note that the numbering is serial; that is, if there are n branches, each of the numbers from 1 to n must be used in the numbering.

4. Assign a base direction. Put an arrow on each line in loop 1, indicating the clockwise direction (as shown in Fig. C1.5). Then put an arrow on each line in loop 2, indicating clockwise direction, except where a line which previously has been assigned a direction is encountered. Then the original assignment is not changed. In Fig. C1.5, line 4 is a member of loop 1 and also of loop 2 but has been given a base direction of loop 1. The line 4 assignment is not changed. This process is continued for every loop in the network, an arrow being assigned in a clockwise direction whenever it has not been assigned previously.

5. In water-distribution systems, the situation often is encountered where system pressure must be raised by the use of booster pumps in series with the supply pipeline. If the higher pressure area is connected to the remainder of the system at one point only, the two pressure-zone networks are hydraulically independent problems. If the pressure zones are connected at two or more points, the booster pumps must be included in the appropriate loops.

For all loops containing booster pumps, an unbalanced or residual head H_0 must be determined. This is done by algebraically summing the assumed constant head changes at the boosters in a clockwise direction.

Note that head *losses* are considered as positive in sign, so proceeding from the suction side of a pump to the discharge side gives a negative head loss.

Following the hydraulic analysis, a check should be made to assure that the pumping head assumptions are sufficiently accurate. The resulting flow-rate values should allow optimum hydraulic design of the booster-station installations.

6. Additional "pseudo-loops" must now be added to the list if there is more than one constant head input (see Fig. C1.6). If the number of such inputs
FIGURE C1.6

is m, trace $(m - 1)$ paths between inputs in the same manner in which the loops were traced, making sure that each constant head input is used at the end of at least one of these loops. If the direction of procedure is from the lower to the higher input in each path, H_0 will be the positive difference in the head loss between the two inputs. If booster pumps are encountered, the head change across such pumps must be algebraically added to the head difference between the inputs in order to obtain the H_0 for the pseudo loops.

When the listing of all the loops has been completed (including the consideration of booster pumps), the work should be carefully checked, preferably by a second person, since any errors will completely upset the calculations.

Note that pseudo loops do not introduce any new lines. Note also that each pseudo loop must be assigned its own number.

7. The only remaining task is to supply initial flow values and pipe characteristics which the computer can use as starting values for the calculations. The only restriction on these values is that they satisfy the mass balance condition at each junction.

That is, the sum of the flow *into* a junction must equal the sum of the flows *out* of the junction. For example, Fig. C1.7 shows the junction of lines 3, 4, and 6; flows of 50 gpm in line 3 and 100 gpm in line 6 would satisfy the condition.
Proceeding in this manner, balance every junction in the network, working toward the variable-flow (constant-head) inputs which can take up the slack.

FIGURE C1.7

When all flows are specified, check the accuracy of the work by summing the inputs and outputs. If these sums are unequal, some computational error has been made and must be corrected. The complete schematic for this system is shown in Fig. C1.8. This schematic includes the assumed starting values of the flows.

Several personal computer (PC)–based and main-frame computer software programs are available that handle steady-state and transient-flow analysis in piping systems. Refer to App. E9 for list of computer programs. Any system configuration, including a variety of components such as storage tanks, pumps, check valves, pressure regulating valves, variable pressure supplies, among others, can be analyzed. These programs can also utilize extended-period simulations of a piping system over a long period of time. These simulations can assess the effect of varying water levels in tanks or reservoirs and can take into account such occurrences as pump operation controlled by water levels or pressure levels. Demand patterns can be varied throughout the simulation to provide a set of solutions for study. These programs can handle any liquid using English and Standard International (SI) units.

In all flow network problems the following conditions must be satisfied:

1. The algebraic sum of the pressure changes around each circuit must be equal to zero.

2. The algebraic flows into and out of each junction must equal zero.

3. The proper relationship between head loss, h, and discharge flow, Q, must be maintained for each pipe.

Parallel and Series Piping. A combination of two or more pipes connected so that the flow is divided among the pipes then joined again, is a *parallel-pipe system*. In *series pipes* the same fluid flows through all the pipes, and the head losses are
FIGURE C1.8

cumulative; however, in a parallel piping system the head losses (h_{f1}, h_{f2}, h_{f3}) are the same in each parallel branch associated with that system, and the discharge flows (Q_1, Q_2, Q_3) are cumulative. When analyzing parallel-pipe systems, an assumption is made to add minor losses into the lengths of each pipe as equivalent lengths.

From Fig. C1.9 the conditions to be satisfied are

$$h_{f1}, h_{f2}, h_{f3} = \left(\frac{P_A}{\gamma} + Z_A \right) - \left(\frac{P_B}{\gamma} + Z_B \right) \tag{C1.1}$$

in which Z_A, Z_B are elevations of points A and B, γ, is the density of the fluid and Q is the discharge flow through the approach pipe and the exit pipe.

Illustrative Example C1.2

$L_1 = 3000 \text{ ft} \quad D_1 = 1 \text{ ft} \quad \varepsilon_1 = 0.001 \text{ ft}$

$L_2 = 2000 \text{ ft} \quad D_2 = 8 \text{ in} \quad \varepsilon_2 = 0.0001 \text{ ft}$

$L_3 = 4000 \text{ ft} \quad D_3 = 16 \text{ in} \quad \varepsilon_3 = 0.0008 \text{ ft}$

$\rho = 2.00 \text{ slugs/ft}^3 \quad \nu = 0.00003 \text{ ft}^2/\text{s} \quad p_A = 80 \text{ psi} \quad z_A = 100 \text{ ft} \quad z_B = 80 \text{ ft}$

For a total flow of 12 ft³/s, determine flow through each pipe and the pressure at B.
Assume $Q'_1 = 3$ ft³/s; then $V'_1 = 3.82$, $R'_1 = 3.82 \times 1/0.00003 = 127,000$, $\varepsilon_1/D_1 = 0.001$, $f'_1 = 0.022$, and

$$h'_{f1} = 0.022 \times \frac{3000}{1.0} \frac{(3.82)^2}{64.4} = 14.97 \text{ ft}$$

For pipe 2

$$14.97 = f'_2 \frac{2000}{0.667} \frac{V'^2_2}{2g}$$

Then $\varepsilon_2/D_2 = 0.00015$. Assume $f'_2 = 0.020$; then $V'_2 = 4.01$ ft/s, $\mathbf{R}'_2 = 4.01 \times$ ⅔ $\times 1/0.00003 = 89,000$ $f'_2 = 0.019$, $V'_2 = 4.11$ ft/s, $Q'_2 = 1.44$ ft³/s.
For pipe 3

$$14.97 = f'_3 \frac{4000}{1.333} \frac{V'^2_3}{2g}$$

Then $\varepsilon_3/D_3 = 0.0006$. Assume $f'_3 = 0.020$; then $V'_3 = 4.01$ ft/s, $\mathbf{R}'_3 = 4.01 \times 1.333/0.00003 = 178,000$, $f'_3 = 0.020$, $Q'_3 = 5.60$ ft³/s.
The total discharge for the assumed conditions is

$$\Sigma Q' = 3.00 + 1.44 + 5.60 = 10.04 \text{ ft}^3/\text{s}$$

Hence

$$Q_1 = \frac{3.00}{10.04} \times 12 = 3.58 \text{ ft}^3/\text{s} \quad Q_2 = \frac{1.44}{10.04} \times 12 = 1.72 \text{ ft}^3/\text{s}$$

$$Q_3 = \frac{5.60}{10.04} \times 12 = 6.70 \text{ ft}^3/\text{s}$$

Checking the values of h_1, h_2, h_3,

$$V_1 = \frac{3.58}{\pi/4} = 4.46 \quad \mathbf{R}_1 = 152,000 \quad f_1 = 0.021 \quad h_{f1} = 20.4 \text{ ft}$$

$$V_2 = \frac{1.72}{\pi/9} = 4.93 \quad \mathbf{R}_2 = 109,200 \quad f_2 = 0.019 \quad h_{f2} = 21.6 \text{ ft}$$

$$V_3 = \frac{6.70}{4\pi/9} = 4.80 \quad \mathbf{R}_3 = 213,000 \quad f_3 = 0.019 \quad h_{f3} = 20.4 \text{ ft}$$

f_2 is about midway between 0.018 and 0.019. If 0.018 had been selected, h_2 would be 20.4 ft.

To find p_B,

$$\frac{p_A}{\gamma} + z_A = \frac{p_B}{\gamma} + z_B + h_f$$

or

$$\frac{p_B}{\gamma} = \frac{80 \times 144}{62.4} + 100 - 80 - 20.8 = 183.5$$

in which the average head loss was taken. Then

$$p_B = \frac{183.5 \times 2 \times 32.2}{144} = 81.8 \text{ psi}$$

Two types of problems occur (1) with the elevation of the hydraulic grade line at A and B known, to find the discharge Q; (2) with Q known, to find the distribution of flow and the head loss. Sizes of pipes, fluid properties, and pipe wall roughness are assumed to be known.

The first type is the solution of a traditional pipe discharge problem, as the head loss is the drop in the hydraulic grade line. The individual discharges are then added to determine the total discharge. The second type is more complex, as neither the head loss nor the discharge for any one pipe is known. This type of problem can be solved by

1. Assuming a discharge Q'_1, through pipe 1
2. Solving for h_f, using the assumed discharge
3. Using h'_{f1}, find Q'_2, Q'_3,
4. With the three discharges flowing with a common head loss, now assume that the given Q is split up among the pipe in the same proportion as Q'_1, Q'_2, Q'_3 thus

$$Q_1 = \frac{Q'_1}{Q'} Q \qquad\qquad \text{(C1.2)}$$

$$Q_2 = \frac{Q'_2}{Q'} \qquad\qquad \text{(C1.3)}$$

$$Q_3 = \frac{Q'_3}{Q'} \qquad\qquad \text{(C1.4)}$$

5. Check the correctness of these discharges by computing h_{f1}, h_{f2}, h_{f3} for the computed Q_1, Q_2 and Q_3 flows.

Some other important relationships to consider in complex flow problems include the following:

Values of (VD^{in}) for water at 60°F (velocity in ft/s × diameter in inches)

VALUES OF (VD″) FOR ATMOSPHERIC AIR AT 60°F

Laminar flow · Critical zone · Transition zone · Complete turbulence rough pipes

Laminar flow $f = 64/R$

Smooth pipes

Friction factor $f = h_1 / (L/D) \cdot V^2/2g$

Relative roughness ϵ/D

Reynolds number $R = VD/\upsilon$ (V in ft/s, D in ft, υ in ft/s)

Computed from Keenan & Keyes' Steam Table.

In the turbulent region, Reynolds number above 2000 (see Moody diagram, Fig. C1.10, to determine region and establish relationship for head loss), the pressure drop h varies as the 1.85 power of the flow rate Q, that is:

$$\frac{h_1}{h_2} = \left(\frac{Q_1}{Q_2}\right)^{1.85} \tag{C1.5}$$

In the viscous flow region (low flow, Reynolds number below 2000), the pressure drop varies directly as the flow or

$$\frac{h_1}{h_2} = \frac{Q_1}{Q_2} \tag{C1.6}$$

For the same flow, pressure drop varies approximately as the fifth power of the inside diameter D, so that,

$$\frac{h_1}{h_2} = \left(\frac{D^2}{D_1}\right)^5 \tag{C1.7}$$

These relationships have been widely used and have resulted in handy pressure drop tables. Appendix E.4 provides friction-loss data for water and commonly used steel pipe and lined ductile iron pipe (DIP) in some representative sizes. Table C1.1 provides properties of water at various temperatures. Figure C1.10 provides friction factors for any kind and size of pipe, based on pipe relative roughness and Reynolds number.

HYDRAULIC AND ENERGY GRADE LINES

The concepts of hydraulic and energy grade lines are useful in analyzing more complex water flow problems (see Fig. C1.11). If, at each point along a pipe system, the term P/γ is determined and plotted as a vertical distance above the center of
FIGURE C1.11   Hydraulic and energy grade lines.

the pipe, the connection of these points is the hydraulic grade line. More generally the plot of the two terms

$$\frac{p}{\gamma} + Z$$

for the flow as the ordinate against length along the pipe as abscissa produces the hydraulic grade line.

The hydraulic grade line is the locus of heights to which liquid would rise in vertical glass tubes connected to piezometer openings in the line. When the pressure in the line is less than atmospheric, p/γ is negative and the hydraulic grade line is below the pipeline.

The energy grade line is a line joining a series of points marking the available energy in ft·lb/lb for each point along the pipe as the ordinate, plotted against distance along the pipe as the abscissa. It consists of the plot of

$$\frac{V^2}{2g} + \frac{p}{\gamma} + Z$$

for each point along the line, where g = acceleration due to gravity, 32.2 ft/sec^2 [9.8 m/sec^2]. The energy grade line is always vertically above the hydraulic grade line by a distance of $V^2/2g$, neglecting the kinetic-energy correction factor.
FIGURE C1.12   Pipes connected in series.

Pipes in Series

When two pipes of different sizes or roughness are connected so that fluid flows through one pipe and then through the other pipe, they are said to be connected in series. By applying the energy equation, including all losses, for the system in Fig. C1.12, for known lengths and sizes of pipes, the relationship between head loss and flow can be expressed as

$$H = K_e \frac{V_1^2}{2g} + \frac{f_1 L_1}{D_1} \cdot \frac{V_1^2}{2g} + \frac{f_2 L_2}{D_2} \frac{V_2^2}{2g} + K_{\text{exit}} \cdot \frac{V_2^2}{2g} \tag{C1.8}$$

where

$$K_e = \text{entry loss coefficient}$$

$$K_{\text{exit}} = \text{exit loss coefficient}$$

$$L_1, L_2 = \text{pipe length of sections 1 and 2 respectively}$$

$$D_1, D_2 = \text{pipe diameter of sections 1 and 2 respectively}$$

$$V_1, V_2 = \text{velocity of flow in sections 1 and 2 respectively}$$

Series pipes may be solved by the method of equivalent lengths. Two-pipe systems are said to be equivalent when the same head loss produces the same discharge in both systems. This is expressed as

$$\frac{f_1 L_1}{D_1^5} = \frac{f_2 L_2}{D_2^5} \qquad (C1.9)$$

Solving for L_2

$$L_2 = L_1 \frac{f_1}{f_2} \left(\frac{D_2}{D_1} \right)^5 \qquad (C1.10)$$

which determines the length of a second pipe to be equivalent for use with velocity of the first pipe.

REFERENCE DOCUMENTS

Codes and Standards

Table C1.2 provides a listing of the most commonly used industry codes and standards in water-systems design, fabrication, assembly, and testing.

American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code. The ASME code covers design and construction of boilers (Section I) or nuclear power plant components (Section III). Insurance companies and most state and municipal authorities recognize this code and make it a prerequisite for acceptance and installation of such power equipment within their jurisdiction.

The Code involves eleven sections, of which the following are concerned with piping:

Section I Power Boilers

Section II Materials

Section III Nuclear Power Plant Components

Section XI Rules for Inservice Inspection of Nuclear Power Plant Components

ASME Code for Pressure Piping, B31

B31.1 Power Piping

B31.3 Process Piping

B31.9 Building Services Piping

Other Standards

American Petroleum Institute

American Welding Society

American Water Works Association

DESIGN BASIS CONSIDERATIONS

Design Criteria

Design Pressure.   In the design of water piping systems the following guidance is provided in determining and specifying system-design pressure requirements.

The design pressure shall be based on the maximum expected operating pressure of a particular system which is determined from the maximum operating pressure

of the connected pump, pressure vessels, relief valve settings, et cetera, depending on the type of system and equipment used. Reasonable margin shall be added to cover variations in expected maximum performance, transients, and control tolerances.

The internal design pressure, including the effect of the static head and allowance for pressure surges, shall not be less than the maximum sustained fluid operating pressure. Consideration shall also be given to pump shut-off pressure.

Piping subject to external pressure shall be designed for the maximum differential pressure anticipated during operating, shutdown, or test conditions, excluding pressure tests. Refer to Chap. B2. For buried piping this includes loading due to earth cover and traffic.

In accordance with ASME B31.1, Paragraph 102.2.4, the piping system shall be considered safe for occasional short operating periods at higher than design pressure or temperature, if the calculated stress value is not exceeded by more than 15 percent during less than 10 percent of any 24-hour operating period or by more than 20 percent during less than 1 percent of any 24-hour operating period.

A piping system is considered safe for operation if the maximum sustained pressure and temperature which may act at any part or component of the system does not exceed the maximum pressure and temperature determined in accordance with Code rules by the Power Piping Code ASME B31.1. Allowable stress values and pressure-temperature ratings are provided by the piping codes and the standards referenced therein.

Design Temperature. In the design of water distribution systems, the following guidance is provided in determining and specifying system-design temperature requirements.

The design temperature shall be determined on the basis of the maximum expected operating temperature. The effects of pumping, throttling, heating, cooling, et cetera, must be considered in the determination of the design temperature of the piping system.

Pipe Sizing Criteria. Typically, total piping system cost is approximately 7 to 8 percent of the total plant investment. These values range upward to 30 percent for municipal water systems and some ships. Selection of pipe sizes, beside affecting initial cost, will also affect operating costs due to their sensitivity to changes in pressure drop, heat losses, and maintenance requirements.

Selection of a pipe-line size involves determination of an optimum size. For instance, if extra pumping is needed to boost the fluid pressure or if the heat rate will be affected adversely, then the cost of the extra energy required becomes a significant factor in the evaluations. The optimum pipe size is obtained when the sum of installed and operating costs is at the minimum.

Piping optimization is not widely used in preliminary calculations. Where the pressure drop is defined by other considerations, the minimum pipe size compatible with good engineering practice will be selected.

Other related considerations which have an important impact on pipe size selection, include:

1. Noise—which can result from high velocity flow, cavitation or two-phase flow.

2. Vibration—which can result from noise, excessive velocities at changes in the direction of the fluid flow, or the causes of cavitation.

3. Erosion or corrosion—due to chemical action of the fluid, excessive velocities, cavitation, and excessive turbulence at fittings, valves, branch connections, etc.

4. Flow distribution—the more uniform the cross-sectional velocity profile, the more likely that the above factors will be reduced. This can be achieved by using reasonable velocities along with a piping layout that will produce a smooth flow pattern.

5. Cavitation—which can result from the collapse of bubbles close to a metallic surface at a high enough velocity to cause erosion, and two-phase flow fluids.

Effects of Velocity. Higher allowable velocities will lead to smaller pipe sizes and higher pressure drops. Excessively high velocities can cause noise, vibration, and erosion. Velocities in pump-suction lines shall be kept sufficiently low in order to maintain the pump's required net positive suction head (NPSH).

The pressure drop in a system can be decreased by selecting a larger pipe size or sometimes by using more than one pipe for the total flow.

For water piping systems a velocity in the range of 4 to 15 ft/sec (1.2 to 4.6 m/sec) is acceptable. Depending upon the material selected, piping design and size is either in the low or high side of this range, considering the economics of system installation and operation. For example, for brass pipe a velocity between 4 to 15 ft/sec (1.2 to 4.6 m/sec) would be recommended, while for steel pipe, a velocity of 7 to 10 ft/sec (2.1 to 3 m/sec) is the recommended range, while velocities to 30 ft/sec (9.1 m/sec) may be acceptable. Higher velocities are acceptable if materials less susceptible to erosion (e.g., stainless steel) are selected. Concurrently reducing vibration and meeting system hydraulic requirements will reduce the piping's susceptibility to erosion. In all cases, it should be recognized that these ranges are recommended only if system operating requirements are also satisfied. High velocities are often conducive to water hammer problems.

Pipe-Wall Thickness Selection. After determining the internal diameter of the pipe, the designer must select materials, consider their strength, and select a pipe-wall thickness or schedule, as a function of temperature, pressure, corrosion, erosion, vibration, and external loads, as required.

Pipe-wall thickness determination begins with the basic hoop stress in the pipe wall. This stress calculation ignores longitudinal wall stress that exists if the pipe has closed ends. An example of this is a flask or short header.

Advanced analysis shows that for thin-wall pipe, the outside diameter should be used in the hoop stress equation:

$$S = \frac{PD_o}{2t_{\min}} \tag{C1.11}$$

where P = internal design pressure, psig (kPa) [gauge]
D_o = outside diameter of pipe, in (mm)
$t_{\min}$ = minimum required pipe wall thickness, in (mm)
S = allowable stress, psi (kPa)

This equation, called the Barlow formula, is the basis for most code stress-pipewall-thickness calculations such as those provided in ASME B31.1 and B31.3. The formula also applies to thick-walled pipe.

The Barlow formula allows determination of wall thickness for flexible pipe required to handle internal pressure. Pipe-wall thickness must also be adequate to handle external loads such as soil cover and vehicle loads, vacuum, and buckling. For flexible pipe such as steel, ductile iron, PVC, and HDPE, determination of thickness for internal pressure and determination of thickness to handle external

loads are calculated separately, and the greater of the two thicknesses is used. For flexible pipe, thickness required to handle deflection from external soil and vehicle loads is calculated using the Modified Iowa formula:

$$\Delta X = (D_L \times K \times W \times r^3)/\{(E \times I) + (.061 \times E' \times r^3)\} \qquad \text{(C1.12)}$$

where D_L = deflection lag factor
K = bedding constant
W = load per unit length of pipe
r = pipe radius
E = modulus of elasticity of pipe material
I = moment of inertia of pipe
E' = modulus of soil reaction
ΔX = deflection

The minimum thickness is determined based on maximum allowable deflection. Maximum allowable deflection varies for different materials, e.g., steel, ductile iron, PVC, HDPE, et cetera. For steel and ductile iron, the limiting factor in maximum allowable deflection is the nature of lining and coating of the pipe, with concrete lining or coating limiting deflection to less than that for a more flexible lining or coating such as epoxy. For PVC and HDPE, the allowable stress and strain in the pipe wall determines the maximum allowable deflection. In the municipal water works industry, guidance for calculating pipe wall thickness for steel pipe is provided in AWWA Manual M11, in AWWA C900 and C905 and Manual M23 for PVC, in AWWA C906 and manufacturers' literature for HDPE, and in AWWA C150 for ductile iron.

For certain types of rigid-pressure pipe, for example, prestressed concrete–cylinder pipe and cast-iron pipe (no longer used), design is based on combined loading, wherein internal pressure and external load are considered simultaneously—as internal pressure increases, allowable external loading decreases, and vice-versa. Design guidelines for prestressed concrete–cylinder pipe are found in AWWA Manual M9.

In the design of pipe, various configurations of bedding, backfill, and trench preparation can contribute to the pipe's adequacy to handle external load. These factors are addressed in the aforementioned manuals and specifications.

The allowable stress in a pipe wall is not determined solely by the material's strength at the service temperature. In pipe with a longitudinal welded seam, the efficiency of the welded joint must also be considered.

ASME Power Piping Code, Section B31.1, provides efficiency factors of 0.60 for a furnace butt weld, 0.85 for an electric-resistance weld, and 1.00 for single or double butt weld with 100 percent radiography. Allowable stress for welded pipe is determined by multiplying the allowable stress value for seamless pipe at the given temperature by the efficiency factor. Tables of allowable stress in Codes, such as B31.1, include the joint efficiency. The B31.1 Code further specifies the following formula for determining the minimum thickness of pipe wall at design temperatures,

$$t_m = \frac{PD_o}{2(SE + Py)} + A \qquad \text{(C1.13)}$$

or,

$$t_m = \frac{Pd + 2SEA + 2yPA}{2(SE + Py - P)} \qquad \text{(C1.14)}$$

and the design pressure shall not exceed

$$P = \frac{2SE(t_m - A)}{D_o - 2_y(t_m - A)} \qquad \text{(C1.15)}$$

$$P = \frac{2SE(t_m - A)}{d - 2_y(t_m - A) + 2t_m} \qquad \text{(C1.16)}$$

where t_m = minimum pipe wall thickness, in (mm)

P = internal design pressure, psig (kPa [gage])

D_o = outside diameter of pipe, in (mm). For design calculations, the outside diameter of pipe, as given in tables of standards and specifications, is used in obtaining the value of t_m. When calculating the allowable working pressure of pipe on hand or in stock, the actual measured outside diameter and actual measured minimum wall thickness at the thinner end of the pipe may be used to calculate this pressure.

d = inside diameter of pipe, in (mm). For design calculations, the inside diameter of pipe is the maximum possible value allowable under the purchase specification. When calculating the allowable working pressure of pipe on hand or in stock, the actual measured inside diameter and actual measured minimum wall thickness at the thinner end of the pipe may be used to calculate this pressure.

SE = allowable stress for the material due to internal pressure and joint efficiency, at the design temperature, psi (kPa)

A = allowance for threading, grooving, mechanical strength, and the effects of erosion and corrosion, in (mm)

y = 0.4 for ferritic steels and austenitic steels for temperatures up to 900°F (480°C). For pipe with a D_o/t_m ratio less than 6, the value of y for ferritic and austenitic steels designed for temperature of 900 F (480°C) and below shall be taken as:

$$y = \frac{d}{d + D_o} \qquad \text{(C1.17)}$$

If pipe is ordered by its nominal wall thickness, the manufacturing tolerance on wall thickness must be taken into account. After the minimum pipe wall thickness t_m is determined by equation C1.13 or C1.14, this minimum thickness shall be increased by an amount sufficient to provide the manufacturing tolerance allowed in the applicable pipe specification or required by the process. The next heavier commercial wall thickness shall then be selected from thickness schedules such as contained in ASME B36.10M, ASME B36.19, or from manufacturers' schedules for other than standard thickness. Refer to Chap. B2 for details on calculating the pipe-wall thickness. For cast piping components, or to compensate for thinning in bends, refer to the applicable Code.

Where ends are subject to forming or machining for jointing, the wall thickness of the pipe, tube, or component shall not be less than t_m, after such forming and machining.

The thickness of gray and ductile-iron pipe conveying liquids may be determined by selection from AWWA/ANSI C110/A21.10, AWWA/ANSI C115/A21.15, AWWA/ANSI C150/A21.50, AWWA/ANSI C151/A21.51, and Federal Specification WW-P-421.

While the thickness of steel pipe determined from Eq. C1.13 or C1.14 is theoreti-

cally ample for both bursting pressure and material removed in threading, the following minimum requirements are mandatory to provide added mechanical strength:

1. Where steel pipe is threaded and used for water service above 100 psi (700 kPa) with water temperature above 220°F (105°C), the pipe shall be seamless, having the minimum ultimate tensile strength of 48,000 psi (330 MPa) and a weight at least equal to Schedule 80 of ASME B36.10M.
2. Where threaded brass or copper pipe is used for the services described previously, it shall comply with pressure and temperature classifications permitted for these materials by other paragraphs of the applicable Code and shall have a wall thickness at least equal to that specified for steel pipe of corresponding size.
3. Plain-end nonferrous pipe or tube shall have minimum thickness as follows:
   a. For nominal sizes smaller than NPS ¾ (DN20), the thickness shall not be less than that specified for Type K of ASTM B 88 for copper tubing.
   b. For nominal sizes NPS ¾ (DN20) and larger, the wall thickness shall not be less than 0.049 in (1.25 mm). The wall thickness shall be further increased as required by determining the minimum wall.
4. After calculating the required minimum wall thickness, choice is usually made from standard thickness or schedules. Tables of pipe sizes and wall thickness (schedules) are presented in App. E2 and E2M. For tubing, refer to App. E3 and E3M.
5. For piping systems other than steel or cast iron, the reader is referred to the applicable code.

Design Features

Materials. This section discusses the most commonly used materials for water-distribution-system piping and piping components. Pipe description, material-specifications characteristics, available sizes, normal use, and advantages or disadvantages of different materials are briefly noted in Table C1.3. It should also be noted that state and local regulations may govern the preferred types of pipe to be used for water distribution systems.

The selection of water-distribution-system piping is based upon the following considerations: strength, ductility, modulus of elasticity, toughness, corrosion, erosion and abrasion resistance, weldability, workability, and surface smoothness. The most common piping materials are steel, either low-carbon, low-alloy, or stainless; plastic, either thermoplastic or thermosetting with fiberglass reinforcement; or concrete, lined and unlined. Aluminum, copper, brass, titanium, and high-nickel alloys are also used for some specific applications.

The metallurgy of the various types of metallic pipe material is somewhat complicated; however, an understanding of the basic physical properties and their effects is necessary for design engineers concerned with selecting pipe material, pipe fabrication process, welding process, and corrosion resistance properties. The most commonly accepted piping standards are those of the American Society for Testing and Materials (ASTM), American Water Works Association (AWWA), American National Standards Institute (ANSI), the American Society of Mechanical Engineers (ASME), and the American Petroleum Institute (API).

These standards have been developed by experimentation, testing, and experience. Most regulatory agencies use these guidelines to set their own requirements. Pipe manufacturers also publish product literature that is useful in pipe selection and installation. Table C1.4 summarizes the advantages and disadvantages of piping materials and related data of pipe joints and their applications.

TABLE C1.3 Piping Material Specifications, Standards, and Applications Material

Material	Industry standards	Common sizes diam in (mm)	Normal maximum working pressure psi (kPa)	Advantages	Disadvantages
Cast-iron pipe Ductile iron Centrifugally cast in metal Molds or sand-lined molds for water and other liquids	ANSI/AWWA/C151/A21.51 ASTM A377	4–30 (100–760)	350 (2414)	Durable, strong, flexural-strength, lighter weight than cast iron, greater carrying capacity, same external diameter, fracture resistant, easily tapped.	Subject to electrolysis and attack from acid and alkali soil, heavy to handle; may require thrust blocks at changes in direction or restraint of joints to counteract unbalanced forces.

Concrete
Reinforced concrete
  pressure
Pipe noncylinder type for
  water and other liquids
	AWWA C302	12–168 (300–4300)	50 (345)	Durable with low maintenance, good corrosion resistance, good flow characteristics, generally suited for gravity systems with low gradient.	May deteriorate in alkaline soil if cement type is improper or in acid soil if not protected; may require thrust blocks at changes in direction or restraint of joints to counteract unbalanced forces.

Prestressed concrete
Pressure-pipe steel cylinder
Type for water and other
  liquids
	ANSI/AWWA C301
	  and C304
		16–144 (410 mm–
		  3660 mm)
			250 (1724)	Durable, low maintenance, good corrosion resistance, good flow characteristics, resists backfill and external loads.	Same as above.

Steel
Seamless pipe for high
  temperature service
Seamless and seam-welded
  pipe
Forged and bored pipe for
  high-temperature service
	ASTM A106, A335, A376
	
	ASTM A53, A312, A333,
	  A714
	ASTM A426, A451, A452
		4–120 (100–3000)	High	Easy to install, tensile strength, low cost, good hydraulically when lined, adapted to locations where some movement may occur.	Subject to electrolysis external corrosion in acid or alkali soil, poor corrosion-resistance welded unless properly lined, coated, and wrapped; low resistance to external pressure in large sizes; air-vacuum valves imperative in large sizes; subject to tuberculation when unlined.

Polyvinyl chloride (PVC)
PVC plastic pipe
Schedule 40, 80 pressure
  rated (SDR) series
PVC pressure pipe
	ASTM D1785
	ASTM D2241
	
	ANSI/AWWA C900 and
	  C905
		4–36 (100–900)	200 (1380)	Light weight, easy to install, excellent resistance to corrosion, good flow characteristics, high tensile and impact strength	Difficult to locate underground; requires special care when tapping; susceptible to damage during handling; aboveground use may require more supports. PVC pipe also requires thrust restraint at change in direction or velocity.

TABLE C1.3 Piping Material Specifications, Standards, and Applications Material   (*Continued*)

Material	Industry standards	Common sizes diam in (mm)	Normal maximum working pressure psi (kPa)	Advantages	Disadvantages
Copper		⅛–12 (3–300)	<700 (4828)	Excellent resistance to corrosion; ideal for use in water supply and plumbing, including DWV, compressed-air-instrumentation lines, and heat transfer equipment.	Copper deteriorates rapidly under high temperature and repeated stresses.
Seamless copper Standard sizes	ASTM B42				
Seamless copper Water tube for general plumbing Purposes	ASTM B88				
Seamless, threadless copper pipe	ASTM B302				
Seamless copper tube	ASTM B75				
Copper nickel, seamless copper, nickel pipe and tube Welded copper nickel pipe	ASTM B466			High level of corrosion resistance of copper nickel; 10% to corrosion and bifouling make ideal for use in piping systems for brackish or sea water. Copper nickel, 30% provides the best service under the most adverse condition. It offers excellent corrosion resistance to high-velocity seawater, immune to stress-corrosion cracking and resistant to the action of ammonia.	May undergo a general attack or uniform thinning in aggressive environment containing high concentration of oxygen and carbon-dioxide.
Welded copper and copper alloy Heat-exchange tube, 90-10 and 70-30	ASTM B467				
Aluminum		⅛–12 (3–300)	<300 (2069)	Light weight, durable, strong, ideal for use in cryogenic systems, heat-transpressure lines, process systems where performance requirements outweigh cost.	Requires special techniques and skills for brazing or welding joints depending on type of alloy.
Aluminum and aluminum alloy Seamless-pipe extruded tube	ASTM B241				
Drawn seamless tube for condensers and heat exchangers	ASTM B234				
Aluminum-alloy drawn seamless tube	ASTM B210				
Titanium		⅛–12 (3–300)	High	Excellent for general corrosion resisting and elevated temperature service. Lighter than steel while having strength comparable with alloy steel. Excellent for use with cooling water, fresh brackish or salt, polluted, etc., essentially immune to all forms of corrosion in condenser environments.	Resistance to bifouling is relatively poor when compared to copper alloy for similar application; coupling of titanium tubes with copper-alloy tube sheets in condensers may result in galvanic attack on the tube sheet in all types and make it essential to provide some form of cathodic protection.
Seamless and welded titanium Alloy pipe	ASTM B337				
Seamless and welded titanium Alloy tube for condensers and heat exchangers	ASTM B338				

Note: Materials used for piping within the jurisdiction of ASME I and ASME III, and boiler external piping are designated by SA/SB numbers and are derived from ASTM "A" specifications for ASME Boiler and Pressure Vessel Code applications, see related specifications SA/SB in Section II of the ASME Boiler and Pressure Vessel Code.

TABLE C1.4 Pipe Joints and Their Applications

Pipe material	Type of joints	Applications
Steel	Mechanical-type couplings	Pipes are less than 24 in od, especially linings.
Steel	Welded joints	Pipes 24 in od and larger with inside coatings ideal for soft soils where settlement may be excessive.
Steel	Flanged joints	Where flanged valves, fittings or nozzles of equipment are to be attached. Offer ease of assembly and disassembly.
Copper	Welded, flanged, threaded, screwed, or brazed, flared fittings	Generally used in underground water service, interior water, steam, gas, fuel, oil and for some underground drainage.
Copper-nickel	Flanged, soldered, or brazed fittings used with hard drain temperatures; flared compression fittings used with annealed temper tubes	Used in condenser tubing, systems for sea or brackish water.
Aluminum	Brazed, welded	Used in cryogenic systems, heat transfer, process systems and pressure lines.
Titanium	Welded	Used with any kind of cooling water in large power plant condenser tubing.

Pipe Toughness.   Pipe toughness is the ability of piping to absorb impact without brittle rupture. Service metal temperature is important in design, as most pipe metals have a transition range over which ductile behavior changes to brittle behavior on impact as the temperature drops.

Gray and Ductile-Iron Pipe.   Cast-iron pipe has been the standard for water distribution systems worldwide for many years. There are more miles of this pipe in use today than any other pipe. Two types of cast iron commonly found in distribution systems are gray cast-iron pipe (CIP) and ductile-iron pipe (DIP). (In this text, CIP is used as the abbreviation for gray cast-iron pipe; it does not stand for cast-iron pipe in general.)

Gray cast-iron pipe is strong but brittle, usually offers a long service life, and is reasonably maintenance free. Ductile-iron pipe resembles CIP in appearance and has many of the same characteristics. It differs from CIP in that the graphite is distributed in the metal in spheroidal or nodular form, that is, in ball-shape form rather than in flake form. This is achieved by adding a material called an innoculant, usually magnesium, to the molten iron. Ductile-iron pipe is much stronger, tougher, and more ductile than CIP. Gray cast-iron pipe has not been produced since 1980, due to the increased reliability of DIP, but is still used in the manufacture of valves and fittings.

Although unlined cast iron has a certain resistance to corrosion, aggressive waters can cause the pipe to lose carrying capacity through corrosion and tuberculation. The process for lining pipe with a thin coating of cement mortar made it possible

to minimize tuberculation and maintain the carrying capacity of the pipe. The cement-mortar lining is approximately ⅛ in (3 mm) thick and adheres to the pipe. The lined pipe may be cut or tapped without damage to the lining. Ductile-iron pipe internal lining can be cement mortar. Various thermoplastic and other epoxy-lined pipe are also available but are expensive. Generally these would be used to handle fluids considerably more corrosive than water. Bituminous external coating and polyethylene wraps are methods commonly used to reduce external corrosion.

Ductile-iron pipe is available with standard wall thickness (referred to as TC) in diameters of 4 in (100 mm) and larger. The standard lengths are 18 and 20 ft (5.5 and 6.1 m). Ductile-iron pipe is strong and can withstand the working pressures found in distribution systems. It is also durable and can be cut and tapped in the field.

CIP and DIP Joints.   Gray cast-iron and ductile-iron joints of the following types have been used to join pipe lengths together (listed in order of development):

- Flanged joints
- Bell-and-spigot joints
- Mechanical joints
- Ball-and-socket or submarine joints
- Push-on joints
- Bolted retainer-gland joints, to prevent pullout
- Push-on joints with restrained gaskets to prevent pullout

Flanged joints are easy to make and require no special tools. They are used aboveground in water plants, pump houses, and other places where rigidity, self-restraint, and tightness are required. Flanged joints will not flex and are not normally used underground.

Mechanical joints are made by bolting a moveable follower ring on the spigot to a flange on the bell and compressing a rubber gasket to form a tight seal. The mechanical joint is less economical than previously mentioned joints but is easily made and requires no special skill. Since the bell-and-spigot ends need not fit tightly, each joint can be made to deflect slightly.

Bell-and-socket joints are special-purpose joints most commonly used for submerged installations. Their great advantage is that they can accommodate large deflections (up to 15°). This makes them very useful for pipe lines laid across mountainous terrain or under rivers. Boltless flexible-pipe joints, designed on the brass-and-socket principle, are also available.

Push-on joints are the most popular joints in water-distribution-system installation today. The joint consists of a bell with a specially designed recess to accept a rubber ring gasket and a beveled-end spigot. The joint offers ease of installation, and when made up, the rubber ring gasket is compressed to produce water tightness and locked in place against further displacement. Push-on joints are available in several designs. In addition to ease of installation and water tightness, the joint permits deflections of 3° to 5°, depending on the design, for installation on a curve or irregular terrain. Small diameters may be assembled by hand; larger sizes usually require mechanical aids. For detailed discussion on the above joints, refer to Chap. A2.

Steel Pipe and Reinforced Concrete Pipe.   Steel pipe and reinforced concrete pipe are sometimes used as large feeder mains in water-distribution systems.

Plastic Pipe.   Plastic pipe is also used in water-distribution applications. Plastic pipe was first introduced in the United States around 1940.

Plastic pipe materials include polyvinyl chloride (PVC), chlorinated polyvinyl chloride (CPVC), polyethylene (PE), and a crylonitrile-butadiene-styrene (ABS). ASTM and AWWA standards cover PVC pipe in sizes from NPS 4 to 12 (DN100 to 300) in diameter. Polyvinyl chloride pipe is a rigid pipe manufactured by an extrusion process. Fittings are made by a mold process. It is available in diameters up to NPS 36 (DN900); lengths of 20–40 ft (6–12 m); and various types, grades, and pressure ratings. Within a given nominal pipe diameter, there are several equivalent systems for specifying internal and external diameters. Larger than NPS 12 (DN300) plastic pipe is normally specified by a sizing system other than the iron-pipe size (IPS) system.

The AWWA standard is based on outside diameter, the same as DIP. A new sizing system, termed the standard dimension ratio-pressure rated (SDR-PR) system, is a ratio of the outside pipe diameter to wall thickness. See Table C1.5. For more detailed discussion of thermoplastic pipe, refer to Chap. D1.

The SDR-PR system recognizes the strength properties of plastic and allows pipe of one pressure rating to be available in various sizes. State and local regulations should be checked to determine what types and sizes of plastic pipe are approved for a particular application.

Manufacturers' recommendations should be consulted when tap diameters exceed NPS 2 (DN50).

PVC pipe may be joined by a bell-and-spigot push-on joint or by a solvent-weld joint. Refer to Chap. D1 of this handbook.

Steel Pipe.   Application may dictate the need for steel piping to be lined or coated with a plastic, tar, plastic-encapsulated cement, or rubber. ASME B31.1 App. IV, Corrosion Control for ASME B31.1—Power Piping Systems provides guidelines for the control of corrosion of steel piping.

The American Water Works Association likewise provides guidelines and standards for coating and lining potable water lines for corrosion protection. Also, refer to Chaps. B9, B10, B11, and B12.

Special applications might require the use of stainless steel, ductile iron, copper, copper alloys, plastic, fiberglass, and aluminum-alloy pipe. Utilization of these materials is generally based on their corrosion-resistance properties and ease of installation.

Copper is widely used in service connections for potable water. Heat-exchanger tubing is a common use for nonferrous metals, including copper, copper-nickel alloys, titanium, and aluminum.

Copper and its alloys, e.g., brass, are useful in this application because of their good thermal conductivity and favorable cold or hot working properties and corrosion resistance.

Aluminum's low density and relatively high strength of its alloys give it good corrosion resistance and good working properties.

Titanium and its alloys have strength comparable to alloy steels at 60 percent of its weight. Corrosion resistance is superior to that of aluminum and even stainless steel.

Expansion, Flexibility, and Support

Expansion and Flexibility.   Water systems piping shall have adequate flexibility to account for thermal expansion. Water systems operating under low temperature (less than 250°F [121°C]) and low pressure (less than 300 psig [2070 kPa(gage)])

conditions are considered to have adequate flexibility if the following conditions are satisfied:

$$\frac{Dy}{(L - U)^2} \leq 0.03 \qquad\qquad (C1.18)$$

where D = Nominal pipe diameter, in (mm)
$\quad\ \ y$ = Thermal growth of the pipe, in (mm)
$\quad\ \ L$ = Length of pipe in the system, ft (m)
$\quad\ \ U$ = Distance between rigid supports, ft (m)

If the conditions above are not met, a detailed analysis of the piping system may be needed. The reader is referred to Chap. B4, Stress Analysis of Piping Systems, for more information.

In piping systems without adequate flexibility, thermal expansion may lead to failure of piping or anchors. It may also lead to joint leakage and excessive loads on nozzles. The thermal expansion of piping can be controlled by use of proper locations of anchors, guides, and snubbers. Where expansion cannot be controlled, flexibility is provided by use of bends, loops, or expansion joints (bellows or slip-joints).

Detailed calculations for underground water-piping systems are not needed unless significant settlement, seismic, or temperature changes are expected. Buried piping, although supported throughout by proper bedding and backfilling procedures, also requires thrust restraint for unrestrained joints at changes of direction.

Pipe Support Systems.   Standard component supports are normally used to carry dead weight and thermal expansion loads. The dead weight and thermal supports typically used are defined in MSS-SP-58. Part B, Chap. B5 of this handbook discusses pipe-support design and selection in detail.

Valve Selection.   In water-piping systems, valves are generally used for isolating a section of a water main, draining the water line, throttling fluid flow, regulating water-storage levels, controlling water hammer, bleed off of air, or preventing backflow. Refer to Chap. A10.

Isolation.   Gate valves are used to isolate specific areas of the system during repair work or to reroute water flow throughout the distribution system. An open gate valve allows water to flow through in a straight line. The valve may be closed during an emergency, such as a water-main break, or during routine maintenance.

Gate valves commonly used in water distribution systems are the iron-body bronze-mounted (IBBM) nonrising-stem (NRS) gate valves. Buried gate valves are usually nonrising-stem valves. In situations where an operator will need to know by observation whether a valve is open or closed, a rising-stem valve with an outside screw and yoke (OS&Y) is often used.

Service stops valves are used to shut off service lines to individual homes or businesses. Specific types of service stops include the corporation stop, which is tapped into the main, and the curb stop, which is located near the property line. Access to the curb stop is through a curb box. Small plug valves are used as curb stops and corporation stops.

Butterfly valves are also used for isolation purposes. Because the disk remains in the water path in all positions, the butterfly valve may create a slightly higher head loss than the gate valve. The position of the disk also makes it difficult to clean scale from a pipeline because the pig or swab is blocked by the valve disk. However, butterfly valves open easily, as the water pressures acting on one-half of the upstream side of the disk tends to force it open, balancing the pressure on the

other half, which tends to force it closed. The cost of NPS 16 (DN400) and larger butterfly valves is less than the cost of large gate valves, as large gate valves normally require reduction gears, a bypass valve, rollers, tracks, and scrapers. Butterfly valves should be located away from sources of turbulence to preclude damaging effects of turbulence to the disk.

Draining the Water Line. Drain or blow-off valves may be installed at low points to flush sediment from the main or to drain the entire main. Gate valves are commonly used as drain valves. Where rapid draining is not important, globe valves may be used to drain lines where sediment accumulation is not a problem. Though quicker to operate and less costly to repair than gate valves, NPS 3 (DN80) and larger globe valves are less economical.

Throttling Flow and Regulating Water-Storage Levels. In addition to on-off control of flow, globe valves may be used to regulate or throttle flow. This can be done manually, although it is usually done automatically. For throttling under low-flow and low-pressure conditions, butterfly valves are also used. Large-plug valves may be used for throttling.

An altitude valve is a type of control valve, diaphragm or piston type, used to control the level of water in a tank supplied from a pressure system. There are two general types of altitude valves: single acting and double acting.

A single-acting altitude valve is used for filling the tank. A bypass line with check valves around the altitude valve is needed to permit backflow out of the tank and into the distribution system when the inlet pressure is lower than the tank. The tank discharges through a separate line or through a check valve in a bypass line around the altitude valve.

A double-acting altitude valve allows to flow both to and from the tank. When the tank becomes full, the valve closes to prevent overflow. When the distribution pressure drops below the pressure exerted by the full tank, the valve opens to discharge water into the distribution system.

Controlling Water Hammer. In a water distribution system, opening or closing a valve too fast can cause water hammer. This phenomena is discussed in Chap. B8. Pressure-relief valves are used to help control water hammer by releasing some of the energy that is created by a sudden stop in flow. They are fitted with an adjustable spring to set the maximum pressure of the line. When line pressure becomes greater than the set pressure, the valve opens until the pressure is equalized. Other choices include standpipes open to atmosphere and various kinds of surge tanks.

Bleed Off of Air and Breaking Vacuum. Air tends to collect in water lines. Under the pressure of the distribution system, air dissolves and can reappear as microscopic air bubbles, which gives water a cloudy appearance. A more common operating problem occurs when air collects in high places in the distribution system producing air pockets. Air pockets effectively reduce the area of pipe through which water flows, causing an affect known as *air binding*. The result is pressure loss and increased pumping costs.

Air vacuum and air release valves can be installed to eliminate these problems in pumping stations where air can enter the system and at high points where it can collect. Air-relief/release valves solve the problem by automatically venting any air that accumulates. Conversely, vacuum caused by column separation can be broken with vacuum-relief valves. Combination air and vacuum relief valves are used for this application.

Figure C1.13 shows a spring-loaded check valve that opens during forward flow and is closed by the spring when flow stops. When pressure drops to a low value, a second valve opens and allows air to enter this breaker. With this arrangement,
FIGURE C1.13   Pressure and vacuum breaker.

the breaker can remain under supply pressure for long periods without sticking and can be installed upstream from the last shut-off valve.

Figure C1.14 shows an atmospheric vacuum breaker, consisting of a check valve operated by water flow and a vent to the atmosphere. When flow is in the forward direction, the valve lifts and shuts off the air vent; when flow stops or reverses, the valve drops to close the water-supply entry and open an air vent.
FIGURE C1.14   Atmospheric vacuum breaker.

Preventing Backflow.   Backflow in a pump discharge line can be prevented by installing a check valve to allow flow in one direction only—away from the pump. However, check valves can contribute to water hammer problems, especially in the case of pump failure. Proper precautions to avoid or relieve these surges must be taken.

Backflow, or reversed flow, could result in contaminated or polluted water entering the water system. Backflow can occur through a cross-connection under two conditions: back pressure and back-siphonage (see Fig. C1.15). If a pressurized nontreated system is cross connected with a lower-pressure treated water system, then the pressure in the nontreated system can force nontreated fluid into the treated supply. This situation is referred to as backflow due to back pressure.

Valves are used as backflow-prevention devices. A device that can be used in every cross-connection situation and with every degree of risk is the reduced-
FIGURE C1.15 Examples of backflow due to back siphonage. (*a*) Backsiphonage due to pressure loss; (*b*) backsiphonage—hose forms cross connection; (*c*) backsiphonage from a booster pump; (*d*) backsiphonage due to a broken main. (*Introduction to Water Distribution Principles and Practices of Water Supply Operations,* American Water Works Association, 1986.)

pressure-zone backflow. This device consists of two spring-loaded check valves with a pressure-regulated relief valve located between them. Two check valves, even though well designed and constructed, are not considered sufficient protection, because all valves leak from wear or obstruction. For this reason, a relief valve is positioned between the two checks. Typical backflow conditions are illustrated in Fig. C1.16.
FIGURE C1.16 Examples of backflow due to back pressure. (*a*) Cross connection between pressurized nonpotable system and lower pressure potable system; (*b*) back-flow from recirculated system. (*Introduction to Water Distribution Principles and Practices of Water Supply Operations,* American Water Works Association, 1986.)

If a treated water-distribution system is cross connected to a nontreated source that is open to the atmosphere, and if the pressure in the treated system falls below atmospheric pressure, then the pressure of the atmosphere can force the nontreated fluid into the treated supply. This situation is called backflow due to *backsiphonage*. Examples of backsiphonage conditions include overpumping by fire or booster pumps, undersized distribution piping, and a broken main. When backsiphonage occurs, the partial vacuum pulls liquid back into the supply line. If air enters the line between a cross-connection and the source of the vacuum, then the vacuum will be broken and backsiphonage will be prevented.

Water Hammer and Surge Control.   The problem of water hammer in water piping systems consists of containing the pressure and dissipating the water-flow energy. For example, the energy necessary to move the water through the piping is supplied by the pump. If a valve is suddenly closed at the end of the discharge line, the moving column of water is brought to a stop at the valve. The kinetic energy contained in the column of water, originally given to the water by the pump, is still present and must be dissipated. The column of water compresses, the pressure rises, and some of the kinetic energy is transformed to internal energy. The higher water pressure acts upon the pipe wall and does work in stretching it, but only a small percentage of energy will be lost in this. The pipe will obey the laws of vibration and return most of the energy to the water.

The water-hammer effects are obtained from equations that define relations between head and flow in the discharge line during the transient flow condition which results from water-hammer wave action.

Water-column separation might occur at high points near the hydraulic gradient on long discharge lines. This condition can create high-pressure conditions at the moment of rejoining of the separated water columns.

TABLE C1.6   Waterhammer Velocity in Piping Systems (a, wave velocity in feet per second)

D/t	Steel ($E = 28 \times 10^6$ psi)	Cast iron ($E = 16 \times 10^6$ psi)	Transite ($E = 3.4 \times 10^4$ psi)
20	4300	4100	3000
40	4000	3600	2300
60	3800	3350	2000
80	3600	3100	1750
100	3400	2900	1600
150	3100	2500	1300
200	2800	2250	1150
250	2600	2050	
300	2400		

Table C1.6 gives the water-hammer wave velocity as a function of diameter-to-thickness ratios for three different piping materials encountered frequently in water-supply or distribution systems. In this tabulation, a is the wave velocity in ft/sec (m/sec), D/t is the dimensionless ratio of diameter to thickness, and E is the modulus of elasticity.

If a valve is closed in the time of one wave cycle (in the time a pressure wave travels to the other end of the pipeline and returns to the closing valve) or less, then the water hammer should be calculated on the basis of instant valve closure.

To determine time for the wave cycle, use

$$T = \frac{2L}{a}$$ (C1.19)

To determine water hammer for instantaneous valve closing, use

$$h = \frac{aV}{g}$$ (C1.20)

where T = time for one wave cycle, sec
$\quad L$ = pipeline length, ft (m)
$\quad h$ = water-hammer head above static head, ft (m)
$\quad a$ = velocity of pressure wave, ft/sec (m/s)
$\quad V$ = water velocity at instant before valve closure, ft/sec (m/s)
$\quad g$ = 32.2 ft/sec^2 (9.81 m/sec^2)

To determine water hammer for slower valve closing, use

$$h_2 - h_1 = \frac{a(V_1 - V_2)}{g} \tag{C1.21}$$

where h_2 = pressure after partial closing of valve, ft (m)
$\quad h_1$ = pressure before start of valve closing, ft (m)
$h_2 - h_1$ = pressure rise due to water hammer, ft (m)
$\quad V_1$ = water velocity before start of valve closing, ft/sec (m/s)
$\quad V_2$ = water velocity after partial closing of valve, ft/sec (m/s)

The phenomenon and damaging effects of water hammer is discussed in detail in Part B, Chap. B8 of this handbook.

A means of eliminating water hammer is to permit the liquid to surge into a tank or discharge to atmosphere. To quickly suppress all the momentum in a long pipe system would require high-pressure piping, which is very costly. With a surge tank or relief valve as near the valve as feasible, the development of excessive pressure in this region is prevented.

Surge tanks may be classified as simple, orifice, and differential. The simple surge tank has an unrestricted opening into it and must be of adequate size so that it will not overflow and so it will not be emptied to permit air to enter the pipeline. An orifice surge tank has a restricted opening between pipeline and tank and allows more rapid pressure changes in the pipeline. A more rapid pressure change causes a more rapid adjustment of flow. A differential surge tank is a combination of an orifice surge tank and a simple surge tank of small cross-sectional area.

Surge tanks under air pressure are utilized in certain circumstances, such as after a reciprocating pump. They are generally uneconomical for large pipelines.

Relief valves are available in various types from spring loaded to control blow-down diaphragm types.

Air Binding. Air which accumulates in water piping will reduce the effective cross-sectional area for water flow and thus increase pumping costs through the resulting extra head loss. Air enters the piping system from several sources, such as the release of air from the water, air carried in through vortices into the pump suction, air leaking in through joints that may be under negative pressure, and having air present in the piping system before filling.

The water from the water source may be nearly saturated with air. If the temperature of this water is raised and the pressure is lowered by the siphon action, the water will release most of its air. However, this air release is not instantaneous but proceeds on a time-rate release and is therefore dependent upon the length of time the water remains in the piping. Experience indicates that the actual air release in a circulating water system of a conventional power-generating plant is probably on the order of 10 percent of calculated theoretical release.

On gentle downward slopes, a continuous air pocket may form along the top of the pipe for the entire slope. In a sharper downward slope, several air pockets may form, each air pocket terminating in a hydraulic jump. Slopes may require a

water velocity in excess of 10 fps (3 m/s) to assure that the piping remains free of air. In a 90° drop, an air pocket may form in the upper portion of the bend and a velocity in excess of 7 fps (2 m/s) may be required for air elimination. Connections for air vents should be provided at all high points in the piping system and along sloping piping of considerable length. Air-release valves at the high points of these systems' mains eliminate air pockets.

Pipeline Alignment.   Alignment, both horizontal and vertical, is one of the most important considerations in the design of a pipeline system. The pipeline must be buried deep enough to prevent freezing of pipe contents as well as to prevent flotation where the pipe is in a high-groundwater environment and may be empty on occasion. The designer must provide an alignment that provides sufficient clearance from other existing and proposed pipelines and structures, minimizes need for fittings, and avoids highways or other paving when possible. Under important roadways, the highway authorities may require the pipe to be placed in a casing. Additionally, the alignment should be such that it minimizes damage to life and property in case of pipeline failure.

Finally, changes in pipeline direction or change in fluid velocity cause unbalanced forces in the pipeline. To provide pipeline stability, these forces must be restrained, using either thrust blocking or harnessing joints of enough pipe lengths to mobilize sufficient friction to counteract unbalanced forces.

Corrosion and Erosion Effects

Corrosion.   All raw water coming from wells, rivers, lakes, or ocean is an extremely dilute water solution of mineral salts and gases. The salts are mineral matter dissolved by water flowing over and through the earth layers. The salts are mainly sulfates, bicarbonates, chlorides of calcium, sodium, and magnesium. These minerals give water its hardness (destroying soap and preventing lather) and precipitate as a white lime-type scale. The dissolved gases are atmospheric oxygen and carbon dioxide, picked up by water-atmosphere contact (e.g., spray, raindrops, and ammonia from decaying vegetable matter).

The dissolved gases are the prime agents of chemical corrosion that act on the metals of piping systems. The oxygen attacks the iron or steel, and the process is accelerated by the carbon dioxide. The rate and extent of the chemical corrosion are influenced by the amounts of mineral salts dissolved in the water.

The calcium content of water is used to measure the tendency of water to corrode or form scale. For this purpose, values are assigned to the calcium content and the alkalinity of the water. Adjustments are made for temperature and the effect of totally dissolved solids. The resultant value is compared with the observed pH of the water to determine whether it is corrosive or scaling. This is basically the Langelier saturation index as reported by Larson-Buswell in the *Journal of the American Water Works Association*, Vol. 28.

The water is corrosive when the Langelier index (calcium carbonate saturation index) is minus ($-$). The water analysis will generally, but not always, show a pH value below 7 (acidic).

The scaling in water lines occurs when the Langelier index is plus ($+$). The water analysis will generally show a pH value above 7 (basic).

The precipitation of calcium carbonate as a scale or film thickness may be desirable as a means of protection against corrosion if the rate of buildup is sufficiently low. Calcium carbonate is undesirable on heat-transfer surfaces. Since temperature lowers the solubility of calcium carbonate and calcium sulfate, the Langelier index will vary for colder water and for warm water.

The exterior of unprotected buried metallic pipe is subject to similar chemical

action due to exposure to water. In addition, the pipe exterior is susceptible to attack by aerobic and anaerobic bacteria, galvanic action, and stray electric currents. The chemical action on the pipe exterior may be more intense because of concentration of oxygen, salts, and other chemicals leached out of the surrounding earth by ground water.

Some forms of anaerobic bacteria that thrive only in the absence of free oxygen obtain their oxygen by the chemical breakdown of oxygen compounds in the earth, with the resultant production of substances such as hydrogen sulfide that will corrode the base-metallic buried pipeline. There are also many types of aerobic bacteria that produce sulfuric acid, sulfate, and ferric hydroxide, compounds that are all corrosive to steel or iron. Organic soil should be kept away from the vicinity of the pipeline to minimize possibility of this corrosive action.

Also, when iron or steel is in contact with a more cathodic material, for example, copper or brass, a galvanic cell is formed, electrolysis results, and the corrosion rate of steel or iron increases. If iron or steel is in contact with a more anodic material, for example, zinc, the zinc will be the affected material and the corrosion rate of the steel or iron will decrease.

There is some natural resistance to chemical corrosion of the base-metallic pipe materials. The chemical-corrosion product, an oxide film, may build up sufficiently to slow down or prevent further corrosion.

The natural coating characteristics of the most commonly used piping materials are mentioned briefly below.

On cast iron, the rust (iron oxide) builds up into a strong adhesive coating that finally forms a barrier sufficient to stop or slow down further corrosion. The higher silicon cast iron has the best characteristics in this respect.

On steel, the rust powders and flakes off easily and does not build up into an adhesive, providing sufficient protective coating.

For concrete and cement piping, the corrosion is of a different form. These materials are subject to leaching of the free lime from the cement, deterioration in alkali soils, and attack by organic growth.

Cathodic Protection.   If no protective coating is used, or if a low-cost, limited-life coating has been selected, cathodic protection may be considered as a means of limiting the main agent of corrosion, which is the electro-chemical process. In this process, the moist earth is the electrolyte, two dissimilar materials are the anode and the cathode, and the pipe wall between them completes the electric circuit. This process may be set in motion in a number of different ways, among which are dissimilar metals, galvanic action of a single metal due to dissimilar soils, variation in moisture and chemical content of soil, nonuniformity of metal caused by mill scale, surface scarring, welding, and even temperature differentials.

The current flows from the anode to the cathode and causes corrosion at a rate greater than that which would occur by normal chemical means. Corrosion rate is increased at the anode end and decreases at the cathode end. The anode is the point or area at which the current leaves the metal, and the cathode is the point at which the current enters the metal.

The electro-chemical galvanic series (Table C1.7) gives the relation between metals. The metal listed nearer the top of the table is the anode that will waste away. The metal nearer the bottom of the table is the cathode and will be protected. The farther from each other the metals are located in the table, the greater the potential difference will be between them and the greater the corrosion rate of the anode end.

A typical example of the galvanic action of dissimilar metals is represented by a steam condenser having a steel shell, steel-tube sheets, and copper-alloy tubes.

TABLE C1.7 Galvanic Series

Anode end (least noble, the wasting end)
Magnesium
Magnesium alloys
Zinc
Aluminum
Aluminum alloys
Cadmium
Carbon steel
Cast iron
Stainless steel (active)
Soft solder
Tin
Lead
Nickel (active)
Brasses
Copper
Bronzes
Nickel-copper alloys
Nickel (passive)
Stainless steel (passive)
Titanium
Silver solder
Silver
Graphite
Gold
Platinum
Cathode end (most noble, the protected end)

The steel is nearer the anode end than is the copper alloy and, as a consequence, the corrosion of the steel tube sheets and shell is accelerated. Always, that metal which is higher in the galvanic series will waste away.

Cathodic protection is a means of diverting the electro-chemical corrosion from the pipeline to wasting anodes.

There are two methods of providing cathodic protection. The less costly installation is the galvanic method based on a natural battery action between the position of metals in the electro-chemical table. An anode or wasting piece is deliberately used. This approach requires very careful analysis of all the varying conditions involved.

The second and more costly cathodic protection is the impressed-current method that requires an external source of electricity. The impressed-current renders the piping cathodic to the surrounding soil by a controlled difference of potential.

In locations where there may be stray currents, the installation of removal wires at designated points so that the current may leave the pipeline should be considered. In other words, stray currents are utilized to provide cathodic protection for the pipeline.

Protective Coatings.   Since corrosion of metal is a surface reaction, it is obvious that, if a protective coating which is continuous, impervious, chemically inert, and electrically insulating can be bonded to the interior or exterior of the piping, corrosion cannot take place on the pipe surface as long as the protective coating remains in place undamaged and without cracks or pinholes.

The basis of selection for the best coating differs for the interior and exterior of the pipe.

The coating on the interior of the pipe, to perform its function properly, would be selected for its chemical inertness, imperviousness, adhesiveness, adjustment to pipe deformation, and resistance to erosion caused by the flowing water.

The coating on the exterior of the pipe would be selected for its chemical inertness, electrical resistance, imperviousness, adhesiveness, adjustment to pipe deformation, and resistance to shear and compression due to varying earth conditions.

Galvanizing.   The zinc used for galvanizing pipe is on the anodic (wasting) or electro-chemical protective side of the steel, and it is wasted or changed to zinc compounds before the steel pipe will be attacked.

Coal-Tar Enamel.   Specification AWWA C203 covers the coal-tar enamel protective coatings for steel water pipe. This standard delineates the specifications for the materials involved, method of application to the inside and outside of the piping, the thickness required, protection of the coatings, testing, and other specifications.

The type of enamel is specified as AWWA coal-tar enamel and is described in this standard with full characteristics and the ASTM tests required.

Erosion.   Erosion effects in water piping systems is fundamentally an accelerated form of corrosion and as such is distinguishable from mechanical processes such as erosion abrasion and cavitation. Single-phase and two-phase erosion-corrosion differ in that a second damage process (droplet impingement) is available under two-phase conditions, and this can accelerate the overall rate of attack. In the most severe cases of two-phase erosion-corrosion, rapid rates of metal loss (approximately 40 mils/year) have been reported.

Erosion is observed only when specific combinations of material, water chemistry, and hydrodynamic conditions coexist. Most problems have been associated with plain carbon or very highly alloyed steels having a low content of dissolved oxygen and a pH less than about 9.3. Detrimental erosion occurs at temperatures within the range of 212°F to 525°F ([100°C to 274°C] but most rapidly between 260°F and 400°F [127°C and 204°C]) and is restricted to locations where the mass-transfer coefficient is high. This can be either as a result of a high-fluid flow rate or because of the presence of a geometric flow discontinuity such as an impingement orifice, bend, tee, et cetera.

Erosion under both single-phase and two-phase conditions can lead to a characteristic *scalloped* surface appearance, and in carbon steels the pearlite is preferentially attacked. Corrosion films are typically very thin and the surface sometimes appears polished, in marked contrast to adjacent regions which generally are more heavily oxidized.

A number of laboratory investigations of erosion have been conducted (almost exclusively in single-phase water flow only), and major variables affecting the process have been identified and their effects documented. Quantitative mechanistic understanding is not yet complete, but empirical predictive models are available. Laboratory studies have shown the feasibility of a variety of mitigating actions and remedies, and several of these have been applied successfully. The physical picture of the erosion process that has emerged from this work is illustrated in Fig. C1.17. As can be seen, erosion can be viewed as a flow-accelerated corrosion process characterized by the presence of a poorly adherent magnetite film.

The rate of metal removal depends on interactions between the rates of a number of subprocesses.
FIGURE C1.17   Phenomena occurring during erosion-corrosion.

The laboratory work shows that three main groups of variables affect the rate of metal loss by erosion under single-phase conditions:

• Material variables (chiefly the chemical composition)
• Water-chemistry variables (temperature, pH, oxygen concentration, impurity content)
• Hydrodynamic variables (flow rate, geometry)

Some largely empirical models have been developed (Ref. 5) and are capable of metal-loss predictions within the range of the data on which they are based.

Erosion occurs most readily in plain carbon steel. Austenitic stainless steels essentially are immune to erosion-corrosion. In ferritic steels, alloying elements such as molybdenum, copper and particularly chromium (even when present at levels of 1 percent or less) can greatly improve the erosion-corrosion resistance.

The effect of steel composition depends on the severity of hydrodynamic conditions; as conditions become more demanding, higher alloy contents are required to confer the same resistance to erosion-corrosion. However, in the relatively mild situation typical of feedwater piping, significant effects of small changes in material composition would be anticipated based on the laboratory data.

The effects on the erosion rates of water temperature, pH, and dissolved oxygen content have been studied by a number of investigators. For the orifice configuration tested, the temperature dependence at pH 9.05 has a flow-rate-dependent peak at about 284°F (140°C), suggesting that the erosion-corrosion rate is controlled by oxide dissolution kinetics at low temperatures and by mass-transfer limitations at higher temperatures. A marked decrease in erosion rate accompanies increases of pH.

Dissolved oxygen also has a marked effect in neutral water. Iron-release rates from carbon steel in 100°F to 400°F (38°C to 204°C) water at a flow rate of 6 ft/sec (1.8 m/s) have been shown to decrease by up to two orders of magnitude as oxygen concentration was increased over the range 1 to 200 ppb. Tests indicated that it is important to keep oxygen levels above 15 to 20 ppb, and oxygen dosing is a fairly common practice.

The effects on erosion of ionic impurities such as chlorides and sulfates have not been widely studied. In particular, there is little information which bears upon the question of whether a long prior period of adverse chemistry could have any irreversible effects.

Plant experience indicates that geometry and flow rate are important factors in erosion. The physical picture of the process shown in Fig. C1.17 suggests that the importance of geometry and flow rate rises through their influence on the rate of mass transfer of oxide dissolution products away from the oxide-water interface. Laboratory studies have confirmed that the mass-transfer coefficient is the controlling parameter; however, the exponent of the power function relating the erosion-corrosion rate and the mass-transfer coefficient is dependent on temperature. Since the mass-transfer coefficients for simple flow geometries can be calculated, the existence of these empirical relationships allows the erosion rate to be estimated for a variety of situations. However, local mass-transfer coefficients are sensitive to local geometrical discontinuities and at present can only be derived empirically.

Component redesign or flow-path geometry improvements, aimed at reducing the mass-transfer coefficient, can sometimes be used to remedy erosion-corrosion problems.

Referring to Fig. C1.17, the phenomena occurring during erosion is

A. Iron hydroxides are generated:

$$Fe + 2H_2O \rightarrow Fe(OH)_2 + H_2.$$
B. Magnetite is formed according to the Schikorr reaction:

$$3Fe(OH_2) \rightarrow Fe_3O_4 + H_2 + 2H_2O.$$
C. A fraction of the hydroxides formed in step B and hydrogen generated in steps A and B diffuse along pores in the oxide.

D. Magnetite can dissolve in the pore.

E. Magnetite dissolves at the oxide-water interface.

F. Water flow removes the dissolved species by a convection mass transfer mechanism.

Example C1.3. The following presents a sample calculation of the rate of erosion-corrosion under single-phase flow conditions. The methodology used is based upon the work performed by Coney (Refs. 6 and 7).

Physical and flow conditions for this example are

$$Pipe\ outside\ diameter = 18.00\ in\ (0.46\ m)$$

$$Pipe\ inside\ diameter\ \ = 17.00\ in\ (0.43\ m)$$

Wall thickness (nom.) = 0.50 in (.013 m)

pH = 9

Pressure = 367 psig (2531 KPa) [gauge]

Temperature = 380°F (193°C)

Flow Rate = 5,000,000 lbm/hr (630 kg/s)

For these conditions the Reynolds number, Re, is

$$Re = VD_H\rho/\mu \tag{C1.22}$$

where V = velocity, ft/sec (m/sec)
D_H = inside diameter, ft (m)
μ = dynamic viscosity, lbm/sec·ft (N·s/m²)
ρ = density, lbm/ft³ (kg/m³)

Since the flow rate is known, the velocity can be calculated:

$$W = \rho AV \tag{C1.23}$$

or

$$V = \frac{W}{A\rho} \tag{C1.24}$$

where W = flow rate, lbm/hr (kg/sec)
A = flow area, ft² (m²)

and

$$Re = \frac{(55)\frac{lbm}{ft^3}\left(\frac{kg}{m^3}\right) \times (17)\frac{ft}{sec}\left(\frac{m}{sec}\right)\frac{17}{(12)ft}\left(\frac{1}{m}\right)}{9.66 \times 10^{-5}\frac{lbm}{sec\text{-}ft}\left(\frac{N\cdot s}{m^2}\right)} = 1.29 \times 10^7$$

$$V = \frac{(5 \times 10^6)\frac{lbm}{hr}\left(\frac{kg}{sec}\right) \times \frac{1\,hr}{3600}sec}{\frac{\pi}{4}\left(\frac{17}{12}\right)^2 ft^2(m^2) \times 55\frac{lbm}{ft^3}\left(\frac{kg}{m^3}\right)} = 17 \text{ ft/sec, (m)/sec}$$

The mass-transfer rate is now calculated.

In order to calculate the mass-transfer coefficient, an empirical correlation must be used. The Berger and Hau correlation is used prediciting this coefficient. The recommended range of this correlation is $10^4 < Re < 10^6$. This correlation will be used for two reasons:

1. The turbulent-flow mass-transfer correlations are based, by analogy, on heat-transfer correlations. And heat-transfer correlations of the same form as Berger and Hau typically are valid up to $Re = 10^7$.

2. In view of the limited mass-transfer data at very high Reynolds number, this was judged to be the most suitable correlation for this application.

The Berger and Hau (Ref. 8) correlation is

$$\text{Sh} = 0.0165\,\text{Re}^{0.86}\,\text{Sc}^{0.33} \qquad\qquad (\text{C}1.25)$$

where the Sherwood number and the Schmidt number are dimensionless numbers defined as

$$\text{Sh} = \frac{KD_H}{d} \qquad\qquad (\text{C}1.26)$$

$$\text{Sc} = \frac{\mu}{\rho d} \qquad\qquad (\text{C}1.27)$$

where K = mass-transfer coefficient, ft/sec (m/sec)
$\quad\ \ d$ = diffusivity, ft²/sec (m²/sec)

The diffusivity of dissolved species in water, d, is equal to about 135×10^{-9} ft²/sec (m²/sec) for the temperature of interest.
Thus,

$$\text{Sc} = \frac{\mu}{\rho d} = \frac{9.66 \times 10^{-5}\left(\frac{\text{lbm}}{\text{sec-ft}}\right)\left(\frac{\text{N}\cdot\text{s}}{\text{m}^2}\right)}{55\left(\frac{\text{lbm}}{\text{ft}^3}\right)\left(\frac{\text{kg}}{\text{m}^3}\right) \times 135 \times 10^{-9}\left(\frac{\text{ft}^2}{\text{sec}}\right)\left(\frac{\text{m}^2}{\text{sec}}\right)} = 13$$

Using the Berger and Hau correlation and rewriting to solve for K,

$$K = \left(\frac{d}{D_H}\right)(0.0165)(\text{Re})^{0.86}(\text{Sc})^{0.33} \qquad\qquad (\text{C}1.28)$$

Since everything is now known, K is calculated

$$K = \frac{\left(135 \times 10^{-9}\,\frac{\text{ft}^2}{\text{sec}}\right)\left(\frac{\text{m}^2}{\text{sec}}\right)}{\left(\frac{17}{12\,\text{ft}}\right)\left(\frac{1}{\text{m}}\right)}(0.0165)(1.37 \times 10^7)^{0.86}(13)^{0.33}$$

$$K = 0.005 \text{ ft/sec or } 1.53 \text{ mm/sec}$$

This mass-transfer coefficient is for a straight pipe. For a rupture occurring near a change in flow direction, the straight pipe value should be increased. Figure C1.18 presents a wide range of data showing the increase of heat and mass transfer with bends of various geometries. At the value corresponding to the elbow (0.5), the data range from about 0.4 to almost 2.0, with most of the data less than 0.7. To bound the problem, three calculations have been made. A low case at a value of 0.4, a midcase at a value of 0.55, and a high case at a value of 0.7. For a straight-pipe mass-transfer coefficient of 1.53 mm/sec, the low-, mid-, and high-mass transfer coefficients in the elbow are: 2.14, 2.35, and 2.60 mm/sec, respectively.

There is a large amount of experimental data correlating mass-transfer coefficient and erosion rate. The data are presented in Fig. C1.19. Using this figure, at the above values, and a pH of 9.0, the predicted erosion-corrosion rates are about 0.4,
FIGURE C1.18 Comparison of Eq. (77) of Ref. 6 with the data of various authors on heat and mass transfer in bends.

0.5, 0.8 mm/year, respectively. How long would it take at the *nd* erosion rate to erode the pipe to one-half its original thickness?

$$\text{time} = \frac{\text{thickness}}{\text{erosion rate}} \tag{C1.29}$$

$$\text{time} = \frac{0.25 \text{ inches} \times 25.4\frac{\text{mm}}{\text{inches}}}{0.5 \text{ mm/year}} = 12.7 \text{ years}$$
FIGURE C1.19 Mass transfer coefficient dependencies at different pHs. Correlations from loss profiles of specimens at four flow velocities.

At the low rate, the time to thin the wall to half the original thickness is about 15.9 years. At the high erosion rate it is about 7.9 years.

Start-Up, Operation, and Maintenance Considerations

Start-Up and Operation.   Prior to start-up of water systems, the piping system should be cleaned as required. In some cases, chemical solvents are utilized, followed by flushing. Care should be taken that components not compatible with the chemical being used are removed during the cleaning and flushing process. Temporary strain-

ers are sometimes included in the system for preoperational purposes. This practice protects pumps and valve-seating surfaces from large particles left in the pipe from the installation and testing periods. Temporary strainers are replaced by spool pieces when the system is ready for start-up. The strainers should be kept on hand and installed in the system during major work or repair to the system and replaced by the spool pieces after the system is certified to be clean. Potable water lines are disinfected prior to being put in service.

Prior to starting any system, the following precautions should be taken and included in plant procedures:

1. Verify that the system is free of debris, has been cleaned and flushed thoroughly, and that all testing and inspections are complete.
2. Verify that all components function as required. Rotate pumps by hand to ensure that impellers rotate freely, exercise valves several times, and if necessary, adjust packing.
3. Verify that all instrumentation is in place and root valves open.
4. Verify that the system piping and components are properly vented and drained. For high-pressure or high-temperature systems, ensure that vents and drains are routed away from personnel or sensitive equipment. Close the valves as evidence of complete venting and drainage occur.
5. Verify valve line up intended for start-up, especially the required positions of pump discharge valves and minimum-flow recirculation valves.
6. Monitor system initial operation for anomalies, such as surges, spikes, leaks, and control failures, and make necessary adjustments or shutdown the system and correct any problems.
7. Monitor system pressures, flow rates, and component response as a regular planned routine. Logs should be maintained to develop a baseline condition for comparison for all modes of operation.
8. System shutdown should generally be performed in reverse of the startup procedure. It is important, however, that specific instructions for the shutdown and securing of a system be included in operational procedures. In most cases drains should be left opened.
9. High-energy systems require extra precautionary measures such as tagging or locking valve positions and the active overrides to controls and interlocks.

Flow Balancing. The system through which water flows offers resistance to flow (as discussed) such as friction, static head, and back pressure. Flow rates in a system vary, depending on several factors, such as

1. Variations in static head
2. Valve alignment
3. System demands or loads
4. Flow control valve operation

All affect system resistance.

To design and operate a system, it would be ideal to assume steady-state operation. If steady-state operation is assumed and the system contains branch lines of flow, it is important for economy and system stability to proportion flow in accordance with the specific demands of each branch or service. This is achieved by flow

balancing. On a theoretical basis this is done by plotting the system resistance curves for each branch for a given system flow. Since the total flow must equal the sum of all branch flows and the total pressure drop across each branch between junction points must be identical, the flow divides to produce these identical losses. The sum of the flow rates through each branch at a particular head provides the total flow rate for the system at that head. The total system flow required can be determined from load data, and resistance can be added to the branch lines by adjusting throttle-valve positions. In some cases orifices may be warranted.

This practice in the field can be tedious but may be made easier with the proper flow- and pressure-measuring instrumentation and favorable throttle-valve characteristics.

Maintenance. A major factor in developing a maintenance program is the accessibility of piping and components. Although accessibility should be designed into a system, it is not always practical; for example, in intake or municipal water systems, where most of the piping is buried. In cases such as this, it is cost effective to maintain piping upon failure. The designer should therefore be attentive about the design for buried pipe, including wall design to handle internal pressure and external loading, coating and linings to protect from corrosion, and other design elements. In considering accessibility of buried piping, the designer considers an alignment that will provide sufficient clearances from adjacent pipelines and structures to allow for possible future excavation and repair. Likewise, the designer may choose an alignment that avoids existing or future paved areas in order to minimize the expense of demolition or repair of the pavement and to minimize traffic disruption during initial construction as well as subsequently if pipeline maintenance is required. Generally, the buried portion of a system is limited to passive components. Piping and normally opened or closed valves not usually requiring normal maintenance fall in this category. Other active components such as pressure regulators, relief valves, pumps, large valves, and metering devices should be located in buildings, modules, or manholes and be readily accessible. For this latter category of components, a rigorous maintenance schedule should be developed.

Depending on the degree of importance for safety and operation of a system, an inspection program should be instituted. Inspection during operation is mostly visual; however, some systems may be fitted with taps or probes for on-line inspection.

Beyond inspection, there are components which must be maintained on a regular basis regardless of need. The components' manufacturer provides instruction manuals which recommend maintenance and spare parts for replacement. The station operator must also use judgment and operating experience in the development and implementation of maintenance procedures. Generally speaking, bolt tensions, gasket condition, and packing leakage can be monitored daily. Pressure and temperature monitoring can show evidence of component deterioration or malfunction. Problems such as clogged strainers, hung-up valves, and leaks or breaks can be determined by instrumentation readings when the problem is not normally visible. Instrument calibration for both system components and testing instruments should be more tightly controlled, although frequency varies. Inspection of coatings and painting on a scheduled basis will help to eliminate corrosion problems for exposed components.

Accordingly, a sufficient supply of spare parts should be on hand. The system can be surveyed to determine which parts should be ordered. Operating experience can also help predict the expected life of parts that wear.

Water sampling should be performed routinely. Depending on the service, it can determine the safety of the supply (if it is for human consumption) or prevent

corrosive or abrasive attack on internal components of the system. Sampling procedures should be developed to locate sampling points and to facilitate storage or transportation to the testing laboratory. Procedures should also contain acceptance criteria for each system application and associated water-treatment solutions for unacceptable water quality.

Occasionally, water systems require flushing or mechanical cleaning. These operations remove bacteriological growth, silt deposits, and scale buildup on pipe walls. Again, strict procedures must be developed and adhered to in order to control work.

Installation and Testing. Designer's piping-arrangement drawings and isometrics, if provided, are the governing documents for installation of piping. Unless existing site conditions warrant otherwise, piping shall be installed in accordance with the piping-arrangement drawings.

Buried Piping. The trench for installation of buried piping shall be of sufficient width and depth to provide necessary bedding and cover, depending on traffic volume and depth of frost line, and to facilitate joining, tapping, and future maintenance considerations. Pipe should be laid flat on the bedding and not supported on the end by the bell.

The trench should be filled in accordance with the specified requirements for fill material, rock size, and compaction. When specified, an insulating type of initial fill may be used. As indicated previously, configuration of trench and type and compaction of bedding and backfill can have a large impact on pipe adequacy to handle external loads. Generally, in the municipal waterworks industry, ductile-iron pipe is installed in accordance with AWWA C600, PVC in accordance with AWWA C905, prestressed concrete pipe in accordance with AWWA Manual M9, and steel pipe with AWWA Manual M11.

Aboveground Piping. For support of aboveground piping, there are two generally accepted procedures. One is to temporarily support the piping during fit-up and then to install the supports. The second procedure is to install the pipe support, then the piping. In either case, location tolerances should be provided and adhered to during design so as not to invalidate stress-analysis calculations. Cold springing of pipe should also be avoided but, if required, kept within tolerances.

Prior to being placed in service, pipelines are generally tested for a specified time period at pressures that include operating and possibly surge-allowance pressures.

INTRODUCTION

General

Fire protection systems are unique in that the majority of their service life is spent in a static, no-flow condition. However, when required to operate in an emergency, fire protection systems can be critically important to the safety of building occupants, the protection of property, and the continued operation of a facility. For these reasons, the piping associated with fire protection systems must be designed to minimize service interruptions and be capable of operating reliably over an extended period of time.

To ensure that fire protection systems are reliable, building and insurance authorities require that they be constructed in accordance with nationally recognized standards. Federal regulations or locally adopted requirements may also be applicable.

Fire protection piping, as treated in this chapter, deals with the network of distribution piping that delivers fire extinguishing agents. This chapter presents general information on piping materials, available references, and design considerations for both aboveground system piping and underground water supply piping.

Types of Fire Suppression Systems

There are numerous types of fire suppression systems. All of them use piping or tubing to convey fire suppression agents to a protected area or to a specific fire hazard. The type of fire suppression system selected for a particular building or location depends on the nature of the fire hazard, the value of the building and contents, applicable code and regulatory requirements, and physical considerations such as environment and aesthetics. The common fire suppression systems are described in the following subsections.

Automatic Sprinkler Systems.   An automatic sprinkler system, for fire protection purposes, is a network of piping to which automatic sprinklers or open sprinklers are attached. The system is connected to an automatic water supply. The piping network and connected sprinklers are distributed throughout the protected area in accordance with fire protection engineering standards.

Automatic sprinkler systems may be wet pipe, dry pipe, preaction, or deluge type (each discussed independently in the following paragraphs) depending upon the conditions by which water is admitted into the piping for distribution out of the sprinklers. With the exception of the deluge-type system, which uses open sprinklers, all automatic sprinkler systems use automatic sprinklers.

Automatic sprinklers are sealed by a heat-responsive element such as a eutectic solder link or a frangible glass bulb. When the heat-responsive element of an automatic sprinkler reaches its predetermined operating temperature during a fire, the individual sprinkler opens, discharging water to control the fire.

System operation is generally stopped manually by closing the system control valve. Control valves should be kept in the open position until the fire is completely extinguished and should be constantly manned during postfire overhaul operations in case the fire rekindles.

The *wet pipe* system is the most basic and common type of automatic sprinkler system. See Fig. C2.1. It is the most economical system as well as the most reliable one due to its simplicity. In the wet pipe system, the system piping is constantly charged with water under pressure. In addition to the *main control valve*, the system may also have *sectional control valves*. The system is also required to include at least a local water flow alarm. It is now common to use central station signaling systems to monitor water flow in the system; to supervise the open position of system control valves; and to supervise the ready condition of water supply elements such as pumps, pressure tanks, and gravity tanks.

The *water flow alarm* device for any automatic sprinkler system is located in the main supply pipe of the system, generally a vertical section of main termed the *system riser*. For a wet pipe system the alarm device is usually either an alarm check valve or a paddle-type water flow switch. An *alarm check valve* (see Fig. C2.2) is a valve with a free-swinging, hinged clapper that opens when water flows through the system and automatically reseats when the flow stops. Moving the clapper from its seat, as in a system flow condition, opens ports that permit water to flow to mechanical water gongs or electric pressure switches. In a *water flow switch,* (Fig. C2.3) the paddle in the water piping lies motionless until water flows through the system. Movement of the paddle by water flow closes contacts used to initiate electrical alarms.

Automatic wet pipe sprinkler systems are provided for general fire suppression throughout an area where fixed suppression is required and where there are no special considerations that restrict their use.

Dry pipe automatic sprinkler systems are used primarily in unheated occupancies and structures. See Fig. C2.4. In a dry pipe system, a *dry pipe valve* is located in the main supply header or system riser. All piping downstream of the dry pipe valve is charged with air or nitrogen to hold the clapper of the dry pipe valve closed. The dry valve is configured to give a mechanical advantage to the downstream pressure, such that 30 to 40 psi (200 to 300 kPa) air or nitrogen pressure can hold back up to 175 psi (1200 kPa) water pressure. When a sprinkler opens, the air or nitrogen is released, tripping the dry pipe valve and introducing water to the system piping. See Fig. C2.5.

Deluge systems are used to provide fire protection specifically for high-hazard equipment or areas such as transformer areas and ammunition magazines. A deluge
FIGURE C2.1 Typical wet pipe system.
FIGURE C2.2 Typical wet pipe system alarm check valve.

valve, as described for the preaction system, is provided in the main supply header or system riser. See Fig. C2.6. A *deluge valve* is a normally closed, automatic control valve located in the system riser that prevents water from entering the system piping until required. Operation of the deluge valve is achieved by an electric, hydraulic, or pneumatic signal initiated by a separate detection system located within the protected space. The detection system can employ fixed temperature or rate-of-rise heat detectors, smoke detectors, infrared or ultraviolet detectors, or separate "pilot line" sprinklers. The deluge valve must also be arranged to be operated manually. Open sprinklers or spray nozzles are mounted to the piping network of deluge systems in lieu of sealed automatic sprinklers. When the deluge valve is opened upon activation of the separate detection system, water simultaneously flows from all sprinklers or spray nozzles on the system.

Preaction sprinkler systems are provided for fixed fire suppression where it is particularly important to prevent the accidental discharge of water into an area. The piping network of a preaction sprinkler system is maintained dry until water is needed for fire suppression. Automatic sprinklers are installed on the piping network. See Fig. C2.7.

A deluge valve is provided for each preaction system. The preaction system is generally required to be charged with a low supervisory air pressure.

Preaction systems can be configured in various ways. The traditional preaction system, in which water enters the piping based only upon the activation of the
FIGURE C2.3 Water flow detector/switch.

detection system, is now termed a *single-interlock* preaction system. A *noninterlocking* preaction system is one configured such that either the activation of the detection system or the operation of an automatic sprinkler permits water to flow into the system piping. A *double-interlock* preaction system, intended for use in freezers and other locations where water trapped in the piping would cause damage, requires both the activation of the detection system and the operation of one or more automatic sprinklers in order to release water into the system piping.

Gaseous Fire Suppression Systems. Gaseous fire suppression systems are provided in areas where water is not the extinguishing agent of choice, such as for specialized electronic equipment rooms or water-sensitive storage areas. Nevertheless, it is often recommended that gaseous fire suppression systems be supplemented with an automatic sprinkler system protecting the same area due to the high reliability of the latter.

Gaseous fire suppression systems formerly included *halogenated gas* (Halon) suppression systems, but these have been largely eliminated by international agreement due to their ozone-depleting properties. New alternative "clean agents" have joined carbon dioxide as acceptable gaseous fire suppression system agents. These extinguishing agents are generally stored in pressurized cylinders or tanks. The number of cylinders and quantity of extinguishing agent required for a particular area is dependent on the volume of the protected space, the design concentration demonstrated to achieve fire control or extinguishment, and the physical arrangement of system piping and nozzles.

Automatic activation of these systems is initiated by an electrical signal from a
FIGURE C2.4 Typical dry pipe system.
FIGURE C2.5 Schematic dry pipe valve diagram.

separate detection system installed in the protected space. When the detection system senses the fire condition, the extinguishing agent is released into the protected space. Manual means for discharging the systems are also provided. Discharge of gases that would create a hazard to life safety must be accompanied by warning systems within and around the protected area.
FIGURE C2.6 Typical deluge system diagram.
FIGURE C2.7 Typical preaction sprinkler system diagram.

To be effective, the extinguishing agent must be maintained in the protected area at design concentrations for a sufficient length of time, often 10 minutes or more. To maintain the concentration level, the protected space should have boundary penetrations appropriately sealed to prevent leakage of the agent.

Foam Fire Suppression Systems.   Foam fire suppression systems are used primarily to protect hazards or areas having flammable liquid fire hazards. The fire extinguishing foam is made by mixing foam concentrate and water within the piping network. The foam extinguishes fire by smothering the fire, suppressing flammable vapor production, and cooling the fuel in adjacent areas.

The specifications for piping material that carries foam concentrate and solution must be closely coordinated with the recommendations of the foam manufacturer. Often stainless steel piping is recommended. Selecting an inappropriate piping material may increase maintenance needs on the system and decrease the piping's usable service life.

Foam can also be added to automatic sprinkler systems to improve performance, especially for fires involving flammable liquids.

Chemical Extinguishing Systems.   Dry and wet chemical extinguishing systems are generally *preengineered* systems, meaning that flow rates, nozzle pressures, and quantities of agent are predetermined for the geometries of specific hazards.

Historically, the most common application for these systems has been for restaurant, commercial, and institutional hoods, plenums, and ducts, mainly those associated with cooking appliances. *Dry chemical* systems employ a powder composed of very small particles, usually with a base of either sodium bicarbonate, potassium bicarbonate, or ammonium phosphate. *Wet chemical* systems employ a solution of water and either potassium carbonate-based or potassium acetate-based chemicals.

Water Mist Systems. Water mist systems were developed in part to substitute for the use of Halon, and in part as an alternative to the use of automatic sprinkler systems where water supply must be kept to a minimum due to limitations on either weight or volume. Water mist systems are distinguished from automatic sprinkler systems by their smaller droplet sizes, which tend to be more effective in cooling but less effective in penetrating upward fire plumes. Some water mist systems are configured much like automatic sprinkler systems, utilizing small orifices to produce the small droplet diameters. Others utilize pressures in excess of 1500 psi (10 MPa) to produce the water mist. Still others employ twin fluid nozzles, using air or nitrogen under pressure to break a water stream up into a fine mist.

Standpipe Systems. A standpipe system consists of a network of piping that supplies water for manual fire suppression throughout a building or facility. The network is supplied by a fire protection water supply system and it distributes water to normally closed standpipe valve outlets or hose stations.

Standpipe systems often serve as the source of water supply to automatic fire sprinkler systems, particularly in high-rise buildings. In such cases, sprinkler systems on each floor are fed from the vertical standpipe riser through floor control valves. Each floor is provided with a water flow switch and a combination test/drain valve, connected to a separate drain riser. This enables the alarms from the flow switches on each floor to be tested.

Hydrant Systems and Water Supplies. Hydrant systems are generally used in conjunction with private fire service mains, which also serve to distribute water from the source of supply to most water-based fire protection systems. In many cases the source of supply is the public water main as maintained by the public water works company. In other instances, such as in a large industrial plant, the water supply system may be privately owned and operated. Regardless of ownership, the design of the water supply to fire protection systems is a critical factor in assuring reliable fire protection.

A fire protection water supply system may consist of storage tanks, pumps, underground and aboveground piping, and associated control and isolation valves. Underground valves are normally of the post indicating type.

The capacity and pressure required of a particular water supply system is generally related to the design demands of the water-based fire suppression system in conjunction with the normal water consumption for a facility. Additionally, local authorities and insurance organizations often prescribe fire flow requirements for individual properties.

REFERENCE DOCUMENTS

Codes and Standards

As a rule, building and fire codes do not specifically address fire protection system piping, but instead reference system installation standards. The generally recognized

standards that address fire protection systems piping are those developed by the National Fire Protection Association (NFPA). Federal regulations may reference applicable NFPA standards, but often include special requirements for unique fire protection systems such as those protecting marine, military, or nuclear facilities. Local, municipal, or state regulations may also be applicable.

Some insurance organizations publish their own standards or supplements to the NFPA standards that may be applicable to a particular project.

Some generally recognized standards that relate to fire protection piping systems are listed in Table C2.1. Table C2.2 contains additional standards referenced with regard to materials, joining and installation methods.

There are additional NFPA codes, standards, and recommended practices and guides which may contain specific design criteria for particular hazards or facilities. A complete listing of available documents developed by NFPA technical committees is available by contacting the National Fire Protection Association, Batterymarch Park, P.O. Box 9101, Quincy, MA 02269–9101.

Fire protection standards often require specific equipment or materials to be ''listed.'' The term *listed* means that the equipment or material has been evaluated by a recognized product evaluation organization and has been found to meet appropriate standards or has been tested and evaluated for use in a particular fire protection application. Recognized organizations concerned with product evaluation publish lists of evaluated and approved, i.e., listed products. Additionally, the listing organization performs periodic follow-up inspections of the production of listed

ASME B31.3	Process Piping Code
ASTM A795	Black and Hot-Dipped Zinc Coated (Galvanized) Welded and Seamless Steel Pipe for Fire Protection Service
ASTM A53	Welded and Seamless Steel Pipe
ASTM A135	Electric Resistance Welded Steel Pipe
ASTM A268	Seamless and Ferretic Stainless Steel Tubing for General Service
ASTM A269	Seamless and Welded Austenitic Stainless Steel Tubing for General Service
ASTM A632	Seamless and Welded Austenitic Stainless Steel Tubing (Small Diameter) for General Service
ASTM A778	Welded Unannealed Austenitic Stainless Steel Tubular Products
ASTM A789/A789M	Seamless and Welded Ferritic/Austenitic Stainless Steel Tubing for General Service
AWWA C203	Standard for Coal-Tar Protective Coatings and for Steel Water Pipelines—Enamel and Tape—Hot Applied
AWWA C205	Standard for Cement/Mortar Protective Lining and Coating for Steel Water Pipe [4 in (100 mm) and Larger]—Shop-Applied
NFPA 51B	Standard for Fire Prevention in Use of Cutting and Welding Processes

equipment and material. It is important that all fire protection piping products be used in applications consistent with their listing.

For fire suppression system equipment, two product evaluation organizations in the United States are generally recognized by authorities having jurisdiction as providing appropriate listing services: Underwriters Laboratories, Inc. (UL) and Factory Mutual Research Corporation (FM).

Other Reference Documents

Other references related to the design of fire protection piping systems include the following:

- NFPA Fire Protection Handbook, National Fire Protection Association
- Fire Protection Equipment List, Underwriters Laboratories, Inc.
- Factory Mutual System Approval Guide, A Guide to Equipment, Materials and Services Approved by Factory Mutual Research for Property Conservation

- Automatic Sprinkler Systems Handbook, National Fire Protection Association
- The SFPE Handbook for Fire Protection Engineering, Society of Fire Protection Engineers
- AWWA Handbooks, Manuals and Standards, American Water Works Association
- Federal Regulations, Standards and Specifications
- State and Local Codes and Standards
- Insurance Organization Standards and Manuals

Federal agencies and departments that regulate fire-protection-related matters reference NFPA standards extensively. However, specific federal regulations may be issued. When issued for enforcement, these federal regulations are published in the Code of Federal Regulations, available from the General Services Administration. Departments of the U.S. Government that issue regulations related to fire protection include the General Services Administration; the departments of Defense, Energy, Labor, Veterans Affairs, and Housing and Urban Development; and the U.S. Coast Guard and branches of the military.

Several insurance organizations publish standards to be used in the evaluation of property insurance risks and to provide fire protection guidance to their insureds. Such organizations include the Factory Mutual Research Corporation (FMRC), Industrial Risk Insurers (IRI), and Kemper Insurance. The Insurance Services Office (ISO) relies exclusively on the use of NFPA standards. Other insurance associations that exist for special underwriting risks such as the nuclear, marine, textile, and food industries sometimes have their own guidelines and special requirements.

Most standards related to fire protection piping have been developed based on the needs and experience of a particular region or industry. In North America, these standards are generally based on NFPA codes and standards. With the increasing global community and economy, awareness of standards from other countries and communities is becoming imperative. Examples include DIN (German Standards Institute), AFNOR (French Standards Association), and BSI (British Standards Institute). It should be recognized that many European standards are currently being harmonized as CE (European Community) standards.

DESIGN CONSIDERATIONS

To ensure that all necessary aspects that could impact fire protection piping systems are considered, design goals should be established based on present and projected system needs and conditions. These design goals must consider expected fire suppression system demands, building locations, economic constraints, reliability, water supply source availability, design pressures, and environmental conditions.

Design Conditions

Working Pressure.   The maximum working pressure of a particular installation must be considered when selecting the type and class of pipe to be used. To determine the maximum working pressure for water systems, designers should

consider fire pump shut-off head, elevation changes, and the expected range of source pressures.

Pipe in underground fire service mains is generally expected to withstand a working pressure of not less than 150 psi (1.0 MPa). System components are listed accordingly.

Pipe in overhead fire protection systems such as sprinkler systems and standpipe systems is generally listed for a minimum working pressure of 175 psi (1.2 MPa). This matches the usual minimum working pressure of system components such as automatic sprinklers, water flow switches, alarm valves, and dry valves. However, some components are listed for higher working pressures. When working pressures exceeding 175 psi (1.2 MPa) are expected, all valves, fittings, and pipe should be rated for the appropriate pressure. Several types of pipe specifically listed for fire protection service are listed for a working pressure of 300 psi (2.0 MPa).

Because sprinkler system components are generally intended for use up to 175 psi (1.2 MPa), higher pressures should be avoided. However, in design situations such as high-rise buildings and large multibuilding complexes, higher pressures may be necessary. When these situations occur, sprinkler system components should be protected from excessive pressures. This is accomplished by utilizing approved pressure-reducing valves.

Pressure-reducing valves are intended to protect components from both high static (nonflowing) and flowing pressures. A pressure relief valve that simply drains away flow to relieve pressure is not a pressure-reducing valve, nor is a restricting orifice that simply reduces flowing pressures. A *pressure control valve* is a pilot-operated pressure-reducing valve that can be used to reduce the downstream water pressure to a maximum specific value under both static and flowing water conditions. The setting of the valve must be carefully controlled and its operability regularly maintained to assure that sufficient pressure is available to properly operate the fire protection systems.

When evaluating the impact of fire pump operating pressures on the maximum working pressure conditions, the total discharge pressure at pump shut-off should be considered. Centrifugal fire pumps, the types of pumps used in most water-based fire protection systems, are permitted to have a shut-off or churn pressure of up to 140 percent of rated pressure.

The minimum operating pressure at the discharge point of sprinklers or spray nozzles must be maintained to assure proper discharge flow and water spray distribution. Operating below these minimums can prevent a system from controlling or suppressing a fire.

NFPA 13 requires a minimum discharge operating pressure of 7 psi (48 kPa) for any sprinkler. Higher minimums are required for devices with special applications or nonstandard coverage areas and flows, such as extended-coverage sprinklers. The minimum pressure required for such specific application sprinklers can be unique to manufacturer, model, and intended application. These higher minimums are part of the sprinkler's listing and are described in the manufacturer's product literature that is approved at the time of the product listing.

The working pressures for gaseous suppression systems and water mist can be substantially higher than those normally found in most water-based fire protection water systems. Storage cylinders with pressures of 600 to 850 psi (4 to 6 MPa) are typical for gaseous systems, and pressures in excess of 1500 psi (10 MPa) are encountered with some types of water mist systems. These pressures result in substantial thrust forces and piping stresses that are critical factors in the design of these fire suppression piping systems.

Sources of Water Supply. Water for fire protection purposes can be obtained from public water systems, storage tanks, and raw water sources such as rivers, lakes, and reservoirs. The source must be reliable and of sufficient flow and capacity to operate the connected fire protection systems.

The required flow capacity and residual pressure for a particular building is dependent on automatic sprinkler system demand, hose stream demand for interior fire fighting purposes, and exterior hose stream demand from fire hydrants. The required flow capacity at minimum residual pressure is often referred to as the *system demand*. For a sprinkler system, system demand is the minimum water supply required to operate the number of sprinklers contemplated to open from a particular fire hazard, plus an allowance for manual hose stream operations. NFPA 13 covers water supply requirements for most automatic sprinkler systems.

NFPA 14 provides requirements for the water supply necessary for various classes of standpipe systems. For fully sprinklered buildings, the water supply for sprinklers need not be added to the standpipe system demand required by NFPA 14. This is in recognition of the reduced likelihood of a large uncontrolled fire in a fully sprinklered building. For partially sprinklered buildings, the sum of the sprinkler system demand and standpipe system demand must be supplied by the water source.

Water demand requirements for a particular building in excess of minimum standards may be set forth by the loss-prevention department of the property's insurance carrier.

When raw water is the supply source for automatic sprinkler systems, special provisions are required to reduce the accumulation of sediment in piping drop nipples. Return bends are required to prevent the accumulation of sediments in drop nipples that might eventually plug sprinklers, obstructing the flow of water (see Fig. C2.8).

All sprinkler system cross mains must be arranged for flushing with easily removable fittings. Internal inspections of fire protection piping systems should be conducted whenever any of the following conditions are observed:

FIGURE C2.8 Typical return bend arrangement.

- Defective intake screens for fire pumps taking suction from open bodies of water
- Discharge of obstructive material during system tests
- Foreign material in fire pumps or system valves
- Plugged sprinklers, nozzles, or piping during system alterations
- Failure to flush yard piping or surrounding public mains at time of new installation or repairs
- Record of broken public mains in the vicinity
- Abnormally frequent false tripping of dry pipe valve(s)
- System returned to service after shutdown exceeding a year
- Reason to suspect sodium silicate or highly corrosive fluxes were used within system piping

Freezing Temperatures. Fire protection piping systems must be protected from freezing when temperatures cannot be constantly maintained above 40°F (4°C). For underground mains, burying pipes below the frost line is the usual method to protect against freezing. The depth of cover for underground water mains to avoid freezing in different regions of the United States and Canada is shown in Fig. C2.9.

In fire protection system piping, there may be no circulation of water through the piping such as exists in a public waterworks system. As such, depth of bury is usually deeper than with other piping systems. Exposed short sections of pipe should be boxed or wrapped and heated, since the use of exterior insulation only on exposed pipes is likely to be ineffective for prolonged exposure to freezing condition.

Aboveground fire protection systems must also be protected from low temperatures. Where required, this is usually accomplished by providing special suppression systems such as a dry pipe sprinkler system. For dry pipe systems, the dry pipe valve must be located within a heated enclosure. Attempts to use heat tape to protect dry valve bodies against freezing can result in damage to internal gaskets and seals.

For residential sprinkler systems, where the pipe is separated from the heated area by no more than a sheet of gypsum board, R-19 insulation carefully installed between the system piping and the exterior walls and roof is considered capable of protecting the pipe from exterior temperatures as low as −40°F (−40°C). This assumes that the building interior is maintained at a minimum 50°F (10°C) temperature. Insulation should never be used between the sprinkler system piping and the heated space.

Corrosive Environments. Corrosive conditions, both in soil and in air, require special precautions for fire protection system piping, fittings, and hangers. The
FIGURE C2.9 Depth of cover (in feet) map.

precautions may involve the use of corrosion-resistant material or the application of protective coatings or wraps. The method of protection depends on the expected severity of the corrosive conditions.

All buried ferrous metal pipe be lined, and steel pipe must be coated and wrapped to meet the requirements of NFPA 24. Galvanizing, either internally or externally, does not satisfy these requirements. Buried steel pipe fittings must also be lined, and fittings and joints must be field-coated and wrapped after assembly.

Cement mortar lining should be in accordance with the requirements of AWWA C104 for ductile iron pipe and fittings, of AWWA C205 for steel water pipe, or of AWWA C602 when lining pipe in place. Polyethylene encasement in accordance with AWWA C105 is recognized for protecting ductile iron pipe. When coal-tar enamel protective coatings are used for steel water pipe, the requirements of AWWA C203 apply. AWWA C105 is referenced for polyethylene encasement of steel pipe as well.

Damage to piping due to corrosive atmospheric conditions can be a problem in areas with high levels of moisture, salt air, or fumes from corrosive chemicals. Where these conditions exist, corrosion-resistant pipe, fittings, and hangers should be used or a protective coating applied to exposed surfaces. In high-moisture areas, consideration should be given to the use of galvanized pipe or copper tubing for aboveground fire protection piping. Commercial grade corrosion-resistant paint can be used in a corrosive environment. As with any coating, maintenance is important for maximum effectiveness.

When a corrosive water supply exists, threaded thin-wall pipe should be avoided. When these conditions exist, piping wall thickness should be at least Schedule 40. NPS 8 (DN 200) and larger pipe may be Schedule 30.

Seismic Integrity. Fire protection piping systems require protection from damage when installed in areas subject to earthquakes. Areas where the potential for earthquake damage exists and special protection is required are determined by building codes, insurance requirements, and regulatory agencies.

Where earthquake protection is required for aboveground piping, NFPA 13 provides appropriate design criteria for automatic sprinkler systems and similar systems. NFPA 13 does not require seismic protection, but rather provides criteria where such protection is required by other codes and standards. Flexible pipe couplings, lateral and longitudinal sway bracing, and prescribed pipe clearances are strategically used to prevent damage to piping.

Flexible mechanical pipe couplings are mandated at strategic points in the system where building components are expected to move differentially. For example, flexible couplings are required near the top and bottom of sprinkler and standpipe risers on each floor of multistory buildings to accommodate maximum expected building drift. Except where flexible couplings are provided on both sides of walls, floors, platforms, and foundations, annular clearances up to 2 inches (50 mm) are necessary. Sway bracing is used to limit excessive lateral and longitudinal movement of mains and large branch lines where the system is expected to move with the building, such as below floor/ceiling slabs.

NFPA 13 provides additional details on the seismic protection of sprinkler systems. Alternate means of protecting automatic sprinkler systems from earthquake damage to those found in NFPA 13 may be used when an analysis demonstrates that acceptable system performance is achieved under expected seismic forces. For additional information on piping system stress analysis and supports, refer to Chaps. B.4 and B.5 of this handbook.

Aboveground Piping

Materials and Wall Thickness. Fire protection piping systems can convey many different suppression agents at a wide range of operating conditions. These agents include water and aqueous solutions, chemicals, and gases, each with different piping material requirements. Therefore, aboveground piping for fire protection systems must be designed and installed in accordance with the applicable NFPA standards relating to the system type being installed. The appropriate type of pipe is determined by design considerations, economics, ease of installation, and trouble-free service and environmental factors.

The vast majority of piping used in aboveground piping for fire protection is steel, which accounts for more than 90 percent of installations. Steel piping for fire sprinkler systems and most other water-based fire suppression systems must either be listed for its service or meet or exceed the requirements of one of the following specifications:

ASTM A795—Black and Hot-Dipped Zinc Coated (Galvanized) Welded and Seamless Steel Pipe for Fire Protection Service

ASTM A53—Welded and Seamless Steel Pipe

ASTM A135—Electric-Resistance Welded Steel Pipe

ASME B36.10M—Welded and Seamless Wrought Steel Pipe

Out of concern for potential clogging of small orifices, water mist systems are not permitted to be constructed of black steel or galvanized piping. Piping is required to have corrosion resistance equivalent to pipe made to the following acceptable standards:

ASTM A269—Seamless and Welded Austenitic Stainless Steel Tubing for General Service

ASTM A632—Seamless and Welded Austenitic Stainless Steel Tubing (Small-Diameter) for General Service

ASTM A778—Welded Unannealed Austenitic Stainless Steel Tubular Products

ASTM A789/A789M—Seamless and Welded Ferritic/Austenitic Stainless Steel Tubing for General Service

NFPA 13 provides wall thickness requirements for steel pipe in sprinkler systems. The wall thicknesses are dependent on pipe size and the method of joining. Heavier wall pipe is required when threaded fittings or cut groove mechanical fittings are used. Refer to Table C2.3.

TABLE C2.3 Sprinkler System Minimum Nominal Wall Thickness, Steel Pipe (ASTM A795, A53, A135) for Pressures up to 300 PSI

Fitting type	Pipe diameter		
	Up to NPS 5 (DN 125)	NPS 6 (DN 150)	NPS 8 (DN 200) and larger
Welded	Sch. 10	0.134 in (3.4 mm)	0.188 in (4.8 mm)
Roll grooved	Sch. 40	0.134 in (3.4 mm)	0.188 in (4.8 mm)
Threaded	Sch. 40	Sch. 40	Sch. 30
Cut grooved	Sch. 40	Sch. 40	Sch. 30

Nearly half of all steel piping used in sprinkler systems today is threaded, with the other half generally roll-grooved or welded. Only a small percentage utilizes cut grooves or other joining techniques. Yet only about half of the threaded pipe conforms to the wall thicknesses shown in Table C2.3. This is because NFPA 13, since the late 1970s, has also permitted other types and thicknesses of pipe to be used for sprinkler systems when the product has been evaluated and listed for fire protection service and installed per manufacturer's instructions.

The original special listed steel pipe was threadable lightwall pipe, with wall thicknesses approximating Schedule 10, but with tolerances tightly controlled such that the outside diameters were held to the low end of the allowable range. This permitted the maximum remaining wall thickness at the most vulnerable point in the piping system: the first exposed thread outside of the fitting. Even so, the remaining wall thickness at that point was substantially less than that of threaded Schedule 40 pipe. Underwriters Laboratories, the product evaluation organization that granted the first listing, developed a mechanism by which to evaluate the severity of the reduced wall thickness. The corrosion resistance ratio (CRR) was calculated for each type and size of pipe as the cube of the ratio of remaining wall thickness compared to that of Schedule 40 pipe in the same nominal diameter:

$$\text{CRR} = (t/t_{40})^3 \qquad\qquad (C2.1)$$

where t is the least wall thickness of the special listed pipe (at the first exposed thread root for threaded pipe) and t_{40} is the wall thickness at the first exposed thread root for Schedule 40 pipe of the same nominal pipe size.

The CRR values for various sizes of threadable lightwall pipe vary from as little as 0.18 to 0.35. Because the rate of pitting corrosion through the wall is believed to progress at a rate comparable to the cube of the wall thickness, these CRR values would indicate a life expectancy of 18 to 35 percent of comparable Schedule 40 steel pipe. The actual life expectancy needed depends on site-specific conditions related to the corrosivity of the water supply and other environmental factors.

Threadable lightwall products now account for almost a third of the threadable pipe installed in fire protection systems. But the fastest growing segment of the threadable steel sprinkler pipe market is made up of listed threadable alternates to Schedule 40. Like the threadable lightwall, they are manufactured with tightly controlled tolerances. However, their nominal wall thickness is closer to that of Schedule 30, so as to produce a first exposed thread root that permits a CRR value of 1.0, equivalent to Schedule 40 pipe.

Special listings are also being obtained for high-strength thinwall pipe for use in automatic sprinkler systems. Between Schedule 5 and Schedule 10 in nominal wall thickness, these products must be joined by roll-groove fittings or welding.

Gaseous suppression systems are often subject to higher operating pressures than water-based suppression systems. Additionally, thrust forces are a major consideration in the acceptability of piping and fittings. For gaseous systems, ferrous piping must be black or galvanized steel pipe conforming to either ASTM A53, Grade A or B or ASTM A106, Grade A, B, or C. Other piping materials appropriate for high pressures, such as stainless steel and copper, may be used for gaseous systems. When these are used, pipe wall thickness must be calculated per the Power Piping Code, ASME B31.1. Refer to Chapter B2 in Part B of the handbook. NFPA Standards do not permit the use of ordinary cast-iron or nonmetallic piping for gaseous suppression systems.

Copper tubing for water-based fire suppression systems must meet or exceed the requirements of ASTM B75 or ASTM B88. Copper tube used in sprinkler

systems must have a wall thickness of Type K, L, or M. Bending of copper tube (Types K and L) is acceptable per NFPA 13, which specifies a minimum bend radius of 6 pipe diameters for NPS 2 (DN 50) and smaller pipe, and 5 pipe diameters for NPS 2-½ (DN 65) and larger pipe.

Several of the NFPA standards permit the use of other types of pipe and tube in aboveground piping systems if they are investigated and listed by recognized testing organizations for fire protection service. When used, the pipes must be installed in accordance with the limitations of the organization's listing, including all installation instructions.

When other pipe materials are investigated for use by a testing laboratory, many factors are considered. These include:

• Working pressure rating

• Beam strength affecting hanger spacing requirements

• Unsupported vertical stability

• Movement during sprinkler operation affecting sprinkler or nozzle distribution

• Corrosion resistance, both internal and external

• Resistance to failure when exposed to elevated temperatures

• Joining methods (strength, permanence, and fire resistance)

• Integrity during earthquakes

Special thermoplastic piping systems have been investigated and have been approved for use in some fire suppression system installations—specifically residential and other light hazard automatic sprinkler and water mist systems. The thermoplastic piping material that is currently listed is chlorinated polyvinyl chloride (CPVC). Not all CPVC pipe that is manufactured is acceptable for use in fire sprinkler systems. Only pipe that is specifically approved for fire protection service and that carries the listing mark of a nationally recognized independent testing laboratory such as Underwriters Laboratories, Inc. may be used. The basic standard used by UL to evaluate thermoplastic sprinkler pipe is UL 1821—Thermoplastic Sprinkler Pipe and Fittings for Fire Protection Service. Polyethylene piping is currently being investigated for use in residential sprinkler systems.

Special installation and design criteria exist for listed nonmetallic fire suppression piping systems. These criteria are contained in the listing information for the material and relate to:

• Limitations on use based on hazard classification

• Physical protection and pipe location

• Hanger spacing

• Piping restraint and deflection

• Maximum ambient temperature

Piping Joints. There are several acceptable means of joining aboveground fire protection piping. Steel pipe with sufficient wall thickness may be joined using *threaded connections*. See Table C2.3. Threads must be cut to the requirements of ASME B1.20.1, Pipe Threads, General Purpose.

In normal applications, threaded fittings which have been listed for use in fire suppression systems by a recognized testing laboratory may be used with steel pipe

with wall thicknesses less than Schedule 40 for pipe sizes NPS 8 (DN 200) and smaller, and Schedule 30 for sizes NPS 8 (DN 200) or larger.

Sections of aboveground fire protection piping may be *shop-welded*. However, field welding of fire protection piping should be avoided. When it is necessary to cut or weld inside a building, strict fire prevention precautions as described in NFPA 51B must be established at the site.

Welding methods for joining fire protection pipe are described in the NFPA standard for the type of suppression system being installed. Welding methods that comply with AWS D10.9, Level AR-3 or Section IX of the ASME Boiler and Pressure Vessel Code are generally acceptable.

Mechanical couplings have become a popular method of joining aboveground fire suppression system piping. Mechanical couplings are assemblies of clamps, gaskets, and bolts. There are mechanical couplings appropriate for use on rolled groove, cut groove, and plain pipe ends. Refer to Chap. A9 of this handbook.

Couplings for rolled groove pipe may be used with pipe having a minimum wall thickness of Schedule 10 unless specifically evaluated and listed for use with for thinner wall pipe. Since cut grooved pipe reduces wall thickness similar to threads, fittings for cut grooved pipe are limited to Schedule 40 pipe in sizes less than NPS 8 (DN 200). Schedule 30 may be used in pipe sizes NPS 8 (DN 200) and larger with cut grooved mechanical fittings. Only mechanical couplings which have been investigated and listed by a recognized testing laboratory specifically for fire protection service may be used. Working pressures, temperatures, system rigidity needs, and external and internal loads should always be investigated when considering mechanical joining methods. Many styles of mechanically joined piping components are available including couplings, fittings, and valves.

Listed pipe couplings and fittings can be either flexible or rigid. *Flexible couplings and fittings* are defined as those that permit axial displacement, rotation, and at least 1 degree of angular movement of the pipe without inducing harm on the pipe. For pipe sizes NPS 8 (DN 200) and larger, angular movement is permitted to be less than 1 degree, but not less than 0.5 degree. *Rigid-type pipe couplings* are those that do not permit sufficient flexibility to meet the noted criteria.

Plain-end pipe fittings are popular for sprinkler system installation due to the lack of needed pipe-end treatment. When used, they must be listed and be used with pipe having a minimum wall thickness specified by the manufacturer's installation instructions.

Only mechanical couplings which have been investigated and approved by a regular testing laboratory specifically for fire protection service may be used. Working pressure, temperatures, system rigidity needs, and external and internal loads should always be investigated when considering mechanical joining methods. Many styles of mechanically joined piping components are available including couplings, fittings, and valves.

In general, copper tubing used in fire protection systems should be joined by brazing in accordance with the requirements of ASME B16.22. However, soldered joints may permitted for wet pipe systems protecting Light and Ordinary Hazard Occupancies when the maximum ceiling temperature is less than 150°F (65°C) and the tube is concealed. Where soldering is used, the fittings shall conform to the requirements of ASME B16.18.

Nonmetallic fire protection piping system components are joined using methods and materials that have been evaluated by the listing organization. A solvent cement is used for CPVC pipe. The methods and restrictions for joining nonmetallic pipe materials are detailed in manufacturer's installation instructions. These instructions are included as part of the product's special listing by the testing organization

that evaluated and listed the product. Nonmetallic materials are prohibited for gaseous systems.

Due to the more extreme operating pressures and thrust forces associated with gaseous suppression systems, fittings capable of withstanding higher pressures are required. ANSI C.S.P. (carbon steel pipe) Class 150 and cast iron fittings are not permitted. For example, fittings for 600 psi (4 MPa) stored pressure Halon 1301 systems are required to have a working pressure of 100 psi (690 kPa). Due to the cooling effect that gaseous system discharges have on the piping system, the relationship between material temperature and coincident pressure rating must be considered. For additional guidance, refer to ASME B31.1 and manufacturer information.

Hangers and Supports. The adequate support of aboveground fire protection piping systems is important. NFPA standards provide detailed information on methods and rules of proper support of sprinkler system piping. Other standards commonly reference NFPA 13 regarding hangers and supports.

Aboveground piping must be independently supported from the building structure. Hangers may not be suspended from ceilings or nonstructural partitions. The points of connection to the structure must be capable of supporting the sprinkler system.

Hanger components for aboveground piping systems are typically made of ferrous materials. Nonferrous hanger components may be used only when they have been evaluated as acceptable through fire testing and are listed by a recognized testing organization.

Hanger components that attach to the pipe or to the building structure (such as clamps, concrete inserts, and hanger rings) must be listed. If the hanger components are not listed, the hanger and installation methods must be designed to support five times the weight of the water-filled pipe plus 250 lb (114 kg) at each point of connection, in addition to any other applied loads at the point of hanging.

The maximum spacing between hangers is related to the piping's rigidity based on the piping material and the pipe size, in accordance with the requirements of the installation standards or the piping's listing. In general, hangers for steel pipe NPS 1-½ (DN 40) and larger can be spaced no more than 15 ft (4.6 m) apart. For steel pipe smaller than NPS 1-½ (DN 40), the maximum spacing is reduced to 12 ft (3.7 m).

Nonmetallic piping systems and some special listed steel piping systems require closer hanger and support spacing. The maximum support spacings are detailed in the product's installation instructions. For example, maximum hanger spacing for NPS 1 (DN 25) diameter UL-listed CPVC sprinkler piping is 6 ft (1.8 m), increasing to 10 ft (3.0 m) for NPS 3 (DN 80) diameter CPVC pipe. For discussion of nonmetallic piping, refer to Part D of the handbook.

Many different styles and types of hangers are available for use with the various types of ceiling construction. Careful evaluation of hanger alternatives will result in a well-supported and reliable piping system. For additional details on hangers and supports, refer to Chap. B5.

Piping Layout and Design. The piping layout for most aboveground fire protection piping systems consists of risers, feed and cross mains, and branch lines. *Branch lines* are the pipe sections to which the sprinklers or nozzles are attached. The *feed mains* and *cross mains* are the pipes which supply the branch lines. *Risers* are essentially vertical feed mains.

The piping layout should be carefully considered to ensure that the resulting arrangement conforms to applicable standards in a manner that provides maximum efficiency and flexibility.

Considerations should include the following:

- Proper location and size of risers
- Available water supply location and its characteristics
- Building construction, height, and area
- Hazard classification
- Interferences to piping layout, including overhead cranes, ducts, and so forth.
- Architectural considerations such as aesthetics

There are three basic piping layout configurations for sprinkler systems: tree, loop, and grid. See Fig. C2.10. The tree configuration is the traditional piping layout. Loop and grid layouts have become popular with the use of hydraulically designed systems.

FIGURE C2.10 Typical sprinkler system piping layouts: (*a*) grid; (*b*) tree; (*c*) loop.

Piping layout of aboveground fire protection piping associated with automatic sprinkler systems involves the following principles:

- Provide automatic sprinklers throughout
- Do not exceed the maximum permitted area of protection per sprinkler
- Position sprinklers to optimize activation and water distribution

The most effective automatic sprinkler system provides full area coverage throughout the protected premises. Partial systems are sometimes used to protect hazardous areas in an otherwise nonsprinklered facility. The use of partial systems should be considered with caution, as it is difficult to predict with accuracy where a fire is most likely to occur. Additionally, a partial sprinkler system may not be capable of controlling a fully developed fire spreading from a nonsprinklered area.

The maximum protection areas per standard sprinkler are shown in Table C2.4. Systems with nonstandard sprinklers may exceed these areas when designed and installed in accordance with the listing limitations of the extended coverage or specialized sprinklers.

Sprinklers should be postioned to optimize activation and distribution. The spacing of branch lines and the location of sprinklers relative to walls, ceilings, structural members, and other obstructions are important factors.

The layout of aboveground fire protection piping for gaseous systems differs significantly from that of sprinkler systems. Rather than sprinklers located at prescribed spacing throughout an area, the objective of gas system nozzle placement is to achieve design gas concentrations by strategic nozzle placement to assure

TABLE C2.4 Maximum Protection Area per Standard Sprinkler

Hazard classification	Ceiling construction	Maximum protection area
Standard pendent and upright sprinklers		
Light	Unobstructed or noncombustible obstructed	225 ft^2 (20.9 m^2)
	Combustible obstructed	168 ft^2 (15.6 m^2)
Ordinary	All	130 ft^2 (12.1 m^2)
Extra	All	100 ft^2 (9.3 m^2)
High-piled	All	100 ft^2 (9.3 m^2)
Standard sidewall sprinklers		
Light	Combustible finish	120 ft^2 (11.1 m^2)
	Noncombustible or limited combustible finish	196 ft^2 (18.2 m^2)
Ordinary	Combustible finish	80 ft^2 (7.4 m^2)
	Noncombustible or limited combustible finish	100 ft^2 (9.3 m^2)

proper distribution and mixing of the gas when discharged. Also, due to working pressures up to 850 psi (6 MPa) and high discharge velocities, the support of the piping layout is critical. For additional information, refer to NFPA 12A or 12B for Halon suppression systems and NFPA 13 for carbon dioxide suppression systems.

Inspection and Testing. Prior to making connections to aboveground piping risers, underground piping must be flushed to remove any accumulated sediment or material which could affect suppression system operation.

To assure adequate cleaning, the minimum flow rate for the flushing should achieve a velocity of 10 ft/s (3 m/s) in the underground piping system.

Newly installed pipe should be hydrostatically tested for leaks and to detect faulty pipe, fittings, or joints. No visible leakage is acceptable for interior fire protection piping. Aboveground fire protection piping should be tested at a minimum hydrostatic pressure of 200 psi (1.4 MPa) for two hours. If the maximum system pressures exceeds 150 psi (1.0 MPa), the hydrostatic test pressure should be 50 psi (350 kPa) greater than the maximum pressure. For example, if the maximum system pressure was 175 psi (1.2 MPa), the hydrostatic test pressure should be 225 psi (1.5 MPa) minimum.

Underground Piping

Materials. The selection of appropriate underground pipe and fittings for fire service mains should consider economical installation, trouble-free service, and easy maintenance. The review of these factors should include the required methods of trenching and laying, the characteristics of the water to be handled, and the corrosiveness of the soil. The pipe material should be recognized by applicable codes and standards, and be suitable for the conditions under which it will be installed.

The majority of pipe for underground fire service mains currently being installed is ductile iron. *Ductile iron* is a cast-iron material where the primary graphite content occurs as nodules or spheroids. The graphite in this form maximizes impact resistance and ductility.

Ductile iron pipe that is manufactured in accordance with ANSI/AWWA A21.51/C151 may be used for fire protection service. The pipe class, or wall thick-

ness, required for a particular condition should be determined on the basis of expected internal pressure, laying conditions (e.g., trench load, vehicle loads), and soil characteristics.

Design methods for determining the minimum required thickness of ductile iron pipe are provided in ANSI/AWWA 21.50/C150. These methods consider the conditions of trench load and internal pressure. The net thickness required to withstand the larger of bending stress or deflection caused by the trench load is added to the thickness required for the hoop stress due to internal pressure. Additional thickness is provided to the sum of these net thicknesses for service allowance and casting tolerance.

As previously indicated, steel pipe is generally not permitted for underground fire mains. However, due to its high strength, it is sometimes used by special permission for locations subject to vibrations or shock as from railroad tracks, truck crossings, or highways. When used, steel pipe should conform to AWWA C200, be standard weight for the size (Schedule 40 minimum), and be lined and coated for corrosion protection.

Nonmetallic pipe is available for use in underground fire service mains. Nonmetallic materials used include polyvinyl chloride, reinforced concrete, and polyethylene and glass fiber reinforced composites. The benefits of these materials may include their light weight and corrosion resistance. When used for underground fire protection service, the pipe should be listed, comply with applicable standards, and be installed according to the manufacturer's installation instructions.

Joints.   Joints for underground fire protection piping vary with piping material. The joint must be suitable for the pipe material, working pressures, and the particular installation conditions. Manufacturers specifications should be followed.

The majority of cast-iron and ductile iron joints are push-on or mechanical. Bell and spigot joints that use jute and molten lead are no longer used but are found in many existing installations.

Push-on joints utilize a special rubber gasket. The rubber gasket is placed in the bell end of the pipe. When the spigot end of the pipe is pushed into the socket past the gasket, the joint is formed. Push-on joints do not require packing or caulking. For more details on push-on type joints, refer to Chap. A2 in this handbook.

Mechanical joints are those which utilize a bolted follower ring or gland to hold the gasket in place. The ring is placed over the spigot end, and bolts are used to compress the gasket and the bell end of the pipe. The bolts must be tightened in accordance with the manufacturer's recommendations. They should also be coated to minimize corrosion. Refer to Chap. A2 and A7 in this handbook for additional information regarding this type of joint.

Joints for steel pipe may be welded, threaded, or mechanical. Welding should conform to AWWA C206, Standard for Field Welding of Steel Water Pipe Joints. Since field welding can damage pipe coatings and linings, the weld ends are left bare. Coating and lining are then applied to the welded joints area after welding is completed. Any damage should be repaired.

Nonmetallic pipe is joined using approved butt fusion, push-on joints, mechanical fittings, or solvent cement and couplings. The limits of the approval and the manufacturer's recommendations should be followed.

Installation.   Many factors need to be considered when laying underground pipe, including preparation of the trench, placing and aligning the pipe, making the joints, and anchoring, leak testing, and backfilling the installation.

Trenches should be excavated carefully to minimize the potential for crumbling walls or cave-ins. In sandy or lose soils, sheeting or bracing may be necessary. The bottom of the trench should conform to the grade of the pipeline. It may be necessary to excavate to an extra depth and prepare a stable pipe bed with a layer of firmly compacted soil. Pipes should not be laid in contact with rocks or boulders.

The trench should be wide enough to allow careful alignment of the pipe and convenient making up of the joint. Space should be provided below joints so that the joint can be properly made and so that there will be no localized bearing load on the joint.

Foreign material and water should not be permitted to enter the pipe during installation. Unattended open pipe ends should be closed using watertight plugs or by other means. Additionally, flotation of pipe during installation due to excessive trench water should be avoided by using sufficient backfilling.

Most types of underground pipe joints are not designed to resist significant axial forces that would tend to pull them apart. The friction between the pipe and the ground will help to resist this lateral movement. However, where such forces are significant such as at bends, tees, plugs, and at points where pipe is laid with a steep slope, special consideration is required. A typical location where lateral restraint is required is at the connection of a fire service main to a fire protection system riser. See Fig. C2.11.

To restrict lateral movement, joints at bends, tees, and plugs should be anchored by clamps, rods, bolts, or concrete thrust-blocks. Mechanical fittings can be obtained with lugs for anchorage by tie-rods. Pipe clamps and anchor straps are also available.

FIGURE C2.11 Typical fire protection riser restraint.

When determining anchorage methods, consideration must be given to the maximum forces produced by water pressure, the direction in which the forces act, and allowances for favorable conditions such as pipe-to-earth friction and the resistance that can be provided by various anchorage methods.

Table C2.5 quantifies forces tending to separate single joints at such locations as plugs, tees, the base of hydrants, and bends having only one joint that needs

TABLE C2.5 Forces (in pounds) to be Resisted by Anchorage at Pipe Joints

Size, in.	Outside diam, in.	Separating force produced by 200 psi at tee and plug	Resultant of forces at bends		
			90 deg (1.41)	45 deg (0.765)	22½ deg (0.385)
6	6.90	7,500	10,600	5,740	2,890
8	9.05	12,900	18,200	9,880	4,970

12	13.20	27,300	38,200	20,850	10,520
14	16.65	38,400	54,200	29,400	14,800
16	17.80	49,700	70,100	38,000	19,150
20	22.96	76,400	108,000	58,400	29,450

anchorage; it also provides the resultant effect of the two forces acting at the ends of an elbow or bend.

As just indicated, thrust blocks may also be used to anchor horizontal pipes at fittings (see Fig. C2.12). For maximum effectiveness, thrust blocks should bear against undisturbed soil yet leaving the pipe joint accessible for inspection and repair. Thrust blocks should only be considered satisfactory where the bearing soil is suitable to provide support.

(a)   (b)
FIGURE C2.12   Typical thrust block configurations.

Thrust blocks should be made of concrete mixed not leaner than 1 part cement, 2½ parts sand, and 5 parts stone. The bearing area should ensure adequate resistance to the thrust force anticipated. NFPA 24 provides guidance on the required bearing area of concrete thrust blocks. The required bearing face area of concrete thrust blocks is dependent on the type of fitting being restrained (such as quarter-bend or tee), the system's water pressure, and the undisturbed soil resistance.

Coatings and linings are used for underground piping installations to resist the corrosiveness of water and soil. Protective coal tar enamel per AWWA C203 and cement-mortar coatings and linings (AWWA C205) are used extensively.

Polyethylene encasement, in accordance with AWWA C105, provides good protection to cast- and ductile iron pipe exposed to corrosive soil conditions. Cathodic protection systems may also be used for the external protection of iron and steel water mains against galvanic action.

The backfill for underground fire protection piping should be free of cinders, refuse, plant material, and rocks, and have a consistency that will compact firmly. The top of the piping shall be buried not less than 1 ft (0.3 m) below the frost line for the locality but in no case less than 2.5 ft (0.75 m) below the surface to prevent mechanical damage. The depth of cover for underground fire protection piping to avoid freezing in different regions of the United States and Canada is shown in Fig. C2.9. Due to variations in pipe material performance under varying temperature conditions, manufacturer's instructions should always be followed.

Inspections and Testing.   Newly installed fire protection mains should be inspected for faulty pipe or fittings. The piping should be hydrostatically tested for tightness. Prior to hydrostatically testing newly installed underground pipe, the installation should be firmly backfilled to above the centerline of the pipe for cast- and ductile iron pipe. For nonmetallic pipe, the backfill should extend 1 to 2 ft (0.3 to 0.6 m) over the pipe, except at joints. All joints, regardless of pipe type, should be left exposed until tests are satisfactorily completed. If used, thrust-blocking should be adequately cured to restrict pipe movement.

Similar to aboveground fire protection piping, all new underground piping

TABLE C2.6 Typical Values for Hazen-Williams Formula

Type of pipe	Value of C
New or in condition of new, pipe	
Cast iron—unlined	120
Cast iron—cement lined	130
Cast iron—bituminous lined	140
Nonmetallic	140
Steel	140

should be hydostatically tested at not less than 200 psi (1.4 MPa) for 2 hours. If the service pressure and rating of the pipe installed exceeds 150 psi (1.0 MPa), the hydrostatic test pressure should be 50 psi (350 kPa) above the service pressure or rating.

An entire installation may be tested at once, or smaller sections may be tested using installed isolation valves. All entrapped air should be released from the test section using hydrants or connected aboveground fire suppression systems.

During the hydrostatic testing, all joints should be inspected for leakage. A small amount of leakage is permitted for new underground fire protection piping installations. The quantity of leakage is determined by pumping from a calibrated container. The maximum amount of leakage permitted by NFPA 24 for new pipe is 2 quarts per hour (1.89 l/h) per 100 gaskets or joints. The pipe diameter and the length of pipe gaskets are not considered. When a metal seated valve is used to isolate a test section, the allowable leakage is increased to compensate for valve leakage at a rate of 1 fluid ounce per inch of valve diameter per hour (30 ml/25 mm/h) for each metal seated valve isolating the test section.

Pipe Sizing

Most modern fire protection piping systems are hydraulically designed. That is, appropriate pipe sizes are determined by considering system demand, available water supply, and pipe network considerations such as friction loss, elevation changes, and pipe type.

TABLE C2.7 Variation in Hazen-Williams Coefficient C with Age of Unlined Cast-Iron Pipe

4,000	—	—	—	—	23.1	10.9	5.69
5,000	—	—	—	—	34.9	16.5	8.60

*For values of c different from 100, multiply the flow rates listed in Table C2.8 by the conversion factors listed in Table C2.9.

†For approximate interpolation between the *tabulated flows*, calculate the actual flow as a percent of the next lower tabulated flow, convert this percent to the given value in Table C2.10 and take this percent of the friction loss corresponding to the lower tabulated flow.

‡Nominal pipe diameters were used in calculating the tabulated friction losses. The inside diameter of pipe conforming to American National Standards Institute or American Water Works Association Standards will vary with the process of manufacture, material, and pressure classification and can be found in the Standards. Some published tables of friction losses are based upon actual internal diameters. The errors caused by minor differences in internal diameter are usually not significant when considered in relation to the uncertainties in assumed coefficients and rates of flow. If desired, adjustment for differences in diameter can be made by applying a factor $d(\text{nominal})^{1.25}/d(\text{actual})^{1.25}$ to the values given in Table C2.10.

The generally accepted formula for estimating friction loss in fire protection piping practice is the Hazen-Williams formula. The form of the Hazen-Williams formula used is:

$$f = \frac{4.52 \, Q^{1.85}}{C^{1.85} \, d^{4.87}} \tag{C2.2}$$

Where f = friction loss, psi per ft
Q = rate of flow, gpm
C = Hazen-Williams pipe coefficient
d = internal pipe diameter, in

TABLE C2.9 Conversion for Different
Values of C in Williams and Hazen
Friction-Loss Table

Value of C	Conversion factor
140	0.537
130	0.615
120	0.714
110	0.836
100	1.000
90	1.22
80	1.51
70	1.93
60	2.57

In metric units, the formula is:

$$f = \frac{6.05 \, Q^{1.85}}{C^{1.85} \, d^{4.87}} \qquad\qquad (C2.2M)$$

Where f = friction loss, bars per m
Q = rate of flow, L/min

TABLE C2.10 Interpolation for Water Flows between
Values Given in Table C2.8

Actual flow as % of next lower tabulated flow	Converted % to be applied to friction loss at next lower tabulated flow
105	110
110	120
115	130
120	140
125	151
130	162
135	174
140	186
145	198
150	211
160	238
180	296
200	361

Example: 8-in. pipe, flow 650 gpm.
Next lower tabulated flow 500 gpm.
Percent of lower flow = 650 ÷ 500 = 130 percent.
Converted percent = 162.
Tabulated lower friction loss at 500 gpm = 3.53.
Approximate actual friction loss = 3.53 × 130 percent =
4.58 psi/1,000-ft.

C = Hazen-Williams pipe coefficient
d = internal pipe diameter, mm

The value for coefficient C varies with pipe type and internal pipe conditions. The lower the capacity-carrying characteristics of the pipe, the lower the value of C. Table C2.6 lists C values for various pipe internal surfaces.

Increasing age generally decreases the capacity-carrying characteristics of unlined steel and cast-iron pipe. The variations of C with age from mildly corrosive water is shown in Table C2.7. Table C2.8 gives the friction loss of nominal pipe in psi per 1000 ft. When using Table C2.8, note the references to Tables C2.9 and C2.10.

Appendix E4 in this handbook contains additional pressure drop tables for different sizes of pipe.

The degradation of C accelerates with moderately or severely corrosive water. In these cases, the coefficient may be reduced to 60 to 75 for 15-year-old pipe. A coefficient of C = 100 is commonly used for average or new conditions. In sections of fire protection pipe in which there is normally no flow, such as sprinkler systems, deterioration is less rapid. For underground piping, lined nonmetallic pipe typically exhibits little decrease in capacity over time.

For moderate- and high-pressure water mist systems with pressures above 175 psi (1.2 MPa), the Hazen-Williams equation is not considered sufficient, and hydraulic calculations must be performed using the Darcy-Weisbach method. This method should also be used for water-based systems with additives, since this method can accommodate fluid densities and viscosities other than those of water.

The determination of proper pipe size for gaseous suppression systems is by complex floor calculations that consider the two phase (i.e., liquid and vapor) characteristics of the agent flowing through the pipe network. These calculation methods consider storage pressure, rate of pressure reduction, elevation line pressure, heat transfer of the piping network, density, and other factors. Details on acceptable calculation methods can be found in NFPA 12 for carbon dioxide systems and NFPA 12A for Halon systems.

CHAPTER C3
STEAM SYSTEMS PIPING

Daniel A. Van Duyne, P.E.
Senior Design Engineer, Northeast Utilities
Millstone Nuclear Power Station, Waterford, Connecticut
Formerly Assistant Chief Engineer, Mechanical Division
Stone & Webster Engineering Corporation
Boston, Massachusetts

INTRODUCTION

General

In this chapter we will first review the basics of piping system design for steam systems applications; we will then consider specifics for underground steam piping and steam piping used in power plants.

Definitions and Terminology

Condensate. Condensed steam.

Trunk line distribution system. Distribution system with a large-diameter line leaving the boiler plant; as lateral branches are installed off it for service, the trunk line gradually diminishes in diameter.

Main and feeder network distribution system. Distribution system that receives its supply of steam through a high-pressure feeder main leading from the plant through the network; the size of the feeder main required in this case is not as large as in a trunk-line system with the same boiler-plant steam pressure.

Protective conduits (typically for underground steam lines). Enclosures for underground steam mains and services to (1) protect the pipe and insulation from damage due to earth pressure and impact loadings, (2) allow free longitudinal expansion and contraction while held in proper alignment, and (3) prevent groundwater seepage or flooding by providing either drains or a completely waterproof structure.

Light water reactors (LWR). Nuclear power reactors of either the pressurized water reactor (PWR) or boiling water reactor (BWR) type.

ASME Class 1[1] piping.   Includes main steam piping up to and including the first stop valve outside the reactor containment for BWRs and it is designated as ASME Class 1.

ASME Class 2[1] piping.   Includes main steam piping up to and including the first stop valve outside the reactor containment for pressurized water reactors (PWRs) and BWR main steam piping after the first isolation valve outside the reactor containment and it is designated as ASME Class 2.

ASME B31.1[2] piping.   Includes main steam piping downstream of the first stop valve outside the reactor containment in PWRs and piping external to boilers in fossil power plants, and it is constructed to the ASME B31.1 Code for Pressure Piping.

ASME B31.3[3] piping.   Includes steam process piping in industrial plants and it is designed to the ASME B31.3 Code for Process Piping.

BEP.   Boiler external piping.

DNBR.   Departure from nucleate boiling ratio.

FFWT.   Final feedwater temperature.

HARP.   Heater above the reheat point.

IP.   Intermediate pressure (turbine).

IV.   (Governor-operated) intercept valve.

kPa.   Pressure in kilo pascals.

LP.   Low pressure (turbine).

MPa.   Pressure in mega pascals.

NSSS.   Nuclear steam supply system.

Pa.   Pressure drop or pressure in pascals.

psi.   pressure drop in pounds (force) per square inch, lb_f/in^2.

psia.   pressure in pounds (force) per square inch, absolute.

psig.   pressure in pounds (force) per square inch, gauge.

PWHT.   Postweld heat treatment.

VWO.   Valves wide open (steam turbine).

Nomenclature

A.   An additional thickness to provide for material removed in threading, corrosion or erosion allowance, and material required for structural strength of the pipe, as appropriate, in (mm). See Table C3.1 for selected values of *A*.

d.   Inside diameter of pipe, in (mm). In using Eq. (C3.4), the value of *d* is for the maximum possible inside diameter allowable under the purchase specifications.

D_o.   Outside diameter of pipe, in (mm). For design calculations, the outside diameter of pipe as given in ASME B36.10M and ASME B36.19M[4,5] and specifications shall be used in obtaining the value of t_m.

L.   Length of pipe, ft (m).

P.   Internal design pressure, psi (Pa).

P_a.   Calculated maximum allowable internal pressure, psi (Pa), for straight pipe which shall be at least equal the design pressure. P_a may be used for piping products with pressure ratings equal to that of straight pipe.[6] For pipe products where the

TABLE C3.1 Selected Values of $A^{1,2}$

Type of pipe	A, in (mm)
Cast-iron pipe centrifugally cast or cast horizontally in green sand molds	0.14 (3.56)
Cast-iron pipe, pit cast	0.18 (4.57)
Threaded steel, wrought-iron or nonferrous ¾ in (19 mm) nominal and smaller	0.065 (1.65)
Threaded steel, wrought-iron or nonferrous 1 in (25 mm) nominal and larger	Depth of thread
Grooved steel, wrought-iron, or nonferrous	Depth of groove plus 1/64 in. (0.40 mm)
Plain-end steel or wrought-iron pipe or tube for sizes 1 in (25 mm) and smaller	0.05 (1.27)
Plain-end steel or wrought-iron pipe or tube for sizes over 1 in (25 mm)	0.065 (1.65)
Plain-end nonferrous pipe or tube	0.00

pressure rating may be less than that of the pipe (e.g., flanged joints and reinforced branch connections where part of the required reinforcement is in the run pipe), the design pressure shall be used instead of P_a.

ΔP. Pressure drop, psi (Pa).

S. Maximum allowable stress for the material at the design temperature, psi (Pa).

t. Specified or actual wall thickness minus, as appropriate, material removed in threading, corrosion or erosion allowance, material manufacturing tolerances, bending allowance (see Table C3.2), and material to be removed by counterboring, in (mm).

t_m. Minimum required wall thickness, in (mm). If pipe is ordered by its nominal wall thickness, the manufacturing tolerance on wall thickness must be taken into account.

W. Steam flow, lb_m/min (kg/hr).

Y. Density of steam, lb_m/cu ft (kg/m³) [used in Eqs. (C3.2) and (C3.2M)].

y. A coefficient having values as given in Table C3.3. For pipe with a D_o/t_m ratio

TABLE C3.2 Minimum Thickness Prior to Bending*[18]

Radius of bend	Furnace bending	Induction and incremental bending	Rotary draw bending	Ram and roll bending
6 Dn	$1.06t_m$	$1.06t_m$	$1.09t_m$	$1.08t_m$
5 Dn	$1.08t_m$	$1.08t_m$	$1.14t_m$	$1.10t_m$
4 Dn	$1.14t_m$	$1.10t_m$	$1.20t_m$	$1.13t_m$
3 Dn	$1.25t_m$	$1.14t_m$	$1.26t_m$	$1.17t_m$
2 Dn		$1.22t_m$		
1.5 Dn		$1.30t_m$		

* t_m is determined by Eq. (C3.3) or (C3.4).

TABLE C3.3   Values of Coefficient $y^{1,2}$

Temperature °F (°C)	900 (482) and below	950 (510)	1000 (538)	1050 (566)	1100 (593)	1150 (621) and above
Ferritic steels	0.4	0.5	0.7	0.7	0.7	0.7
Austenitic steels	0.4	0.4	0.4	0.4	0.5	0.7

Note: The value of y may be interpolated between the 50°F (28°C) values shown in the table. For nonferrous materials and cast-iron, y equals 0.4.

less than 6, the value of y for ferritic and austenitic steels designed for temperatures of 900°F (482°C) shall be as calculated from Eq. (C3.1), as follows:

$$y = \frac{d}{d + D_o} \tag{C3.1}$$

Types of Systems

Steam Distribution Systems.   While there are no fixed standards for the design of steam distribution piping systems, most of the systems fall into one of two general classes: (1) a trunk-line distribution network system and (2) a main and feeder distribution network system.

In Case 1, the diameter of the trunk line leaving the boiler plant is large, and as lateral branches are installed off it for service, the diameter of the trunk line is gradually reduced as the needs for carrying capacity are diminished.

In Case 2, the main and feeder network distribution system receives its supply of steam through a high-pressure feeder main leading from the plant through the network. Advantage is taken of the pressure drop available for the transportation of large volumes of steam to the low-pressure network.

Figures C3.1 and C3.2 show typical steam distribution systems.

Since piping is the largest individual factor in the selection and design of a steam distribution system, the major items that must be resolved are as follows: (1) pipe size, (2) wall thickness, (3) materials selection, (4) types of joints, (5) proper insulation, (6) a protective conduit for the pipe and insulation from water and mechanical damage, (7) drainage of condensate, (8) provision for thermal expansion with controlling anchorage, and (9) safety provisions.

Underground Steam Piping.   Underground piping for steam distribution has been a highly specialized field of engineering peculiar to the district-heating industry; today underground steam piping is also used to carry process steam. With the advent of groups of buildings such as in housing developments, institutions, and industrial plants, central heating systems and steam distribution problems are no longer restricted to the district-heating industry. Steam piping systems may be buried and not readily available for enlargement, replacement, and repair. Such piping must be protected from ground elements and excessive heat losses; thus it is important that before such a system is installed every phase of its design and operation be understood. Figures C3.1 and C3.2 show typical steam distribution systems which would be fed by underground steam lines.

See "Protective Conduits for Underground Lines" for more information about
FIGURE C3.1   Typical steam distribution system for a housing development.

protective enclosures and "Drainage of Condensate" for condensate drainage considerations for underground piping.

Fossil-Fueled Power Plants.   The main steam system conducts superheated steam from the steam generator (economizer plus evaporator and superheater) to the turbines as shown in Fig. B1.1 in Part B of this handbook. Figure C3.3 shows a simplified schematic of a main steam system. The main steam system may also provide steam for various auxiliary services.

The piping layout, for a steam power plant, in addition to paying due respect to economic factors, should consider (1) the layout's mechanical design or ability to function properly and efficiently with respect to the mechanical equipment which it serves, (2) the layout's convenience from an operating standpoint, and (3) the layout's appearance as a coordinated part of the plant. Although the relative importance of these basic points obviously falls in the order named, each has an important bearing on the acceptability of any arrangement, as will be discussed in the following sections.

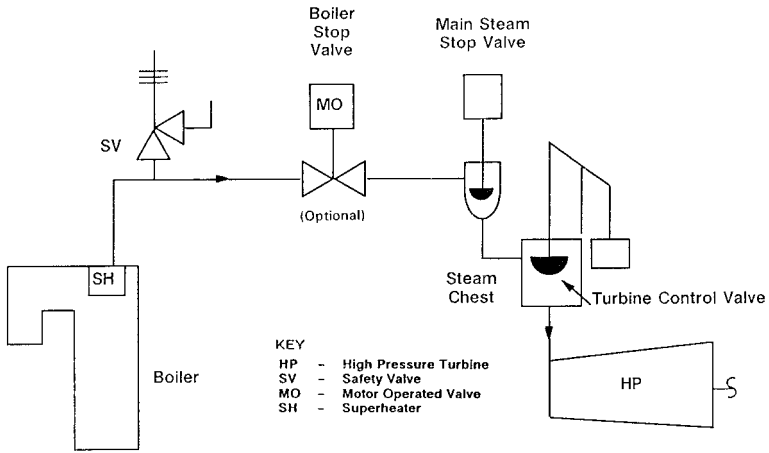
B31.1[1] states that when boilers are connected to a common header, the connection from each boiler having a manhole opening shall be fitted with two stop valves having an ample free-blow drain between them. The discharge of this drain shall be visible to the operator while manipulating the valve. The stop valves shall consist preferably of one automatic nonreturn valve (see next to the boiler) and a second valve of the outside-screw-and-yoke type, or two valves of the outside-screw-and-yoke type shall be used. When a second stop valve or valves is required, it shall have a pressure rating at least equal to that required for the expected steam temperature and pressure at the valve, or the pressure rating at least equal to 85 percent of the lowest set pressure of any safety valve on the boiler drum and for the expected temperature of the steam at the valve, whichever is greater. All valves and fittings on steam lines shall have a pressure rating of at least 100 psig [700 kPa (gauge)] in accordance with the applicable American National Standard.
FIGURE C3.2 Typical high-pressure steam-distribution system in a tower office building.


FIGURE C3.3 Main steam system.

Availability of steam generators has increased to the extent that single units are used almost universally to supply the steam to turbines of sizes up to approximately 1000 MW. In fossil-fueled power plants exhaust steam from the high-pressure turbine is piped back to the steam generator, where it is reheated in a special section before being returned to the inlet of the intermediate pressure or reheat turbine.

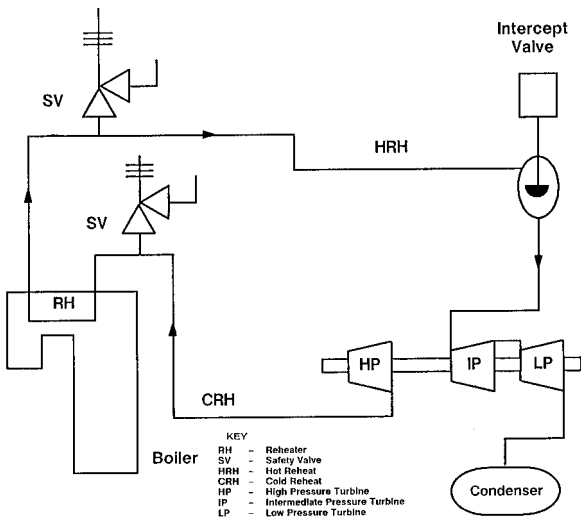
The cold reheat system (CRS) and the hot reheat steam (HRS) system shown in Fig. C3.4 are treated here in one section because they are parts of the same overall system used for reheating steam. The CRS conducts steam from the outlet


FIGURE C3.4 Reheat steam system.

of the high-pressure turbine to the reheater inlet and provides steam for the auxiliary steam and extraction steam systems. The CRS is the normal auxiliary steam source, but at low loads auxiliary steam is usually augmented from the main steam system via a pressure-reducing station.

The exhaust steam from the high-pressure turbine is transported in single or multiple leads into the reheater inlet. Each reheater may have a desuperheater for reheater outlet temperature control, and safety valves at the reheater inlet. A cross-connection (cross-tie) may be used between the two cold reheat leads to provide steam to the associated feedwater heater and the auxiliary steam system without creating a pressure imbalance at the reheater inlet. This system has provisions for isolation of the reheater for hydrostatic testing.

The extraction steam system conducts steam from the high-pressure turbine, cold reheat line, intermediate-pressure turbine, and the low-pressure turbines to the feedwater heaters. This extraction steam is required for feedwater heating. Feedwater heating increases cycle efficiency; in addition, the extraction steam system may provide steam for the feedwater pump turbine. In nuclear units, the system also removes moisture from the turbine to provide protection for the lower-pressure turbine blades and to increase turbine efficiency.

The hot reheat system conducts superheated steam from the reheater outlet header to the intermediate-pressure turbine or to the inlet of the low-pressure turbine. One or more hot reheat leads may be furnished. Each lead has a safety valve for reheater protection. A cross-connection between the two hot reheat leads is often furnished to ensure equal pressure at each reheat stop and intercept valve before entering the turbine.

Nuclear-Fueled Power Plants.   Only the stationary light water reactor, either of the PWR or BWR type, is discussed in this chapter as being typical of nuclear practice. In the typical boiling water reactor the reactor is the steam generator. Water is circulated through the reactor core, producing steam which is separated from recirculation water, dried in the top of the reactor vessel, and directed to the steam turbine.

The pressurized water reactor uses two closed systems—a primary system including the reactor and its cooling system, and a secondary system including a turbine-generator, a condensate system, and a feedwater system. The two systems communicate with each other at the steam-generator tube interface, where pressurized water of the primary system transfers fission-reaction heat to the steam-generator feedwater in the secondary system, producing steam to drive the turbine generators. PWR power plants typically utilize two, three, or four primary loops, each containing a steam generator which transfers the energy from primary coolant to the feedwater on the secondary side.

The nuclear steam supply system (NSSS) customarily consists of those components in contact with the reactor coolant, and specialized auxiliary machinery.

The main steam system in LWRs transports steam from the outlet of the reactor/steam generators to the turbine stop valves. The main steam system also provides steam for various auxiliary services. Additionally, it provides a means of controlled heat release from the NSSS during periods of station electrical load rejection.

In PWRs, each steam generator supplies steam to a line which connects to a common main steam manifold. Valves in each line permit isolation of individual steam generators. Safety valves on each line provide pressure-relief protection for the steam generators. The main steam manifold supplies steam to the high-pressure turbine throttle valves, the moisture separator reheaters, and auxiliary steam loads.

The main steam system includes a turbine bypass system that provides a direct
FIGURE C3.5 Typical NSSS performance curves.

steam path to the condenser and to the atmosphere in order to prevent unnecessary reactor trips during load rejections up to 100 percent of full electrical load.

The turbine bypass system also permits testing NSSS at power levels up to 55 percent without having the turbine loaded. It is also used to maintain reactor coolant temperature during hot standby and shutdown operation and is used to conduct controlled cooldown of the plant to the point where the residual heat removal system can be placed in operation.

For the PWR and BWR, the main steam system design pressure is typically about 1200 psia (8280 kPa) (see Fig. C3.5) and 600°F (316°C). Actual design conditions depend upon the specific reactor design. Main steam line sizing is determined by performing an economic analysis of pressure drop, pipe cost, and so on, with a maximum velocity of 15,000 fpm (250 fps) (4570 m/min, 76 m/s); see "Preventing

Turbine Overspeed'' for more flow velocity data. Preliminary pipe sizing is based on a 3 percent pressure drop from the steam generator outlet to the turbine stop valves. Wall thickness is calculated using the equations presented in ''Design Pressure.''

For PWR and BWR main steam lines, turbine water induction problems are of a great concern as the main steam is saturated or contains some moisture. Prevention criteria are to be as specified in ASME Standard No. TDP-2,[7] ''Recommended Practices for the Prevention of Water Damage to Steam Turbines Used for Electric Power Generation,'' Nuclear Fueled Plants.

Each type of nuclear plant has isolation valves outside of the reactor containment. BWR plants also have isolation valves in main steam lines inboard of the reactor containment. Since the BWR main steam is radioactive, it must be shielded, and special considerations must be made in its design to minimize crud traps (small deposits of radioactive contaminants in flow passages). When welding pipes together, the use of backing rings is avoided.

In LWR nuclear plants, reheating is achieved in a combined moisture separator and reheater unit. High-pressure turbine exhaust steam passes through the moisture separator portion of the unit, where most of the moisture is removed mechanically. The steam is then reheated in one or two stages by passing over the bundles of tubes containing high-temperature heating steam. For single-stage reheat and for the second stage of two-stage reheat, the heating steam is supplied from the main steam system at a point ahead of the turbine stop valves. Pipelines carrying live steam to reheaters belong to the main steam system. For two-stage reheat, the first-
FIGURE C3.6   Steam header in industrial plant. *(Courtesy of Valve World.)*

stage heating steam supply is from an intermediate stage of the high-pressure turbine. More advanced liquid metal cooled fast breeder reactor (LMFBR) nuclear power plants may employ the liquid metal for steam reheating.

Industrial (Process) Power Plants. In industrial power plants, power generation may be considered as a by-product, depending upon the process steam requirements. Process steam is the main product of the cogenerating plant. Industrial turbines, with controlled exhaust and extraction pressures, are very efficient throttling devices (replacing valves), supplying steam at desired pressures to a process plant (e.g., oil refinery) while generating electricity. Variations in process heat and power demands usually do not coincide. In a case where electrical power generation requirements are specified, separate condensing steam turbines or gas turbines must be installed in the power plant to make up the difference between electric power demand and the process-heat dependent power generated by industrial steam turbines.

A typical steam header in a modern industrial plant is shown in Fig. C3.6, which is a photograph of an installation in the Wabash, Indiana, plant of the General Tire Company. As may be noted, the boiler leads and connections supplying steam to process, heating, pumps, and so on, are brought down to this header, which is located near the floor so that all valves are readily accessible.

REFERENCE DOCUMENTS

Various codes and standards and other reference documents used for the design of steam systems piping are listed under ''References'' at the end of this chapter. The reader may find other documents suitable for use in the area of steam systems piping.

Extensive safety requirements for power-piping systems are contained in the ASME Boiler and Pressure Vessel Code, Section I, Power Boilers, and ASME Section III, Nuclear Power Plant Components, and the ASME B31.1 Power Piping Code. In designing the component parts of piping systems within the jurisdiction of these codes, reference should be made to specific provisions as representing standards for minimum safety requirements, but this is not intended to indicate necessarily the best practice known to the art. Requirements of the Code for Pressure Piping are not compulsory in any state until they have been adopted as law by that state. They are in common use, however, and frequently are referred to in contract specifications and similar documents. Sometimes, even though the state has not adopted the codes, the insurance carriers make it a requirement to comply with certain codes.

The selection of suitable dimensional standards for flanges, fittings, valves, pipe, and bolting for ordinary service conditions can be made from the appropriate publications of the American National Standards Institute (ANSI), American Standards for Testing and Materials (ASTM), and American Society of Mechanical Engineers (ASME) which are referenced in the governing codes, such as B31.1, ASME I, ASME III, and ASME B31.3. Appendix E10 provides a partial list of international codes and standards.

DESIGN CONSIDERATIONS

Design Conditions

Design conditions or loadings include design pressure, design temperature, and design mechanical loads.

The ASME Code, Section III, NCA-2142.1[1] defines *design pressure* as follows: "The specified internal and external Design Pressure shall not be less than the maximum difference in pressure between the inside and outside of the item, or between any two chambers of a combination unit, which exists under the most severe loadings for which the Level A Service Limits are applicable. The Design Pressure shall include allowances for pressure surges, control system error, and system configuration effects such as static pressure heads." Level A service limits encompass those normal loadings which a component may be subjected in the performance of its specified service function.

The B31.1 code, paragraph 101.2[2] defines *internal design pressure* as follows: "The internal design pressure shall not be less than the maximum sustained operating pressure (MSOP) within the piping system including the effects of static head." *External design pressure* is defined as follows: "Piping subject to external pressure shall be designed for the maximum differential pressure anticipated during operating, shutdown, or test conditions."

The ASME Code, Section III, NCA-2142.1[1] defines *design temperature* as follows: "The specified Design Temperature shall not be less than the expected maximum mean metal temperature through the thickness of the part considered for which Level A Service Limits are specified. Where a component is heated by trace heating, such as induction coils, jacketing, or by internal heat generation, the effect of such heat input shall be considered in establishing the Design Temperature. The Design Temperature shall consider control system error and system configuration effects."

The B31.1 code, paragraph 101.3[2] defines *design temperature* as follows: "The piping shall be designed for a metal temperature representing the maximum sustained condition expected. . . . For steam, feedwater, and hot water piping leading from fired equipment (such as boiler, reheater, superheater, economizer, etc.), the design temperature shall be based on the expected continuous operating condition plus the equipment manufacturer's guaranteed maximum temperature tolerance."

The ASME Code, Section III, NCA-2142.1[1] defines *design mechanical loads* as follows: "The specified Design Mechanical Loads shall be selected so that when combined with the effects of Design Pressure, they produce the highest primary stresses of any coincident combination of loadings for which Level A Service Limits are designated in the Design Specification."

The B31.1 code, paragraph 101.5[2] identifies *design mechanical loads* generally as dynamic effects as follows: Impact forces caused by all external and internal conditions shall be considered in the piping design. Water or steam hammer is a form of impact load which is caused by rapid opening or closing of a valve in the system. Exposed piping shall be designed to withstand wind loadings, using meteorological data to determine wind forces. The effect of earthquakes, where applicable, shall be considered in the design of piping, pipe supports and restraints, using data for the site as a guide in assessing the forces involved. Piping shall be arranged and supported with consideration of vibration. Suitable vibration dampers, sway braces, restraints, and anchors shall be used to control the movement of piping due to vibration.

Design Pressure. The factors which determine the size of a steam pipe for a specific installation are as follows: (1) the initial steam pressure, and other conditions (temperature), (2) the minimum permissible discharge pressure, (3) the allowable velocity, (4) the quantity of steam, and (5) the length of line, including equivalent

lengths for fittings. By knowing or assuming any one or all of these factors, the pipe size may be calculated by means of one of the pressure-drop formulas of Chap. B8 in this handbook.

The Unwin formula[8,9] has been widely used in the district-heating industry for many years. At elevated velocities, Unwin's formula gives pressure drops known to be higher than actual. This formula, in English units, is as follows:

$$\Delta P = \frac{0.0001306 W^2 L(1 + 3.6/d)}{Y d^5} \tag{C3.2}$$

where P = pressure drop (psi)
  W = steam flow rate (lb/min)
  L = length of pipe (ft)
  d = pipe inside diameter (in)
  Y = steam density (lb/ft^3)

Example C3.1. Find the pressure drop in an NPS 8 straight pipe 100 ft long with a flow of 40,000 lb/hr of saturated steam and an initial pressure of 150 psia [steam density (Y) = 0.3318 lb/ft^3].
Solution. P = 0.774 psi
The Unwin formula in Sl units is as follows:

$$\Delta P = \frac{0.6753 \times 10^6 W^2 L(1 + 91.4/d)}{Y d^5} \tag{C3.2M}$$

where P = pressure drop (Pa)
  W = steam flow rate (kg/hr)
  L = length of pipe (m)
  d = pipe inside diameter (mm)
  Y = steam density (kg/m^3)

Example C3.1M. Find the pressure drop in a 203.2 mm diameter straight pipe 30.48 m long with a flow of 18,144 kg/hr of saturated steam and an initial pressure of 1034 kPa [steam density (Y) = 5.313 kg/m^3].
Solution. P = 5337 Pa
Note that both of these examples represent the same physical pipe and flow conditions, and both result in the same pressure drop.

Pressure drops through fittings such as elbows, tees, and valves vary in proportion to the pressure drop through straight pipe. Because of this fact, it is possible to express the resistance of fittings as equivalent lengths of straight pipe and to compute the pressure drop for the whole line as if it consisted only of straight pipe as discussed in Chap. B8.

Where grid or network systems are involved, the computation of pipe size, pressure drops, and quantities of steam flowing presents a more complex problem. See Chap. B8 for a discussion of calculating these properties.

Minimum pipe-wall thickness for either heavy-wall or thin-wall pipe may be calculated from the following formulas from NC-3641 of Section III of the ASME Code[1] or equivalent, ASME B31.1 or B31.3 Code.[2,3] See Chap. B2 in this handbook for more information on wall thickness. The y factors adjusts for elastic or plastic

properties of the respective materials over the expected range of operating temperatures:

$$t_m = \frac{PD_o}{2(S + Py)} + A \tag{C3.3}$$

$$t_m = \frac{Pd + 2SA + 2yPA}{2(S + Py - P)} \tag{C3.4}$$

Equation (C3.3) is used when outside pipe diameter D_o is considered for calculating required minimum wall thickness, t_m, whereas Eq. C3.4 is utilized with inside pipe diameter, d.

The allowable working pressure of pipe may be determined from the following equation:

$$P_a = \frac{2St}{D_o - 2yt} \tag{C3.5}$$

Large fossil power plants generally use a 2400 psig (16.6 MPa) drum-type steam generator or 3500 psig (24.2 MPa) once-through, supercritical steam generator. Small- and medium-sized power plants of less than 200 MW use lower standard pressures. For the large fossil power plants, the main steam design pressure is typically 2650 or 3860 psig (18.4 MPa or 26.7 MPa) (lowest superheater safety valve setting), and design temperature is 1015 or 1050°F (546 or 566°C) (maximum expected superheater outlet temperature). The steam at these conditions is superheated, so there is no moisture, but the lines must still have moisture-removal capabilities.

Boiler External Piping (BEP).   ASME B31.1[2] Paragraph 122.1.1 presents the minimum pressure and temperature and other special requirements for boiler external piping including the following:

It is intended that the design pressure and temperature be selected sufficiently in excess of any expected operating conditions, not necessarily continuous, to permit satisfactory operation without operation of the overpressure protection devices. Also, since the operating temperatures of fired equipment can vary, the expected temperature at the connection to the fired equipment shall include the manufacturer's maximum temperature tolerance.

For steam piping the value of design pressure, P, to be used in Eqs. (C3.3), (C3.4), and (C3.5) according to ASME B31.1 Paragraph 122.1.2 shall be as follows:

(A.1) For steam piping connected to the steam drum or to the superheater inlet header up to the first stop valve in each connection, the value of P shall be not less than the lowest pressure at which any drum safety valve is set to blow, and the S value shall not exceed that permitted for the corresponding saturated steam temperature.

(A.2) For steam piping connected to the superheater outlet header up to the first stop valve in each connection, the design pressure, except as otherwise provided in (A.4) below shall be not less than the lowest pressure at which any safety valve on the superheater is set to blow, or not less than 85 percent of the lowest pressure at which any drum safety valve is set to blow, whichever is

greater, and the S value for the material used shall not exceed that permitted for the expected steam temperature.

(A.3) For steam piping between the first stop valve and the second valve, when one is required by Para. 122.1.7, the design pressure shall be not less than the expected maximum sustained operating pressure or 85 percent of the lowest pressure at which any drum safety valve is set to blow, whichever is greater, and the S value for the material used shall not exceed that permitted for the expected steam temperature.

(A.4) For boilers installed on the unit system (i.e., one boiler and one turbine or other prime mover) and provided with automatic combustion control equipment responsive to steam header pressure, the design pressure for the steam piping shall be not less than the design pressure at the throttle inlet plus 5 percent, or not less than 85 percent of the lowest pressure at which any drum safety valve is set to blow, or not less than the expected maximum sustained operating pressure at any point in the piping system, whichever is greater, and the S value for the material used shall not exceed that permitted for the expected steam temperature at the superheater outlet. For forced-flow steam generators with no fixed steam and waterline, the design pressure shall also be no less than the expected maximum sustained operating pressure.

(A.5) The design pressure shall not be taken as less than 100 psig [700 kPa (gauge)] for any condition of service or material.

For example, for a fossil power plant with the lowest pressure at which any drum safety valve is set to blow at 2400 psig (16.6 MPa), the design pressure shall not be less than maximum sustained operating pressure for all steam piping connected to the steam drum or to the superheater outlet header up to the first stop valve, or 2040 psig (85 percent of 2400) (14.2 MPa, 85 percent of 16.6 MPa), whichever is greater, for piping as noted in A.2, A.3, or A.4.

Initial steam conditions at the steam generator outlet depend upon the plant under consideration. For process plants, steam parameters are dictated by the process requirements. In nuclear power plants, steam parameters depend upon the characteristics of the nuclear reactor which is the source of heat for generating steam. The maximum permissible heat-flux for fuel, reactor vessel pressure, and the DNBR are limiting factors influencing turbine initial steam conditions of nearly saturated steam at about 1100 psia (7.6 MPa) (see Fig. C3.5) in a NSSS with a PWR. In BWR the steam moisture problem assumes a major role in optimizing steam pressure at about 1000 psia (6.9 MPa).

The most freedom in selecting initial steam conditions is found in fossil-fueled power plants, which may be designed as subcritical or supercritical units. The question then arises: What are the most economical initial steam conditions for the present technological state of the art? Generally, from a thermodynamic point of view, an increase in initial steam temperature or pressure increases the power plant cycle efficiency (see Fig. C3.7).

Cold Reheat Systems. The cold reheat and hot reheat steam systems for fossil power plants, are designed to ASME B31.1. For PWR- and BWR-equipped plants the reheat lines are part of the turbine manufacturer's area of responsibility and are designed to turbine manufacturer's criteria which must equal or exceed the rules and requirements of ASME B31.1. Design temperatures and pressures are the maximum ones expected in the system (consult appropriate heat balance diagrams and system descriptions).
FIGURE C3.7   Effect of steam conditions on heat rate.

Extraction Steam Systems.   The extraction steam system is designed to ASME B31.1. The extraction line design pressure and temperature depend upon the specific extraction point from the turbine as shown on the full-load heat balance diagram at valve wide open (VWO) and 5 percent overpressure. Extraction steam is typically superheated steam except for the lowest extraction points, which are in the wet steam region.

Extraction line sizing is determined by performing an economic analysis of pressure drop, pipe costs, and so on, with a maximum velocity limit of 15,000 fpm (250 fps) (4570 m/min, 76 m/s) for superheated steam. See "Determining Reasonable Flow Velocity" for more flow velocity data. Since extraction steam piping affects heat rate and output of a plant, this piping is sized so that pressure drop does not exceed about 5 percent of turbine stage pressure for the low-pressure lines and 3 percent for the higher-pressure lines. However, these pressure drops should be as low as practical, especially those related to the higher-pressure heaters. Also, keep them low to avoid erosion/corrosion problems.

Design Temperature.   Historical development of throttle parameters reveals that in the field of throttle temperatures certain stabilization was reached, while the throttle pressures are continuously rising and the condenser back-pressure is steady at approximately 1 psia (7 kPa). The effect of steam-turbine throttle conditions on overall power plant efficiency is shown in Fig. C3.8. The results shown in Fig. C3.8 indicate that the efficiency increases by 1.5 to 2.5 points as pressure increases from 2400 to 5000 psia (16.6 to 34.5 MPa) at constant throttle and reheat temperature of 1000 to 1400°F (538 to 760°C). It is also seen that the 3500 psia (24.1 MPa) plant efficiency increases by nearly four points as the throttle temperature is increased from 1000 to 1400°F (538 to 760°C).

Some utilities have installed units using supercritical steam pressure; that is, pressures higher than 3206 psia (22.1 MPa), at which point the specific volumes of steam and water are equal. Thus, the main steam pressure for larger units lies between, say, 1450 psia (10.0 MPa) and the supercritical region. Main steam tempera-
FIGURE C3.8 Effect of steam turbine throttle pressure and temperature on overall efficiency of a power plant.

ture may then range up to and beyond 1050°F (566°C), necessitating the upgrading of main steam line material as the temperature increases, as noted in the following recommendations:

Up to 775°F (413°C)—Carbon steel.

Up to 950°F (510°C)—Use 1¼ Cr.

From more than 950 to 1050°F (510 to 566°C)—Use 2¼ Cr.

From 1000 to 1200°F (540 to 650°C)—Consider using 9–12 Cr such as P91 as discussed in "Design Features, Pipe Size and Materials" later in this section.

From 1050 to 1200°F (566 to 650°C)—Consider using austenitic stainless steel.

Beyond 1200°F (650°C)—Use austenitic stainless steel.

Weight Effects. See Chap. B2 of this handbook for consideration of weight effects.

Thermal Expansion and Contraction Loads. Thermal expansion of pipelines can be compensated for by use of pipe bends, offsets, or expansion loops, or changes in direction of the pipeline itself. Where pipe bends or offsets can be used or where the pipeline direction is changed to provide for expansion, the provisions of the appropriate codes must be followed as required to ensure that all expansion stresses are within the applicable code limits.

Dynamic Effects. Consider transient effects for turbine trip and safety and relief valve discharge early in the design schedule so that pipe supports and structural steel are adequate to withstand dynamic loads. Typical turbine trip loads on pipe segments in a main steam system (Fig. C3.3) range up to 17,500 lb (78,000 N) after the main steam stop valve closes in approximately 100 milliseconds.[11] Corresponding
FIGURE C3.9 Steam-propelled water slug: (*a*) slug forms in closed drain line; (*b*) rapidly moving slug loads pipe due to impact on elbows or restrictions.

reheat steam system (Fig. C3.4) pipe segment loads range up to 13,200 lb (58,700 N) after the reheat intercept valve simultaneously closes in approximately 150 milliseconds.

Another significant dynamic event to be considered in steam piping is steam-propelled water slug,[12] as shown schematically in Fig. C3.9. When a drain valve opens, an upstream slug of condensate could be propelled through the drain piping, causing large loads at each bend until the slug dissipates or exits the piping. Condensate in nearly horizontal steam lines may be swept into slugs, which could also result in large steam-propelled water slug forces, particularly when initiating steam flow into cold piping. The recommended method to prevent steam-propelled dynamic events is to eliminate condensate in steam lines by proper line sloping and drainage, and by carefully warming up cold steam lines.

Also, nozzle design loads for safety and relief valve discharges should be considered. See Chap. B8 in this handbook for more information about transient flow analysis.

Design Features

Pipe Size and Materials. Specific materials for components used in steam piping systems must satisfy the requirements of the applicable codes. Any standards or specifications quoted in this chapter are minimum requirements. Construction at least equal to that required by the applicable codes is mandatory. The following discussion for piping and fittings is generally acceptable for American National Standards Institute (ANSI) and may be used as a guide. However, other codes and standards, including Deutche Industrie Norm (DIN), Japanese Industrial Standard (JIS), and many others such as British, Canadian, Norwegian, and Swedish codes, must be considered for worldwide steam piping applications. See Apps. E2 and E3 for pipe and tube properties, and see App. E6 for "International Piping Material Specifications." Appendix E5 lists ASTM/ASME material specifications acceptable for use for the ASME B31, Pressure Piping Code, and the ASME Boiler and Pressure Vessel Code, Sections I and III. Refer to App. E10 for international codes and standards.

Steel pipe, either seamless or welded, is generally used in steam systems, although the piping codes permit a variety of materials and several types of welded pipe. For welding and bending, a carbon seamless steel pipe is recommended. Seamless or electric-resistance welded steel pipe A53, Grade B and seamless steel pipe A106, Grade B are popular selections.

Adjusted ratings at temperatures above and below 750°F (399°C) for carbon and alloy steels and other alloys are given in the standards to govern their use under pressure or temperature other than the primary service ratings.

Selection of materials for temperatures above 750°F (399°C) from the various grades of alloys described in ASTM Specifications for high-temperature service is

facilitated by reference to specific standards. The multiplicity of services in a large plant and the variety of dimensional standards and materials, possible joints, and different types of welding available make it desirable to provide proper standards, design details, and materials selection guidelines.

Main steam line sizing is determined by performing an economic analysis of pressure drop, pipe cost, and so on, with a maximum velocity limit of 15,000 fpm (250 fps) (4570 m/min, 76 m/s). See ''Determining Reasonable Flow Velocity'' for more flow velocity data. Preliminary pipe sizing is often based on approximately a 3 percent pressure drop from the superheater outlet to the turbine stop valves. Wall thickness is calculated using the equations presented in ''Design Pressure.'' Thus the main steam piping between the turbine and boiler may consist of one or more lines, with metallurgy varying from pressure-temperature rating requirements.

Because of the high cost of alloy piping, the selection of its size is usually the subject of an economic study where the increased pressure drop and its effect on turbine output are weighted against unit pipe cost including installation and hangers. For systems operating at or below 1050°F (566°C), chrome-moly alloy steel is often used in order to bring the pipe thickness down to an economically acceptable value for the steam pressures used.

Main steam piping at 1015°F (546°C) is typically 2¼ percent chrome, 1 percent molybdenum steel to ASTM A335, Grade P22 in U.S. fossil power plants (see ''Design Temperature''). However, there have recently been extensive investigations of using higher levels of chrome, ranging up to 12 percent. There is a gap between the low- and medium-alloyed ferritic steels on one side and the high-alloyed austenitic steels on the other, as shown on Fig. C3.10.[13] This gap in the creep rupture strength versus temperature diagram is occupied by the group of ferritic/martensitic 9–12 percent chromium steels. Compared to P22 (10 CrMo 9 10), the creep rupture strength of P91 is even twice as high.[14] Several of these 9–12 percent chromium steels have been developed and used worldwide,[13] including X 12 CrMo 9 1, which has been used as steel under hydrogen pressure for tubes and pipes mainly in chemical plants, and X 20 CrMo 12 1, which has been used with great success in power plant piping, tubing, and headers. A similar steel, X 10 CrMoVNb 9 1, developed in the United States, has been standardized in ASTM A213 for tubing (T91), in ASTM A335 for piping (P91), and in ASTM A336 for forging (F91). Parallel developments include the Japanese steel NF 61615.[15]

For the given initial steam conditions, power plant capacity, pipe material, and economic factors, the number of main steam leads should be optimized considering the steam generator manufacturer's header arrangement and the turbine valve arrangement. Selection of the operating steam pressure and temperature for a turbine-generator installation is based on an economic study or on experience derived from previous installations. Studies have shown that higher pressures and temperatures are associated with larger units or with higher expected fuel costs.

Main steam piping for the PWR and BWR is typically carbon steel to ASTM A106, Grade B or C.

In practical applications, steam generator and main steam line material limitations, plant reliability, and economic considerations influence the initial steam conditions. For a given pipe, an increase of initial steam temperature above certain values requires lower initial pressure. The maximum allowable stress values in tension for pipe materials for various metal temperatures may be obtained from the appropriate codes being used for design of the piping.

If better materials are used for main steam (MS) pipes, steam generators, and turbines, additional steam reheat may be beneficial, since this will allow higher throttle pressure at fixed throttle steam temperature. This additional steam reheat
FIGURE C3.10   Creep rupture strength of heat-resistant ferritic and austenitic steels. *(From Ref. 13.)*

not only guards a turbine against operation in a high moisture region, but also increases fuel savings due to the carnotization of a Clausius-Rankine Cycle. See "Understanding the Extraction Steam System."

The high-pressure main steam piping must be designed with attention to the need for adequate size (pipe diameter), thermal expansion, piping supports, and drain of condensate, with the last factor being especially important when warming up the system preparatory to a start.

Pressure drop in steam lines to turbines and heat losses to the surroundings have an important influence on power plant performance. Long runs of pipe, or shorter runs of expensive, thick-walled, alloy steel, high-pressure pipe create the need for an economic determination of optimum pipe size. The higher the steam velocity, the smaller the required size of pipe, but unfortunately the frictional pressure loss increases as the square of the velocity. In an economic analysis, the higher capital cost of larger pipe diameters, including insulation and support, must be weighed against the lower operating costs resulting from better plant performance. For more information on the economic optimization of line sizes, see Chapter B8 in this handbook. The amount of insulation to apply is a separate economic

consideration and is also governed by the maximum allowable surface temperature for personnel protection.

Piping Joints. To a large extent, pressure piping is welded. Welded joints have generally replaced most of the screwed or flanged joints in new construction of steam distribution system mains and customers' service lines. Joint construction must satisfy the requirements of the code applicable for construction.

Although welding has largely displaced flanged joints, some flanged connections are nevertheless required, particularly in making connections to flanged valves, expansion joints, or fittings where space limitations do not permit welding, or where easy removal of a fitting or valve is desired. Malleable, cast-iron, bronze, or brass fittings may be used for pressures not exceeding 250 psi (1725 kPa) and temperatures not in excess of 450°F (232°C). Cast or forged carbon steel fittings are required for pressures above 250 psi (1725 kPa). For temperatures above 775°F (413°C), carbon steel is not recommended. Welded fittings must comply with the American Standard for Factory-Made Wrought Steel Buttwelding Fittings (ASME B16.9[6]) or American Standard for Forged Steel Fittings, Socket-Welding and Threaded (ASME B16.11[16]) where applicable, and the material shall conform to ASTM Specification A216, A234, or A105. Special fittings or welded assemblies fabricated in either the shop or field are required to conform to the requirements of the appropriate codes.

Gaskets. Gaskets may be made of metal or other material which will not burn, char, or change in character so as not to perform the service intended. Asbestos is prohibited. Several alternatives for asbestos, including spiral-wound gasket applications, have recently been developed by the gasket manufacturers. A summary of material specifications for selected lines for a 150 MW circulating fluidized bed power plant is given in Table C3.4.

Threaded Joints. Limitations for threaded joints are contained in both the ASME Code, Section III[1] and ASME B31.1.[2] Paragraph 114 in B31.1 includes the following guidance, which is similar to that in the ASME code for Class 2 and 3 piping (threaded joints are not allowed in ASME Class 1 piping): All threads on piping components shall be taper pipe threads in accordance with the applicable Standards listed in Table 126.1.[2] Threads other than taper pipe threads may be used for piping components where tightness of the joint depends on a seal weld or a seating surface other than the threads, and where experience or test has demonstrated that such threads are suitable.

Threaded joints shall not be used where severe erosion, crevice corrosion, shock, or vibration is expected to occur, nor at temperatures over 925°F (495°C). Size limits for steam and hot water service [above 220°F (105°C)] shall be as listed in Table C3.5. Threaded access holes with plugs, which serve as openings for radiographic inspection of welds, are not subject to the limitations of Table C3.5. Threaded connections for insertion-type fluid temperature determination and sampling devices are not subject to the temperature limitations stated in Table C3.5. At temperatures greater than 925°F (495°C) or at pressures greater than 1500 psi (10,350 kPa), these threaded connections shall be seal-welded. The design and installation of insertion-type fluid temperature determination and sampling devices shall be adequate to withstand the effects of the fluid characteristics, fluid flow, and vibration.

Paragraph 104.1.2(C) of B31.1[2] states that ''Where steel pipe is threaded and used for steam service at pressures above 250 psi (1750 kPa) or for water service above 100 psi (700 kPa) with water temperatures above 220°F (105°C), the pipe shall be seamless having the minimum ultimate tensile strength of 48,000 psi (330 MPa) and a weight at least equal to Schedule 80 of ANSI B36.10M.[4]

Note: For instrument, control, and sampling lines, refer to Para. 122.3.6.[2]

Paragraph 102.4.2 of B31.1[2] states that "The calculated minimum thickness of piping (or tubing) which is to be threaded shall be increased by an allowance equal to thread depth; dimension h of ASME B1.20.1 or equivalent shall apply. For machined surfaces or grooves, where the tolerance is not specified, the tolerance shall be assumed to be ¹⁄₆₄ in (0.40 mm) in addition to the specified depth of cut."

Cast-Iron Flanges.   It is advisable to express a word of caution regarding connecting cast-iron flanges and fittings to steel flanges and fittings. Class 25 and Class 125 cast-iron flanges have plain faces, while the Class 250 flanges have raised faces which come out practically to the inner edge of the bolt holes whereas those of steel flanges are narrower and stop some distance inside the bolt holes. The plain face or wide raised face on cast-iron fittings and flanges is a necessary precaution to prevent cracking the flange in drawing up the bolts. Numerous instances have been observed where cast-iron flanges have cracked when being bolted to raised-face steel flanges. In cases where it is necessary to bolt cast-iron and steel flanges together, the raised face of the steel flange should be machined down flush with the flange edge. For the same reason, when lap-joint pipe is made up with cast-iron flanges, the lapped end should be brought out to the inner edge of the bolt holes. These type of flange joints should only be used where permitted by the governing code.

For reasons similar to those just stated, it is inadvisable to use alloy steel bolts in cast-iron flanges. Commercial carbon-steel bolts (A307, Grade B) are amply strong for use in cast-iron flanges up to a temperature of 400°F (205°C), and there is no occasion to risk cracking such flanges through the use of high-strength bolts. Steel flanges are properly designed, both as regards dimensions and material, for use with a narrow raised face and alloy-steel bolts.

Valves.   Valves must be of a design at least compatible with the service conditions and constructed of the materials allowed by the appropriate codes for design pressure and design temperature.

ANSI pressure class determination should be based on the design and operating conditions of the system (i.e., temperature, pressure). It should be noted that for valves with elastomeric or plastic gaskets, packing, or seating elements, the valves may not meet the entire range of pressure/temperature conditions for their designated ASME pressure class. See Chap. A10 for selection and application of valves.

For power work, the following codes give pressure/temperature tables for valves:

ASME B16.34—"Valves-Flanges, Threaded, and Welding End"[17]
API602—"Compact Steel Gate Valves, Fifth Edition"[19]

When selecting a valve, consider the following:

- The system safety category
- The design and operating conditions of the system, or portion of the system in which the valve will be installed
- Valve function; that is, isolation, throttling, or modulating
- Radioactivity level, if any
- Whether pressure drop is critical
- Preferred end connection; that is, socket weld, butt weld, threaded, flanged, or mechanical
- Special features, including minimum operating time, stem leakoff required, exceptional tightness required for seat and/or seals, body taps
- Material requirements; that is, alloy, carbon steel, hard-facing, and so on

Isolation and Control Valves.   Selecting the proper valve for a particular purpose depends on the operating pressure and temperature and on the type of valve best-suited for the use to which it will be put. In general, it is customary to use *gate valves* in locations where pressure drop through the valve is a consideration, and where the valve will either be wide open or fully closed. Guard valves and shutoffs for boiler and turbine leads, and so on, are almost always of the gate type. *Globe valves* are commonly used in water, steam, and air lines for control or throttling purposes, as the globe type permits closer regulation of flow. Throttling often involves some steam cutting of the seat and disk, and these parts of globe valves are more easily repaired or replaced than in gates. Some appropriate uses for globe valves under these conditions are turbine and engine throttles, bypasses around traps or reducing valves, and hand-feed regulation on boilers.

Check valves are required in feed lines close to a boiler to prevent water or steam from blowing back from the boiler, if, for any reason, the feed line ruptures or its pressure fails. It is advisable to use check valves in individual pump or trap discharges before they join a common header and where different lines are joined together to discharge into a common header. A check valve cannot be counted on for closing a line off completely against pressure working back through, but it will stop a considerable flow. In pump discharges where the header remains under pressure after the pump is shut down, a gate valve should be provided in addition to the check valve. It is also desirable to provide a small relief valve on the pump suction to prevent pressure backing up through the pump and overpressurizing the suction side of the system pump.

With pressure-reducing or other control valves it is desirable to select a size that is loaded somewhere near capacity under normal operation, as such valves are then more stable in their operation. If there is considerable seasonal variation in the load on a reducing or control station, it is good practice to install a large and a small valve in parallel, and use the one best fitting the load at any particular time. It is frequently desirable to install a hand-operated bypass around a control valve so that service can be maintained while the special valve is being repaired. Such an arrangement with provision for shutoff to repair the special valve while the line
FIGURE C3.11   Pressure-reducing station.

is in operation is shown in Fig. C3.11, which includes flanged valves. Advantage can be taken of improved valve design, wherein weld ends are used while still permitting the internals to be removed for repairs. Main steam lines usually do not use flanges. Filler pieces should be provided between a flanged reducing valve and the adjacent gates, as reducing valves usually are constructed so it is impossible to remove all the end-flange bolts when they are bolted directly to other valves or fittings because of close clearance at the valve bonnets or fitting necks. For convenience in removing these valves from the line, flanged connections are used frequently at such points, even though the rest of the line is made with screwed or welded joints. When reducing from a pressure that requires the use of a heavy standard for flanges and fittings to a pressure with which a lighter standard is used or to which low-pressure equipment is connected, relief valves should be provided on the low-pressure side. The use of the heavier standard should be continued through to the last valve ahead of the relief valve, as it is possible to have full pressure up to that point. A reducing valve seldom has a tight shutoff, and at times of negligible steam consumption, leakage through the valve may be enough to build up full line pressure on the low-pressure side. The ASME Code for Power Piping requires that the combined discharge capacity of the safety or relief valves shall be such that the pressure rating of the lower-pressure piping will not be exceeded in case the reducing valve sticks open.

Safety and Relief Valves.   Safety and relief valves are defined in Section I of the ASME Code[20] as follows:

Safety Valve: An automatic pressure relieving device actuated by the static pressure upstream of the valve and characterized by full-opening pop action. It is used for gas or vapor service.

Relief Valve: An automatic pressure relieving device actuated by the static pressure upstream of the valve which opens further with the increase in pressure over the opening pressure. It is used primarily for liquid service.

Safety Relief Valve: an automatic pressure-actuated relieving device suitable for use either as a safety valve or relief valve, depending on application.

The construction and method of installing safety valves for power boilers are explained in Section I of the ASME Boiler and Pressure Vessel Code.[20] The boiler safety valve requirements are excerpted as follows:

Each boiler shall have at least one safety valve or safety relief valve and if it has more than 500 ft^2 [46 m^2] of bare tube water-heating surface, or if an electric boiler has a power input more than 1100 kW, it shall have two or more safety valves or safety relief valves. For a boiler with combined bare tube and extended water-heating surface exceeding 500 ft^2 [46 m^2], two or more safety valves or

safety relief valves are required only if the design steam generating capacity of the boiler exceeds 4000 lb/hr [1810 kg/hr]. . . .

The safety valve or safety relief valve capacity for each boiler shall be such that the safety valve, or valves will discharge all the steam that can be generated by the boiler without allowing the pressure to rise more than 6 percent above the highest pressure at which any valve is set and in no case to more than 6 percent above the maximum allowable working pressure. . . .

One or more safety valves on the boiler proper shall be set at or below the maximum allowable working pressure. If additional valves are used the highest pressure setting shall not exceed the maximum allowable working pressure by more than 3 percent. The complete range of pressure settings of all the saturated-steam safety valves on a boiler shall not exceed 10 percent of the highest pressure to which any valve is set. Pressure setting of safety relief valves on high-temperature water boilers may exceed this 10 percent range.

Additional requirements and requirements for alternate protection against over-pressure are included in Section I of the ASME Boiler and Pressure Vessel Code,[20] Section PG-67.

Where more than one safety or relief valve is used on a boiler or other pressure vessel, it is desirable to set one or more of the valves to relieve at a lower pressure than the rest. This serves as a warning before too much steam is lost through all the valves opening at once and also tends to facilitate repairs by confining any cutting action to the one or more valves that open first. In some cases an extra safety valve, known as the power-control valve, is set to blow before the others and is mounted above a gate valve so that it can be removed for repairs while the boiler or steam line is in service. The capacity of this valve cannot be considered in meeting Code or other safety requirements, because it might be shut off. Where the hazard involved does not require the installation of a full-size relief valve, it is sometimes desirable to install a small-size pop valve as a telltale to give warning when the usual working pressure is exceeded. The operator can then attend to restoring it to normal conditions. A safety valve for use with a compressible fluid, such as steam or air, is distinguished from a relief valve in that a safety valve has an adjusting, or huddling, ring and chamber to control the amount the pressure blows down before the valve reseats.

Bolting.   In bolting cast-iron flanges or steel flanges to cast-iron flanges, valves, fittings, and so forth, bolts must be of carbon steel equivalent to ASTM A307, Grade B, without heat treatment other than stress relief. Otherwise, they may be too strong for the cast-iron flanges. Threads in accordance with the coarse-thread series of the standard for screw threads, ASME B1.1 and B18.2.1,[21,22] are recommended for carbon-steel bolts. Carbon-steel bolts conforming to A307 may be the standard regular or heavy hexagonal-head bolts and must be used with standard heavy semifinished hexagonal nuts, B18.2.2,[23] which conform to ASTM A194.

For high-temperature service or for insurance of a tight joint in the case of steel flanges, bolts or stud bolts should be of alloy steel, conforming to ASTM A193, typically Grade B7. Nuts must be of steel according to ASTM A194, Grade 2H.

Bolt and nut selection for use with flanges in power piping may often be made from the alloy-steel bolts listed in Tables 112 and 126.1 and Section 108.5 of ASME B31.1.[2] See Chap. A7 in this handbook for additional information on bolted joints.

Following is a summary of the principal bolting selections by the architect/

constructor for a typical 150 MW circulating fluidized bed power plant (see Table C3.4):

- *Bolt studs:* Eight threads per in (25.4 mm) [coarse thread for less than 1 in (25 mm)] with two nuts.
- No bolted joints are allowed for main steam.
- *Stud material:* A193, B16 for hot reheat, if present; A193, B7 for all other systems noted.
- *Nuts:* Hexagon semifinished Heavy Series per B18.2.2.[23]
- *Nut material:* A194, Grade 4 for hot reheat; A194, Grade 2H nut standard for all other systems noted.

Protective Conduits for Underground Lines. Protective conduits for underground steam mains and services are necessary to protect the pipe and insulation from damage due to earth pressure and impact loadings; to allow free longitudinal expansion and contraction while held in proper alignment; and to prevent groundwater seepage or flooding by providing either drains or a completely waterproof structure.

Many types of conduits are used by the steam-piping industry today. They can be categorized into the following general classifications: prefabricated, boxtype, solid pour, granular fused, and tunnels.

Prefabricated conduits are popular with utilities located in large cities, where conditions exist such as congested subsurface, heavy surface traffic, tidewater, and rock areas. The ideal design for these conditions is one with the smallest cross-sectional area, consistent with thermal requirements, to fit into limited subsurface space. Two prefabricated designs are shown in Fig. C3.12.

In Fig. C3.12*a*, the insulated pipe is placed within a corrosion-resistant, helically corrugated metal jacket which is protected with a heavy asphaltic coating. In Fig. C3.12*b*, the insulated pipe is placed concentrically within the corrosion-resistant metal jacket, and the intervening space between jacket and insulation is poured full of high-melting-point asphalt, which is a protective medium for the insulation. Some of these prefabricated designs are also available with cast-iron casings with fittings designed for joints, bends, and so on.

Boxtype conduits have many variations. Depending on loading conditions, reinforcement may or may not be necessary. Drainage is provided by filling drainage pockets with crushed stone or gravel; these pockets may be installed on either or both sides of the conduit. They conduct water from the top of the conduit to the lower drain, which is connected to a sewer.
FIGURE C3.12 Prefabricated conduits for underground steam pipes: (*a*) coated and wrapped corrugated conduit; (*b*) poured asphalt protects thermal insulation.
FIGURE C3.13 Solid-pour protection for underground steam pipe: (*a*) insulated and wrapped pipe in structural concrete; (*b*) pipe is surrounded by insulating concrete.

Solid-pour construction, such as is shown in Fig. C3.13*a*, consists of poured structural concrete which is vibrated or tamped around a conventionally insulated steam line. If the insulation has a high compressive strength, such as is characteristic of diatomaceous earth or silica, it can support the pipe; otherwise, it should be supported independently. Reinforcing is sometimes used to prevent settlement. An eccentric space may be left around the pipe by using insulation larger than the outside diameter of the pipe. This permits the pipe to rise during the warming-up period without crushing the insulation.

The design of Fig. C3.13*b* utilizes an insulating concrete as a conduit. The concrete is poured around the steam pipe, which is supported on precast blocks of the same material. The insulating concrete may consist of any mixture of insulation or other cellular materials and portland cement or a mixture of a special foaming material mixed with portland cement; the aim is to create a cellular mass composed of minute air cells in the concrete so as to develop insulating qualities. The piping (which could be a number of pipes) is wrapped with corrugated paper before the insulation is poured, and a heavy-asphalt-coated waterproofing membrane, or equivalent waterproof sheeting, is installed to protect the top and side of the structure before backfilling.

Granular-fused types of conduits as shown in Fig. C3.14 consist of a granular
FIGURE C3.14 Granular-fused conduit for underground steam pipe.

bitumen, selected for the required temperature range and poured and tamped around the pipe or pipes in a trench. Heat passing through the pipe forms three concentric zones: (1) a dense semiplastic core fused on by the pipe's own heat, (2) a sintered zone providing thermal insulation and moisture proofness, and (3) an outer layer of granules providing a final zone of thermal insulation and the load-bearing portion of the structure.

Walk-through tunnels are usually not provided for steam mains unless they are required for underground passage between buildings, as in institutions, and then, they are usually constructed to accommodate other utilities services such as electricity, water, and gas. Tunnels are very costly and are constructed only out of necessity.

Provision for condensate drainage, ventilation, and insulating methods to reduce heat loss are considered for all portions of underground steam mains.

The illustrations shown here are only a few of the many designs utilized in practice today. Choice and application depend upon the project design requirements and site conditions. In the economic evaluation, factors to be considered include life expectancy, operation and maintenance costs, impact of geotechnical conditions on foundations, external and internal drainage, corrosive action of soil conditions, loads to be imposed, field installation practices, and necessary insulating properties.

Drainage of Condensate.   To prevent a water slug type of water hammer and a possible rupture of the steam main, condensed steam or condensate within the steam main must be removed. Even superheated steam lines need drainage since condensation forms during the warming-up period, or while the line is hot but without flow. The points to be drained are the low points in the line, moisture separators, drip pockets, and valves, especially in vertical lines. Horizontal portions of the steam lines should be pitched downward approximately ⅛ in/ft (10 mm/m) in the direction of flow or ¼ in/ft (20 mm/m) for lines that contain a steam/water mixture or require draining periodically. Condensate flow against the steam should be avoided if possible.

Since the contour of the ground or subsurface structures will dictate the pitch of the steam main, provisions must be made during construction to grade the steam main carefully so as to pitch the pipe adequate for condensate drainage. Since it is unlikely that a continuous slope can be maintained in a long run of main, removal of condensate (drainage) must be provided for at all low points where a water pocket will exist. In any event, recommended lengths of steam main for draining off condensate should not exceed 300 to 400 ft (90 to 120 m).

To provide for condensate drainage from a steam main, a drain pocket is welded to the bottom of the pipe to be drained. The diameter of the pocket should be about one-third the diameter of the line, up to a maximum of NPS 6 (DN 150) for NPS 18 (DN 450) and larger mains. The pocket not only provides for condensate removal but also allows for sediment removal. Figure C3.15 shows this design. Figure C3.16 is a design in the form of a separator, which is more prevalent in underground steam mains.

For systems which supply high flow rates to concentrated loads, it probably will be economical to return the cond-
FIGURE C3.15   Drain pocket for steam-trap connection to low-velocity steam main.

ensate in order to recover the energy in the condensate and thereby reduce the costs of treating raw makeup water.

Sometimes, however, it is not economically feasible or practical to return the condensate from district-heating systems because of the high cost of installing and maintaining pumping equipment, manholes, and return piping.

In such cases, traps off the drain pocket can often be discharged through cooling coils to the city sewer system. City regulations may require the condensate discharge to be cooled before entering the sewer. In some cases, condensate discharge lines are piped to sump pits in manholes, where the water is removed by float-controlled electric pumps which discharge it into the sewer. See Figs. C3.17 and C3.18.

In process and power system piping, condensate removal is an important

FIGURE C3.16   Drain pocket for steam-trap connection to high-velocity steam main.

consideration to prevent water slug formation in steam lines. Paragraph 122.11 of ASME B31.1[2] contains the following provisions for drains, drips, and steam traps:

Drip lines from piping or equipment operating at different pressures shall not be connected to discharge through the same trap. If two or more traps discharge into the same header which is, or may be, under pressure, a stop valve and a check valve shall be provided in the discharge line from each trap.

FIGURE C3.17   Manhole for sump pump.
FIGURE C3.18   Manhole for sectionalizing valve and drain valve assembly.

Trap discharge piping shall be designed for the same pressure as the inlet piping unless the discharge is vented to atmosphere, or is operated under low pressure and has no stop valves. In no case shall the design pressure of trap discharge piping be less than the maximum discharge pressure to which it may be subjected.

Steam traps are automatic devices used to trap or hold steam until it has condensed and to allow condensate and air to pass as soon as they accumulate. In general, a trap consists of a vessel in which the condensate accumulates, an orifice through which the condensate is discharged, a valve to close the orifice port, mechanisms to operate the valve, and inlet and outlet openings for the entrance and

TABLE C3.6   Reasonable Design Velocities for Flow of Fluids in Pipes

			Reasonable velocity	
Fluid	Pressure, psig	Use	Ft/minute	Ft/second
Water	25–40	City water	120–300	2–5
Water	50–150	General service	300–600	5–10
Water	150 up	Boiler feed	600–1,200	10–20
Saturated steam	0–15	Heating	4,000–6,000	67–100
Saturated steam	50 up	Miscellaneous	6,000–10,000	100–167
Superheated steam	200 up	Large turbine and boiler leads	10,000–20,000	167–334

discharge of the condensate from the trap vessel. Steam traps are discussed in detail in Chap. A2.

Determining Reasonable Flow Velocity.   Before proceeding beyond a preliminary layout of piping systems, it is necessary to determine pipe sizes which allow reasonable velocities and friction losses. The maximum allowable velocity of the fluid in a pipeline is that which corresponds to the permissible pressure drop from the point of supply to the point of consumption or is that which does not result in excessive pipeline erosion. The economic optimization of line sizes is discussed in Chap. B8 in this handbook. The values of velocity listed in Tables C3.6 and C3.6M (Metric) are reasonable for use in such cases. The lower velocities should be used for small pipes, and the upper limits for large ones. These values represent good average practice and may be used as a guide in many cases where actual pressure drops are not computed. Additional steam line velocity information is given in Chap. B8 in this handbook.

Erosive action on valve seats and similar exposed parts also affects permissible velocity. This action is much more pronounced in the case of wet steam than with superheated steam, and velocities should be correspondingly lower when there is much moisture in the steam.

High velocities are sometimes used in dry steam lines where excess pressure exists, to absorb the higher pressure drop. The high velocity is not in itself objection-

TABLE C3.6M (Metric)   Reasonable Design Velocities for Flow of Fluids in Pipes

			Reasonable velocity	
Fluid	Pressure (kPa gauge)	Use	m per minute	m per second
Water	172–276	City water	36–91	0.61–1.52
Water	345–1034	General use	91–183	1.52–3.05
Water	1034 up	Boiler feed	183–366	3.05–6.10
Saturated steam	1–103	Heating	1220–1830	20.4–30.5
Saturated steam	345 up	Miscellaneous	1830–3050	30.5–50.9
Superheated steam	1380 up	Large turbine and boiler leads	3050–4570	50.9–76.2

Source: Courtesy of Stone & Webster.

able, since with dry steam there is no appreciable erosion of the pipe walls and no undesirable effects save that high velocities are accompanied by considerable noise (which would be objectionable in heating systems in office buildings and dwellings but may not be in power plants).

In the selection of pipe sizes for exhaust lines from auxiliary turbines and similar services where high velocities may be used to advantage, consideration should be given to the limiting velocities which can be obtained. This limiting or sonic velocity has a definite value for each combination of steam density and pressure (see Chap. B8).

It is often cheaper to use a larger standard pipe size than to use a unique pipe size. Table C3.4 shows a special size for main steam piping and standard sizes recommended for the other systems. Where space is at a premium, it may be necessary to use a smaller size than would otherwise be good practice. The calculation of velocity or pressure drop is a valuable check, but in the last analysis judgment is the deciding factor, and the blind use of generalized criteria is impracticable.

Special attention should be given to sizing hot and cold reheat piping since pressure drop in reheat systems affects turbine heat rate. Cost of piping must be compared with these effects to arrive at the most economical piping arrangement. Normally, total pressure drop in reheat piping and the reheating section of the steam generator should be 7 to 9 percent of high-pressure turbine exhaust pressure. It is desirable to use a smaller-diameter hot reheat line and larger-diameter cold reheat line, taking a greater pressure drop in the more expensive (alloy) hot reheat line.

Loss Due to Steam Leaks. Modern power plants with almost all welded joints experience leakage through only a few nonwelded joints at valves or other equipment connections. The hazard of high-pressure, high-temperature steam leaks, together with the cost of chemicals required in most makeup systems, makes early repairs mandatory.

Existing low-pressure plants using flanged or screwed joints experience considerable leakage and where maintenance is deferred are wasting both water and energy at a rate which depends on the size of the opening and steam pressure.

The value of steam which can be lost through a comparatively small leak becomes appreciable when considered over a period of time. The amounts of steam which will escape through various sizes of orifices at different pressures can be computed by an appropriate flow formula. Table C3.7, which was computed by Grashof's formula,[24] gives the pounds of steam and gallons of water wasted per month, while Table C3.7M (Metric) gives the kg of steam and m^3 of water wasted per month.

Expansion, Flexibility, and Supporting. Chapters B4 and B5 in this handbook provide basic information on the thermal expansion, the needed flexibility, and the supporting of piping systems. In underground steam piping, expansion joint fittings are more commonly used for thermal expansion owing to the limitations of space and costly trenching. Expansion joints are often used for application in underground steam mains.

The basic design of a *slip-type joint* consists of a cast-iron or steel body with a stuffing box and a sliding sleeve. The advantage of slip-type joints is the longer traverses that can be obtained to absorb pipe expansion; the disadvantage is the necessity for maintaining packing. By the very nature of its construction, the slip joint is capable of absorbing only axial movement.

The *metallic bellows expansion joint* is composed of the following components: (1) the flexible element proper (corrugated metal tube), the rings enabling reinforced

TABLE C3.7 Loss Due to Steam Leaks*

Size of orifice, in	Pounds steam wasted per month	Water wasted, gal
250-lb gauge		
½	1,780,000	213,600
⅜	1,001,000	120,100
¼	445,000	53,400
⅛	111,000	13,300

1/32	7,000	800
300-lb gauge		
½	2,125,000	255,000
⅜	1,195,000	143,400
¼	531,000	63,700
⅛	132,800	15,900
1/16	33,200	4,000
1/32	8,300	1,000
400-lb gauge		
½	2,804,000	336,500
⅜	1,577.000	189,200
¼	701.000	84,100
⅛	175,200	21,000
1/16	43,800	5,300
1/32	11,000	1,300
600-lb gauge		
½	4,157,000	498,800
⅜	2,338,000	280,600
¼	1,039,000	124,700
⅛	259,000	31,200
1/16	65,000	7,800
1/32	16,300	2,000

* Values in the table are based on the use of Grashof's formula.

elements to support higher pressures, and the end collars or other structures serving to increase pressure capacity of cylindrical ends and transfer spring force and hydrostatic end thrust to connected piping, and (2) the end nipples or flanges and, for other than anchored axial joints, the various hardware items used to cross-connect the ends, such as tie rods, hinges, and gimbals.

The advantages of the bellows type of joint which permit its use in buried steam piping are that it requires no maintenance and can absorb a combination of axial, lateral, and angular movement within a large range of pressures and temperatures. Its disadvantage is the limitation of traverse, generally 7 to 8 in (180 to 200 mm) of axial movement.

Adequate anchoring and guiding are essential for the proper functioning of all expansion joints. Main anchors for end thrusts must be designed for the sum of the pressure thrust, the force required to deflect the joint, and the force due to friction in the piping guides. Intermediate anchors are used between balanced or double-type joints where the pressure thrust is balanced and the anchor need be designed only to restrict the expansion movement of the pipe. Guides are essential

TABLE C3.7M (Metric)   Loss Due to Steam Leaks*

Size of orifice (mm)	Steam wasted per month (kg)	Water wasted (m³)
1,724 kPa gauge		
12.70	807,000	808.6
9.52	454,000	454.6
6.35	201,800	202.1
3.18	50,300	50.3
1.59	12,600	12.5
0.79	3,200	3.0
2,068 kP gauge		
12.70	936,900	965.3
9.52	542,000	542.8
6.35	240,900	241.1
3.18	60,200	60.2
1.59	15,100	15.1
0.79	3,800	3.8
2,758 kPa gauge

0.79	7,400	7.6

* Values in the table are based on the use of Grashof's formula.

to assure proper pipe alignment into the expansion joint so that undesirable torques are not imposed on the expansion element.

Cold springing of expansion joints used only for lateral deflection can provide several advantages. The most significant of these is the optimization of the position of the expansion joint. In addition, the joint is more stable at high pressures, since the maximum angular displacement of the corrugations is reduced. Joints with internal sleeves and external covers must have adequate clearance to permit the lateral deflection of the expansion element. If the deflection can be reduced by 50 percent, these clearances can also be reduced by 50 percent. Internal sleeves can then be of maximum diameter, and external sleeves are held to a minimum diameter.

All piping systems expand with an increase in temperature in the system. Long runs of high-temperature piping generally use bends, fittings, and offsets to assist in keeping the stresses within the code's allowable values, and reactions (forces and moments) on the turbine or boiler connections within the manufacturer's allowable values. Rigid hangers, constant and variable support hangers, guides, and anchors are also useful to control the thermal growth but must be carefully engineered.

For piping such as main steam and hot reheat systems operating in the creep

range [900°F (482°C) and above], cold springing may prove useful in controlling the reactions on the equipment within the manufacturer's specified limits, although this technique is not universally recommended. (Cold springing is the process of cutting short the piping by a certain percentage of the expected thermal growth so that equipment loading in the cold, erected position is that percentage of the calculated hot reactions from the thermal analysis.) Cold springing does not reduce the stresses in the piping as allowed by the Code, but may be useful in meeting the vendors' limits on allowable forces and moments on their equipment, provided that the piping does not creep significantly at operating temperature. As the piping heats up and cycles through a number of thermal cycles in the creep range, the cold reactions will gradually be self-relieved to a certain extent. See ASME B31.1 Code,[2] Paragraphs 119.9 and 119.10 or ASME Section III,[1] Paragraphs NC-3673.3 and NC-3673.5 for a more complete discussion of this subject.

The piping designer needs to work closely with the vendors of the equipment in laying out the high-temperature piping and support systems, in conjunction with the flexibility analyst, so that these systems will meet all requirements over the life of the plant. Especially critical are the loads imposed on rotating equipment such as steam turbines, since clearances are critical and distortion due to piping loads can cause real problems to this equipment.

The true economics of the system design must include all the above factors plus the normal cost factors (piping, insulation, hangers, etc.).

Fabrication, Assembly, and Erection.   For underground steam piping, manholes are required for sectionalizing valves and bypass valve piping, trap piping and traps, some types of expansion joints, and convenience of location of other expansion joints and anchorage. Modern manholes are constructed of reinforced concrete, cast-iron, or steel. In field-pour concrete construction, waterproofness should be assured by pouring the walls and floor monolithically. Prefabricated enclosures are pretested for waterproofness before installation. Other provisions that should be considered in manhole design are (1) adequate working space for maintenance, (2) clearance for removal of equipment, (3) ventilation, and (4) drainage. If the manhole floor elevation is below the sewer or if a sewer is not accessible for drainage piping from the manhole, sump pump manholes with automatic pumps or water ejectors must be provided. An example of such an installation is shown in Fig. C3.17. In prefabricated steam-main construction, prefabricated manholes with the necessary valves and piping installed may be delivered to the job site as a unit. This type of manhole is shown in Fig. C3.18.

With prefabricated installation, expansion joints of the bellows design may be delivered to the job site and welded into the steel piping and conduit of the steam main. This provides for directly buried expansion joints in a fully-encapsulated system. Where convenient or necessary, expansion joints are installed in manholes with sectionalizing valves and thrust-type anchors. For ease of maintenance, traps are usually installed in their own manholes; that is, in a manhole separate from that which houses the sectionalizing valve.

Steam piping in power plants is fabricated and installed in accordance with the appropriate code. The following discussion highlights several of the requirements for ASME Class 2 piping,[1] but specific codes should be reviewed as applicable. Components, parts, and appurtenances shall be fabricated and installed in accordance with the rules in the code and shall be manufactured from materials which meet the requirements of the code.

Material for pressure-retaining parts shall carry identification markings which will remain distinguishable until the component is assembled or installed. If the

original identification markings are cut off or the material is divided, either the marks shall be transferred to the parts cut, or a coded marking shall be used to ensure identification of each piece of material during subsequent fabrication or installation. In either case, an as-built sketch or a tabulation of materials shall be made identifying each piece of material with the Certified Material Test Report, where applicable, and the coded marking. For studs, bolts, nuts, and heat exchanger tubes, it is permissible to identify the Certified Material Test Reports for material in each component in lieu of identifying each piece of material with the Certified Material Test Report and the coded marking. Material supplied with a Certificate of Compliance and welding and brazing materials shall be identified and controlled so that they can be traced to each component or installation of a piping system, or else a control procedure shall be employed which ensures that the specified materials are used.

Material originally accepted on delivery in which defects exceeding the limits of acceptance are known or discovered during the process of fabrication or installation, is unacceptable. However, the material may be used, provided the condition is corrected in accordance with the requirements for the applicable product form.

Materials may be cut to shape and size by mechanical means such as machining, shearing, chipping, or grinding, or by thermal cutting. When thermal cutting is performed to prepare weld joints or edges to remove attachments or defective material, or for any other purpose, consideration shall be given to preheating the material, using preheat schedules such as suggested in the code.

Any process may be used to hot- or cold-form or bend pressure-retaining materials, including weld metal, provided the impact properties of the materials, when required, are not reduced below the minimum specified values, or they are effectively restored by heat treatment following the forming operation. *Hot-forming* is defined as forming with the material temperature higher than 100°F (38°C) below the lower critical temperature of the material.

When impact testing is required by the design specifications, a procedure qualification test shall be conducted using specimens taken from materials of the same specification, grade or class, heat treatment, and with similar impact properties as required for the material in the component. These specimens shall be subjected to the equivalent forming or bending process and heat treatment as the material in the component. Applicable tests shall be conducted to determine that the required impact properties of the code are met after straining.

The tolerance requirements for formed or bent piping include maintaining minimum wall thickness and ovality. Bending processes shall be selected and qualified to ensure a wall thickness for bent piping sufficient to satisfy the requirements of the design calculations at the resultant section thickness. Unless otherwise justified by the design calculations, the ovality of piping after bending shall not exceed 8 percent as noted in Eq. (C3.6):

$$100 \times \frac{D_{\max} - D_{\min}}{D_o} \leq 0.08 \qquad \text{(C3.6)}$$

where D_o = the nominal pipe outside diameter, in (mm)
 $D_{\min}$ = the minimum outside diameter after bending or forming, in (mm)
 $D_{\max}$ = the maximum outside diameter after bending or forming, in (mm)

Parts that are to be joined by welding may be fitted, aligned, and retained in position during the welding operation by the use of bars, jacks, clamps, tack welds,

or temporary attachments. When the inside surfaces of items are inaccessible for welding or fairing, alignment of sections shall meet the following requirements:

For circumferential joints the inside diameters shall match each other within ¹⁄₁₆ in (1.5 mm). When the items are aligned concentrically, a uniform mismatch of ¹⁄₃₂ in (0.8 mm) all around the joint can result. However, other variables not associated with the diameter of the item often result in alignments that are offset rather than concentric. In these cases, the maximum misalignment at any one point around the joint shall not exceed ³⁄₃₂ in (2.4 mm). Should tolerances on diameter, wall thickness, out-of-roundness, and so on, result in inside diameter variation which does not meet these limits, the inside diameters shall be counterbored, sized, or ground to produce a bore within these limits. Offset of outside surfaces shall be faired to at least a 3:1 taper over the width of the finished weld or, if necessary, by adding additional weld metal.

For longitudinal joints the misalignment of inside surfaces shall not exceed ³⁄₃₂ in (2.4 mm), and the offset of outside surfaces shall be faired to at least a 3:1 taper over the width of the finished weld or, if necessary, by adding additional weld metal.

No welding shall be undertaken until after the welding procedures which are to be used have been qualified. Only welders and welding operators who are qualified in accordance with code requirements shall be used. All welding procedure qualification tests shall be in accordance with the requirements of the code.

The method used to prepare the base metal shall leave the weld preparation with reasonably smooth surfaces. The surfaces for welding shall be free of scale, rust, oil, grease, and other deleterious material. The work shall be protected from deleterious contamination and from rain, snow, and wind during welding. Welding shall not be performed on wet surfaces. Rules for making welded joints in piping are described in the following paragraphs.

Backing rings which remain in place may be used for piping in accordance with the requirements of the code. The materials for backing rings shall be compatible with the base metal, but spacer pins shall not be incorporated into the weld.

In double-welded joints, before applying weld metal on the second side to be welded, the root of full penetration double-welded joints shall be prepared by suitable methods such as chipping, grinding, or thermal gouging, except for those processes of welding by which proper fusion and penetrations are otherwise obtained and demonstrated to be satisfactory by welding procedure qualifications.

Where single-welded joints are used, particular care shall be taken in aligning and separating the components to be jointed so that there will be complete penetration and fusion at the bottom of the joint for its full length.

When components of different diameters are welded together, there shall be a gradual transition between the two surfaces. The slope of the transition shall be such that the length-offset ratio shall not be less than 3:1, unless greater slopes are shown to be acceptable by analysis. The length of the transition may include the weld.

Thickness of weld reinforcements for piping is specified in Table C3.8. For double-welded butt joints the limitation on the reinforcement given in Column 1 of the table shall apply separately to both inside and outside surfaces of the joint. For single-welded butt joints, the reinforcement given in Column 2 shall apply to the inside surface and the reinforcement given in Column 1 shall apply to the outside surface. The reinforcements shall be determined from the higher of the abutting surfaces involved.

Fillet welds may vary from convex to concave. A fillet weld in any single continu-

TABLE C3.8 Thickness of Weld Reinforcements for Piping[1]

Material nominal thickness in (mm)	Column 1: Both double-welded butt joints and outside single-welded butt joints	Column 2: Inside single-welded butt joints
Up to ½ (3.2), incl.	³⁄₃₂ (2.4)	³⁄₃₂ (2.4)
Over ⅛–³⁄₁₆ (3.2–4.8), incl.	⅛ (3.2)	³⁄₃₂ (2.4)
Over ³⁄₁₆–½ (4.8–12.7), incl.	⁵⁄₃₂ (4.0)	⅛ (3.2)
Over ½–1 (12.7–25.4), incl.	³⁄₁₆ (4.8)	⁵⁄₃₂ (4.0)
Over 1–2 (25.4–51), incl.	¼ (6.4)	⁵⁄₃₂ (4.0)
Over 2 (51)	The greater of ¼ in (6.4 mm) or ⅛ times the width of the weld in inches (mm)	⁵⁄₃₂ (4.0)

ous weld may be less than the specified fillet weld dimension by not more than ¹⁄₁₆ in (1.5 mm), provided that the total undersize portion of the weld does not exceed 10 percent of the length of the weld. Individual undersize weld portions shall not exceed 2 in (52 mm) in length. In making socket welds, a gap of approximately ¹⁄₁₆ in (1.5 mm) at the end of the pipe shall be provided prior to welding. The gap need not be present nor be verified after welding.

Structural attachments shall conform reasonably to the curvature of the surface to which they are attached. Full penetration, fillet, or partial penetration continuous or intermittent welds are acceptable, depending on service conditions.

Attachments may be welded to the piping system after performance of the pressure test provided the welds do not require postweld heat treatment (PWHT); welds shall be restricted to fillet welds not exceeding ⅜ in (9.5 mm) throat thickness and to full penetration welds attaching materials not exceeding ½ in (12.7 mm) in thickness; welds shall not exceed a total length of 24 in (60 cm) for fillet welds or 12 in (30 cm) for full penetration welds; and welds shall be examined as required by the code.

The need for and temperature of preheat are dependent on factors such as the chemical analysis, degree of restraint of the parts being joined, elevated temperature, physical properties, and material thicknesses. Postweld heat treatment must provide the required heating and cooling rates, metal temperature, metal temperature uniformity, and temperature control.

The threads of all bolts or studs shall be engaged in accordance with the design. Any lubricant or compound used in threaded joints shall be suitable for the service conditions. All threading lubricants or compounds shall be removed from surfaces which are to be seal-welded. In bolting gasketed flanged joints, the contact faces of the flanges shall bear uniformly on the gasket in accordance with the design principles applicable to the type of gasket used. All flanged joints shall be made up with uniform bolt stress.

Examination, Inspection, and Testing.   The inside of all pipes, valves, fittings, traps, and other apparatus shall be smooth, clean, and free from all blisters, loose mill scale, sand, and dirt when erected. All main steam lines and significant branch lines shall be steam-blown before placing in service.

Steam piping in power plants must be examined, inspected, and tested in accordance with the appropriate code. The following discussion summarizes several

general requirements for ASME Class 2 piping,[1] but specific codes should be reviewed as applicable.

The examinations required by the code shall be performed by personnel who have been qualified as required by code, and results of the examinations shall be evaluated in accordance with the specified acceptance standards.

Following any nondestructive examination in which examination materials are applied to the piece, the piece shall be thoroughly cleaned in accordance with applicable materials or procedure specifications.

Acceptance examinations of welds and weld metal cladding shall be performed at the following stipulated times during fabrication and installation.

1. Radiographic examination of welds will usually be performed after an intermediate or final PWHT, when required.

2. Magnetic particle or liquid penetrant examinations of welds shall be performed after any required PWHT, except that welds in P-No. 1 materials may be examined either before or after PWHT.

3. All dissimilar metal weld joints such as in austenitic or high nickel to ferritic material or using austenitic or high nickel alloy filler metal to join ferritic materials which penetrate the wall shall be examined after final PWHT.

4. The magnetic particle or liquid penetrant examination of weld surfaces that are to be covered with weld metal cladding shall be performed before the weld metal cladding is deposited. The magnetic particle or liquid penetrant examination of weld surfaces that are not accessible after a PWHT shall be performed prior to the operation which caused this inaccessibility. These examinations may be performed before PWHT.

5. Ultrasonic examination of electroslag welds in ferritic materials shall be performed after a grain refining heat treatment, when performed, or after final PWHT.

The codes provide specific acceptance standards for radiographic, ultrasonic, magnetic particle, liquid penetrant, and metallographic examination of all components. Unique examination requirements are usually specified for bellows expansion joints.

Pressure Testing. Before installation, all valves, fittings, and so forth shall be capable of withstanding an appropriate hydrostatic shell test, and piping shall be capable of meeting the hydrostatic test requirements contained in the respective material specifications under which it was purchased. All pressure-retaining components, appurtenances, and completed systems shall be pressure tested. Bolts, studs, nuts, washers, and gaskets are exempted from the pressure test. Pressure testing required by the applicable code often must be performed in the presence of the inspector.

After installation, the complete system shall be hydrostatically tested as noted in Table C3.9. When conducting pressure tests at low metal temperatures, the possibility of brittle fracture shall be considered. At no time during the hydrostatic test shall test pressure exceed the maximum allowable test pressure of any nonisolated components, such as vessels, pumps, or valves. Nor shall any of the maximum allowable stress limits be exceeded for any components being tested.

Following the application of the hydrostatic test pressure for the required time, all joints, connections, and regions of high stress (such as regions around openings and thickness transition sections) shall be examined for leakage, except in the case of pumps and valves, which shall be examined while at test pressure. The piping

TABLE C3.9 Selected Hydrostatic Test Pressure and Allowable Limits[1,2]

Code class and category of component	Hydro test pressure as a multiple of the design pressure (DP)	Maximum allowable stress at test temperature, circumferential (hoop) stress, if not noted otherwise
ASME Class 1		
Vessels	1.25 times DP	Note 1
Piping	1.25 times DP	Note 1
Equipment	1.5 times DP	Note 1
Valves	Per NB-3531[1]	Per NB-3531[1]
Relief valves	1.5 × set pressure	Per NB-3531[1]
ASME Class 2 and 3		
Vessels	1.25 times DP	Note 2
Piping	1.25 × DP, Note 3	Note 2
Equipment	1.5 times DP	Note 2
Valves	Per NC/ND-3500[1]	Per NC/ND-3500[1]
ASME B31.1		
System	1.5 times DP	90% of yield strength, Note 4
Piping	1.5 times DP	90% of yield strength, Note 4
Equipment	Note 5	Note 5
Valves	Note 5	Note 5

Notes: 1. Primary membrane stress intensity less than 90% of tabulated yield strength at test temperature and other limits in NB-3226.[1]
2. Primary membrane stress intensity less than 90% of tabulated yield strength at test temperature and other limits in NC-3218.[1]
3. As an alternative, piping between the discharge side of a centrifugal pump and the first shutoff valve may be hydrostatically tested at the shutoff head of the pump (NC/ND-6221[2]).
4. In addition, the sum of longitudinal stresses due to test pressure and live and dead loads at the time of test, excluding occasional loads, shall not exceed 90% of the yield strength at test temperature (Para. 102.3.3[2]).
5. Hydrostatic test pressure shall not exceed the maximum allowable test pressure of any nonisolated components, such as vessels, pumps, or valves.

system, exclusive of possible localized instances at pump or valve packing, shall show no visual evidence of weeping or leaking. Leakage of temporary gaskets and seals, installed for the purpose of conducting the hydrostatic test, and which will be replaced later, may be permitted unless the leakage exceeds the capacity to maintain system test pressure for the required amount of time. Other leaks, such as from permanent seals, seats, and gasketed joints in components, may be permitted when specifically allowed by the design specifications.

The component or system in which the test is to be conducted shall be vented during the filling operation to minimize air pocketing. Water or an alternative liquid, as permitted by the design specification, shall be used for the hydrostatic test. It is recommended that the test be made at a temperature that will minimize the possibility of brittle fracture. The test pressure shall not be applied until the component, appurtenance, or system and the pressurizing fluid are at approximately the same temperature.

The pressure test may be performed progressively on erected portions of the system. Components and appurtenances shall be pressure-tested prior to installation in a system except that the system pressure test may be substituted for a component or appurtenance pressure test provided the following is true: The component can be repaired by welding, if required, as a result of the system pressure test; the

component repair weld can be postweld heat-treated, if required, and nondestructively examined, as applicable; and the component is resubjected to the required system pressure test following the completion of repair and examination if the repair is required to be radiographed. Valves also require pressure testing prior to installation in a system.

All joints, including welded joints, shall be left uninsulated and exposed for examination during the test. Components designed to contain vapor or gas may be provided with additional temporary supports, if necessary, to support the weight of the test liquid. Expansion joints shall be provided with temporary restraints, if required, for the additional pressure load under test. Equipment that is not to be subjected to the pressure test shall be either disconnected from the component or system or isolated during the test by a blind flange or similar means. Valves may be used if the valves with their closures are suitable for the proposed test pressure. Flanged joints at which blanks are inserted to isolate other equipment during the test need not be retested. If a pressure test is to be maintained for a period of time and the test medium in the system is subject to thermal expansion, precautions shall be taken to avoid excessive pressure. The test equipment shall be examined before pressure is applied to ensure that it is tight and that all low-pressure filling lines and other items that should not be subjected to the test have been disconnected or isolated.

The hydrostatic test requirements for bellows expansion joints require that the completed expansion joint shall be subjected to a hydrostatic test in accordance with the applicable code. This test may be performed with the bellows fixed in the straight position, at its neutral length, or in some cases, this test shall be performed with the bellows fixed at the maximum design rotation angle or offset movement.

Pressure test gauges used in pressure testing shall be indicating pressure gauges and shall be connected directly to the component. If the indicating gauge is not readily visible to the operator controlling the pressure applied, an additional indicating gauge shall be provided where it will be visible to the operator throughout the duration of the test. For systems with a large volumetric content, it is recommended that a recording gauge be used in addition to the indicating gauge. All test gauges shall be calibrated against a standard dead-weight tester or a calibrated master gauge. The test gauges shall be calibrated before each test or series of tests.

When hydrostatic testing is impractical, it shall be required that the piping be tested with steam at a pressure at least equal to the pressure at which the piping is to be operated. These tests shall be made on sections, or on the whole of the piping system, but the connections between the sections must be similarly tested.

Special Design Criteria

Overpressure Protection.   Overpressure protection of the components in a steam system shall be provided as an integrated system using pressure-relief devices and associated pressure-sensing elements. Detail requirements for overpressure protection for ASME Class 1, 2, and 3 systems are provided in Articles NB-7000, NC-7000, and ND-7000,[1] respectively.

Each main steam lead generally has safety valves at the superheater outlet and often a motor-operated block valve which is used for isolation. A main steam stop valve at the boiler outlet facilitates boiler hydro testing prior to completion of turbine erection; whether to provide it is a matter of economics. In the case of two leads, the cross-connection between the two main steam leads shall permit full-closed testing of one turbine stop valve at a time while the turbine is operating.

The cross-connection line may have connections to the steam-generator feed pump turbines, auxiliary steam loads, turbine-generator gland seal system, and the steam-generator restart system, depending on system design requirements.

Protecting District Heating and Steam Distribution Systems. Construction of underground steam mains must adhere to the requirements as provided for in Section 122.14 of ASME B31.1[2] when the piping is within the jurisdiction of ASME B31.1. Where pressure-reducing valves are used, one or more relief devices or safety valves are provided on the low-pressure side of the system. The relief or safety devices are located as close as practicable to the reducing valve. The combined relieving capacity provided must be such that the design pressure of the low-pressure system will not be exceeded if the reducing valve fails to open.

In district heating and steam distribution systems where the steam pressure does not exceed 400 psi (2760 kPa) and where the use of relief valves as previously described is not feasible, alternative designs may be substituted for the relief devices. For example, this could occur if there is no acceptable discharge location for the vent piping. Two or more steam-pressure-reducing valves capable of independent operation may be installed in series, each set at or below the safe working pressure of the equipment and piping system served. In this case, no relief device is required. A trip-stop steam valve set to close at or below the design pressure of the low-pressure system may be used in place of a second reducing valve or a relief valve.

Design of Restrained Underground Piping. Appendix VII in B31.1[2] provides non-mandatory procedures which may be conservatively applied to the design and analysis of buried piping systems. Buried piping is supported, confined, and re-strained continuously by the passive effects of the backfill and the trench bedding. The effects of continuous restraint cannot be easily evaluated by the usual methods applied to exposed piping, since these methods cannot easily accommodate the effects of bearing and friction at the pipe/soil interface. All components in the buried system must be given consideration, including the building penetrations, branches, bends, elbows, flanges, valves, grade penetrations, and tank attachments. Welds should be made in accordance with the B31.1 code, and appropriate corrosion protection procedures for buried piping are to be followed.

Preventing Turbine Overspeed. Turbine water induction problems from main steam lines would normally only occur during start-up or shortly after shutdown, so prevention criteria are limited to low-point drain design per ASME Standard No. TDP-1.[26] Steam storage in the turbine, reheater, and reheat piping presents a problem in turbine speed control because surplus energy can continue to be gener-ated in the IP and the LP sections for some time after the main governor has reacted to a load decrease. This condition could result in dangerous overspeeding. To prevent this, governor-operated intercept valves are installed ahead of the point of reintroduction of the reheated steam to the turbine. The IVs are adjusted to begin closing when the normal speed is exceeded but before turbine speed has increased to the point (approximately 10 percent over normal RPM) where an emergency overspeed trip would shut down the whole unit.

Understanding Reheat Steam Systems

Advantages of Reheat Cycles. The example of power plant cycle efficiency im-provement by increased initial steam conditions in "Design Temperature" suggests

that maintaining the initial temperature constant over a range of pressures (as in the Carnot Cycle) might also prove fruitful. This would require reheating the main steam to its initial temperature again after each infinitesimal amount of expansion in the turbine. Such a cycle might be said to have an infinite number of reheats.

There is also another important advantage derived from using steam reheat in a power cycle. Reheating is a feature associated with high steam pressures where there is insufficiently high initial steam temperature to yield an expansion that will end with an acceptable moisture content at the condenser pressure. This limit of moisture at the last stage of a turbine is roughly 12 to 14 percent. Moisture in the steam flow causes erosion of turbine buckets, shortening their useful life, and also results in an efficiency loss in the turbine. The purpose of reheat is to take full advantage of higher initial steam parameters discussed in "Design Temperature" as they become commercially available.

Reheat Performance Efficiency.   The number of reheats to be used must be evaluated. The high-pressure, high-temperature steam generator, together with the extra cost of a turbine, piping, and controls, makes plants with reheat more expensive than those without this feature. Economically, single reheating has proved desirable on most machines above 100 MW. In actual practice the gain from single reheating is about 4 to 7 percent in thermal efficiency over an equivalent nonreheat cycle. The gain in performance which can be realized from a second reheating is smaller than that from the first. For large units operating at 3500 psig (24.2 MPa), the gain in performance due to a second reheat is in the neighborhood of 2 percent of the net heat rate (see Fig. C3.8). Performance gains for additional reheats diminish rapidly, and the justification for greater expenditures for equipment depends strongly upon the price of fuel.

For every set of initial steam conditions there exists an optimum reheat pressure (or pressures in a double-reheat cycle) which yields the maximum efficiency (minimum heat rate) of the power plant. Studies made of the performance and economic application of single-reheat cycles indicate that for a seven (or less) feedwater heater cycle the cold reheat pressure is adjusted by the turbine manufacturer to provide either the optimum or desired final feedwater temperature. If eight (or more) feedwater heaters are used, it proves economical to design the cycle with the first point heater located above the reheat point (HARP extraction). Figure C3.19[27] indicates typical optimum reheat pressures corresponding to 2400 psig/1000°F/1000°F (16.6 MPa/538°C/538°C) steam conditions for units taking extraction for the top heater at the reheat point (curve marked "Top heater at reheat point") or above the reheat point where the optimum reheat pressure is found at the low point of a curve corresponding to required final feedwater temperature.

It is seen from this figure that minor deviations from the optimum reheat pressure have a small effect on performance; however, the performance penalties should always be estimated. Size of the turbine, throttle temperature, and reheat temperature have a relatively minor effect on the indicated optimum conditions, and Fig. C3.19 may therefore be considered as reasonably accurate for any single-reheat unit at indicated throttle pressure. However, if more accurate information is needed, it should be obtained from the turbine manufacturer. It should be noted that the relative performance indicated applies only at rated output.

The selection of optimum reheat pressures for a double-reheat turbine is an involved problem. It is affected not only by thermodynamic optimization but also by design limitations (e.g., second-reheat intercept-valve pressure must be fixed at about 300 to 400 psia (2070 to 2760 kPa) at rated conditions due to the very large volumetric steam flows which would result at lower pressures). Figures C3.20 and
FIGURE C3.19 Relative performance for typical single-reheat units with various combinations of first-reheat intercept-valve pressure and final feedwater temperature.[27] *(Courtesy of General Electric Co.)*

C3.21[27] show the heat rate penalty which results from the use of reheat pressures other than optimum when the throttle pressure is 3500 to 4500 psig (24.2 to 31.1 MPa), respectively, and the second cold reheat pressure is fixed at 300 psia (2070 kPa).

Tables C3.10[28] and C3.10M (Metric) compare the basic cycle parameters for the 738-MW, 3500-psig (24.2-MPa) unit and the 900-MW, 4500-psig (31.1-MPa) design. The relatively higher first reheat pressure of the 4500-psig (31.1-MPa) cycle makes possible an additional attractive thermodynamic gain when an eighth feedwater heater, extracting steam from the first reheat section, is added to the cycle. The use of a heater above the reheat point in the 3500-psig (24.2-MPa) cycle will result in an improvement in the heat rate. In this case the required final feedwater temperature would set the limit on the HARP extraction pressure.

Understanding the Extraction Steam System

Regenerative feedwater heating improves the Rankine cycle efficiency. It is achieved by withdrawing a portion of steam flowing through the turbine at a number of points along the flow path (extraction, bleeding). The steam so extracted is condensed in
FIGURE C3.20   Relative performance for typical double-reheat units with various combinations of first-reheat intercept-valve pressure and final feedwater temperature.[27] *(Courtesy of General Electric Co.)*

a series of heat exchangers (feedwater heaters) through which flows the feedwater from the condenser on its return to the steam generator. Bleeding is also advantageous for the turbine in that it reduces the mass flow rate of steam in the lower-pressure stages, which is a desirable feature from the turbine designer's point of view. In most cases it reduces the exhaust losses which occur between the last turbine stage and the condenser.

One of the most frequent cycle changes which is considered in designing a power plant is whether to increase the number of feedwater heating extraction points. This problem does not have a simple answer applicable in every case. Theoretical prediction of a change in station heat rate, as published by many authors, is based
FIGURE C3.21 Relative performance for typical double-reheat units with various combinations of first-reheat intercept-valve pressure and final feedwater temperature.[27] *(Courtesy of General Electric Co.)*

TABLE C3.10 Basic Cycle Parameters[28]

	738 MW, 3500 psig	900 MW, 4500 psig
Maximum capability, MW	826	1000
Maximum throttle pressures, psia	3500	4500
First reheat intercept valve pressure, psia	980	1360
Second reheat intercept valve pressure, psia	340	390
Final feedwater temperature, °F	548	590
Number of feedwater heaters	7	8

TABLE C3.10M (Metric)   Basic Cycle Parameters[28]

	738 MW, 24.13 MPa gauge (3500 psig)	900 MW, 31.03 MPa gauge (4500 psig)
Maximum capability (MW)	826	1000
Maximum throttle pressure (MPa)	24.13	31.03
First reheat intercept valve pressure (MPa)	6.76	9.38
Second reheat intercept valve pressure (MPa)	2.34	2.69
Final feedwater temperature (°C)	287	310
Number of feedwater heaters	7	8

on the assumption that the enthalpy (or temperature) rise is divided equally among the heaters. This is difficult to achieve in practice since the actual feedwater enthalpy rises in the heaters are determined by the extraction location available in the turbine. As a result, the heat-rate gains due to additional heaters typically may be only about one half the theoretical value. Normally for optimum application, the heater above the reheat point has a feedwater temperature rise of 50 to 100°F (10 to 38°C). The number of feedwater heaters to be used is also an economic consideration which must be determined on the basis of power plant cycle optimization. Recently, seven or eight heaters have been used in both fossil-fueled and nuclear power plants.

It must be emphasized that the stage pressures at extraction points change with turbine load and are roughly proportional to the mass flow rate of steam to the following stage.

In a multistring cycle when a heater is removed from service, the extraction cross-tie arrangement will be one of the deciding factors in the turbine load limitation. Extraction cross ties are the means by which extraction pipes at the same pressure level can be connected.

EXPERIENCE FEEDBACK

Use appropriate materials and welding processes and procedures for all piping. Be aware of erosion and corrosion problems in high-moisture-content steam lines (>5 percent moisture steam extraction lines) and in drain lines (feedwater heater, moisture separator, and reheat drain lines).

Preventing Turbine Water Induction

Turbine water induction prevention criteria for hot reheat lines in fossil-fired power plants are similar to those for main steam, that is, low-point drain design per ASME TDP-1.[26] Turbine water induction prevention criteria for cold reheat lines are more of a concern due to reheater atemperator (regulating the hot reheat steam temperature) spray or feedwater heaters which extract steam from the cold reheat line. The special prevention criteria for cold reheat lines are specified in the ASME Standard No. TDP-1. For nuclear power plants with light water cooled reactors (PWR, BWR), cold reheat lines carry steam containing moisture. Therefore, the special prevention criteria specified in ASME Standard No. TDP-2[7] must be applied.

REPAIRS, REPLACEMENTS, AND MODIFICATIONS

Use of flanges in high-pressure and high-temperature steam may cause leakage problems. Defects in weld metal detected by examinations or by tests shall be eliminated and repaired when necessary or the indication reduced to an acceptable limit. Weld metal surface defects may be removed by grinding or machining and need not be repaired by welding, provided the remaining thickness of the section is not reduced below that required. The depression, after defect elimination, is blended uniformly into the surrounding surface; and the area is examined by a magnetic particle or liquid penetrant method in accordance with the code after blending. Defects detected by visual or volumetric method and located on an interior surface need only be reexamined by the method which initially detected the defect when the interior surface is inaccessible for surface examination. Excavations in weld metal, when repaired by welding, shall meet the requirements of the code. The repaired area shall be heat treated, if required.

It is important, for the convenience of the operating and maintenance personnel and to minimize the possibility of making mistakes, that piping be arranged so as to make the purpose of each line and valve as obvious as possible. Good arrangement is especially important to personnel making repairs, replacements, and modifications to piping systems and components. Valves in general, and bypass valves in particular, should be installed so that their purpose is evident at a glance. It is desirable that bypass valves be grouped together where all can be seen at once rather than placed in scattered locations close to separate pieces of equipment. The possibility of an error in operation or maintenance procedures can be further reduced by stenciling the purpose of each line on the pipe close to its valve. A simple illustration of this point is shown in Fig. C3.22, a photograph of the piping for a small deaerator.

A good piping arrangement should utilize the foregoing criteria. It must also
FIGURE C3.22   How to make the purpose of valves obvious.

be coordinated with the plant structure; heating, ventilating, and air-conditioning (HVAC) systems; electrical layout; equipment selection; and other local features that impact access, visibility, and related factors. The concepts in Chap. B1 and B3, the flow characteristics in Chap. B8, and the computer methods in App. E9 of this handbook provide guidance for the design phase of steam piping systems. Operational and life-extension phases must also be considered in steam systems.

CHAPTER C4
BUILDING SERVICES PIPING

Mohammed N. Vohra, P.E.
Senior Mechanical Engineer
Delon Hampton & Associates
Washington, D.C.

Paul A. Bourquin, P.E.
Consultant
Pleasantville, New York

This chapter discusses the building services piping for heating, cooling, and compressed air installed in industrial, institutional, commercial, and public buildings and multiunit residences. Generally building-services piping operates at relatively low temperatures and pressures. ASME Pressure Piping Code, Sec. B31.9, Building Services Piping, was developed to employ a simplified approach. ASME B31.9 covers the piping which does not require the ranges of sizes, pressures, and temperatures covered in ASME Pressure Piping Code, Sec. B31.1, Power Piping.

CONSTRUCTION CODES

Every plot of land is under the authority of a jurisdiction. It is necessary to obtain a building permit from the authorities having jurisdiction over the property on which the building is to be placed. To obtain a permit the plans must show that the building is to be built in conformance with the building code which has been adopted by the local authority. The local authority has its own construction codes or has adopted one of the several national codes.

Building codes are omnibus-type documents which treat all aspects of construction and specify safety requirements as well as referencing safety codes written by other code-writing organizations. Building codes, safety codes, and standards are updated periodically by the issuing organizations, and the latest revision should be used.

A listing of code-writing bodies and the specific sections of the codes which control piping follows:

Building Codes

International Mechanical Code—A comprehensive International Mechanical Code was prepared in 1995 by a development committee appointed by and consisting of representatives of Building Officials and Code Administrators International

(BOCA), International Conference of Building Officials (ICBO), and Southern Building Code Congress International (SBCCI). The International Mechanical Code is supported and maintained jointly by BOCA, ICBO, and SBCCI for use with each organization's family of codes.

Requirements for piping were specified in the mechanical sections of the building codes and in the referenced safety sections. The 1995 edition of International Mechanical Code supersedes the earlier editions of the individual mechanical codes published by each code writing body, i.e., National Mechanical Code, Uniform Mechanical Code, and Standard Mechanical Code. When referenced, the applicable section of the ASME B31 Pressure Piping Code should be used.

Safety Codes

Safety codes give rules for the construction of piping systems. These codes are often listed as reference documents in building codes. They have also been adopted as law by some states. Applicable codes are listed in Table C4.1

Component Standards

Component standards list dimensions, chemical composition, and tensile strength of materials. They sometimes contain pressure-temperature ratings. These standards

are referenced in both the building codes and the safety codes. Component standards used for building piping are listed in Table C4.2.

Responsibility

The ultimate responsibility for the proper design and construction of a building and its various systems remains with the owner. The owner can use professionals and experts to do the actual work and perform the inspections, but in the event of a failure, the owner is the first person who will be sought out for satisfaction. Based on the requirements of the local law, however, the division of responsibility may differ from one jurisdiction to another.

BASIC SYSTEMS

Each piping system in a building is used to convey a fluid to heat, cool, or perform some other service. Energy must be used to move the fluid: For a liquid, the energy is provided by a pump; for steam systems, a boiler; and for compressed air, a compressor. Systems fall into two broad categories:

1. Recirculating
2. Distributing

Steam

Steam systems are usually of a recirculating type to return the condensate to the boiler. If the condensate is not recoverable or may be contaminated, it is wasted and the system becomes, in effect, distributive. The return of a steam-recirculating system is in the form of liquid condensate which is recovered through steam traps which pass the condensed steam in the form of a liquid but do not pass steam. Steam piping should be pitched downward in the direction of steam flow. Steam takeoffs should always be from the top of the main. As condensation is constantly occurring due to heat loss through the pipe walls, a trap must be installed at any rise in pipe elevation, at the end of horizontal mains, and at intermediate points of long runs. Traps are also used at the discharge of heating devices such as radiators, unit heaters, and steam coils.

The condensate system should be pitched downward in the direction of flow to the boiler or recovery tank. If it is not feasible to have continuous pitch to the boiler, a condensate pump can be used and the pump discharge line can change elevation as needed.

Some small low-pressure systems do not use traps; the condensate returns by gravity to the boiler through the supply or return pipes. All piping must pitch downward toward the boiler. Supply pipe-steam velocities should be kept low to prevent slugs of condensate from being carried along with the steam and producing loud knocks at changes in direction. Noise is apt to occur during warm-up when cold pipes result in heavy condensation.

* This list is limited to some of the basic piping standards. There are more than 200 ASTM standards relating to plastic pipe.

Condenser Water

A typical condenser-water system recirculates the water from the refrigeration machine condenser, through the pump, up to the sprays on the top of the cooling tower, and from the basin of the tower back to the condenser. Since this is an open system, expansion of the water is not a factor; the water level in the basin compensates.

Because it is sprayed through the air, the water contains oxygen and other contaminants and becomes extremely corrosive. For many years chromates were used to inhibit steel-pipe corrosion with success. Recent environmental rules have prohibited chromate water treatment, and new methods which require closer control are being used. It is important to clean condenser-water systems carefully and monitor treatment closely to prevent the destruction of the piping system.

Chilled Water

Chilled water systems are closed recirculating systems and therefore require expansion tanks. An open expansion tank can be used at the highest point of the system, with makeup water provided through a tank level control device. Expansion can also be provided for by use of a closed hydropneumatic tank at any point in the system. For this type of tank the water level is maintained by a pressure pump controlled by a tank-level sensor. As sufficient air pressure must be maintained above the water in the tank to support the water to the highest point of the system, it is sometimes necessary to provide a method for increasing the air pressure in the tank. The tank must be constructed for the proper pressure, and a relief valve

must be provided. The corrosion problem is not as severe as in condenser-water systems, but water treatment should be used.

Hot Water

A high-temperature hot-water system is a closed recirculating system that returns the hot water to the boiler. High-temperature hot water is relatively high-pressure water distributed to the point of usage by means of pumps. High-temperature hot water can be directly piped to heating coils or to heat exchanger where it can be converted to a lower pressure system, steam, or low-temperature hot water. Generally the circulation is limited to mechanical rooms for safety concerns.

Low-temperature hot water is a relatively low-pressure recirculating system and requires an expansion tank when a heat exchanger is utilized for conversion. Air vents and air separators are required to remove trapped air which affects the flows. Because it is a secondary recirculating system, water treatment is required. Normally an expansion tank is a closed hydro-pneumatic tank equipped with an air diaphragm which is sized to meet the expansion of the fluid in the system.

Compressed Air

A compressed-air system is an example of a distributive system. The air is piped to its point of use for a control or tool system, at which point energy is recovered and reduced to atmospheric pressure and released.

PIPE DESIGN

Piping systems are designed to withstand the combined effects of the internal pressure and temperature of the contained fluid and other external stress-imposing forces such as expansion or contraction, support spans, earthquake, and wind.

The internal pressure produces two types of stresses in the pipe:

1. *Hoop stress,* also called the tangential stress, is the result of the radial pressure in the pipe. This force tends to split the pipe open along a seam.
2. *Longitudinal stress* is caused by the force of the pressure on the end of the pipe. This force is exerted equally on a closed end such as a cap or on an open component such as an elbow. It acts along the axis of the pipe and tends to pull the pipe apart around its circumference or at a joint. Other longitudinal stresses are caused by the pipe acting as a beam between supports and by expansion or contraction where the pipe ends are fixed by anchors.

Pressure

The internal pressure of steam systems is the gauge pressure of the steam as determined by the boiler control or the setting of a pressure-reducing valve. For compressed air or other gasses, the gauge pressure is determined by the compressor control or the setting of a regulator. This pressure can be considered constant throughout the system.

For liquid piping systems the pressure at any point is determined by adding the pressure produced by the circulating pump to the static pressure. The static pressure is calculated in a state of no flow (pump off) and is the result of the weight of the liquid in the pipe from the highest point of the system to the lowest. This pressure varies with the elevation of each point in the piping.

The pressure in liquid-piping systems is also referred to as *head*. This is the height of a column of the liquid in the pipe which would be supported by the pressure.

The weight of one cubic foot (0.028 cubic meter) of water at Standard Temperature and Pressure (STP) is 62.5 pounds (28.3 kg.). The footprint of a cubic foot is 144 square inches. The weight per square inch of a column of water one foot high is:

$$62.5/144 = 0.43 \text{ psi (3 kPa) or}$$
$$1 \text{ psi (6.9 kPa)} = 2.3 \text{ ft (0.7 m) of water}$$

For circulating liquid piping systems, the datum pressure is at the expansion tank. With an open tank the pressure at the surface is atmospheric (0 psig). A hydropneumatic tank has a regulator or relief valve which determines the pressure on the surface of the water in the tank. The pressure at other points in the system is found by adding the pressure produced by the circulating pump to the static pressure of the system. For a flowing closed-loop system the pump pressure is highest at the pump discharge and will decrease, due to friction, as the fluid flows through the pipe and other elements of the system back to the pump suction. For a system which may have no flow with the pump running, the pump shutoff pressure may be imposed on the system, depending on the location of the expansion tank. See Fig. C4.1 for examples.

In Fig. C4.1*b* a 30-story building with two subgrade levels could have a water piping–elevation difference of 400 ft (122 m) from the open expansion-tank water surface in the penthouse down to the pump in the basement. This is called a static head of 400 ft (122 m) the design static pressure would be calculated as follows:

$$400 \text{ ft} \times 0.43 \text{ psi/ft} = 172 \text{ psi (1186 kPa)}$$

Horizontal offsets in the piping system do not affect the static pressure.

The total pump head is 70 ft, which is required to overcome the resistance of the system. The pump-discharge pressure in this example is 48 ft, or 21 psi, which when added to the static pressure would provide the system design pressure:

$$\text{Design pressure} = 172 \text{ psi} + 21 \text{ psi} = 193 \text{ psi (1331 kPa)}$$

All pipe, fittings, valves, pumps, and heat exchangers on the pump-discharge part of the system must be designed to withstand this pressure at the lower elevation. If it is possible to block the flow in the system, a study should be made to see if the pump shutoff pressure may cause a higher design pressure. On the suction side of the pump, the design pressure will be 172 psi (118 kPa), which will be the pressure when the pump is not operating. It is advantageous to locate the heat exchangers and associated valves in the lower pressure portion of the piping system. At the higher elevations it is economical to use valves and fittings of a lower pressure class rating.

Temperature

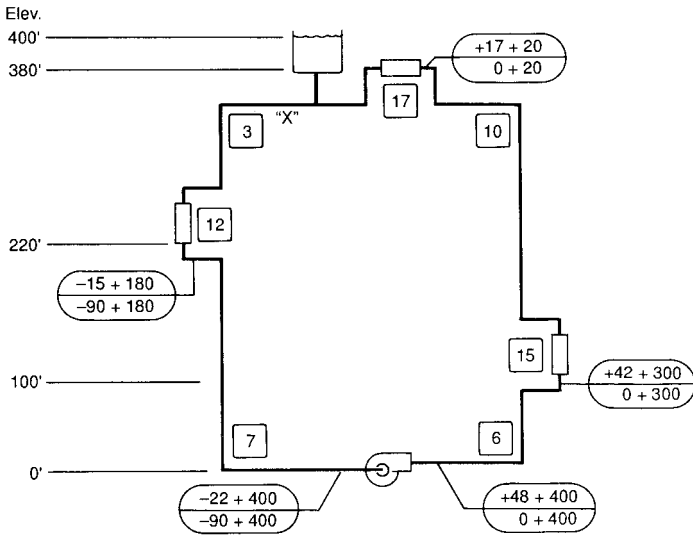
The pipe-material temperature is considered to be the same as the temperature of the fluid in the pipe. For saturated steam systems it is the saturation temperature corresponding to the gauge pressure. The temperature is important since the


FIGURE C4.1   (*a*) Horizontal piping system; (*b*) vertical piping system.

strength of materials used in the systems decreases as the temperature rises. For ferrous materials in building systems fluid temperatures are not usually high enough to be a factor. However, copper and aluminum and the joints in these materials can be affected by the temperatures encountered. Thermoplastics, as a group, lose strength rapidly as the temperatures rise above 70°F (21°C). At 100°F (38°C) they have lost approximately 25 percent of their strength and at 140°F (60°C) less than 50 percent remains.

Allowable Stress

Allowable stresses for pipe materials are tabulated in the safety codes listed in Table C4.1. As this chapter concerns piping in buildings, App. A of ASME B31.9, Building Services Piping, will be used for allowable stress values.

The published allowable stresses are determined for various materials by using the lowest of the following criteria for each material:

1. Cast iron or ductile iron
   a. One-tenth of the specified minimum yield strength at room temperature
   b. One-tenth of the tensile strength at the listed temperature
2. Malleable iron
   a. One-fifth of the specified minimum tensile strength at room temperature
   b. One-fifth of the tensile strength at the listed temperature
3. Other metals
   a. One-fourth of the specified minimum tensile strength at room temperature
   b. One-fourth of the tensile strength at the listed temperature
   c. Two-thirds of the specified minimum yield strength at room temperature
   d. Two-thirds of the yield strength at the listed temperature
4. Thermoplastics
   a. One-half of the hydrostatic design basis at design temperature as determined by the methods in ASTM D2837
5. Reinforced thermosetting resins
   a. One-half of the hydrostatic design basis at design temperature as determined by the methods in ASTM D2992

The tensile and yield strengths are found in the standards listed in Table C4.2 for each material specification. The shear and bearing stress values of pipe materials can be determined by applying multipliers:

$$\text{Shear stress} = 0.8 \times \text{basic allowable stress}$$

$$\text{Bearing stress} = 1.6 \times \text{basic allowable stress}$$

When pipe is produced by a method of manufacture which results in a welded longitudinal seam, the basic allowable stress for the pipe is modified by a factor E, called the joint efficiency factor. Table C4.3 lists some piping materials used for building piping and the allowable stresses and E factors for each material. The listed values are SE, which is the product of the allowable stress S and the longitudinal joint efficiency factor E.

Pipe Wall Thickness

The dimensions of steel pipe are governed by ASME B36.10M. This standard lists nominal pipe sizes (NPS) from NPS 1/8 to NPS 80 (DN 6 to DN 2000), with a range of wall thicknesses for each size. There are 23 different standardized wall thicknesses listed for NPS 8 (DN 200) pipe. Not all of the diameters and thicknesses are manufactured by the mills on a regular basis. Before making a selection check with a pipe supply warehouse for availability. Mills will make large quantities on order.

Pipe sizes up to and including NPS 12 (DN 300) have a standardized outside diameter which is greater than the nominal size. For sizes NPS 14 (DN 350) and larger the outside diameter is equal to the nominal size.

Two different systems for describing commonly used pipe-wall thicknesses have developed. The first, which has been used commercially for many years, uses these designations:

STD   Standard

XS   Extra strong, also called extra heavy

XXS   Double extra strong, also called double extra heavy

The second system developed from an attempt to establish a set of schedule numbers. Each schedule was to designate a wall thickness for each pipe size so the pressure-carrying capacity would be the same regardless of size. Some schedules in use are

Sch 40   Schedule 40

Sch 80   Schedule 80

Sch 160   Schedule 160

Standard and Sch 40 are the same thickness through NPS 10 (DN 250). Standard wall thickness is ⅜ (9.5 mm) in for all larger sizes, whereas Sch 40 becomes increasingly thicker. Extra strong and Sch 80 are the same thickness for all sizes through NPS 8 (DN 200). For all larger sizes extra strong pipe remains at ½-in (12.7 mm) wall thickness whereas Sch 80 becomes increasingly thicker.

Even though pipe-stress calculations are seldom required for building piping, a brief review of the basics is given so that the principles can be understood. To find the required pipe-wall thickness to contain the fluid at the design pressure use the following formula:

$$t_m = \frac{PD}{2SE} + A \qquad (C4.1)$$

Conversely, to find the pressure a pipe of known wall thickness will withstand the formula is

$$P = \frac{2SE(t_m - A)}{D} \qquad (C4.2)$$

where t_{in} = minimum required wall thickness (in)
P = internal design pressure (psig)
D = outside pipe diameter (in)
S = basic allowable stress (psi)

E = longitudinal joint efficiency factor
A = allowance for corrosion, mill tolerance, joint preparation, mechanical strength, and so on

For example, this is the procedure to find the proper wall for a NPS 2 (DN 50) 125-psig (860 kg/mm^2) steam line with threaded fittings using A53 Grade B ERW pipe:

$$t_m = \frac{PD}{2SE} + A$$

$$P = 125 \text{ psig } (878 \text{ kg/mm}^2)$$

$$D = 2.375 \text{ in } (60 \text{ mm})$$

$$SE = 12{,}800 \text{ psi } (90{,}000 \text{ kg/mm}^2)$$

$$= 0.012 \text{ in} + A \text{ } (0.3 \text{ mm} + A)$$

The factor A requires some consideration. The corrosion allowance depends on the expected service and the maintenance of a chemical water-treatment system. For closed systems a value of 0.025 in (0.6 mm) may be sufficient. For open systems a value of 0.065 in (1.6 mm) or higher may be needed. These values can be varied for the expected service conditions in the system being designed. The allowable mill minus tolerance for A53 pipe is given in the ASTM specification as 12.5 percent of the nominal wall thickness. If the pipe is to be threaded or grooved, the depth of the groove or the depth of the thread, as listed in Table C4.4, plus a tolerance of 0.015 in (0.4 mm) should be allowed. For threaded NPS 2 (DN 50) standard weight pipe which has a nominal wall thickness of 0.154 in (4 mm) the factor A will equal the sum of:

Corrosion allowance =	0.025
Mill tolerance = 0.125 × 0.154 =	0.019
Thread depth (from Table C4.4) = 0.070 + 0.015	= 0.085
Total A =	0.129

Note: 1 in = 25.4 mm

The minimum required wall thickness plus allowance is

$$t_m = 0.012 \text{ in } + 0.129 \text{ in } = 0.141 \text{ in } (3.6 \text{ mm})$$

Select the next larger commercially available wall thickness for use. In this case standard weight pipe with a wall thickness of 0.154 in (4 mm) is suitable for the service.

Mechanical strength should be considered as the overriding wall thickness needed to withstand the shear loads at hangers, the rough handling during installation, and unanticipated use of the pipe such as for scaffolding or hoisting after installation.

If in the above example the pipe was used for 5-psig (34 kPa) steam, the wall thickness needed to withstand the pressure would be 0.0005 in. The allowances do not change so the minimum pipe wall thickness required would be 0.0005 in (0.013 mm) + 0.129 in, which is 0.1295 in (3.3 mm). This points out that the prime consider-

TABLE C4.4 Thread and Groove Depths (tolerances not included)

Nominal pipe size (DN)	Thread depth (in)*	Groove depth (in)†
½ (15)	0.057	—

20 (500)		0.109
24 (600)		0.172

* Dimension h, the height of thread, from ASME B1.20.1, Pipe Threads—General Purpose. Pipe more than 6 in is rarely threaded.
† Reference groove depth as listed by Victaulic Co.
General Note: As the plus tolerance on the pipe's outside diameter increases, the fixed thread or groove diameter cuts away more of the pipe wall thickness. Victaulic limits the plus tolerance to ¹⁄₃₂ in. This is less than that allowed by ASTM A53 or A106. If the pipe is ¹⁄₃₂ in oversize, the groove or thread depth is increased by about 30 percent. If large pipe is to be used for grooving, the plus tolerance should be stated on the pipe purchase order.
Note: 1 in = 25.4 mm.
For DN equivalents refer to Chap. A1 or App. E2.

ation for low-pressure piping systems is the mechanical strength rather than pressure containment.

Elbows, Bends, and Miters

A change in pipe direction for building piping is done by using an elbow fitting. Bends and miters may also be used but are generally not economical when labor costs are high.

Additional wall thickness must be provided when a bend is made, since the heel of the bend will stretch and thin. Table C4.5 gives the added thickness needed to provide the required minimum thickness in a 90° finished bend. The flattening of pipe during a bend should not result in a reduction of the original diameter by more than 8 percent.

For miter joints, an angular offset of 3° or less is considered to be the same as a girth weld and does not require an increase in the calculated pipe-wall thickness. The angular offset is the change in direction of the axis of the pipe. A 3° offset will result in a miter angle of 1½° to be cut on the end of each of the pipe segments to be joined. Miters can be used for offsets from 3° to 45° at pressures of 50 psig

TABLE C4.5 Pipe Thickness for Bends

Radius of bend pipe diameters*	Thickness increase†
6 or greater	$1.06t_m$
5	$1.08t_m$
4	$1.14t_m$
3	$1.24t_m$

* The pipe diameter is the nominal diameter.
† t_m is the minimum required wall thickness.

(345 kPa) or less. For miters at higher pressures the formulas in ASME B31.9 or B31.3 should be used.

Pipe Branch Design

Branch connections for pipe sizes under NPS 3 (DN 80) are usually made with threaded or grooved tees. For larger pipe sizes with welded joints, branches are made by using a welding tee, an integrally reinforced outlet fitting, or by welding the branch pipe directly to the main using a full-penetration weld.

When welding the branch directly to the main, the opening in the main for the branch pipe weakens the main, and the need for added reinforcement to replace the removed material must be evaluated. Reinforcement is *not* needed when

1. The branch connection is made using a fitting made to an ASME B16.9-listed standard
2. The branch connection is made using a threaded or socket-weld coupling not exceeding
   a. NPS 2 (DN 50) or
   b. One-fourth the nominal diameter of the main

   The coupling wall thickness should be not less than that of the branch pipe and welded to the main with a full penetration weld.
3. An integrally reinforced outlet fitting is used

Table C4.6 lists the maximum internal pressure permitted without reinforcement for various combinations of branch and main sizes for ASTM A53 Grade B and A106 Grade B pipe at 90° and 45° branch angles. For pressures higher than those listed, use a fitting or use the rules in ASME B31.1 for determining the required reinforcement and the method of application.

Closures and Blanks

Closures are made at the end of pipe runs using standard fittings such as caps, plugs, or blind flanges. A flat plate can also be used as a closure when it is welded to the pipe with a full penetration weld.

Notes: Pressures change directly with the ratio of SE to S.
1. For A53 Type F Butt Weld Pipe use a multiplier of 0.75.
2. If the branch opening in the main cuts the stem of pipe with a longitudinal weld, multiply table values by
    Electric resistance weld pipe 0.85
    Type F butt weld pipe   0.45
3. Based on the rules in B31.1.
4. A 12½ percent mill tolerance and a ¹⁄₃₂-in corrosion allowance have been used to calculate the pipe wall thickness for this table.
5. 1 in. = 25.4 mm.
6. For DN equivalents refer to Chap. A1 or App. E2.

The minimum thickness of the closure plate, t_c, can be calculated by

$$t_c = d \sqrt{CP/S} + A \qquad \text{(C4.3)}$$

where d = inside pipe diameter (in)
    $C = 0.5t_m/T$, but not less than 0.3
    t_m = minimum required pipe-wall thickness (in)
    T = nominal wall thickness of pipe (in)
    P = internal design pressure (psi)
    S = maximum allowable stress of plate material (psi)

A blank can be installed between two flanges to close off a portion of a system. The minimum thickness of the blank, t_b, can be calculated by

$$t_b = d_g \sqrt{3P/16S} + A \tag{C4.4}$$

where d_g = inside diameter of the gasket (in)

When the blank is to be left in place during operation, use the same nomenclature as above. If the blank is to be used only during hydrostatic testing, P is the test pressure and S is 0.95 times the specified minimum yield strength of the blank material.

PIPE MATERIALS

Pipe, fittings, and valves suitable for building service piping systems are available in many different materials. A brief discussion of the advantages and disadvantages of commonly used materials follows.

Steel

Steel (ASTM A53, A106) is the most widely used material for pipe. Its advantages are strength, availability, and economy. Because of its wide use there is a large pool of skilled labor knowledgeable in its installation. The disadvantages of steel pipe are its weight and low resistance to corrosion.

Copper

Copper tube (ASTM B88) is widely used as a material for sizes up to 3 or 4 in. It is available up to 8 in and on order up to 12 in, but it is not usually economical in the larger sizes. ASTM B88 gives dimensions for copper tube up to NPS 12 (DN 300) but it is not commonly made. Refer to App. E3M.

The nominal sizes of copper tubing approximate the inside diameter. The outside diameter is always ⅛ in (3 mm) larger than the nominal size. Copper tube for refrigerant service (ACR tube) is referred to by its actual outside diameter.

Copper tube is furnished in two tempers—drawn and annealed. The pressure rating of annealed tube is about 60 percent of that of drawn tube. When joints are made by brazing, the tube in the vicinity of the joint becomes annealed and the annealed pressure rating should be used. Drawn tubing is used for most building applications. Drawn tubing has been work hardened and is furnished in straight lengths. In the annealed form the tube is soft and very easily bent. It is furnished in coils or straight lengths.

Copper pressure tube is furnished in three standard thicknesses which vary with the size. The heaviest is Type K, followed by Type L and Type M. All three are suitable, but Type M is thin walled and does not have mechanical strength and is therefore easily damaged.

The advantages of copper are its resistance to corrosion and the fact that it is light weight. It is not as strong as steel and not available in sizes over 12 in. Copper can readily be bent using bending tools which keep the tube from flattening. The

disadvantages of copper as a material are its low strength compared to steel and its high cost. The high cost is offset in the smaller sizes by the ease of installation.

Red Brass Pipe

Red brass pipe (ASTM B43) is made up to NPS 12 (DN 300) for standard weight and NPS 10 (DN 250) for extra strong weight. Copper tube has largely replaced brass pipe for reasons of economy. It is made to steel pipe dimensions and is sometimes used where the added mechanical strength is needed.

Thermoplastics

Thermoplastics, which are discussed in detail in Part D of this handbook, are widely used for liquids with temperatures up to 100°F (38°C) for PVC and 180°F (82°C) for CPVC. These plastics have exceptional resistance to corrosion, are light weight, easy to install, and readily available and economical. The disadvantages of thermoplastics are lower strength, which necessitates short hanger spans, high coefficients of expansion, which must be compensated for when using long straight runs of pipe, and the emission of toxic fumes under fire conditions. Fire codes in some locations do not permit the use of some plastic materials.

PVC pipe can be used as underground pressure pipe as well as for aboveground service.

Thermosetting Resins

Thermosetting resins are used for reinforced thermosetting resin pipe (RTPP), also called fiberglass reinforced plastic (FRP) pipe. This pipe is made in larger sizes and can be used at higher pressures and temperatures than thermoplastics. It is suitable for aboveground or underground service. Refer to Part D, Chap. D2 of this handbook for more information. See manufacturers' data for specific ratings.

Ductile Iron

Ductile iron has replaced cast iron as water main pipe and is used for corrosion-resistant buried pipe. It is stronger and less brittle than cast iron. Ductile-iron pipe is made in standard thickness classes, the use of which is determined by the depth of bury and laying condition. This pipe is made in standard sizes from NPS 3 to NPS 54 (75 mm to 1350 mm).

Stainless Steel and Aluminum

Stainless steel and aluminum are expensive and therefore used only when corrosion resistance and strength are needed. Schedule 5S and Schedule 10S light-wall stainless pipe are commonly used to reduce cost.

Discontinued Pipe

Discontinued pipe materials, which are no longer made, are A72 wrought iron pipe, low-alloy (Yoloy) pipe, and ASTM A120 steel pipe.

PIPE FITTINGS AND JOINTS

Pipe joints fall into two basic categories—restrained and unrestrained. Restrained joints have inherent mechanical properties that prevent the joint from separating axially as well as containing the fluid. Unrestrained joints rely on packing to contain the fluid and the friction of the packing to keep the joints from separating. Systems with unrestrained joints must be provided with external restraint if they are to withstand pressure.

Bell and spigot piping is unrestrained. Mechanical joint and sleevetype couplings, which rely on a bolted gland retainer, are also unrestrained.

Threaded, flanged, and grooved joints are restrained. Welded, soldered, brazed, flared, and compression joints are considered to be restrained but are dependent on the skill of the assembler.

Some of the fittings discussed here are also made for higher pressures and temperatures than those mentioned.

Steel Pipe

Steel pipe is joined by threading, welding, or grooving. Threaded fittings are made of cast iron, malleable iron, ductile iron, and forged steel for joining pipe up to NPS 8 (DN 200). It is an industry standard, however, to change to welding or grooving at sizes above NPS 2 (DN 50). Threaded joints are made using ASME B1.20.1 standard taper pipe threads. Pipe lighter than standard weight must not be threaded.

Cast iron threaded fittings (ASME B16.4) are made in Class 125 (standard) and Class 250 (extra heavy) and are used in most threaded applications. Cast iron is brittle, so if ductility or higher strength is required malleable- or ductile-iron fittings should be used.

Malleable-iron threaded fittings (ASME B16.3) are made in Classes 150 and 300 and are stronger and less brittle than cast iron. Care must be taken when threading steel pipe into Class 150 malleable-iron fittings. The joint can be overtightened since the malleable fitting will stretch. Two threads should be exposed on the pipe when the joint is properly made up.

Ductile-iron threaded fittings are made in Class 300 and fall between the Class 150 and 300 malleable-iron fittings in strength. There is no listed ASTM standard for ductile-iron threaded fittings.

Forged-steel threaded fittings (ASME B16.11) are made in smaller sizes and have high pressure-temperature ratings. They are used primarily for high-pressure steam.

Welding is normally used to join steel pipe from NPS 2 ½ (DN 65) and up. Welding fittings (ASME B16.9) are made to match steel-pipe diameters and wall thicknesses. They are furnished with a standard bevel end for butt welding to the pipe. Weld fittings have the same pressure-temperature ratings as the equivalent thickness scamless pipe.

For smaller sizes, forged steel socket-weld fittings (ASME B16.11) can be used for high-pressure service.

Properly made welded joints are as strong as the pipe, do not deteriorate, and have a smooth inside contour to minimize friction losses.

Flanges are used in large piping to connect to valves and equipment and to provide a means of disassembly in welded piping systems. Flanges are made of cast iron, ductile iron, bronze, and steel.

Cast-iron threaded flanges and flanged fittings (ASME B16.1) are available in Classes 125 and 250. Ductile-iron threaded flanges and flanged fittings (ASME B16.42) are made in Classes 150 and 300. Threaded flanges are used for mounting equipment and valves in larger sized threaded pipe systems.

Class 125 cast-iron flanges have a flat face and are often mated to Class 150 steel flanges which have a raised face. Great care must be taken in tightening the bolts to avoid cracking the cast-iron flange. The steel flanges can be ordered with the raised face removed by machining.

Steel flanges (ASME B16.5) are made in Classes 150 and 300 for the services discussed in this chapter. They are available for higher pressures up to Class 2500. Steel flanges are generally used in welded piping systems. These flanges are made in weld neck, slip-on, and socket weld configurations. Classes 150 and 300 have a raised face.

Gasket material (ASME B16.21) should be suitable for the fluid and pressure to be contained. Full-face gaskets are used for flat-faced flanged joints and ring gaskets are used in raised-face joints. The flange bolts should be suitable for the pressure and flange facings.

Grooved pipe–joining systems are made by several manufacturers, but as yet there is no ASME standard for dimensions or pressure ratings. All the leading manufacturers use the same ''standard'' cut-groove and roll-groove dimensions. The joint consists of a circumferential groove cut into the outside of each pipe, close to the end to be joined. A coupling with continuous internal ridges engages the grooves in the pipe, and a gasket inside the coupling is expanded by the pressure in the pipe and seals against the pipe and coupling.

Grooves can be rolled into standard weight and lighter steel pipe. Cut grooves can be used on standard weight and thicker pipe. Gaskets are available for a great variety of liquids and gases.

These systems are extremely versatile and offer many advantages. They are easy to install, have inherent expansion compensation and flexibility, and are easy to disassemble. Grooved systems are not recommended for steam.

Copper Tube

Copper tube is joined by soldering or brazing using solder joint fittings (ASME B16.18, B16.22) or using flare (ASME B16.26) or compression fittings. Solder joints are also referred to as sweat joints.

Solder (ASTM B32) is defined as a filler metal whose melting point does not exceed 800°F (427°C). Brazing filler metals (ANSI/AWS A5.8) are specified as those whose melting points are 1000°F (538°C) or higher. Soldered and brazed joints rely on capillary attraction to draw molten filler metal into the gap between the socket on the fitting end and the tube.

The strength of the joint depends upon the composition of the solder used. Brazing provides much stronger joints than soldering but anneals drawn tubing in the vicinity of the joint. It is against the law to use solders containing lead for

TABLE C4.7 Pressure Ratings of Copper Tube Joints*

Solder or brazing alloy used in joints	Service temperature (°F max.)	Tube size, Types *K*, *L*, and *M* (in)					Steam

* Ratings for solder joints are from ASME B16.22 and B16.18. Ratings for brazed joints and steam are from *The Copper Tube Handbook,* published by the Copper Development Association, Inc.
† B31.9 prohibits compressed air or other gases above 20 psig in these sizes.
‡ It is prohibited by law to use lead solder for potable water.
§ The pressure rating of the tube determines the strength of this joint.
Note: 1.8 °C = °F − 32.

drinking water–piping systems, but they can be used for heating, cooling, and other building-service applications. Table C4.7 gives working pressures for copper-tube joints made by soldering and brazing.

Flared and compression-type fittings are made by many manufacturers for copper, steel, stainless steel, and aluminum tubing. Fittings are available for sizes NPS 2 (DN 50) and under but are used primarily in sizes NPS 1 (DN 25) and under. These joints can be taken apart and reassembled with ease. The manufacturers' catalogs give pressure ratings which can be as strong as the tube being joined.

Grooved-joint couplings and fittings are made to match copper-tube sizes. Since tube walls are thin, roll grooving is used.

Bronze pipe flanges and flanged fittings (ASME B16.24) are made in Classes 150 and 300 and can be used to join copper tube to flanged valves or equipment.

Red Brass Pipe

Red brass pipe is joined in the smaller sizes using cast-bronze threaded fittings (ASME B16.15) which are made in Classes 125 and 250. ASME B16.24 flanges as mentioned above can be used for sizes above NPS 2 (DN 50).

Plastics

Plastic piping is the subject of Part D of this handbook. To aid those reading this chapter, a brief summary of joining methods and fittings is given here.

Solvent cementing is the most common method used for joining PVC (ASTM D2564, D2855), CPVC (F493) pipe, and ABS (D2235). Socket-type fittings are available in Sch 40 (PVC-ASTM D2466, CPVC-ASTM F438) and Sch 80 (PVC-ASTM D2467, CPVC-F439) for pressure systems to at least NPS 8 (DN 200). Check on availability before deciding to use larger sizes. Solvent cement joints are best made when the ambient temperature is between 40 and 100°F (4°C and 38°C).

Threaded fittings up to NPS 4 (DN 100) are available for PVC (ASTM D2464) and CPVC (ASTM F437) piping systems. Only Sch 80 pipe should be threaded, and its pressure rating should be reduced by 50 percent. This type of joint can be taken apart and reassembled.

Flanges are available with solvent cement sockets up to NPS 8 (DN 200) and are made to Class 125 dimensions. Threaded flanges are made up to NPS 4 (DN 100). Flanges can be installed in cemented systems for ease in disassembly. An ASTM standard for thermoplastic flanges has yet to be developed.

Heat joining methods are also available for certain polyolefin joints (ASTM D2657), particularly for polypropylene. Pipe and fittings of this plastic are used for acid-resistant drainage systems. A wire filament is embedded in the socket of the joint then electrically heated with a special timing device to fuse the joint.

Bell and spigot PVC–pressure pipe (AWWA C900) is made for underground water mains. The bell is made to contain an elastomer gasket (ASTM F477), and the joint is assembled by pushing the spigot into the bell. RTRP can be joined using a special taper on the end of the pipe which can be cemented into a matching bell on a coupling or fitting. Refer to Part D of this handbook.

Mechanical joint fittings (AWWA C110/ANSI A21.10) of ductile or cast iron can be used with PVC or RTRP pipe made to AWWA ductile-pipe dimensions (AWWA C151/ANSI A21.51).

Ductile Iron

Ductile iron pipe is used primarily for underground systems. Fittings are rated in pressure classes (AWWA C110/ANSI A21.10).

Bell and spigot fittings are available and made of cast or ductile iron with bell ends. Pipe is made with one end belled. An elastomer gasket fits into a special groove in the bell, and the plain end of the pipe to be joined is pushed into the bell. This can be difficult with large pipe.

Mechanical joint fittings made from cast or ductile iron are available and are easier to work with in larger pipe sizes. The pipe is assembled into the bell before the gasket is in place, which reduces the friction. The gasket is then slid into the bell and a retainer ring is bolted into place to secure the gasket.

Grooved couplings are available and made to fit AWWA ductile-iron pipe diameters (AWWA C151/ANSI A21.51) from NPS 3 to NPS 36 (DN 80–DN 900). Special cut grooves are needed on the pipe. Grooved fittings are not made. Bell and spigot or mechanical joint fittings can be used.

Stainless Steel and Aluminum

Stainless steel and aluminum pipe and fittings are joined using the same methods as those for steel. The availability of fitting sizes is limited and should be investigated before using them in design.

* Pressure ratings for steel pipe are calculated using a mill tolerance of −12.5 percent of the wall thickness, the thread or groove depth, a corrosion allowance of 0.025 in for pipe to NPS 2, and 0.065 in for 2½-in and larger pipe. No pipe reinforcement value is applied for the strength of threaded fittings or grooved couplings.

† Pressure ratings are for the highest temperature and largest pipe size in each group. Higher ratings can be found for lower temperatures and smaller pipe sizes.

MATERIAL SELECTION

The selection of the material to be used for each system is based on an evaluation of the following factors:

1. Requirements and limitations of the building and piping codes
2. The fluid in the pipe
3. The pressure and temperature of the fluid in the pipe
4. The location and external environment of the pipe

5. Availability of the material

6. The expected life of the facility where the system is to be installed

7. The installed cost of the system

The first four factors relate to safety and are of primary importance. The last three are related to the economics of the project and are weighted to suit.

Steam and Condensate Systems (to 150 psig) (1035 kPa)

Steel pipe is used for steam and condensate systems. Fittings for sizes under NPS 2½ (DN 65) are threaded cast iron. Larger fittings are steel with welding ends.

* Pressure ratings for steel pipe are calculated using (a) a mill tolerance or −12.5% of the wall thickness, (b) the thread or groove depth where used, and (c) a corrosion allowance of 0.025 to NPS 2 and 0.065 for NPS 2½ and larger. No pipe-wall reinforcement value is applied for the strength of threaded fittings or grooved couplings.

† Copper tube pressures are based on the joint strength when soldered or brazed.

‡ Pressure ratings are for the largest pipe size in each group. Smaller pipe sizes have higher ratings.

Bronze valves are used for small sizes and cast or ductile iron, as required by the pressure, for valves NPS 2½ (DN 65) and over. Large gate valves in high-pressure systems should be provided with a bypass to allow warm-up of the downstream pipe before full opening. Equalizing the pressure with a bypass also allows the valve to open.

Ball valves and special steam butterfly valves may be used, but only if the valve has a gear operator so it cannot be opened rapidly. Ball valves can be used for small valves on low-pressure systems.

Copper tubing with brazed joints may be used up to 120 psig (827 kPa). The high energy content of steam makes mechanically restrained joints preferred. However, when space is limited, copper tubing with wrought brazed fittings, which is a much less bulky system than steel, can be used. Welding and brazing should be performed by qualified operators.

Steam condensate piping requires additional attention, since condensate corrodes steel pipe. To lengthen the life of small size pipe, extra heavy weight pipe is often specified. For larger pipe sizes, the increased wall thickness of standard weight pipe provides added material to prolong pipe life. For small low-pressure systems, copper tube with 95-5 solder joints may be used. Fittings and valves for condensate are the same as those used for steam.

Table C4.8 shows some of the materials which can be used for steam and condensate service. Code pressure ratings for the various components or joints are

Fitting					Valve						
		Pressure rating							Pressure rating		
Joint	ASTM standard	@ 75°F (psig)	@ 150°F (psig)	@ 220°F (psig)	Class	Material	Type	Joint	@ 75°F (psig)	@ 150°F (psig)	@ 220°F (psig)
Mech. joint	A 21.10	350	350	350	Same as listed in H and I above.						
Flange	A 21.10	250	250	—

Mech. joint	A 21.10	350	350	350	Same as listed in H and I above.						

listed. The table should not be read line by line. For example, any of the fittings and valves listed on lines D(1)–(4) may be used with any of the pipe types listed on lines D(1)–(3).

Recirculating Water Piping Systems

Closed recirculating water systems such as chilled water, hot water, and dual temperature water are used for heating and cooling. System temperatures can range from 50 to 200°F (10 to 93°C) and the pressure can be above 200 psig (1380 kPa) on the lower floors of tall buildings.

For pipe NPS 2 ½ (DN 65) and larger the preferred material is steel with welded or grooved joints. The selection of materials for water piping systems NPS 2 (DN 50) and under is usually based on economics. The fluctuating price of materials and the skills of the labor to be used for installation make a number of combinations possible. For pressures above 150 psig (1035 kPa) and temperatures above 200°F (93°C), seamless or extra strong steel pipe with the proper class of threaded fittings or grooved joints can be used. Copper tube with solder or brazed joints is also widely used. For low temperatures, plastic piping systems can be used.

Bronze gate and ball valves are used on small pipe systems, and cast-iron gate, plug, and butterfly valves are used with large pipe.

Table C4.9 lists materials for pipe, fittings, and valves and gives pressure ratings at 75, 150, and 220°F (24, 65, 104°C). The rating at 75°F (24°C) can be used down to 0°F (−17°C). Materials within any letter group can be mixed when a suitable joint can be made.

TABLE C4.10   Material Application Chart for Air, Gas, and Oil Systems*,†,‡

  * Pressure ratings for steel pipe are calculated using (a) a mill tolerance or −12.5% of the wall thickness, (b) the thread or groove depth where used, and (c) a corrosion allowance of 0.025 in to NPS 2 and 0.065 for NPS 2½ and larger. No pipe-wall reinforcement value is applied for the strength of threaded fittings or grooved couplings.
  † Copper tube pressures are based on the joint strength when soldered or brazed.
  ‡ Pressure ratings are for the largest pipe size in each group. Smaller pipe sizes have higher ratings.

Condenser Water Systems

Refrigeration condenser water is usually cooled in a cooling tower where the water temperature is reduced by evaporation to the atmosphere. Lake, river, and well water are also used for condensing refrigerant. As oxygen and atmospheric contaminants are regularly induced into the water, corrosion becomes a major problem.

When a cooling tower is used, the same water plus makeup water are recirculated and chemicals must be added to the system to protect the pipe against corrosion.

With river water or well water, corrosion-resistant materials must be used for the system or the interior of the pipe must be lined with a corrosion-resistant material. Refer to Chaps. B9, B10, B11, and B12 for lined piping systems.

Steel pipe is most often used for large condenser-water piping systems aboveground. Where chemical treatment is possible it does not have to be lined, but the use of extra heavy pipe should be considered. Where chemicals cannot be used, steel pipe can be cement lined using welded or grooved joints. Plastic lining can also be used with grooved joints (Refer to Chap. B12). Linings do not add to the strength of the pipe and may reduce the flow capacity.

Condenser-water lines are often run below ground. Ductile-iron or plastic water-main pipe can be used, since both the interior and exterior are corrosion resistant. Copper is a good alternative for both aboveground and underground condenser-

water piping. Table C4.9 lists some materials suitable for condenser water and the pressures at which they can be used.

Compressed Air

High temperatures are not usually involved, but compressed air contains stored energy, and system failure can result in explosive reactions. Welding or a restrained joint should be used for large sizes. Do not use PVC or CPVC or any material subject to brittle failure for compressed air. Other thermoplastics which are not subject to brittle failure may be used. Check with the manufacturer of the material to be sure it is recommended for compressed air service.

Steel and copper pipe with malleable iron, cast-iron, or copper fittings are suitable materials for compressed air. Ball, butterfly, or gate valves can be used. For large sizes use welded, flanged, or grooved systems. ASME B31.9, Building Services Piping, does not permit the use of copper with soldered joints for sizes above NPS 4 (DN 100) size at pressures exceeding 20 psig (138 kPa). Table C4.10 lists some suitable materials.

Fuel Gas

Pipe material for use in buildings should be standard weight, electric resistance weld, or seamless steel or copper tube Type *K* or *L*. Copper is not to be used if the gas contains more than an average of 0.3 grain of hydrogen sulfide per 100 standard cubic feet of gas. Fittings for steel pipe may be threaded malleable iron or ductile iron for sizes up to and including NPS 3 (DN 80). Some jurisdictions require cast fittings to be galvanized to seal casting-pin holes. For sizes NPS 2½ (DN 65) and over, welded joints should be used with steel fittings and flanges.

Copper tube should be joined by brazing, using a brazing alloy that does not contain phosphorus, or by the use of flared connections. Table C4.10 lists some suitable materials.

Fuel Oil

For piping to boilers operating at or under 15 psig (103 kPa) steam or 30 psig (207 kPa) water, use electric-resistance welded, seamless steel pipe, or copper tube, Type *K* or *L*. When threaded joints are used, malleable-iron, ductile-iron, or forged-steel fittings may be used. A thread-sealing compound suitable for oil should be used when making the joints. Joints in copper tube may be brazed or made by using flared or compression fittings.

Oil piping to boilers operating at steam pressures from 16 to 150 psig (110 to 1035 kPa) should be seamless steel, standard weight, when welded or extra strong if threaded. Threaded joints using ductile-iron or forged-steel fittings may be used if unavoidable. Valves should be made of ductile iron or brass.

Outside the boiler room malleable-iron threaded fittings may be used. Type *K* or *L* copper tube with brazed joints may also be used outside the boiler room. Table C4.10 lists some suitable materials.

WELDING

Welding Qualification

To comply with the B31 Pressure Piping Code sections, all welding procedures and welders must be qualified as required by Sec. IX of the ASME Boiler and Pressure Vessel Code. B31.9, Building Services Piping, also permits qualification to AWS D10.9, Qualification of Welding Procedures and Welders for Piping and Tubing.

A welding procedure specification is written to outline a method for making a weld. It lists the conditions under which the weld must be made. The procedure is qualified by making a weld following the specification. If the weld passes the prescribed tests, the procedure is qualified as being able to make a sound weld.

Welders and welding operators are tested to see that they have the necessary skills by making a weld using a qualified weld procedure specification. If the weld passes the required test, the welder can be termed qualified by his employer.

Boiler External Piping

For boilers operating at pressures higher than 15 psig (103 kPa), the ASME Boiler and Pressure Vessel Code has administrative control over the welding on boiler external piping (BEP), which is broadly defined as the piping between the boiler and (1) the first steam stop valve, (2) the second feedwater valve, and (3) the second blowdown valve. When multiple boilers are connected to a header, the BEP extends to the second steam valve.

The boiler external piping must be fabricated and installed by an organization holding an ASME certificate and must be provided with data reports, inspection, and stamping as required by the boiler code.

The ASME Pressure Piping Code B31.1, Power Piping, does not require nondestructive examination of welds unless the pressure is above 1025 psig (7067 kPa) with a temperature above 350°F (177°C) or the temperature is above 750°F (400°C) at all pressures. If radiography or other nondestructive examination is desired in excess of code requirements, it should be clearly spelled out in the contract or specification.

HANGERS AND SUPPORTS

This section gives a brief outline of the use of hangers, supports, anchors, and guides. See Part B of this handbook for a detailed discussion of hangers and hanger loads.

Hangers support the pipe from above; supports bear the load of the pipe from below; anchors restrain pipe movement; guides allow only axial movement of the pipe and direct expansion forces.

Buildings are built to provide usable floor space; therefore, piping is usually hung from the structure above. Hangers are concentrated loads; an allowance of extra distributed–dead load in the structure above mechanical rooms will not necessarily be sufficient to support the point loads of large pipelines or suspended equipment. Piping should be arranged to allow the use of major structural elements for hanging pipelines. Major loads that pipe hangers impose on a structure should be reviewed by a structural designer.

Hanger loads are calculated according to B31.9 by taking the following elements into account:

1. The dead weight of the pipe, fittings, valves, insulation, and the hanger itself.
2. The weight of liquid in the pipe.
3. Occasional loads, such as ice, wind, earthquake, a test liquid, and water hammer. Occasional loads need not be considered as acting concurrently.

The forces acting on pipe anchors are

1. The hanger loads listed above.
2. Forces caused by expansion and contraction of the pipe.
3. Expansion joint forces needed to overcome joint friction and separation. The separation force is the product of the line pressure and the largest inside cross-section area of the joint.

When supporting a riser, the entire weight of the riser pipe and the fluid or test liquid in that vertical section of the pipe must be carried by the base elbow or anchor.

Hanger design is based on using one-fifth of the minimum tensile stress of the hanger material. If the minimum tensile strength of a material is not known, a value of 9500 (65 MPa) psi may be used. During hydrostatic testing this value may be increased to 24,000 (165 MPa) psi. Allowable stress values for shear are 80 percent and for bearing are 160 percent of the values determined above.

The carrying capacity of threaded rod is based on the rod area at the root of the thread. The allowable stress is reduced by 25 percent for cut threads. See Table C4.11 for rod-carrying capacities.

TABLE C4.11   Capacities of Threaded Steel Rods

Rod diameter (in)	Root area of thread (in²)	Unknown steel rolled threads, $S = 9.5$ ksi (lb)
¼	0.027	260
⅜	0.068	650
½	0.126	1200
⅝	0.202	1900
¾	0.302	2900
⅞	0.419	4000
1	0.551	5200
1⅛	0.693	6600
1¼	0.889	8400
1⅜	1.054	10000
1½	1.294	12300

Hangers should be designed to permit vertical adjustment. When this is done with threaded elements, double nuts or other locking devices should be used to prevent vibration from working the nut loose.

Hangers are attached to the structure by welding, beam clamps, concrete inserts, and metal-deck inserts and by drilling expansion anchors directly into the concrete. Loads on inserts in, or attachments to, concrete should be limited to one-fifth of the ultimate strength of the attachment as determined by the manufacturer's tests.

1. Spans based on (1) lesser of half that permitted by allowable stress in simple beam formula or (2) deflection of 0.1 × NPS to 0.2 in max.

2. Formulas used: Simple beam span (ft) = $[\{8Z(S - SL)/W\}^{0.5}]/12$; Deflection span (ft) = $[(384\ EIG/W)^{0.25}]/12$, where E = modulus of elasticity, I = moment of inertia, G = permitted deflection, Z = section modulus, S = allowable stress, SL = longitudinal stress caused by pressure, W = weight (lb/in).

3. Hanger loads listed are the full weight of the longest span in each category.

If the compressive strength of the concrete is unknown, it can be assumed to be 2500 psi (17250 kPa) and the results of the manufacturer's test derated proportionally. Explosively actuated fasteners should not be used where a group of pins is needed to support a load.

Spring hangers should be used where expansion can cause vertical movement of a pipeline. For example, if a branch line is connected to a vertical heating-cooling riser on the 12th floor of a high-rise building, the connection point could be 1 in (25 mm) above its ambient elevation during the heating season and 1 in (25 mm) below in the summer. Using spring hangers on the branch near the riser connection will provide support under both conditions.

Hanger spacing is often determined by the building steel available for suspending the pipe. Tables C4.12, C4.13, C4.14, and C4.15 show maximum spans for steel, copper, aluminum, and plastic pipe. These tables are calculated using a simple beam formula to determine stress and deflection. The basic allowable stress of the pipe will not be exceeded at double the span shown in the tables. The usable stress for bending is that which remains after the stresses due to longitudinal pressure have been deducted from the basic allowable stress of the material. The tables also have

TABLE C4.14 Pipe Spans for Standard Weight Aluminum Pipe for Straight Runs with No Valves or Components

Nominal pipe size NPS (DN)	Pipe and insulation			Pipe, water, and insulation

    1. Spans based on (1) lesser of half that permitted by allowable stress in simple beam formula or (2) deflection of 0.1 × NPS to 0.2 in max.

    2. Formulas used: simple beam span (ft) = $[\{8Z(S - SL)/W\}^{0.5}]/12$; deflection span (ft) = $[(384\ EIG/W)^{0.25}]/12$, where E = modulus of elasticity, I = moment of inertia, G = permitted deflection, Z = section modulus, S = allowable stress, SL = longitudinal stress caused by pressure, W = weight (lb/in).

    3. Hanger loads listed are the full weight of the longest span in each category.

the deflection limited to the smaller of 0.2 in or 10 percent of the nominal pipe diameter at the listed span.

    The tables show the effect of internal pressure on pipe spans. In general the deflection is the governing factor in the smaller sizes. The weights and spans have been calculated based on mineral-fiber insulation.

EXPANSION AND FLEXIBILITY

Expansion in building-service piping must be recognized and allowed for. The temperature extremes may run from 40°F (4°C) for chilled water, which will result in the contraction of a pipe installed at 70°F (21°C), to 360°F (182°C) for 150 psig (1035 kPa) steam; which will give rise to a much greater expansion of a pipe. Part B of this handbook gives a detailed discussion on expansion and flexibility as well as tables giving coefficients of expansion and the actual expansion for various materials between given temperatures.

    Uncontrolled expansion forces can be harmful at equipment connections by imposing loads on the equipment. Manufacturers will provide the allowable forces

1. Spans based on lesser of (1) half that permitted by allowable stress in simple beam formula or (2) deflection of $0.1 \times$ NPS to 0.2 in max. For empty pipe and glass fiber insulation.

2. Formulas used: Deflection span (ft) $= [(384EIG/W)^{0.25}]/12$; simple beam span (ft) $= [\{8Z(S - SL)/W\}^{0.5}]/12$, where E = modulus of elasticity, I = moment of inertia, G = permitted deflection, Z = section modulus, S = allowable stress, SL = longitudinal stress caused by pressure, W = weight.

EX—At this pressure the hoop stress in the pipe exceeds the allowable stress for this size and larger.

and moments. When necessary these forces can be controlled by providing an anchor or restraint on the piping at or near the connection.

Long straight runs of pipe with no offsets, or very short offsets, need to be checked for total linear expansion. These are found most often as risers in vertical buildings and mains in horizontal buildings. If the amount of expansion encountered cannot be absorbed by the flexibility in the pipe configuration at take-offs from a main, or at the end of a main, an expansion joint or pipe loop must be used.

There are three categories of expansion joints: corrugated bellows, packed slip joints, and rotary or ball joints. All expansion joints must be placed between anchors to direct the forces and in some cases to keep the joint from separating due to the internal pressure.

1. Corrugated joints have no packing, which is an advantage since they do not develop leaks. The pipe leading to this type of joint must be provided with adequate guiding to keep the pipe axially aligned and direct the expansion forces into the joint. If the pipe is improperly guided the joint may squirm, which results in misalignment and possible catastrophic failure.

2. Packed slip joints have the disadvantage of packing, which must be maintained. They must also be guided, but catastrophic failure is unlikely unless an anchor fails.

3. Ball joints are used in pairs in branch pipes, or in the main after an elbow, to take up the expansion offset. These are packed swivel joints which need maintenance but will not separate.

Flexibility is inherent in a building system due to the elbows and offsets usually necessary to get from the source to the destination. An unrestrained piping system will find its own point of least stress and have the lowest end forces. If an inspection of the pipe route does not reveal any places where the expected expansion will interfere with walls, columns, ducts, or other pipes, it is advisable not to introduce anchors. Detailed flexibility analysis methods can be found in Part B of this handbook.

TESTING

Before putting a system in service it should be tested for leakage or proof tested to demonstrate its ability to withstand the design pressure. This can be done by several methods.

Hydrostatic Testing

Hydrostatic testing is the preferred method of testing, since leaks are detectable and the stored energy in the pipe is low. All joints should be exposed and uninsulated. Before initial filling, the following precautions should be observed:

1. A survey of the entire pipeline should be made to ensure that there are no open ends; all hangers, anchors, and guides are in place; and all joints are properly made.

2. All equipment that will be damaged by the test pressure should be isolated from the system.

3. Expansion joints and anchors in the pipeline should be checked for their ability to withstand the test pressure.

4. If the test pressure is to be left on the system for an extended period, a relief valve should be installed to prevent overpressurization due to expansion of the fluid caused by an increase in temperature.

5. Vents should be used to release air from high points of the system. Drains should be provided to remove the test liquid.

Test Medium. The test medium should be water unless there is a risk of freezing or water will damage the system. A glycol solution can be used if provisions are made to flush the system and properly dispose of the glycol at the end of the test. The system should be filled gradually and examined to detect leaks as the filling progresses.

Test Pressure. The test pressure required by B31.9 is 1.5 times the design pressure at all points of the system. For vertical systems the pressure at the bottom should not exceed the lower of

1. 90 percent of the minimum yield strength of the material
2. 1.7 times the SE value of brittle materials
3. The rated pressure of valves or equipment which will be subjected to the pressure

Examination. Examination of the entire system for leaks should be made after the test pressure has been on the system for at least 10 minute. If leaks are found they should be repaired and the test repeated until no leakage is detected.

Pneumatic Testing

Pneumatic testing is dangerous and should only be used within the following conditions:

1. There are no soldered joints in the system over NPS 4 (DN 100).
2. If brittle plastic, no pipe is larger than NPS 2 (DN 50).
3. Water will be detrimental to the system.
4. The test pressure does not exceed 150 psig (1035 kPa).

The test medium should be air, nitrogen, or any other innocuous gas.

Test Pressure. The test pressure for a pneumatic test is limited by B31.9 to a maximum of 1.25 times the design pressure. The pressure should be introduced gradually with the first increment not more than 10 psig (69 kPa), at which time an inspection can be made for major leaks. The pressure can then be raised in increments of 25 percent, pausing at each increment to allow system equalization.

Examination. Examination for leaks should be made after the full test pressure has been on the system for 10 minute or more. Leaks can be detected by soap bubbles, special testing fluids, ultrasonic means, or test-gauge monitoring.

Service Testing

Service testing can be used in place of the above tests for low-pressure systems that operate below 15-psig (103 kPa) steam pressure or 30-psig (207 kPa) water pressure. Proof testing is not needed, and an examination for leaks can be made when the system is placed in initial operation for the service intended.

PROBLEMS AND SOLUTIONS

Some of the problems occurring most often with piping systems are discussed below.
   The cost of the installation is too high. If this comment is heard, check the following:

1. Has seamless pipe been used when furnace butt-weld or electric resistance-weld pipe will be adequate?
2. Has Type *K* copper tubing been called for when Type *L* is adequate?
3. Have steel valves been used when ductile-iron or cast-iron valves are strong enough?
4. Has radiography of welds been called for when it is not required by the piping code?
5. Are too many anchors and expansion joints called for when the system has inherent flexibility?
6. Have factory-made tees or reinforced outlet fittings been used when welded branch connections are suitable?
7. Has the use of grooved-type joints been permitted where they are economical?
8. Has the use of plastic materials been considered?
9. Are pipe sizes too large? This requires analysis of the long-term pumping costs, since smaller pipe sizes will result in greater friction.
10. Has the hanger spacing been checked to make sure the most economical spacing has been allowed?
11. Has the system configuration been reviewed to be sure the most direct route possible has been selected?

   The system does not circulate the proper GPM. Look for the following:

1. Are all of the valves open?
2. Is the system fully vented?
3. Are all the strainers clean?
4. Is the pump providing the proper pressure differential?
5. Is there an obstruction in the piping? Check pressures along the system to find an unpredicted drop.

   The system is noisy. Look for the following causes:

1. Has the system been fully vented? Air in the system is noisy.
2. Is the pump circulating too much fluid? If the required system head has been

predicted higher than the actual one, the pump is circulating too much fluid and causing velocity noise. Throttle a pump-balancing valve to introduce more pressure drop in the system. If this solves the problem, the pump impeller should be changed for long-term economy.

The chilled water expansion tank overflows. Investigate the following:

1. The makeup level in the tank is set too high and water is added when the system is operating cold.
2. The tank does not have the capacity for the expansion volume.
3. There is a cross connection to another system.

The steam pipes make knocking noises. Investigate the following:

1. The steam pipe has not been pitched in the direction of condensate flow.
2. The distance between drip legs on long runs is too great. If the knocking only occurs on warmup, look for a slower warmup method.

The water pipes hammer or shake. Water hammer can be caused by the following:

1. The sudden opening or closing of a valve. Automatic valves can be made to operate slower to prevent water hammer. Manual valves should always be operated slowly.
2. The starting or stopping of a pump. A spring-loaded or hydraulically operated check valve should always be installed at the discharge of large pumps.
3. Air can be sucked into a piping system at a cooling-tower basin and cause violent pipe movement. Install a vortex breaker in the basin.

Is the system ready to be placed in operation?

1. The pressure test should be performed and all blanks removed.
2. The system should be flushed, and the water treatment system should be operable.
3. A visual inspection should be made to be sure all open ends have been secured, all block valves are in the proper position for operation, all safety and relief valves are installed, and if a water system, the system is full and vented.
4. A visual inspection should be made to be sure adequate pipe expansion room is available. Some approximations that can be used for visual inspection are as follows per 100 ft (30.5 m) of straight pipe per 100°F (38°C) from ambient temperature (do not use for exact calculations):

Ductile iron	Expands	1 in
Steel	Expands	1 in
Stainless steel	Do	1¼ in
Copper or brass	Do	1½ in
Aluminum	Do	2 in
RTRP	Do	2 in
PVC & CPVC	Do	5 in
Polypropylene	Do	6 in
ABS	Do	7 in
PB	Do	9½ in

5. Check that all anchors and guides are in place.

Life Expectancy. Piping in power plants, refineries, industrial plants, and so on, where the piping is a part of the process, is subjected to extreme service conditions and is therefore closely monitored. Building piping, while necessary to the operation of a building, is not subject to severe service and therefore not watched as closely. Because the pipe is built into walls and shafts, it is expensive to replace and is generally designed to last as long as the building.

The corrosion of steel pipe is the biggest concern. Closed recirculating systems such as chilled water or heating water can circulate for years with very little corrosion, since no new oxygen is introduced into the system. Cooling tower piping systems require very close monitoring, and alternative materials should be considered.

CHAPTER C5
OIL PIPELINE SYSTEMS

Charles L. Arnold
Principal Pipeline Consultant,
Albany, California

Lucy A. Gebhart
Pipeline Engineer,
Bechtel Corporation

INTRODUCTION

This chapter on oil pipeline systems has been prepared as a basic guide to the design of cross-country pipelines for liquid petroleum and related products. It focuses on the fundamentals of pipeline design, emphasizing practical guidelines for real systems. It provides a general overview of the system approach to design, which integrates the hydraulic, mechanical, and operations and maintenance aspects in the design of a system, along with project economic analysis, in determining the preferred pipeline system.

This chapter also includes discussion of design topics for related pipeline-system components such as pump station and location and sizing, material selection for pipe, metering, leak detection, and system control. Aspects of petroleum-system design related to the special characteristics of some petroleum commodities are also addressed, in particular topics related to high-vapor pressure systems, multiproduct systems, and systems requiring consideration of variable thermal properties of the fluid, i.e., hot oil systems. Finally, design considerations for seismic and underwater design of pipeline systems are outlined.

Scope

There are three basic codes developed by the American Society of Mechanical Engineers (ASME) which govern the design of piping systems in chemical, petroleum liquid, and gas usage.

Piping inside the boundaries of a chemical plant, refinery, or gas processing plant falls under the scope of ASME B31.3 and is covered separately in this handbook (see Chap. C7). Likewise, ASME B31.8, covering gas transmission and distribution piping systems, is specifically addressed in Chap. C6 of this handbook.

This chapter specifically addresses oil transportation systems as covered by the ASME B31.4 Code—*Pipeline Transportation Systems for Liquid Hydrocarbons and Other Liquids*.[1] In this chapter, references to specific sections of the ASME B31.4 Code will be cited as "Sec.   of the Code," or in some cases "the Code."

Figures C5.1a and C5.1b are schematic diagrams illustrating the scope of ASME B31.4 for liquid petroleum piping systems other than carbon dioxide and carbon dioxide respectively.

Code Compliance

The ASME Codes set forth the practices required for design and operation of safe pipeline systems. Section 400.1.1 of the Code states its scope, in part, as follows:

> This code prescribes requirements for the design, materials, construction, assembly, inspection, and testing of piping transporting liquids such as crude oil, condensate, natural gasoline, natural gas liquids, liquified petroleum gas, carbon dioxide, liquid alcohol, liquid anhydrous ammonia, and liquid petroleum products between producers' lease facilities, tank farms, natural gas processing plants, refineries, stations, ammonia plants, terminals (marine, rail, and truck), and other delivery and receiving points.

While the Code gives guidelines for pipeline system design, it is not intended to provide complete specifications for all phases of design and operation. Furthermore, there may be additional federal (or country), state, and local regulations governing pipeline design, construction, and operation.

It is the intent of this chapter to supplement the Code with discussion of the principles governing the design of a petroleum transportation system, identifying the analytical and design tools and procedures an engineer might use. This chapter in itself may not address all the design problems which will arise in the real world, and there are some cases where even the best design guide or reference cannot replace experience and judgement. Specific engineering and operating companies may also have guidelines which they require an engineer to follow in the course of designing a pipeline transportation system.

The responsibility rests with the engineer or designer to identify the specific requirements and applicable codes for a given system with regard to design and operational conditions, as well as to follow specific guidelines mandated by the engineering or operating company and any relevant additions to the Code, and other regulations which may govern the design.

Codes, Standards, Specifications, and Recommended Practices

In general, pipelines which are designed in accordance with the Code will meet the requirements in the USA for liquid petroleum pipelines and associated facilities.

In addition to the ASME B31.4 Code, the following codes, specifications, standards, regulations, and recommended practices may be applicable to a proposed pipeline system or component thereof (this list is representative but is not comprehensive):

These codes, specifications, et cetera, also cross reference additional standards and recommended practices that apply to various aspects of petroleum pipeline system components.

Systems of Units. The metric units used herein are adopted from reference codes ASME B31.4a (1994); ASTM E380–93 Standard Practice for International System of Units (SI); ANSI/ASTM D1250 Manual of Petroleum Measurement Standards (MPMS)—Chap. 11.1, Volume Correction Factors[6]; ANSI/ASTM D1298 API Manual of Petroleum measurement Standards; API 5L Specifications for Line Pipe; and API 6D Pipeline Valves (Gate, Plug, Ball, and Check Valves). Each of these codes presents metric values, originally standardized in the English system, to the accuracy with which the conversions warrant. The reader should refer to these references for additional detail.

The engineer is concerned with physical dimensions and mechanical properties of materials comprising the pipeline system to an accuracy limited by repeatability and error of measurement. Similarly, the quantity of commodity transported is determined by the combined accuracy and repeatability of quantity measurement and determination on a weight basis at the time of delivery for commercial transaction, relative to standard temperature and pressure. The Manual of Petroleum Measurement Standards, Chap. 15—Guidelines for the use of the International System of Units (SI) in the Petroleum and Allied Industries (API Publication 2564),[7] establishes both SI units and acceptable exceptions.

Within these guidelines, SI units will be used herein with the exceptions °C for °K, and limiting expressions of pressure, head, and flow rate to the range 0.1 to 1,000 by powers of 10. Additionally, the period will be used for the radix as in customary English usage rather than the comma. The examples illustrating pipeline design methods are shown in metric units, and example calculations and tables include both customary English and metric units.

Conversion factors between English and metric systems are based on six significant figures to enhance repeatability. However, fewer significant figures are used for exact values, or when precision of the determinable value is limited. The Manual of Petroleum Measurement Standards expresses volume and density measurements to four significant figures. API 5L tabulates nominal metric pipe dimensions to 0.1 mm and pipe minimum yield and ultimate tensile strengths in MPa as integers to three significant figures. API Specification 6D, Pipeline Valves, designates pressure class as nominal pressure (PN) and nominal pipe diameter as (DN). For NPS 4 and larger sizes, multiply the NPS by 25 to obtain the corresponding DN.

This chapter of the *Piping Handbook* includes at the end of this chapter three tables of conversion factors useful in pipeline engineering practice but may not be

inclusive of all used. The range of operating pressures, flow rates, fluid characteristics, size and strength of materials used in designing and fabricating pipeline systems introduces a requirement for numerical presentation in consistent scales that include the range of a particular application without introducing varying powers of 10. The examples in this chapter follow the practice of showing calculations in the same numerical form used in the illustrations.

References

General references and supplements for the material covered in this chapter are supplied at the end of the chapter. The majority of the material covered in this chapter is also available in numerous petroleum reference books and technical papers through trade publications. No attempt has been made to reference all sources of relevant data available. Only those most pertinent to the discussions are included here, or those considered most useful.

LIQUID-PETROLEUM PIPELINE SYSTEMS

It is interesting to note that liquid-petroleum pipeline systems have been in operation since the late 1800s; and, as illustrated in the title of the Code, a number of different commodities are transported via pipeline, with widely varying properties. Therefore, to begin the discussion of liquid-petroleum pipeline systems, it is useful to illustrate some of the characteristics of fluids covered by the B31.4 Code, based on examples of real pipeline systems. Then, as this chapter is intended to be an aid in the selection of the preferred pipeline design, the concept of the *system approach* to design is introduced, wherein the hydraulic, mechanical, and operations and maintenance aspects of design are integrated and evaluated with economic analysis to select the most economically attractive system.

Characteristics of Transported Commodities

ASME B31.4 covers a wide range of petroleum liquid commodities, including crude oils, residuals, and products of refining such as diesel oil, jet fuel, gasoline, natural gas liquids, oil-water emulsions, anhydrous ammonia, alcohols, carbon dioxide, and others. The physical properties of these commodities are also variable, and each pipeline system design is based on specific properties of an identified commodity, or group of commodities in the case of multiproduct pipeline systems.

Table C5.1 identifies general characteristics of some fluid commodities covered under the Code. The API gravity, viscosity, and temperature values shown (where available) are specific examples of operating pipeline systems and should only be considered as examples. The table also identifies specific considerations for different commodities which can have an effect on the design and operation of a pipeline sytem.

Table C5.1 includes reference to API gravity, which relates specific gravity of the petroleum commodity at 60°F to water at 60°F (60/60°F). While API gravity and specific gravity are related, API gravity characterizes boiling-point fraction range and, historically, has been indicative of the commercial value of the commodity and vapor pressure.

For pipeline hydraulics, the engineer is concerned with density, viscosity, vapor pressure, and pour point. Section 15.4.10 of the Manual of Petroleum Measurement Standards (MPMS) advises that API gravity and specific gravity are to be eliminated for use. API gravity is to be replaced with absolute density in kg/m^3, and specific gravity(sg) by relative density(rd) to water, both at standard conditions 15°C and 101.325 kilopascals. Vapor pressure is determined by ASTM D323-Reid Method, for volatile crudes and products except liquified petroleum gas (LPG). Vapor pressure for LPG is determined by ASTM D1267-LP Gas Method.

System Approach to Design

In the design of an oil transportation system, it is necessary to consider many aspects of design and operation as well as project economics in determining the preferred pipeline system to transport a commodity, or commodities, from a source to a destination. On a technical or engineering level, there are three aspects of design which are interrelated in the system approach to design:

- Hydraulic
- Mechanical
- Operations and Maintenance

Decisions in one area of design directly affect, or limit, the options in another area. For example, it may be necessary to locate a pump station such that it is accessible, for example, on a main road, near an electrical power source. Thus the pipeline route will have an intermediate location point set, in addition to the origin and terminal points. Likewise, preliminary design and cost estimating are not separate and independent procedures but are instead closely related and proceed concurrently.

The hydraulic design is the process of evaluating the physical characteristics of the commodity or commodities to be transported, the quantities to be transported, the pipeline route and topography, and the range of pressures, temperatures, and environmental conditions along the route. Identifying the number and location of pump stations with respect to the hydraulic characteristics of the system is also part of the hydraulic design. There may be several viable hydraulic designs for any given pipeline-design basis and route. The most feasible is identified in conjunction with the owner or operator of the system, giving consideration to early use requirements and future capacity plans for the system.

For any one hydraulic design there are a number of mechanical system designs that can be developed to meet the criteria of the design basis and deliver the commodity from origin to destination. The mechanical design is governed by the codes and standards developed from experience in operating petroleum pipelines systems, and focuses on selection of pipe material and the specification of physical line-pipe properties such as pipe diameter and wall thickness as required by the stresses imposed on the system by the hydraulic and thermal conditions, yet within the limits set by the Code. Other aspects of the mechanical design include the type, size, and power required of pumps and other equipment or ancillary facilities required to meet the hydraulic-thermal design, such as heating stations, and the support or burial requirements for the pipeline.

The final aspect of design takes into consideration the day-to-day tasks of operating and maintaining the functional integrity of the system. These include the

TABLE C5.1 Petroleum Commodity Characteristics for Pipelines

Commodity	Temp range F/(C)	Relative density	API gravity	Viscosities cSt at F/(C)	cSt at F/(C)	Pour point F/(C)	Vapor press psi (kPa)	Remarks: flow regime, rheology, general conditions
Residuals:	150 to 250 (65 to 121)	1.02	7.2	50,000 at 130 (54)	330 at 250 (121)	130 (54)	—	Common design temperature in the range of 150 to 250°F (65–105°C). [One design for 800°F (427°C) is operating.] Thermal design required. Laminar flow.
	150 to 250 (65 to 121)	0.96	15.9	1,000 at 100 (38)	45.7 at 210 (99)	90 (32)	—	
Crudes:								
General	40 to 160 (4 to 70)	0.84	12–40	11 at 68 (11 at 20)	4.1 at 122 (4.1 at 50)	55 (13)	15 (103)	Generally newtonian in range of operating temperature. May require thermal design considerations. Transition to fully turbulent flow.
High wax content	70 to 140 (20 to 60)	0.81	35–45	7.4 at 122 (7.4 at 50)	3.3 at 140 (3.3 at 60)	95 (35)	15 (103)	Generally newtonian above cloud point; develops yield stress and nonnewtonian flow characteristics after static cooling. Transition to fully turbulent flow.
Shale oil	40 to 120 (4 to 50)	Data still emerging in shale oil systems—state of the art						Fluid properties vary with method of extraction and preparation for transport. Require considerations for vapor pressure, interfacial mixing and fluid properties when setting operations requirements.
Products:								
No. 2 furnace	30 to 80 (−1 to 27)	0.82–0.84	39	5.7 at 30 (5.7 at −1)	2.6 at 100 (2.6 at 38)	—		Newtonian fluids. Fully turbulent flow. May require thermal design.
Diesel–No. 1	30 to 80 (−1 to 27)	0.83		2.8 at 30 (2.8 at −1)	1.4 at 100 (1.4 at 38)	—		Multiproduct hydraulic design is based on the combination of fluid properties in the system that produces the maximum system stress and required pumping power at stations.

TABLE C5.1 Petroleum Commodity Characteristics for Pipelines *(Continued)*

Commodity	Temp range F/(C)	Relative density	API gravity	Viscosities cSt at F/(C)	cSt at F/(C)	Pour point F/(C)	Vapor press psi (kPa)	Remarks: flow regime, rheology, general conditions
Diesel–No. 3	30 to 80 (−1 to 27)	0.88		10 at 30 (10 at −1)	3.6 at 100 (3.6 at 38)			
Jet fuel	30 to 80 (−1 to 27)	0.78		2.2 at 30 (2.2 at −1)	1.3 at 100 (1.3 at 38)			
Gasoline	30 to 80 (−1 to 27)	0.71–0.73	65	0.8 at 30 (0.8 at −1)			30@100 (207@38)	Require considerations for vapor pressure, interfacial mixing, and fluid properties when setting operations requirements, selecting pumps.
Natural gas liquids (NGL) and other high–vapor pressure petroleum liquids	30 to 130 (−1 to 55)	0.5		0.23 at 30 (0.23 at −1)	0.2 at 100 (0.2 at 38)	—	200 at 60 (1380 at 15) to 700 at 120 (4830 at 50)	Pressure is maintained above the critical pressure to avoid two-phase flow. Special considerations for loading pumps and blowing down pipeline sections are required. Fully turbulent flow.
Other:								
Oil-water emulsions	There is no specific example pipeline system for this commodity, or the information is proprietary or confidential.							May be either an oil or water suspension; fluid properties are extremely variable.
Alcohols	There is no specific example pipeline system for this commodity, or the information is proprietary or confidential.							Toxic; flame may be invisible in daylight.
Anhydrous ammonia	There is no specific example pipeline system for this commodity, or the information is proprietary or confidential.							Toxic and corrosive—Code requires >0.2 percent water by weight to inhibit stress corrosion cracking.
Carbon dioxide	There is no specific example pipeline system for this commodity, or the information is proprietary or confidential.							(See high–vapor pressure liquids.) Dehydration is required for pipeline quality. Heavier than air, toxic in elevated concentrations.

necessary control systems to operate the system within its design parameters and to promote safe and continuous operation.

The preferred pipeline system for a given set of conditions is selected through an economic comparison of several systems, seeking to identify the system that yields the best economic return on the investment dollar, depending on the initial and subsequent capital costs, the method of financing, and the operating and maintenance costs for the economic life of the investment. If alternatives require capital investments, e.g., for pumping stations, at different future dates, then these costs should be compared on a present-value basis, discounted at a real (after inflation) interest rate, to ensure a valid, unbiased selection of the preferred system. The details of economic analysis are addressed in financial analysis references.[22]

Programs are available for hand-held calculators, personal computers and mainframe computers for separately performing the hydraulic, thermal, mechanical, and economic analyses and design of petroleum pipeline systems.[28,29]

Concurrent with the hydraulic, mechanical, and operations and maintenance designs, the pipeline project team will also be performing many tasks related to the construction of the pipeline. These include technical and environmental surveys of the pipeline route and surrounding areas, preparation of environmental impact reports, acquisition of permits and rights-of-way, procurement of construction materials, development of construction costs considering pipe diameter, wall thickness, grade of steel and welding procedures, and preparation of contract specifications and bidding papers. These and other topics related to construction of pipelines are covered in other handbooks.

The investigation of any pipeline system begins by establishing the design basis for the commodity, then making a preliminary selection of pipe diameters and cost estimates for comparative economic attractiveness. If the preliminary estimates indicate further consideration is desirable, then preliminary feasibility considerations begin by selecting possible routes and developing a preliminary design.

The preliminary cost estimates developed in Tables C5.7, C5.7M, C5.8, and C5.8M, are examples of initial order-of-magnitude cost estimates for selecting alternative pipe diameters and overall cost feasibility. The pipe diameters used in Table C5.8M are the basis for the discussion of the hydraulic designs illustrated in the section that follows. The pipe diameters used have been selected to illustrate considerations in the hydraulic analysis and effect on mechanical design and cost rather than to select a preferred design for the example system discussed.

HYDRAULIC DESIGN

The hydraulic design integrates the physical characteristics of the transported commodity along a given pipeline route, within specified operating conditions as established in the design basis. The result of the hydraulic design is identification of the total system energy required to meet the design criteria. In addition, the hydraulic calculations indicate a range of feasible pipe diameters and preliminary spacing of pump stations along the route.

When the design is finalized, i.e., the route selected, pipe-line size determined, and type of pipe selected, the hydraulic calculations are refined to determine the conditions for over-pressure control during line shutoff and surges during operation. Hyraulic calculations can also be made for the variables in the operating conditions (temperature, ranges of viscosities for products pipelines, et cetera) and for future expansion of system capacity.

Route Selection

Given the task of transporting a liquid commodity from one point to another—whether it is from the point of production or storage to a processing plant, or from the process plant to distribution facilities—the first selection of route will logically be the shortest course, or a straight line.

While a straight-line route is a reasonable first approximation of the pipeline route, there are several common-sense reasons for deviation, including:

- Significant natural obstacles such as mountain ranges, rivers, swamps, et cetera.
- Minimizing of control points in the hydraulic profile (discussed later).
- Access for construction equipment and materials.
- Permitting restrictions.

A preliminary route is determined using suitable maps of the area which need to show geographic features such as contour lines as well as towns, roads, rivers, railroads, existing pipelines and utility corridors, et cetera. World Aeronautical Charts are available for most parts of the world, on different scales, for this purpose. U.S. Geological Survey maps are particularly useful for pipeline routing in the United States. Aerial photographs are also useful.

Several of the factors which will influence the selection of the design route may not be readily identifiable or resolved until later phases of design, in particular, environmental and permitting requirements and land acquisition. However, a preliminary route can be selected and later modified when more information on the specific and final route is available. Once an initial route is identified, the ground profile is plotted for use in the hydraulic design.

Example C.5.1. Figure C5.2 is a potential pipeline-route profile for a crude-oil pipeline design illustrated in this chapter. This example is a simplified profile. Real
FIGURE C5.2 Example pipeline route profile.

pipeline systems typically have much more detail, showing river crossings, mountain ranges, and other geographical points.

It should be emphasized that this is not a cross-section of a straight-line course from origin to terminal but represents the real route, avoiding major obstacles mentioned earlier. The selected route results in a length of 248 miles (400 kilometers). Elevations of significant points along the route are shown.

If more than one reasonable alternative route has been identified, they are also plotted, and designed and analyzed simultaneously. Following sufficient identification, the alternatives will be evaluated on the basis of construction, operation, and maintenance cost, and a comparative economic analysis spanning the effective project or system life is performed to identify the preferred alternative. This topic is covered in more detail later in this chapter.

Design Basis

When beginning the design of a pipeline system, it is necessary to define the basis of the design as completely as possible. The general parameters which are required for the design of the system include:

- System operating parameters, such as design *throughput* or flow rate; operating temperature of the system
- Environmental conditions, such as ambient ground and air temperature (average and extremes)
- Properties of the transported fluid(s), or commodity, such as viscosity, relative density, vapor pressure, and pour point temperature.

System Parameters.   There are a number of system parameters which are typically defined by the operating company or owner of the system. It is helpful for the design flow rate for the system to be defined as closely as possible. Maximum, minimum, and forecast future daily or annual throughputs of the pipeline system are required for good design, resulting in selection of the economically preferred line size as early as possible. This limits the iterations of the design as well as the range of alternatives.

The design throughput of an oil pipeline may vary by year and is usually expressed as the average daily flow rate in barrels per day (BPD) or 1000 m^3 per calendar day (1,000 m^3/cd), or in million tonnes[a] per annum (MTA), which requires conversion to daily rates for computation. The actual flow rate that a system must be capable of attaining to compensate for lost capacity from shutdowns and reduced flow conditions is the flow rate per operating day BPOD, or (1,000 m^3/d), which is greater than the flow rate per calendar day. The ratio of flow rate per calendar day to operating day is the load factor.

$$\text{load factor} = \text{rate per calendar day/rate per operating day} \qquad \text{(C5.1)}$$

A well-operated pipeline can be expected to have a load factor of 92 to 95 percent. For domestic pipelines, this may be used in the design procedure unless special circumstances dictate a lower factor. Pipelines to be located in remote areas, more complex systems with many pump stations, or pipelines operated with expected flow variations would be more reasonably designed to a lower load factor, 85 to

---

[a] A tonne is equal to 1,000 kg (2205 lbs).

90 percent, to account for greater system downtime, i.e., from interruptions in service as a result of operations and maintenance.

Environmental Parameters. The critical environmental parameter for the hydraulic design is the ambient temperature of the ground, for buried pipelines, or the air, for aboveground systems. Most locations will have seasonal variations, and long pipeline systems may have variations over the length of the system. It is important to identify the mean or average ambient temperature as well as the seasonal and local extremes.

Properties of the Commodity. Specification of the commodity to be transported includes identification of viscosity, density, vapor pressure, and pour-point temperature. Some of these properties will have to be determined from laboratory tests on specific commodity samples. However, design may proceed on the basis of a typical commodity and include flexibility for a specified range of variation.

Viscosity is the physical property of fluids which resists flow and, for liquids, varies inversely with temperature. Besides density, viscosity is a key characteristic of the fluid to be considered in the design of liquid pipelines, having a significant effect on determining line size, station spacing, and pumping-power requirements. A discussion of viscosity, including the definitions of kinematic and absolute viscosity, has been included in Chap. B8, Flow of Fluids. Several of the references may also be consulted for viscosity data on specific hydrocarbons and other fluids.[7,8,9,10,11,12]

Example C5.2. Figure C5.3 shows the approximate viscosity-temperature (for a limited range of temperatures) relationship for a crude oil sample, having a viscosity of 6.0 centistokes (cSt) at 129.2°F (54°C), and 23.7 cSt at 59°F (15°C). This will be used for the basis of the example.

The viscosity-temperature is not truly linear, unless plotted on a special ASTM graph paper designed for this purpose. Figure C5.3 is plotted for the range 32 to 140°F (0 to 60°C) to the coordinates of ASTM D-341, Chart VII: kinematic viscosity, middle range, degrees Celsius, for the temperature range of −40 to 302°F (−40 to 150°C).

Reference ASTM D-341[11] for further discussion.

For crude oils, the pour point of the oil, i.e., the temperature at which viscosity of a cooling oil abruptly increases, needs to be considered to determine if special measures are required to move the oil when ambient ground and air temperatures are below this temperature. An oil with a pour-point temperature above the ambient condition will require dilution with a lighter stock oil (sometimes referred to as cutter stock), addition of a pour-point depressant, or a heated pipeline system.

Isothermal Systems

Oil transportation pipelines typically will have some variation in temperature over the entire system. As this then affects viscosity and has other design impacts, the discussion of the hydraulic design will continue based on isothermal—constant temperature—systems, with the assumption that temperature variations are limited. Special considerations for nonisothermal systems are discussed later.

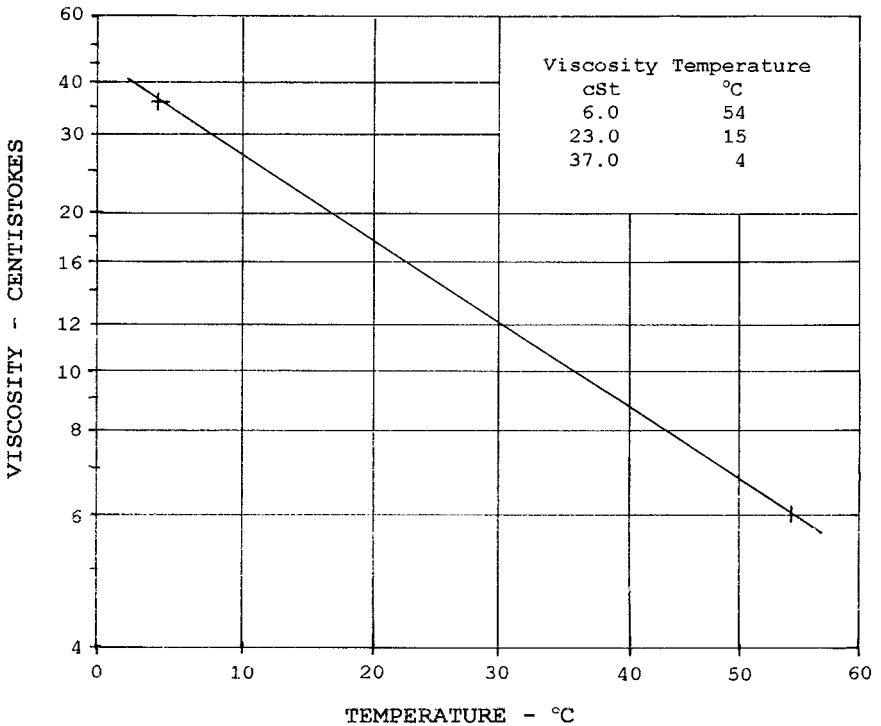
Example C5.3. Crude-oil pipeline system, isothermal flow, 248 ground miles (400 km) over a route with a maximum elevation of 1476 ft (450 m). Figure C5.2, included earlier, shows the route profile for this example. The initial elevation is 131 ft (40 m) at the origin, and a liquid head level of 492 ft(150 m) with respect to the datum is maintained at the terminal.


FIGURE C5.3 Example viscosity versus temperature, crude oil.

Design Basis:

API gravity at 60°F	32.6
Specific gravity (relative density) based on water @60°F (15°C)	0.8623
Ambient design temperature	39.2°F (4.0°C)
Viscosity @ 59°F (15°C)	23.0 cSt
Viscosity @ 129.2°F (54.0°C)	6.0 cSt
Flow rate (average)	169,800 BPCD (27,000 m³/d)
Load factor	0.9

The design temperature for average operation differs from the measurement standard of the design crude. Consequently, it is necessary to make adjustments from the values given here at standard conditions @ 60°F (15°C) to the operating conditions.[7,8,10,11]

MPMS Chap. 11.1[7] Tables 5.3A and 5.4A tabulate correction factors for density and volume that adjust standard conditions to the design conditions for generalized crude oils, which will be used here. Additionally, Tables 5.3B and 5.4B tabulate correction factors for generalized products.

The correction factors are applied to the standard conditions to adjust density and volume to the design conditions. Density-and volume-correction factors are reciprocals of each other and can be applied by multiplication or division as required.

$$\text{Relative density } (rd) = \text{standard density kg/m}^3 \text{ /1,000 kg/m}^3 \qquad \text{(C5.2)}$$

Relative density @ $4°C = 862.3/1,000 \times 1.0091 = 0.8701$

Design flow rate $= 27,000/(0.9 \times 1.0091) = 29,790\text{m}^3/\text{d}$

adjusted for both load factor and volume correction factor.

Use 188,700 BPOD (30,000 m^3/d) (rounded)

Viscosity @ $4°C = 37$ cst, see Fig. C5.3

System Energy

Both head, H, and pressure, P, are used in discussing system energy. The conversions from head to pressure, and vice versa, are given by the following formulas, for standard conditions 60°F (15°C), with correction for specific gravity (sg) or relative density (rd) of the commodity, which adjusts the pressure or head to operating conditions.[7,8,10,11]

$$H, \text{ ft} = 2.31 \times P, \text{ psi}/sg \qquad \text{(C5.3)}$$

or

$$H, \text{ m} = 9.807 \times P, \text{ kPa}/rd$$

$$P, \text{ psi} = H, \text{ ft} \times 0.433 \times sg \qquad \text{(C5.4)}$$

or

$$P, \text{ kPa} = H, \text{ m} \times 0.102 \times rd$$

The total pressure drop in a pipeline system comprises three components:

1. Static pressure drop, due to changes in elevation
2. Acceleration pressure drop, due to changes in pipe geometry or phase
3. Friction pressure drop, due to flow rate, fluid properties, and pipe characteristics

When using the term *head* of fluid to denote system energy, the three components of head are typically referred to as static, or elevation head, H_s, velocity head, H_v, and friction head, H_f. These are the terms of the Bernoulli equation discussed in Chap. B8. Head loss expressed per unit of pipe length uses the lower case h, with the same subscripts.

The elevation head, H_s, is the difference between the inlet and outlet elevations between points on a system. The velocity-head component for long pipeline systems,
Note: DN (metric) = 25 x NPS (English)

FIGURE C5.4 Flow rate versus nominal pipe diameter for velocities of 0.5, 1.0, 2.5, 2.0, and 3.0 m/s.

and generally for systems with high head requirements, is a small percentage of the total head and is often assumed to be negligible in energy calculations.

Friction-head loss, on the other hand, is the dominant effect in most liquid pipeline systems and can be calculated using one of the following equations previously discussed in Chap. B8, Flow of Fluids:

• Darcy-Weisbach
• Fanning
• Hazen-Williams

The former two equations require a determination of friction factor as a function of the Reynolds number. The Hazen-Williams equation accounts for friction in a coefficient C, which is an empirically determined factor for the specific commodity.

Friction-loss tables based on the Darcy-Weisbach formula are available in many engineering reference books for water and viscous liquids.[9,13] Generally these tables, as illustrated in App. E, give friction loss in units of head loss, ft

of head per 100 ft of pipe. Multiplying by 10 gives pipe friction loss in ft/1000 ft, or m/1000 m of pipe length. Each of these unit friction losses can be converted to pressure loss per unit of length using the appropriate conversion factor and density of fluid.

Hydraulic calculations are not complex for pipelines with a single commodity having little variation in viscosity. The first task is to specify the nominal pipeline diameter, or range of diameters, based on the design flow rate.

An approximation of line size can be made for the design flow rate using the tables available in handbooks, standard fluid-design manuals, or engineering reference books. The selection of line size is based on a preliminary economic analysis of alternatives discussed in Table C5.7 or C5.7M. Depending upon commodity, location, distance, and energy costs, velocities for preliminary estimates of line size are typically in the range of 2 to 10 ft/s (1 to 3 m/s). Figure C5.4 shows daily flow rate in 1000 m³/d versus nominal pipe diameter, DN, in millimeters for velocities between 0.5 to 3 m/sec.

At this point a preliminary choice of one or more wall thicknesses is necessary, as eventually a cost of pipe will be found and because wall thickness will also be a component of the internal pressure and stress limitations. For a given diameter, *D*, also referred to as the nominal pipe size (NPS) or diameter (DN), a range of pipe Specified Minimum Yield Strength (SMYS) and wall thickness, *t*, is available.[1,2] Standard pipe wall thickness, depending on diameter, such as 0.250 in (6.4 mm) or 0.375 in (9.5 mm), may be used for the early design, and later adjusted if special commodity or system requirements are identified, such as high pressure or limitation on the allowable pipe stress in a section of the system.

The examples that follow use the internal design pressure, calculated by Code formula for the pipe grade and wall thicknesses, to determine the maximum allowable operating pressure (MAOP). After converting MAOP in units of pressure to units of head (MAOH) in feet or meters for the particular density of the fluid, the calculated slopes of hydraulic gradients between the MAOH at a pump station and the intersection with the ground profile determine pump-station locations for the given diameter and flow rate.

Example C5.4. Returning to the example, for the flow rate of 188,700 BPOD (30,000 m³/d), assume that there are three diameters of pipe which are viable to illustrate the effect of pipe diameter on design. The following table can be constructed using a tabulation of the Darcy-Weisbach formula and a minimum wall thickness of 0.250 in (6.4 mm), for the three diameters:

TABLE C5.2 Example: Pipeline System Parameters

Parameter	NPS 16		NPS 20		NPS 24	
O.D. and wall thickness, in	16.0 × 0.250		20.0 × 0.250		24 × 0.250	
Flow rate, MBPD nominal	126.8	251.6	126.8	251.6	126.8	251.6
Roughness, in	0.0018	0.0018	0.0018	0.0018	0.0018	0.0018
Reynold's number	20,385	40,450	16,200	32,150	13,445	26,680

Unit friction loss, m/km	12.22	41.78	4.09	13.90	1.68	5.67
Velocity, m/s	1.90	3.80	1.20	2.40	0.825	1.65

Figure C5.5 is graphed using the data from Table C5.2M. The use of log/log scales results in an approximately linear relationship between flow rate and unit friction loss, h_f.

Two of the diameters also show the effect of adjusted viscosity to the operating condition of 39.2°F (4°C).

It is important to point out the adjustments made for the viscosity at operating temperature. If using a reference table based on water ($sg = 1.0$) to determine unit friction loss, or if the friction loss chart is based on viscosity at 60°F, corrections would need to be made for the design temperature and viscosity of the specific commodity at operating conditions.

Summing the friction losses for a specific set of pipeline diameters along the system results in the net friction head that must be overcome by the pump stations of the system. In addition, the positive or negative static head due to elevation difference between the inlet and outlet must be considered in determining the pumping requirements of the system. Minor losses at valves and fittings between stations are normally ignored, initially, or an allowance of an added length of pipe may be added to the scaled length to determine the estimated total system friction head loss.

Hydraulic Gradient

The hydraulic gradient is a profile representing the static head at any point in the pipeline system, relative to a common datum elevation, which is usually mean sea level. Ground elevation is represented by the route-elevation profile to the same datum. Energy added to the system through a pump station is plotted above the elevation profile. Head losses from friction, et cetera, are also shown graphically. For a pipeline system with constant parameters along the system, such as viscosity, relative density, and diameter, the hydraulic gradient will be a straight line with a slope equal to the friction loss per unit of length, h_f, for a specific flow rate. Therefore, the actual pressure in the pipeline at any point along the route is the difference between the hydraulic gradient and the ground elevation.

Figure C5.6 illustrates the slope of hydraulic gradients based on the 188,700 BPOD (30,000 m³/d) flow rate and the three diameters tabulated in Table C5.2M, where an assumed pump-station discharge head of 3281 ft (1000 m) is shown at the origin. The hydraulic gradient, being the available head at any point along the pipeline route, cannot be less than the elevation of the pipeline-route profile. Therefore, where the gradient intersects the pipeline elevation, a pump station is required. It is obvious from Fig. C5.6 that unrealistically high station discharge
FIGURE C5.5 Unit friction loss versus flow rate.

heads would be required for only one pump station using NPS 16 (DN 400) or NPS 20 (DN 500) pipe. However, one station could be used on the NPS 24 (DN 600) pipeline by elevating the hydraulic gradient at the station discharge sufficiently to clear the ground profile at mile post 202 (kilometer post 325). The station discharge head is usually selected on the basis of the maximum allowable pressure rating for valves and fittings, or the MAOP of the selected pipe, whichever provides the required operating flexibility, and is the most attractive economically.

The example above for the NPS 24 (DN 600) pipeline illustrates an important use of the hydraulic gradient for identifying hydraulic control points on a pipeline route. A hydraulic control point is a high elevation point that will govern the inlet head for a section of pipeline as discussed above. In the example, the maximum profile elevation of 1476 ft (450 m) at milepost 199 (kilometer post 320) is a control point. It is logical that the hydraulic gradient must clear the ground elevation control point, but in doing so, two situations may result downstream as shown in Fig. C5.7 for the hydraulic gradient of the NPS 24 (DN 600) line.

1. Either the line is designed to flow full, requiring that back pressure control is provided at the terminal, or
FIGURE C5.6   Example hydraulic gradient for 30,000 m³/d for DN 400, DN 500, and DN 600 nominal pipe size.

2. Without back pressure control, the length of line downstream of the control point will flow partially full in a cascade or slack-line condition. Slack flow may not be a desirable condition in some pipeline systems; however, systems transporting crudes having low vapor pressures can, and do, operate successfully with slack flow.
FIGURE C5.7   Example for clearance of a control point illustrating backpressure control and slack flow for 30,000 m³/d.

In this example, the hydraulic gradient of the NPS 20 (DN 500) line clears the elevation of the control point, and the considerations for back-pressure control or slack flow only occur at lower flow rates.

Throughout this section, the example which will be discussed is a system with constant flow rate and one delivery point. In general, pipeline systems may have intermediate injection or delivery points along the route such that flow in the main line is increased or decreased. Hydraulic design of this type of system requires that the gradients for each section of the system with different flow rates be calculated and plotted in succession along the pipeline.

Maximum Allowable Operating Pressure

Section 404.1.2 of the Code expresses the required wall thickness for the internal design pressure for straight pipe by Eq. C5-5.

$$t = P_i \times D/(2 \times S) \qquad (C5.5)$$

where P_i = maximum allowable internal gauge pressure, psig (SI and metric units, see Eq. C5.6)
   D = outside diameter, in (mm)
   S_A = allowable stress, psig (MPa)—see sec. 4.2
   t = wall thickness, in (mm)

Expressing Eq. C5-5 in the following form for calculating the internal design pressure,

$$P_i = B \times S_A \times t/D \qquad (C5.6)$$

The constant B is determined by the units of the allowable stress S_A, and the units of pressure to be determined using the ratio of t/D in consistent units.

Units	SI	bar	Metric	English
Allowable stress S_A	MPa	MPa	MPa	psi
Pressure	MPa	bar	kPa	psi
Constant B	2.0	20	2000	2.0

Wall thickness, t, for calculation of the MAOP excludes additional thickness for corrosion allowance, or imposed stresses such as concentrated loads at supports, thermal expansion or contraction, and bending. Determination of additional required wall thickness for these considerations is discussed later in this chapter.

At this point, the reader is referred to the tabulations for specified minimum yield strength and allowable stress which can also be found in API Specification 5L, Specification for Line Pipe,[2] which is based on the restrictions on allowable stress, according to the Code.

The following example uses the tabulated allowable stress values of API Specification 5L, and solves Eq. C5.6 for P_i based on an assumed diameter, wall thickness, and material.

Example C5.5. For the example pipeline system, assume the steel pipe is API grade 5L-X60, having a specified minimum yield strength of 60,000 psi (413 MPa).

TABLE C5.3 Maximum Allowable Operating Pressure

Pipe nominal size, NPS	1	6	2	0	2	4
Pipe wall thickness, in	0.250	0.312	0.250	0.312	0.250	0.312
MAOP, psig	1,350	1,684	1,080	1,347	900	1,123
MAOH, ft^2	3,580	4,468	2,864	3,574	2,387	2,978

TABLE C5.3M Maximum Allowable Operating Pressure

Pipe nominal diameter, DN	400		500		600	
Pipe wall thickness, mm	6.4	7.9	6.4	7.9	6.4	7.9
MAOP, kPa[1]	9,366	11,561	7,493	9,249	6,240	7,702
MAOH, m^2	1,097	1,354	878	1,083	731	902

[1] API wall thickness in millimeters is approximately 0.6% greater than direct conversion of API wall thickness in inches, which yields a corresponding increase of MAOP when converted from wall thickness in English units. Maximum allowasble operating pressures are gauge.
[2] Allowable head is based on 0.8701 specific gravity (rd).

Tables C5.3 and C5.3M tabulate the MAOP and MAOH for grade X60 pipe for three diameters and two wall thicknesses.

(Calculations are based on Eq. C5.5, using actual pipe diameter, mm, and tabulated value of SMYS from API 5L. Allowable stress, S_A, calculated using Eq. C5-14, is 74.93 bar (7,493 kPa) with design factor of 0.72, and SMYS of 413 MPa per tables in API Spec 5L.)

The MAOP is used in the development of the system hydraulic design as a limit on the internal pressure component of the hydraulic gradient. When plotted above the route profile, the hydraulic gradient may not exceed this limit and still be designed to the B31.4 Code. MAOP is also used in determining the approximate number of pump stations.

Pump Stations

The calculated total system head required to achieve a given flow rate through a pipeline system with a selected diameter, which includes the total friction component and the static elevation difference between inlet and outlet, determines the pumping requirements of the system. As seen in Fig. C5.6, at least one intermediate pump station is required for the example system and pipe diameters illustrated. This section discusses a method of determining how many pump stations are required and locating them on the basis of hydraulic balance and a graphical method.

Number of Pump Stations.   A rough number of pumping stations is found by dividing the total system pressure or head required to overcome elevation changes and friction, by the maximum allowable operating pressure or head, MAOP or MAOH, for a specific diameter, wall thickness and pipe material, using consistent units. For example:

No. of pump stations = Total System Head/(MAOH − NPSH)   (C5.7)

Example C5.6. The first step to determining the number of pump stations is to determine the pressure or head required to overcome the frictional resistance caused by the flow of oil. Using a NPS 20-(DN 500) diameter pipe size with 0.250 in- (6.4 mm) wall thickness (this is usually written 20×0.250 in $(508.0 \times 6.4$ mm) and a hand-held calculator programmed with the Darcy-Weisbach equation, the unit friction head loss, h_f, for the design flow of 188,700 BPOD (30,000 m^3/d) is 44.06 ft/ mi (8.35 m/km).

Summing the friction head loss over the 248 miles (400 kilometers) measured length of the system yields 10,958 ft (3,340 m) of total head loss due to friction, H_f.

There is also a static head, H_s, of 361 ft (110 m) to be pumped against due to a change in elevation between the initial point and the head required at the terminal.

The total head, H, which is required from all pump stations on the system, is the sum of the static head and the friction head:

$$H, \text{ ft} = (H_f + H_s) \text{ ft} \qquad H, \text{ m} = (H_f + H_s) \text{ m}$$
$$= 10{,}958 + 361 \qquad\qquad = 3{,}340 + 110 \qquad\qquad \text{(C5.8)}$$
$$= 11{,}319 \text{ ft} \qquad\qquad\quad = 3{,}450 \text{ m}$$

The MAOP of API 5L Grade X60 pipe NPS 20×0.250 in wall (DN 500×6.4 mm), expressed in units of head is 2 864 ft (873 m). Assuming 82 ft (25 m) of head loss in station piping, the available head per station is

$$\text{Number of pump stations} = 11{,}319 \text{ ft}/(2{,}864 - 82) \text{ ft} = 4.07$$
$$= 3{,}450 \text{ m}/(878 - 25) \text{ m} = 4.04$$

Fractional stations may be accounted for by using heavier wall pipe for a limited length, or by installing a booster station. These alternatives are evaluated on the basis of economics.

Location of Pump Stations. One pump station is located at the initial point of the pipeline. Downstream stations are initially located such that each of the pipeline sections will be in hydraulic balance, i.e., with each station having approximately the same differential head or pressure, thereby distributing the energy load equally.

$$\begin{array}{ccc} \text{Pump Station} & \text{Total} & \text{Number of} \\ \text{Differential Head} = & \text{System Head}/ & \text{Pump Stations} \end{array} \qquad \text{(C5.9)}$$

In level terrain, this procedure for determining the number of pump stations would space stations equally along the route. However, in uneven terrain, such as in the example, the stations can be balanced using a graphical technique.

Figures C5.8 and C5.9 illustrate stations located graphically for the NPS 20 (DN 500) and NPS 24 (DN 600) pipelines by beginning at the elevation required at the terminal, then drawing the hydraulic gradient upstream to the intersection of the MAOH of the pipe, which is plotted above the ground-elevation profile. This location establishes the Actual Discharge Head (ADH) at the discharge valve of the pump station. The ADH is used here to avoid confusion with the term Total Discharge Head (TDH), which refers to pump performance relative to the centerline elevation of a pump.[13]

The elevation of the hydraulic gradient into the station is plotted above the ground elevation by the allowance to provide station losses to the pumps, and provide the required Net Positive Suction Head (NPSH) at the pumps. In this
FIGURE C5.8   Hydraulic gradient for DN 500 pipeline example, 30,000 m³/d.
FIGURE C5.9   Hydraulic gradient for DN 600 pipeline example, 30,000 m³/d with profile control point and backpressure control at terminal.

example the allowance is 25 meters. The difference between the ADH and the elevation of the incoming head is the difference between the head at the station discharge valve and the station suction valve, and is the station differential. In this example, the station differential is the MAOH of the pipe, minus the allowance for station suction losses and NPSH. The example below shows the calculation for the station differentials for the NPS 20 (DN 500) and NPS 24 (DN 600) systems.

Example C5.7: Station Differentials

	NPS 20 (DN 500)	NPS 24 (DN 600)
Nominal pipe size		
OD and wall, in (mm)	$20 \times 0.250(508.0 \times 6.4)$	$24 \times 0.250(610.0 \times 6.4)$
MAOH, ft(m)	2863(873)	2387(731)
Station loss, ft(m) and NPSH	82(25)	82(25)
Station differential, ft(m)	2781(848)	2305(706)

The actual differential head required of the pumps, however, is greater than the station differential by adding the total of all station losses including a discharge pressure-control valve if one is included in the station discharge piping.

Generally, an allowance of 50 to 100 feet (15 to 30 meters) of head at the intake of the pump station will account for the suction requirements of the pumps, station valves, and fittings losses. The estimate may be revised once specific pumps at a given station—station piping and control discharge head and the associated suction head requirements—are determined. Subsequent pump stations are located similarly with the use of a parallel-rule drafting tool to draw the gradients.

Alternatively, in more complicated terrain, pump-station locations may be determined beginning at the initial point and the MAOH, then progressing downstream using the same graphical procedure. Using this procedure, the station is located at the elevation required for the incoming hydraulic gradient above the ground profile.

While it is not required that the pump stations along a pipeline system be equal in energy, or discharge head, doing so results in a better operating environment. Other considerations may preclude a pure balance between the stations. For example, it may be necessary to fix or shift the location of intermediate pump stations due to unsuitable terrain, population and infrastructure criteria, or operations and maintenance considerations. Many designs, especially in rugged terrain or populated regions, may involve fixing certain key stations in accessible locations, i.e., near power lines, then locating other stations by the trial and error method.

The graphical technique described here allows leeway to make these adjustments. A considerable amount of adjustment can be made with little effect on the total hydraulic design, with respect to pipe diameter or total pump station power. However, moving stations to accommodate unequal station differentials may require using heavier wall pipe on the discharge of some stations. Figures C5.8 and C5.9 illustrate using 0.312-in (7.9 mm) wall pipe for the NPS 20 (DN 500) and NPS 24 (DN 600) systems at the discharge of station 1 to accommodate the hydraulic gradients that exceed the MAOH of 0.250-in (6.4 mm) wall pipe used farther downstream. In this case, the total requirement for heavier wall pipe to avoid a fractional station is installed at the initial station rather than distributed in shorter sections to the discharge of the remaining stations.

In the cases illustrated, using 0.312-in (7.9 mm) wall pipe increases the friction loss between station 1 and station 2, and the pumping head at station 1.

Example C5.8: Incremental Friction Loss

	NPS 20 (DN 500)		NPS 24 (DN 600)	
Nominal pipe size	NPS 20 (DN 500)		NPS 24 (DN 600)	
Pipe diameter, in (mm)	20.0(508.0)		24.0(610.0)	
Wall thickness, in (mm)	0.250(6.4)	0.312(7.9)	0.250(6.4)	0.312(7.9)
Friction loss, ft/mi	44.06	45.43	18.09	18.55
(m/km)	(8.35)	(8.58)	(3.42)	(3.50)
Incremental friction, ft/mi	45.43 − 44.06 = 1.37		18.55 − 18.09 = 0.46	
due to increase of				
wall thickness, (m/km)	8.58 − 8.35 = 0.23		3.50 − 3.42 = 0.08	
Length of pipe, mi (km)	19.3(31)		24.9(40)	
Total incremental friction				
loss, ft(m)	26.4(7.1)		11.5(3.2)	

In cases where the hydraulic gradient crosses deep defiles in the terrain, heavier wall pipe may be required to prevent exceeding the MAOH at these locations. Increased friction loss is determined for these locations similar to this example, or by accumulating the distance and friction loss for each of the selected wall thicknesses.

System Growth and Station Bypass. Many pipeline systems are designed to operate, initially, at a reduced flow rate, with increments added in subsequent years. The design basis for these systems is usually the economic-maximum future flow rate, considering oil characteristics, pipe diameter, wall thickness, and grade of steel.

During the early years of operation, only the stations necessary to transport the initial flow rate are installed. Stations are then added as flow rate is increased until the pipeline is fully developed. Intermediate pumping stations are installed at locations determined from the design for the maximum flow rate. As part of the system design, each station, except the first, is omitted from the system to establish the maximum flow rate possible through the system for that configuration. In other words, each omitted station creates a bottleneck in the system at some maximum flow rate.

Example C5.9. The bypass operating conditions for the NPS 20 (DN 500) and NPS 24 (DN 600) pipeline systems are shown in Fig. C5.10 and C5.11.

The hydraulic gradient bypassing a single station is drawn, and the unit head loss determined, graphically or numerically. Then, using the unit friction-loss graph constructed earlier for the specific crude oil transported in the system, Fig. C5.5, the limiting flow rate is found. In Fig. C5.10, the section between stations 1 and 3 is a bottleneck section that limits the flow rate to 116,800 BPOD (20,800 m³/d.)

Designing for bypassing station 2 in the NPS 20 (DN 500) and NPS 24 (DN 600) systems would use 19 and 24 (nominal) miles (31 and 40 km) of 0.312-in (7.9 mm) wall pipe respectively, as illustrated in Figs. C5.10 and C5.11. Pipe tonnage would be adjusted upward as shown in Tables C5.8 and C5.8M to
FIGURE C5.10 Hydraulic gradient for DN 500 pipeline example, 20,800 m³/d with bypass at stations 2 and 4.
FIGURE C5.11 Example hydraulic gradient for DN 600 pipeline, 18,900 m³/d with bypass at station 2 and profile control point at kilometer 325.

reflect the effect of ground-elevation profile on the mechanical design and cost. Additional heavier wall pipe would be inserted in other locations where the MAOH would lie below the hydraulic gradient to accumulate the appropriate pipe tonnage. Additionally, the increasing wall thickness adds to the friction loss. In this case, the added friction loss would appear at station 1 and increase the pumping power at this station.

Figures C5.9 and C5.11 for the NPS24 (DN 600) pipeline illustrate a hydraulic control point establishing the elevation of the hydraulic gradient out of a station. The elevation added to clear a hydraulic control point adds to the static head difference for pumping. In Fig. C5.9, the added head for the design flow rate shifted the intermediate pump station closer to the hydraulic control point than for a level line. The added head was then moved to station 1 by limiting the discharge head at station 2 to the MAOP of NPS 20 (DN 500) wall pipe.

In this case, 0.312-in (7.9 mm) wall placed at station 1 for the design flow rate is available for increasing flow rate when bypassing station 2. The incremental length of 0.312-in (7.9 mm) wall pipe at station 1 to bypass station 2 is 25 mi (40 km) to utilize the available MAOH of 0.312-in (7.9 mm) wall pipe at station 1, which is illustrated in Fig. C5.11 Placing any length of 0.312-in (7.9 mm) wall pipe at station 2 would not be available for improving the flow rate to bypass station 2.

Depending upon the ground profile and the length of the system, bypassing one station may also allow bypassing other stations and redistributing units of pumping energy among the remaining stations, as illustrated for the NPS 20 (DN 500) system in Fig. C5.10. This same analysis can also be used to establish the logical growth pattern for installation of intermediate stations.

Once the logical growth pattern has been established, and the hydraulic gradients plotted for each stage of growth, it is possible to identify sections of the pipeline where different wall thicknesses, material with higher yield strength, or reductions in line diameter may be economical. When the pipeline system is fully commissioned and operating, this design becomes the operating design for the system when any station is bypassed.

System Curves. The basis for selecting the actual type and size of pump unit(s) at a station is aided by plotting the resistance curve for the section the station must deliver energy to and superimposing it on the characteristic operating, or performance, curve of the pump(s) being considered.

The system-resistance curve is constructed using the unit head loss curve, such as Fig. C5.5. For several flow rates, h_f is multiplied by the distance to the next station, resulting in the friction loss in that section of pipeline for each of the several flow rates. A graph can be constructed this way for a range of operating flow rates. Superimposed on this is the head required to overcome elevation changes between two stations, or the elevation of a critical profile point, plus an allowance for station losses resulting from flow-through fittings, control valves, et cetera. The resulting curve is the system-resistance curve and is concave upward, i.e, the total friction head increases at a faster rate than flow rate increases.

Example C5.10. Figure C5.12 is the system-resistance curve for Station 1 of the NPS 20-(DN 500) diameter example.

A pump unit of a given model and size can deliver a specific quantity of flow at a given discharge pressure or head. Pump manufacturers publish this information in the form of head-capacity curves, otherwise known as pump-performance curves. Performance curves for centrifugal pumps are characteristically concave downward, i.e., delivered head decreases as capacity increases for a given model.
FIGURE C5.12   System curve for Station 1 with example pump-performance curve.

Superimposing a pump-performance curve on the system-resistance curve results in an intersection of the two curves, which is the operating point of the pump units at the station. The configuration of multiple pumps at a station is also considered. For example, pumps in parallel result in increased capacity without a similar increase in head delivered. Pumps in series yield increased head at a given capacity, which is roughly additive.[13,14] Therefore, the net performance curve of the combination of pumps at the station and the combination of pump units that satisfies the required pumping head and power requirements most efficiently are selected for that station.

Nonisothermal Systems[15,16]

Up to this point, the discussion of hydraulic design has focused on isothermal pipeline systems. However, in general, the physical properties of petroleum commodities are temperature dependent, and the significance of temperature change varies with the commodity. Therefore, the true nature of liquid petroleum systems is nonisothermal.

Temperature Profiles.   The basis for nonisothermal hydraulic design is an analysis of the thermal nature of the system, considering variations of external, or environ-

mental, temperature as well as systemic factors, i.e., flow rate and its effects on friction, including heat generated by friction. The analysis of a particular system's hydraulic design is based on an analysis of the temperature profile for the range of operating conditions.

The temperature profile can be calculated by the following equation (holds for any set of consistent units):

$$T(x) = T(a) + [T(0) - T(a)] \times e^{[-(uAx)/(wcv)]} \qquad (C5.10)$$

where $T(x)$ = temperature at distance x along the pipeline, °F (°C)
  $T(a)$ = ambient temperature, °F (°C)
  $T(0)$ = temperature at the initial point, °F (°C)
   u = overall heat transfer coefficient per unit of area, Btu/ (hr-ft-°F) (W/m$^2 \cdot$°C)
   A = pipe surface area per unit of length, ft^2/ft (m^2/m)
   x = distance from initial point, ft (m)
   w = weight of fluid per unit of length, lb$_f$/ft (kg$_f$/m)
   c = specific heat of fluid, Btu/lb$_f \cdot$°F (J/kg$_f \cdot$°C)
   v = velocity of fluid, ft/s (m/s)
   J = joule, N$\cdot$m
   W = watt, J/s

Hydraulic designs for heavier commodities, such as heavy crude oils and residual fuel oils, are influenced largely by the effect of temperature on viscosity and related friction losses. For lighter commodities, such as gasoline and natural gas liquids (NGL), hydraulic friction losses diminish continuously with declining flow rate, but for some heavy commodities, continuing reduction of flow rate may cause an increase in pump-station discharge pressure to overcome the fluid's resistance to motion by increasing viscosity. Hydraulic design for the lighter commodities, although relatively independent of viscosity, is more dependent on vapor pressure, which is also a function of temperature.

In the discussion of isothermal oil systems, Fig. C5.5 illustrated that at constant flow rate, unit friction loss increases with declining temperature, and that at constant temperature, unit friction loss reduces with declining flow rate. In nonisothermal systems, temperature typically decreases at increasing distance from a heating station, increasing the unit friction in the direction of flow, which is illustrated in Fig. C5.13. Generally, total friction loss in a hotoil pipeline decreases with declining flow rate as in isothermal systems. However, for some commodities, friction loss reaches a minimum, then increases at lower flow rates. Figure C5.14 shows that pipeline friction for 113,200 BPD (18,000 m^3/d) lies above the pipeline friction for 150,950 BPD (24,000 m^3/d) at distances greater than 53 mi (85 km), and above 188,700 BPD (30,000 m^3/d) at distances greater than 65 mi (105 km). Figure C5.14 includes the beneficial effect of heat of friction. Friction loss would be greater if heat of friction were ignored.

Heat of Friction.   In a flowing fluid, the pressure dissipated by friction becomes heat. The effect of friction heating generally increases with flow rate, viscosity, insulation, and line length. Heat of friction should be considered at high flow rates to assure that overheating will not occur. Pipeline insulation to reduce heat loss during cold weather may contribute to overheating in summer.

When heat of friction is considered, the limit of cooling while the line is operating can be obtained by adding the temperature offset by heating to the ambient tempera-
FIGURE C5.13 Example temperature profiles for DN 500 hot-oil system, 18-, 24-, and 30-thousand m³/d.

ture. The temperature offset is calculated by solving the heat-flow equation for temperature difference where the heat flow equals the frictional heat generated by a unit length of fluid flowing in the pipe:

$$(T - T_A) = Q/(u \times A) \qquad (C5.11)$$

where Q = unit heat of friction, Btu/ (h · ft) (J/s · m)
u = heat transfer coefficient per unit of area, Btu/ (h · ft² · °F) (W/m² · °C)
A = pipe surface area per unit of length, ft²/ft (m²/m)
T = flowing temperature, °F (°C)
T_A = ambient temperature, °F (°C)
J = joule, N · m
W = watt, J/s

The heat of friction, Q, can be calculated by converting the unit friction loss to heat, and multiplying by the weight of fluid per unit length and velocity in m/sec.
FIGURE C5.14 Example DN 500 pipeline friction versus temperature, 18-, 24-, and 30-thousand cubic meters per day.

For large diameter pipelines and high flow rates, heat generated by friction loss should also be included in the temperature profile, and the following equation results:

$$T(x) = [T(a) + Q/uA] + \{T(a) - [T(a) + Q/uA]\}e^{[-(uAx)/(wcv)]} \quad (C5.12)$$

where Q = heat generated per linear unit of flowing liquid in a unit of time by converting the unit friction loss to thermal units as previously described.

Example C5.11.   Figure C5.13 shows calculated temperature profiles versus distance, including heat of friction, for a 0.976-specific gravity- (976.0 kg$_t$/m^3) density crude oil, flowing between 113,200 BPD (18,000 m^3/d) and 188,700 BPD (30,000 m^3/d) in a NPS 20-(DN 500) diameter pipeline.

Figure C5.14 shows friction loss as a function of the distance from a pumping and heating station, with an initial temperature of 149°F (65°C) to correspond with the temperature profiles of Fig. C5.13.

Thermal-Hydraulic Gradients

For initial hydraulic designs, once the temperature profile is determined, the system can be divided into discrete sections and the thermal-hydraulic gradient calculated for appropriate sections using the average viscosity of the successive sections. Station locations and sizes are then determined in the manner described for the isothermal case.

For a more detailed hydraulic design, it is recognized that the hydraulic gradients of nonisothermal systems are curves of increasing friction loss as a result of cooling, as the distance from the pumping and heating station increases, unless heat of friction is a significant factor, such as in a large diameter line at high flow rates and with a low initial temperature, wherein temperature may actually increase with distance from the station.

Example C5.12. Table C5.4M and Fig. C5.15 illustrate the hydraulic gradients of a pipeline system for 0.976 sg–(976.0 kg$_f$/m^3) density crude oil along the given route, for three flow rates—113,200 BPD (18,000 m^3/d), 150,950 BPD (24,000 m^3/d), and 188,700 BPD (30,000 m^3/d). The discharge temperature at each station is 149°F (65°C), and the ground temperature is 50°F (10°C).

Table C5.4M illustrates the effect of increasing distance between heating stations by comparing the difference in friction loss between Station 1 and the remaining stations as flow-rate increases.

This example illustrates, by comparison with Fig. C5.8, the effect of characteristics between a 0.8701 and 0.976-relative-density (32.6 and 13.5 API gravity) crude oil on the hydraulic, mechanical, and operating designs that differ between an isothermal and nonisothermal system for a given pipeline route.

The hydraulic and mechanical designs of nonisothermal systems are more detailed than systems within the isothermal range at usual ambient temperatures including the additional effects of temperature on stresses and of materials and components for the operating conditions. Mechanical design is discussed in the following section.

Intermediate pumping and pumping and heating stations would be investigated in this example to determine the effect increasing the average flowing temperature would have on reducing average viscosity and the total friction loss, and on establishing the required wall thickness between pumping stations. Further analysis would also include increasing the temperature of the heated crude leaving the stations and insulating the pipeline and analyzing other pipe diameters.

With some commodities such as heavy and waxy crudes, the effect of friction heating can be significant, and it results in a decrease in the energy required for pumping. The decrease in pumping energy is a factor of how much the viscosity decreases by increasing temperature and how sensitive the flow regime is to changes in viscosity, i.e., pressure drop in laminar flow is a stronger function of viscosity than in transition flow and is a relatively insignificant function of viscosity in the fully turbulent flow regime.

Shutdown and Restart. During periods when flow ceases, fluid in the pipeline cools statically without the heat of friction until flow resumes, or the system reaches

TABLE C5.4 Example: Hot Oil System Station Discharge Heads, NPS 20 System

	Unit	Station 1 at origin			Station 2 MP 46.6			Station 3 MP 108.7			Station 4 MP 174.0

the ambient temperature. During static cooling, the temperature may be calculated by

$$T(t) = T(a) + [T(0) - T(a)] \times e^{-(uAt)/(wc)} \qquad (C5.13)$$

where $T(t)$ = temperature at time t, °F (°C)
$T(a)$ = ambient temperature, °F (°C)
$T(0)$ = temperature at the initial point, °F (°C)
t = time from start of static cooling, s
e = base of natural logarithms
u = heat transfer coefficient, Btu/h · ft² · °F (W/m² · °C)
w = weight of fluid per unit length, lb$_f$/ft (kg$_f$/m)
c = specific heat, Btu/lb$_f$ · °F (J/kg$_f$ · °C)

On restart, the viscosity, determined by the local temperature, determines the local friction loss. The restart flow rate and pressure may be determined by dividing the pipeline into segments, then summing the friction losses of the segments. Repeating this process stepwise as sequential segments are displaced with heated oil determines the calculated startup pumping rate and restart time. Waxy crudes may develop a yield stress on cooling, which may require additional pressure to reestablish flow.

Figure C5.14 showed that a flow rate can be reached where friction loss can increase for decreasing flow rates. At lower flow rates, where friction loss increases, the friction loss may increase beyond the head capacity of the pumps or the pressure rating of the pipeline leaving the station. This condition would plug the pipeline

and must be avoided. Methods of preventing plugging a pipeline that cools below the limit of pumpability, either by low flow rate or static cooling include:

- maintaining the flow rate above the temperature at which the viscosity effect increases friction loss
- blending with a lighter oil having a lower pour point (a cutter stock) to reduce the viscosity at lower temperatures
- displacing with a displacement fluid before static cooling
- insulating and heat tracing

Pipelines using the displacement method generally require preheating before refilling the line with the commodity. These systems are preheated by circulating heated displacement fluid until the system is sufficiently warm to accept the heated commodity and allow time to redisplace if a false start should occur during the refill and restart operation.

MECHANICAL DESIGN

Mechanical design of a pipeline system is the selection of materials, including type of steel and diameter and wall thickness of pipe. Selected also are methods of support and restraint for the system in response to the loadings and stresses imposed on the pipeline system by physical pressures and forces such as the internal and external design pressures; static loadings and weight effects of the pipe, fluid, and soil; dynamic loadings from wind, waves, earthquake, and other natural forces; and relative motion of connected components. These factors impose loadings on the pipe and result in longitudinal, hoop, and radial stresses which must be evaluated in the mechanical design of the piping system.

In addition to the mechanical factors that affect the allowable stress levels for design, the grade of steel and wall thickness determine welding procedures and affect construction cost. Section 434.8 of the Code prescribes the requirements for welding. Section 434.8.3 specifies welding qualifications with reference to API 1104 and Sec. IX of the ASME Boiler and Pressure Vessel Code. The engineer should refer to these references for welding requirements that may determine the maximum diameter, wall thickness, or grade steel for the system on the basis of cost.

The mechanical design of the pipeline, with respect to restraint against longitudinal, or axial, and radial motions, considers the pipeline as a unit and must provide sufficient flexibility in the system to ensure that expansion or contraction, as a result of the internal or external loadings, do not cause excessive stresses in the piping material, bending moments at joints, or excessive forces or moments at points of connection to equipment or at supports.

Mechanical piping-system design primarily utilizes computer programs, many of which operate on personal computers. In most cases, the code requirements are built into the programs, so for a set of internal pressures and external loadings, the program will give the optimum wall thickness, pump locations, and maximum stress values on the basis of parameters input by the engineer. However, this does not preclude the possibility of error. The engineer must be able to determine accurately the required loadings and pressure and to analyze the computer results, verifying their validity to the overall system.

Line Pipe, Fittings, and Valves

Specifications for line pipe and for fittings, valves, and flanges are given in various API, ANSI, and ASME standards and specifications including:

- ANSI/ASME B36.10M, Welded and Seamless Steel Pipe
- ANSI/ASME B36.19M, Stainless Steel Pipe
- API 5L, 5LU, Line Pipe
- ANSI B16.5, B16.9, B16.10, B16.11, B16.25, B16.28, Flanges, Fittings, Valves
- API 6D Pipeline Valves, Gate, Plug, Ball, and Check Valves
- API 600, 602, 603, Valves

Additional information on components of piping can be found in Chap. A2, Piping Components. Chapter A10 deals with selection and application of valves.

Line pipe is manufactured by several methods, the most common being seamless (SMLS), electric resistance welded (ERW), and submerged arc welded (SAW) in the form of longitudinal and helical (spiral) welds. Table C5.5 summarizes some of the characteristics for these four types of pipe manufacture. Each has advantages and disadvantages for different uses, and there are also economic and availability considerations which enter into the decision on the type specified and supplied on a particular project.

With respect to the mechanical design of a pipeline, the characteristic of line pipe which is of critical interest is the specified minimum yield strength (SMYS) of the material. API 5L, Specifications for Line Pipe, is available in various strength grades, ranging from Grade B, rated at 35,000 psi (241 MPa) to Grade X80, rated at 80,000 psi (551 MPa), where the Grade X80 refers to the SMYS in ksi, which is defined as kips per square inch, a kip being 1,000 pounds.

There is some advantage to the higher strength grades, principally that wall thickness may be reduced. In some cases this may have an economic impact on the project, as thinner walls translate into lower steel tonnage for the entire pipeline system, and this may be a significant factor, even though higher grades of pipe cost more per ton. Cost savings can also result from reduced time required to field weld the thinner wall sections. There are other considerations which will affect the decision to use higher strength, thinner wall pipe. These include aspects of construction which are the result of experience in the field, such as the way the pipe handles with regard to field bending, laying stresses, tendency to go *out of round*, et cetera. In addition, there may be limitations placed on the grade of pipe and wall thickness used for a particular project, particularly for a system which will be in *sour* or corrosive service.

Valves, pipe flanges, and fittings are described by class ratings, which are not the same as the rated pressure for a particular class. For example, API 6D, Specification for Pipeline Valves, Class 300 (PN 50) valves, standard flanged end and standard weld end, have a nominal pressure rating of 720 psig at −20 to 100 F° (−29 to 38°C), not 300 psig (91.2MPa). Metric designations, PN for nominal pressure and DN for nominal pipe size replace class and nominal pipe diameter respectively. Refer to Chaps. A1 and A10.

However, API 6D, App. B, states that English units are preferred and are the standard. Section 402.2.1 of the Code specifies for pressure-temperature ratings of piping components as follows: "Within the metal temperature limits of −20°F (−30°C) to 250°F (120°C), pressure ratings for components shall conform to those stated for 100°F (40°C) in material standards listed in Table 423.1."

TABLE C5.5 Availability and Usage for Types of Line Pipe

	Seamless	ERW	SAW, longitudinal welds	SAW, helical (spiral) welds
Minimum diameter	2.375 in (DN 60) or less.	2.375 in (DN 60) or less.	NPS 16 to 20 (DN 400 to 500).	NPS 16 (DN 400).
Maximum diameter	NPS 16 to 26 possible. (DN 40 to 650 possible.)	NPS 24 to 26 possible. (DN 600 to 650 possible.)	64 to 84 in. (DN 1,600 to DN 2,100.)	80 to 100 + in. (DN 2,000 to DN 2,500.)
Maximum wall thickness	0.75 to 2.00 in (19.1 to 51 mm).	0.312 to 0.750 in (7.9 to 19.1 mm).	0.625 to 1.500 in (15.9 to 38.1 mm).	0.500 to 1.500 in (12.7 to 38.1 mm).
Grades	B through X-80. Grades X-60 and higher are heat treated.	B through X-70. X-52 and higher are made from controlled rolled skelp.	B through X-80. X-52 and higher are made from controlled rolled plate.	B through X-70. X-52 and higher are made from controlled rolled skelp.
Service	All services: on and off shore.	All services: generally not used for offshore.	All services: on and offshore.	Experience limited to less critical service; used as equivalent to SAW in other countries.
Relative cost	More expensive than ERW. Cost premium for larger diameters/wall thickness, higher grades.	Less expensive than seamless.	Less expensive than seamless, more than ERW (within size overlap range).	May be less expensive than SAW (depends on manufacturer).

TABLE C5.6   Pressure Ratings of Valves

	Class					
	150	300	400	600	900	1500
Temperature °F	Pressure rating, psig					
−20 to 100	275	720	960	1440	2160	3600
150	270	705	940	1415	2120	3540
200	260	675	900	1350	2025	3375
250	255	665	885	1330	1995	3325

Interpolation is permitted for intermediate temperatures.

TABLE C5.6M   Pressure Ratings of Valves

Class (PN)	150 20	300 50	400 68	600 100	900 150	1500 250	2500 420
Temperature °C	Rating, bar						
−29 to 38	19.0	49.6	66.2	99.3	149	248	414
50	18.8	49.2	65.6	98.5	148	246	411
66	18.6	48.6	64.8	97.6	146	244	407
75	18.4	47.9	63.9	96.0	144	240	400
93	17.9	46.5	62.1	93.1	140	233	388
100	17.7	46.4	61.8	92.7	139	232	387
121	16.9	45.9	61.0	91.7	138	229	382

For temperatures below −29°C the rating shall be not greater than rating for −29°C.

Few pipelines now in operation utilize fittings heavier than Class 600 (PN 100), rated at 1,440 psig (9,930 kPa), although the trend is toward higher pressure ratings. Deep-water subsea pipelines which have heavier wall thickness due to laying stresses and high external pressures may have fittings and flanges rated at Class 1,500 (PN 250), rated at 3,600 psi (24,000kPa). Tables C5.6 and C5.6M list maximum operating temperatures and pressures for standard flanged-end and standard weld-end valves by nominal pressure rating, Class (PN), from API 6D, App. B, Table B2.1.

Allowable Pipe Stress

Paragraph 402.3.1 of the Code establishes the allowable stress value, S_A in psi (MPa), to be used in the temperature range −20°F to 250°F (−30°C to 120°C) for design calculations:

$$S_A = \text{design factor} \times \text{SMYS} \times \text{joint weld factor} \qquad \text{(C5.14)}$$

Paragraph 402.3.1 describes application of Eq. C5-11 for allowable stress values of S_A depending on new, used, or reclaimed straight pipe of known or unknown specification. Sub paragraphs 402.3.1 (a) through 402.3.1 (d) are summarized below.

Reference paragraph	Application for straight pipe	Formulations and reference paragraphs
402.3.1(a)	New pipe of known specification	$S_A = 0.72 \times E \times$ SMYS psi(MPa) where E = joint factor, Table 402.3.1(a).
402.3.1(b)	Used or reclaimed pipe of known specification	$S_A = 0.72 \times E \times$ SMYS psi(MPa) in accordance with paragraph 405.2.1(b), Table 423.1, and limitations in paragraphs 437.4.1, 437.6.1, 437.6.3, and 437.6.4.
402.3.1(c)	New, used, or reclaimed pipe of unknown or ASTM A 120 specification	$S_A = 0.72 \times E \times$ minimum yield strength of pipe, psi (MPa) [24,000 psi (165 Mpa) or yield strength determined in accordance with paragraphs 437.6.6 and 437.6.7], and limitations in paragraph 405.2.1(c).
402.3.1(d)	Pipe cold worked in order to meet specified minimum yield strength and subsequently heated to 600°F (300°C) or more except welding.	$S_A = 75\%$ of applicable allowable stress value as determined by paragraphs 402.3.1(a), (b), or (c) for design calculations of wall thickness in paragraph 404.1.2 (see Eqs. C5.12 and C5.12M).

Table 402.3.1(a) of the Code tabulates allowable stress values for various grades of material specifications and manufacturing processes.

Specified minimum yield strength of a pipe material is used as the basis of design because it is a property which can be determined for a specific material. Furthermore, steel generally behaves elastically below this stress level. Ultimate yield strength has also been used as the basis for design and may still be used in other countries.

A particular batch of steel line pipe may be tested and determined that its elastic yield strength is higher than the nominal value; however, Section 402.3.1 (g) of the Code specifies, "In no case where the Code refers to the specified minimum value of a physical property shall a higher value of the property be used in establishing the allowable stress value."

Table 402.3.1 (a) also includes the joint weld factor E in calculating allowable stress as a consideration to the way the line pipe is manufactured. In most cases, the joint weld factor is 1.00, but it may be 0.80 or 0.60 for specific grades of steel and welding method of the manufacturing process.

It is useful at this point to clarify a question that arises periodically as to whether the mechanical stress calculations are based on a particular design temperature, i.e., if S_A is temperature dependent. Section 401.3.1 of the Code states "it is not necessary to vary allowable design stress for metal temperatures between $-20°F$ ($-30°C$) and $250°F$ ($120°C$)." However, for applications where ground or air temperature is expected to be extremely low, seasonally or locally, the properties of pipe-component materials at low temperatures should be considered to verify that the design will be adequate.

Allowable stress limits for shear and bearing are given in Sec. 402.3.1(e) of the Code. For shear, S_A shall not exceed 45 percent of SMYS; for bearing, S_A is limited to 90 percent of SMYS. Limits on calculated stresses due to sustained loads and thermal expansion and due to occasional loads in operation and test conditions are specified in Sec. 402.3.2 and 402.3.3 of the Code. In general, these limits fall within the definition of allowable stress given previously; however, special circumstances may apply, and the engineer is encouraged to verify the stresses and relevant limitations.

Pipe Diameter

In the hydraulic design of a pipeline system, line size is initially based on a preliminary choice of diameter and wall thickness from experience and from simplified charts. Further calculations are needed to verify the selection and finalize the system design based on the Code requirements as well as on considerations for project cost and material availability.

For most pipeline systems, the pipe cost, which is based on the diameter and wall thickness, will be the highest material cost in the system. In addition, the size of pipe will have a direct effect on the cost of installation. Therefore, total project cost is impacted by the selection of pipe size. For this reason, it is important to optimize the pipe diameter, wall thickness, and grade of steel to be used so that the overall project cost is contained.

As discussed earlier in the hydraulic-design section of this chapter, the diameter of pipe is based on the design flow rate, and mechanical-design considerations have little effect on diameter selection. However, internal and external pressure, allowable stress, and other considerations do affect the final design of the wall thickness for the selected diameter.

Wall Thickness

In the hydraulic design, a preliminary determination of wall thickness is based on experience for the preliminary selection of pipe diameter and grade of steel. The actual design of a system must reflect Code requirements for the wall thickness,

which is based on internal design pressure and additional loads at the design temperature.

Internal Design Pressure.   By definition, Sect. 401.2.2 of the Code prescribes the following:

> The piping component at any point in the piping system shall be designed for an internal design pressure which shall not be less than the maximum steady state operating pressure at that point, or less than the static head pressure at that point with the line in a static condition. The maximum steady state operating pressure shall be the sum of the static head pressure, pressure required to overcome friction losses, and any required back pressure. Credit may be given for hydrostatic external pressure, in the appropriate manner, in modifying the internal design pressure for use in calculations involving the pressure design of a piping component (see Para. 404.1.3). Pressure rise above maximum steady state operating pressure due to surges and other variations from normal operations is allowed in accordance with para. 402.2.4.

The earlier discussion of MAOP in the hydraulic design defined it as a function of diameter, wall thickness, and allowable stress for a material, per Code restrictions. Section 402.2.4 of the Code provides for an additional allowance of 10 percent over the internal design pressure for surges and other variations from the normal operation.

Additional Loads.   Additional loads for determining wall thickness include loadings applied on a pipeline system from pipeline material and commodity weight, wind, hydrostatic, and other external forces such as impact loads. In some applications, external pressure may be a significant factor in pipeline wall thickness determination. One such example is a subsea pipeline. Section 401.2.3 of the Code specifies that a component of the pipeline system shall be designed to withstand the maximum differential between external and internal design pressures.

Wall Thickness Calculation.   Minimum wall thickness, t, is a function of internal pressure, P_i, nominal diameter, D, and the allowable stress, S_A, as specified by Sec. 404.1.2 of the Code by solving Eq. C5-4 for wall thickness. Refer to Eq. C5.4 for determination using various pressure units.

$$t = P_i \, D/(2 \, S_A) \text{ English units} \qquad\qquad (\text{C5.15})$$

$$P_i, \text{ psig}, \; D \text{ and } t, \text{ in}$$

$$t = P_i \, D/(20 \, S_A) \text{ metric units} \qquad\qquad (\text{C5.15M})$$

$$P_i \text{ gauge pressure, bar, } D \text{ and } t, \text{ mm}$$

Nominal wall thickness, t_n, includes an allowance for manufacturing tolerance.

$$t_n = t + \text{allowance}(s) \qquad\qquad (\text{C5.16})$$

The actual wall thickness used in the system will be equal to or greater than this calculated value. API 5L, Specifications for Line Pipe, Table 6.2, lists commonly manufactured wall thickness for various grades of materials.

With respect to construction and installation of a pipeline, there is also a practical minimum wall thickness, based on handling during installation, as the pipe wall must be able to resist damage and maintain roundness during construction. Good

judgement should be used in balancing higher strength steel materials versus heavier wall thickness.

It is not a requirement that wall thickness be constant for the entire length of the system. Specific sections of the system may have different wall-thickness requirements as determined by the internal pressure and other imposed stresses, and making use of the hydraulic gradient developed in the hydraulic design. Thinner wall may be installed at some distance downstream of pumping stations as the operating pressure in the system declines. There are economic benefits to utilizing the minimum wall thickness allowed under Code design; however, there are other considerations, such as complications in construction, i.e., field welding, of a system with frequent variations in wall thickness. Practically speaking, changes in wall thickness should be limited. Furthermore, anticipated growth or expansion of the system capacity should be considered carefully.

Design of Restrained and Unrestrained Pipelines

A pipeline system is subjected to static and dynamic loads due to local environmental and operating conditions, and provision must be made for the system to have flexibility and expansion capability to prevent excessive stresses in the pipe or components, excessive bending or unusual loads at joints, or undesirable forces or moments at points of connection to equipment. The types of loadings which will affect the flexibility and expansion of the pipeline as a system include:

- Thermal expansion and contraction
- Internal pressure
- Fluid expansion
- Pipe and soil–friction interaction
- External pressure
- Bending (sag or uplift) due to

   Dead Loads, including weight of the pipe, coatings, backfill, and unsupported pipe appurtenances

   Live Loads such as liquid transported, wind, snow, earthquake, waves, or currents

The stresses that may develop in the pipe are functions of both the loadings on the pipeline system and the degree of restraint against motion of or in the pipeline system or a section of the system. Stresses may be reduced to acceptable levels by a combination of anchors; extra depth of burial of piping; use of bends, loops, or offsets in the piping; heavier wall-piping components; or other interventions. The reader is referred to Chap. B4, Stress Analysis of Piping Systems, and Chap. B5, Piping Supports, for additional information on stress and supports.

Long, cross-country pipelines are generally buried for the following reasons:

1. Surface use of pipeline corridor
2. Protection from intentional or accidental damage
3. Protection against expansion and contraction from ambient-temperature changes and radiant-energy gains and losses
4. Minimizes variations of ambient temperature and resultant effects on fluid viscosity

5. Provides restraint longitudinally along pipeline length

6. Regulations restrict aboveground installation

Although a buried pipeline can be considered restrained against expansion or contraction radially and longitudinally as a result of the overburden of soil and soil-pipe friction, expansion calculations are necessary, per Sec. 419.6.4 (b) of the Code, if significant temperature changes are expected, as in a heated oil system. Furthermore, thermal expansion of buried lines may cause movement at a transition to an aboveground section and at the termination points of the pipeline or a section of line. There may also be movement where the buried line changes direction, i.e., when there is insufficient soil restraint, therefore either the system should be designed with adequate flexibility in these areas or anchors against motion should be provided.

Pipeline systems may be partially or wholly installed aboveground for reasons of economy of construction, maintenance, et cetera. Likewise, installation on the surface may be practical for pipelines requiring insulation or heat tracing. An aboveground pipeline can be designed with longitudinal restraints at certain support locations such that expansion or contraction due to temperature or pressure changes is absorbed by axial, or longitudinal, compression or tension stress, in addition to radial expansion. The additional consideration in aboveground pipeline systems is that beam-bending stresses in spans between and at supports must be evaluated.

Thermal Expansion and Contraction.   Thermal expansion and contraction calculations are necessary for buried and aboveground systems if a substantial temperature change is expected between installation and operation, such as when the line is to carry a hot oil, or where significant variations in local environmental temperatures will occur. Thermal expansion may cause movement where the line changes direction or terminates or where a discontinuity occurs, such as a change in size. In some pipeline systems, these motions may not be restrained by anchors or supports, i.e., absorbed by direct axial stress of the pipe, in which case flexibility must be provided using loops, bends, or expansion joints.

The total maximum range of temperature is used to determine thermal expansion, with the linear coefficient of thermal expansion, α, for carbon and low alloy high tensile steel being 6.5×10^{-6} in/in °F (11.7×10^{-6} mm/mm °C) up to 250°F (120°C). For a section of pipe restrained at both ends, longitudinal stress, $S_{L/T}$, due to a temperature change, ΔT, is given by

$$S_{L/T}, \text{ psi (MPa)} = \text{E}\, \alpha\, \Delta T \qquad \text{(C5.17)}$$

where E is the modulus of elasticity for steel 30×10^6 psi (2×10^5 MPa). An increase in temperature results in a compressive longitudinal stress, and vice versa. The general convention is that tensile stress is positive and compressive stress is negative.

Internal Pressure.   Internal pressure imposes a radial and longitudinal component of stress in the pipe material. The hoop stress, which is in the radial direction due to internal pressure, was discussed earlier in Eq. C5.4. In a free, or unrestrained, section of pipe material, or pipeline system, as internal pressure increases, the length of a section will decrease due to the Poisson effect.

Restrained systems will develop a component of longitudinal stress as a result of the internal pressure, $S_{L/IP}$, given by

$$S_{L/IP} = v \, S_H \quad \text{psi (MPa)}$$
$$= v \, P_I \, D/2 \, t \tag{C5.18}$$

where v = Poisson's ratio, 0.30 for carbon steel

This is generally a tensile (positive) stress in the longitudinal direction. For most liquid lines, maximum internal pressure will most likely occur during the hydrostatic test prior to operation.

Fluid Expansion. The expansion of the fluid in a liquid pipeline due to increase in temperature will impose an additional component of pressure which will have both a radial and a longitudinal component, resulting in stress in the pipe material. This stress, $S_{L/E}$, is calculated in the same manner as the stresses from internal pressure after conversion of the expansion of the fluid to equivalent pressure terms.

Pipe and Soil–Friction Interaction. The combined longitudinal effects of temperature, pressure, and expansion of the fluid can cause significant stresses in long sections of pipe. For buried pipelines, the interaction of the pipe material and the soil will have an opposing friction effect, with the maximum stress due to soil friction occurring at the midlength of the section. The friction stress is calculated as follows, with any set of consistent units:[17]

$$S_{L/F} = L \times H \times \rho \times \sigma/(2t) \tag{C5.19}$$

where L = length of pipe section, ft (m)
H = depth of cover above the pipe, ft (mm)
ρ = unit weight of the soil cover, lb_f/ft^3 (kg_f/m^3)
σ = coefficient of friction between pipe and soil
t = wall thickness, in (mm)

External Pressure. For sections of pipe laid underwater, external hydrostatic pressure needs to be considered in the stress analysis. The hoop and longitudinal stresses resulting from hydrostatic pressure are calculated in the same way as the internal pressure stresses are calculated and are opposite in sign. A similar condition arises when thin-walled pipe is drained and a vacuum is produced inside the pipe.

The critical collapse pressure, P_{cr}, for round thin-walled pipe with a diameter-to-wall thickness is calculated by the equation:[18]

$$P_{cr} = 2 \times E \times (t/D)^3/(1 - v^2) \tag{C5.20}$$

where E = modulus of elasticity, 30×10^6 psi $(2 \times 10^5$ MPa)
v = Poisson's ratio, 0.3

Eq. C5.20 assumes the stress is within the elastic range and the ratio of length to radius is greater than 20. If the pipe section is out-of-round, the resistance to collapse is reduced by flattening. Stiffening rings or heavier wall pipe may be used to prevent or limit collapse due to external pressure. Collapse of buried pipe can also be controlled by careful preparation of the bedding and compaction of the backfill around the pipe. Additional detail is beyond the purpose here, and the

reader should refer to appropriate references or specialists where collapse by external pressure is a concern.

Considering all the longitudinal components of stress discussed to this point, the net longitudinal stress, S_L, imposed on a restrained pipeline due to the combined effects of internal pressure, external pressure, temperature, fluid expansion, and soil and pipe friction is the algebraic sum of Eqs. C5.14, C5.15, and C5.16, where tensile stress is the positive convention:

$$S_L = S_{L/IP} + S_{L/EP} S_{L/T} + S_{L/E} + S_{L/F} \qquad \text{(C5.21)}$$

where S_L = net longitudinal stress, psi (MPa)
$\quad S_{L/IP}$ = internal pressure, psi (MPa)
$\quad S_{L/EP}$ = external pressure, psi (MPa)
$\quad S_{L/T}$ = thermal expansion/contraction, psi (MPa)
$\quad S_{L/E}$ = fluid expansion, psi (MPa)
$\quad S_{L/F}$ = pipe/soil friction, psi (MPa)

The net longitudinal stress is generally tensile, as the internal-pressure and fluid-expansion components are tensile, countered by the compressive temperature component and by the soil and friction interaction in buried pipeline systems; the external hydrostatic pressure component is only applicable to deepwater crossings. Concentrated loadings at highway and railroad crossings require special consideration and may require casing. Refer to Sec. 434.13.4 of the Code.

It is important to note that in an axially restrained line, if the increase in temperature between placement of the line and operation is great enough, the compressive stress from the restraint to pipe ''growth'' by thermal expansion from Eq. C5.17 will exceed the tensile stress due to internal pressure.

The numerical sum of the longitudinal stress and the hoop stress is called the equivalent tensile stress. In the case where net S_L is negative, i.e., compressive, then the absolute values are used for pipe stresses, and the equivalent tensile stress is the sum of the absolute value of S_H and S_L. Section 419.6.4(b) of the Code specifies that the equivalent tensile stress for restrained lines is not to exceed 90 percent of the SMYS calculated for the nominal pipe wall thickness. Stresses may be reduced by burial, anchors, heavier pipe wall components, or expansion provisions such as loops, offsets, or bends. The following section discusses the beam-bending stresses which are included in longitudinal stress calculations for aboveground portions of restrained as well as unrestrained lines.

Bending or Beam Stresses.   For most cases, welded pipelines are very stiff longitudinally and make good beams capable of sustaining typical loadings from the weight of the pipe itself, the commodity within, and any coatings applied. However, a bending-stress analysis is a standard part of pipeline system design, in particular aboveground sections, and is generally carried out by an expert, using one of several computer programs available.

When considering the structural nature of a pipeline system, one of two types of *beam* or structural models can be assumed. A buried pipeline or section of a longer pipeline system can be considered continuously supported as long as the bedding it is laid on is uniform. Even if not perfectly uniform, the stiffness of the pipe will allow reasonable spans across low or soft areas in the soil bedding or rock protrusions.[19]

An aboveground pipeline system and a buried pipeline system with nonuniform bedding can be modeled as a continuous beam system with multiple supports. At each support there will be reactions to the loadings on the pipeline due to pipe

material, commodity, and coating weights, as well as loadings from environmental factors such as snow, earthquake, and wind.

Beam-bending stresses resulting from sagging (deflection) are included in the analysis of maximum stresses. This means evaluating the pipeline for different loading cases and combinations of loadings. Section 419.6 of the Code provides for the possibility for bending moments in the plane of the pipe (M_i); transverse to the plane (M_o); and torsionally, i.e., about the axis of the pipe (M_t); with the resultant stress due to expansion from bending for unrestrained pipelines in the expansion stress as follows:

$$S_E = \sqrt{S_b^2 + 4 \times S_t^2} \tag{C5.22}$$

where S_E = stress due to expansion
　　S_b = equivalent bending stress, psi (MPa)
　　$S_b = \sqrt{(i_i \times M_i)^2 + (i_o \times M_o)^2}/Z$
　　S_t = torsional stress, psi (MPa)
　　　 = $M_t/2 \times Z$
　　i_i = stress intensification factor (in-plane)
　　i_o = stress intensification factor (transverse)
　　Z = section modulus of pipe, in³ (mm³)

For straight pipe, the stress intensification factors (in-plane and transverse) have a value of 1, therefore the S_b component reduces to the flexure formula ($S_b = M/Z$). Stress intensification factors for elbow, miter bends and tee sections of pipe can be found in Fig. 419.6.4© in the ASME B31.4 Code. This figure also includes a correction of pressure (Note 7) to be applied to large-diameter, thin-walled pipe fittings, as pressure can significantly affect the stress intensification and flexibility of these components.[1]

Code Stress Limits.[1]　Sections 402.3.2 and 402.3.3 of the Code specify that the calculated stresses due to sustained loads, thermal expansion, and occasional loads are to be limited by:

- Internal pressure stresses—not to exceed S_A as discussed in the Code paragraph 402.3 (see Sec. 4.2 of this chapter).

- External pressure stresses—considered within bounds where the minimum wall thickness has been calculated based on the code formulas.

- Expansion stresses—allowable stress, S_A, values for the equivalent tensile stress for restrained lines is not to exceed 90 percent of SMYS; for unrestrained lines, it shall not exceed 72 percent of SMYS.

- Additive longitudinal stresses—the sum of longitudinal stresses due to pressure, weight, and other external sustained loadings shall not exceed 75 percent of S_A calculated for the expansion cases stated above.

- Additive circumferential stresses—the sum of circumferential stresses due to internal design pressure and external loads is not to exceed allowable stress calculated for internal pressure.

- Longitudinal stresses from occasional loads—the sum of the longitudinal stresses produced by pressure, live and dead loads, and occasional loads such as wind or earthquake (not considered concurrently), shall not exceed 80 percent of SMYS.

Pump Selection

The concept of pump curves and preliminary pump selection was discussed earlier. Expanding on that discussion, it is assumed that the hydraulic and pipe design are essentially complete. The next step is to choose the pumps and drivers. The first decision is what type of driver—diesel, turbine, or electric. This is primarily an economic decision influenced by the availability of fuel and cost of electric power. When electric power is readily available, electric motors provide simple operation, low cost, and low maintenance; where natural gas or other unrefined fuels are available, gas turbines may give low fuel costs; and occasionally a steam turbine or some combination of machines proves the best choice. It may even be possible to draw off commodity from the system, to fuel the pump drivers themselves, for example, with a diesel transport system.

Pumping power requirements for the entire system can be calculated using the following formula, where H_T and P_T refer to the total system head and pressure requirements:

$$\text{Power, hp} = \text{Flow, BPOD} \times H_T, \text{ ft} \times \text{sg}/(136{,}000 \times \text{eff}) \tag{C5.23}$$

$$= \text{Flow, GPM} \times P_T, \text{ psi}/(1{,}714 \times \text{eff}) \tag{C5.24}$$

$$\text{power, kW} = \text{Flow, m}^3/d \times H_T, \text{ m} \times \text{rd}/(8{,}810 \times \text{eff}) \tag{C5.25M}$$

Pump efficiency in percent typically ranges from 70 to 80 percent for centrifugal pumps to 90 percent for reciprocating pumps. Determination of pumping power for individual stations and pumps is similar, using the head or pressure required for the downstream section between one station and the next. As motor power is provided in standardized increments, the power provided by the motor will exceed the required pumping power.

Example. In the example for the NPS 20 (DN 500) pipeline, assuming 82 percent efficiency for the pumps, the required system operating power at the design temperature is:

$$\text{power, hp} = 188{,}700, \text{ BPOD} \times 10{,}984, \text{ ft} \times .8701, \text{ sg}/(136{,}000 \times .82)$$

$$= 16{,}200 \text{ (rounded)}$$

$$\text{power kW} = 30{,}000, \text{ m}^3/d \times 3{,}450, \text{ m} \times 0.8701, \text{ rd}/(8{,}810 \times 0.82)$$

$$= 12{,}460 \text{ (rounded)}$$

Specification for the main line pumps should stress performance, efficiency and ease of maintenance, because over the life of a pipeline, the cost of fuel and power will be the major operating or annual expense. Therefore, a percent or two in pump or driver efficiency has a major impact. Consideration should also be given to variable speed contrifugal pumps, on the basis of economics, in order to satisfy varying flow and pressure or head requirements over the life of a pipeline system. It may be that the added cost of a variable speed pumping unit is favorable versus controlling station discharge pressure by throttling.

Valve Spacing

The location and spacing of section block valves along an oil pipeline is a matter of design procedure and may be dependent on factors such as the terrain that the

pipeline is crossing. In general, valves should be installed at locations where they will contribute to the safe operation of the line and enhance the safety of the system. Section 434.15.2 of the Code provides the details for these considerations.

Typically, valves are installed at the origin and termination of a pipeline and at branch points to provide isolation of a section and to facilitate hydrostatic testing, i.e., anywhere that the test pressure is differentiated such as sections of higher operating pressure or a change in wall thickness. Section block valves should be located in easily accessible positions, e.g., aboveground on a buried pipeline or in an impervious pit where the groundwater level is high.

OPERATIONS AND MAINTENANCE DESIGN

Operating Conditions

The operating conditions for a pipeline system are defined by the operator of the system and are part of the design basis. Many of the design decisions are directly related to the operating philosophy of the system, both in an intermediate stage, as with a phased or growth system, and in the final system. For example, if the pipeline will be transporting a hot oil, it is critical that the system not be underdesigned, i.e., that the operating temperature be reasonably set, thereby leading to a viable design of the pumping and heating station requirements. Maintenance aspects of the system will also influence the design with regard to location of facilities (near fuel or power sources) and spacing of stations for cleaning facilities (pigging). The aspect of operator training and required level of supervision to monitor and verify the function of the pipeline system may dictate the location of controls and instrumentation readout panels, spacing of head operator and control function locations, and required personnel to operate the facilities.

The following sections discuss some of the specific operation and maintenance considerations for liquid pipeline design.

Surge

An important consideration in the design of liquid pipelines is surge, also known as water hammer. It is comprised of the pressure wave and reflected wave which travel through the fluid up and down a length of pipe when the velocity of the flowing column of fluid is altered or stopped suddenly. For example, water flowing at 10 ft/s (3 m/s) can generate a surge pressure of 500 psi (3400 kPa).

If a valve is closed against a flowing stream or if the velocity of the stream is slowed, as when a pump station is stopped, the kinetic energy of flow is converted to pressure energy and a positive wave is sent upstream at the velocity of sound in the medium:

$$V_s = \sqrt{\frac{BK/\rho}{1 + (KdC)/(Et)}} \tag{C5.26}$$

where V_s = speed of sound through commodity, ft/s (m/s)
B = 4,637 in^2/ft.s^2 for Eng units (1.0 for metric units)
K = bulk modulus of liquid,[8,10] psi (kPa)

ρ = density of liquid, lb_m/ft^3 (kg/m^3)
d = inside diameter of pipe, in (mm)
E = modulus of elasticity, psi (kPa)
t = wall thickness, in (mm)
C = constant of pipe fixity (0.91 for an axially restrained line, 0.95 for unrestrained)

In the case of a main-line block valve closing instantaneously some distance downstream of a pump station, flow is stopped in the vicinity of the valve but continues to flow from the pump station. The continued pumping packs the line section between the pump and the valve. The surge wave beginning at the valve travels up the hydraulic gradient reaching the pump several seconds later, raising the discharge pressure high enough to reach the shutoff head or setpoint of the pump, causing the discharge check valve to close. This closed valve reflects the wave back toward the valve, reinforcing the incoming wave and resulting in line pressure much higher than normal. This case is exaggerated as instantaneous, while in reality valve closure is not. However, in a real situation such as described, the effect is measurable and can be dramatic.

The surge wave travels upstream and is reflected downstream, oscillating back and forth until its energy is dissipated in pipe wall friction. The amplitude of the surge wave, or the magnitude of the pressure surge, P_{surge}, is a function of the change in velocity and the steepness of the wave front and is the inverse of the time it took to generate the wave:

$$P_{surge} = B v_s \rho \Delta V \qquad \text{for } T < 2L/v_s \qquad \text{(C5.27)}$$

where P_{surge} = pressure, psig (kPa)
$\quad$ B = 2.157E–04 for Eng units; (1.0 E–03 for SI units;)
$\quad$ v_S = speed of sound through commodity, f/s (m/s)
$\quad$ ρ = density of liquid, lb_m/ft^3 (kg_m/m^3)
$\quad$ ΔV = total change in velocity of fluid, ft/s (m/s)
$\quad$ $2L/v_S$ = propagation time, s
$\quad$ T = valve closing time, s
$\quad$ L = distance from inception, ft (m)

This is only an approximation of the surge pressure magnitude for cases limited by the stated time of closure criteria.

Computer programs are utilized to give specific and accurate analysis of the maximum surge pressure, location of critical points in the system, and other factors.

The surges are attenuated by friction, and the surge arriving at any point on the line is less than at the origin of the surge wave. Nevertheless, when flow velocity is high and stoppage is complete, or when a pump station is bypassed suddenly, the surge energy generated can produce pressures high enough to burst pipe, sometimes at points distant from the point of origin of the event.

Another case of surge is when a pump station is shut down suddenly, as in a power failure at an electrically powered station, causing the station to be bypassed automatically. This produces a drastic change in velocity of the flow but not a complete stoppage. As in any other surge, a pressure wave is sent upstream and a refraction wave is sent back downstream from some point in the system where there is sufficient discontinuity to permit total or partial reflection of the wave, i.e., a valve, or major bend in the pipe. The positive surge wave, traveling upstream, reaches the next upstream station, raising both its discharge and suction pressure (with the wave effectively passing counter to flow through the pump since the check

valve does not close). It is possible that this situation may shut down the upstream station on high discharge pressure, thereby starting a new surge wave which effectively adds to the first. This pyramiding of surges can travel hundreds of miles knocking down pump station after station in domino style and producing higher and higher pressures upstream. In the downstream direction, the negative wave may shut down stations downstream of the event by starving their suction pressure.

Severe surge problems can be mitigated through the use of quick-acting relief valves, tanks, and gas-filled surge bottles. These facilities tend to be expensive single-purpose devices which are seldom needed and are often inadequately maintained by operators. An inexpensive feature of modern computer-based control systems is the *permissive* circuit, which can be rigged so that the system cannot be operated at a rate above an intrinsically safe level unless all outside parameters are satisfied. The loss of a signal saying for example, that a given station is operating will cause other stations, set points to be backed off to a level consistent with any surge situation.

Design for the control of surges requires a thorough understanding of the particular pipe, pump, valve, and tank systems and their instrumentation. Therefore the total evaluation of the surge problems on a new system must await a fairly complete design (pipe size, wall thickness, taper, profile, flow velocity, tankage requirements, block-valve spacing, number, size and arrangement of pumping units, type of devices, and static-relief systems must be defined). Certain rudimentary surge considerations can be observed from the beginning which will help surge-proof the system. These include:

- Provide interlocks such that all pumping stops before main-line block valves can be closed.
- Low flow velocities ensure that changes in velocity cannot be too great.
- Long station spacing ensures maximum surge attenuation.
- Multiple pumping units at each pump station minimize the opportunity for a complete station failure.
- Looped feeders for electric stations.
- A margin of error between the hydraulic gradient and the MAOP based on wall thickness.
- SCADA communications to prevent upstream pump stations from over pressuring the downstream section.

Section 402.2.4 of the Code addresses the topic of surge pressure, stating that ". . . the level of pressure rise due to surges and other variations from normal operations shall not exceed the internal design pressure at any point in the piping system and equipment by more than 10 percent."

Corrosion Protection[20,21]

Corrosion of a pipeline can be both external and internal. Internal corrosion, apart from exceptional cases of corrosive fluid components such as H_2S, is usually a gradual process resulting in a lowering of pipeline efficiency and is characterized by indentations and pits. Regular line cleaning with scraper *pigs*, discussed later, can be utilized to care for the internal surface of most installations. Internal corrosion can also be controlled by injecting a corrosion inhibitor into the transported fluid.

Another method of reducing internal corrosion is by internally lining the pipe. While there are few examples of existing liquid hydrocarbon pipeline systems using epoxy coatings, they give good protection, long life, and have a low friction factor.

External corrosion is a major factor in the design and operation of a pipeline system; external corrosion can reduce the life of a pipeline and impair its safety. External corrosion is mitigated by application of a pipe coating and the installation of a cathodic protection system. The external coating increases the pipe-to-soil electro-chemical resistance, and the cathodic protection (impressed current or galvanic anodes) system makes the pipe cathodic with respect to the surrounding soil.

There are a number of methods and materials available for external coatings, offering different benefits and a range of cost. Methods include over-the-ditch after welding, and precoating pipe joints at the pipe mill before shipping or in plants located near the jobsite before stringing.

Materials for over-the-ditch include cleaning and priming followed by one or more sequential layers of hot-applied asphalt or coal-tar enamel, felt wrap, and a final wrap of kraft paper. The most recent applications of plant-applied materials are fusion-bonded, thin-film epoxy (FBE), followed by an extruded copolymer adhesive and an extruded polyethylene jacket. (Refer to Chap. B10 for more details on FBE lining and coating.) Consideration for selection of a coating should include, in addition to installation and shipping costs, quality and integrity of the completed coating system as installed and other concerns, such as chemical resistance to soil conditions, stray electrical currents, maximum service temperature, storage and handling, et cetera. Specialty coating systems for thermally insulated pipelines in high-temperature service may require an exterior jacket impervious to intrusion by water vapor.

Further discussion of internal and external coatings and of cathodic protection systems can be found in Chap. C6, Gas Systems Piping. The same material is applicable to liquid petroleum systems.

ASME B31.4 does not specify that an allowance be made for corrosion in determining nominal wall thickness for fluids and services covered by the Code, with the provision that internal and external corrosion control is provided as directed by Chap. VIII of the Code.

Metering

Early methods for monitoring the volume of flow through a liquid pipeline relied on tankage gauge readings at different points along the system. With the development of computer monitoring systems, liquid pipeline systems are now monitored continuously. Metering devices used in the pipeline business today fall into three groups:

- Pressure drop
- Positive displacement
- Turbines
- Miscellaneous, including sonic and vortex meters

The first group measures the pressure drop created when flow is restricted either across an orifice plate or a venturi tube. This type of meter is unable to identify variations in density and viscosity, which may be variable in liquid petroleum

services, and therefore is not used for fine measurements except in conjunction with a viscosity or density meter.

The positive displacement group of meters includes a wide variety of mechanical devices which entrap a discrete quantity of fluid and move it physically from one side of the meter to the other. Screws, pistons, buckets, gears, and sliding vanes have been used successfully, especially with viscous fluids, but are subject to wear in continuous, high-capacity low-lubricity situations.

Turbine meters consist of a turbine wheel with tiny magnets mounted axially between sleeve bearings inside a short length of pipe. As the fluid turns the turbine wheel, the rotations are recorded and counted electronically by the passage of the magnets. These meters have been successful because they are simple in design, essentially having only one moving part. The turbine wheel, when in motion, tends to center itself in the pipe so there is almost no bearing friction.

All three of these meter types have their uses. The orifice, because it is rugged and low in cost, is used where exact measurement is not required. Positive displacement meters are used where the fluid is viscous or a high range of viscosity is expected and close measurements are needed for custody transfer. Turbine meters are used for the continuous, high-capacity bulk movement of fluids because they are reliable and accurate over a wide range of flow rates.

The fourth group has more specialized meters. Information on a particular type of meter or installation is available from manufacturers.

Leak Detection

Detection of major leaks is a major concern of pipeline operating companies. Large leaks can be detected with relatively simple instrumentation; however, to detect small leaks requires computer systems that can also monitor and account for variations in temperature, pressure, density, and composition. To illustrate the problem of leak detection, with an order of magnitude comparison, consider that for an NPS 8 (DN 200) line transporting 24,000 BPD (3,815 m^3/d), a detectable deficiency of $+/-$ 2 percent of flow is a 14 gpm (3.18 m^3/h) leak. A 0.2 percent deficiency, detectable only with a sophisticated leak detection system, on a NPS 48 (DN 1,200) line pumping 2.4 MMBPD (381,000 m^3/d), is a 140-gpm (31.8 m^3/h) leak. The hole in the pipe which would leak 140 gpm (318 m^3/h) at gage pressure of 500 psig (34.5 bar) is more that 0.50 in (12.7 mm) in diameter. The hole which would leak 14 gpm (3.18 m^3/h) at the same pressure is less than 0.0625 in (1.59 mm) in diameter.

For years, basic leak detection has been based on the principle of line balance, based on the continuity of flow in the pipeline, i.e., flow in equals flow out. In its simplest form, leak detection can rely solely on readings of flow meters or tank gauges at periodic intervals, with a recurring discrepancy indicating a leak. For line balance to be viable, accurate flow measurements at both ends of the pipeline or section of pipeline must be made and reconciled regularly. In early pipeline systems, minor differences in reading time, temperature, line pack et cetera, made the results somewhat erratic, but a continuous shortage in delivery for several hours was sufficient cause for a line patrol to be sent out or for the system to be shut down and pressure tested. Large leaks or line breaks were detected by comparing suction and discharge pressures with flow at pump stations, e.g., falling discharge pressure combined with increased flow meant a leak downstream; falling suction pressure combined with decreased flow meant a leak upstream.

In modern pipeline systems, computer-based monitoring systems compare flow rates as well as total flow and record the variables of the flow (temperature, viscosity,

et cetera) The determination of whether there is a leak in the system is based on the readout differentials. For reliable pipeline surveillance, both short-term (minutes) and long-term (days) calculations should be maintained and compared against respective threshold values.

Perhaps the more important problem in leak detection is location of the leak once it has been detected. While line balance will indicate the magnitude of the leak, other means are required to pin-point the location between two monitoring positions.

A general method for location of a leak is to compare the hydraulic gradient for the flow measured upstream with that of the flow measured downstream, with the intersection of the hydraulic gradients being the approximate leak location. Methods for location of rapidly formed leaks include monitoring the rate of change of pressure and flow (dp/dt and dq/dt, respectively) and the pressure-wave differential which occurs as the result of a rapid leak, propagating from the leak in both directions, with the velocity of sound in the liquid (see surge discussion). Similarly, the transient pressure wave can be monitored with transducers which will detect the transient pressure wave, its magnitude being the generated pressure wave at the leak location delayed exponentially as a function of the distance to the leak and the velocity of sound in the liquid.

More discussion on the theory of these leak detection and location methods can be found in standard hydraulic texts, manufacturer's literature, and in some of the references and bibliography.

Pipeline Pigs

A ''smart'' pig is an instrumented device which travels internally along a pipeline, monitoring the operating parameters (flow, temperature, etcetera) and the physical condition of the pipe (wall thickness, corrosion, out-of-roundness, et cetera). Pigs are also used to ''listen'' for the acoustical traces of leaks. Simple pigs, on spheres, are sometimes used to mark the transition between two commodities in a multiproduct pipeline.

The information the pig collects must be relayed to the master control center, and the pumping, heating, or pumping-heating stations along the route must have facilities designed for the handling of pigs, including launching and receiving traps. Additionally, the design for use of pigs may influence the specifications for elbows, tees and valves.

SCADA[23]: Supervisory Control and Data Acquisition

Maintaining the integrity of a pipeline system which spans hundreds of miles (kilometers) is a complicated task, involving the monitoring, measurement, and analysis of a continuous flow of data from meters, pipeline pigs, transducers, and other collecters. Just as critical as collecting the data from source points along the length of the system is the transmission of the data to the facilities of the pipeline operating company, which may be remote from the pipeline itself. There is also the aspect of control and coordination of multiple stations along the system so that they operate in conjunction with each other rather than in opposition.

Early pipeline systems relied on analysis of data at the local station and communication of information by voice over telephone or wireless. The operating philosophy

of many pipeline systems today is to limit the number of manned control stations. Today's technology relies instead on SCADA (Supervisory Control and Data Acquisition) systems to collect data from monitor points by fiber optics, microwaves, and satellite-communications technology to transmit the data to control stations. Here, high-speed computers analyze the data and perform on-line control functions required to maintain system parameters within their operating limits. Application of these technologies requires consideration early in the mechanical design to include the operating components for the intended modes of operation and control.

The result of this technology has been to maximize the safety and operating efficiency of the system. Additionally, the collection and storage of operational information over the life of a pipeline system facilitates new pipeline design and operation through the verification of computer models which are used in the design phase to:

- Identify out-of-range operating variables
- Select preferred operations at and among pumping stations to control use of pumping units and cost of energy
- Identify limits for pumping rates and fluid properties of commodities transported
- Predict effects of modifying system facilities, operations, or changing characteristics of commodities transported
- Schedule tenders, or contracts, for transporting commodities by various fluid properties, ownership, source and destination

SYSTEM COST ANALYSIS[22]

The first several sections of this chapter have shown that for a given proposed pipeline, there are many possible pipeline systems which can be assigned to transport the commodity. Selection of the preferred pipeline route, diameter, material, wall thickness, pump-station location, pump units, and operational equipment or facilities is typically the result of economic analysis and investment-capital evaluation of the most reasonable scenarios developed through the design phase.

Typically, even before the detailed design of a pipeline systems has begun, an order-of-magnitude cost study will be performed, with the goal of determining the feasibility of continuing to invest time and capital in the design phase of the project. At this point, a preliminary route may have been selected; however, other possibilities may still exist, and further developments may indicate a change in the assumptions or information available during the preliminary analysis. In conjunction with the hydraulic, mechanical, and operational and maintenance designs, the economic analysis progresses, at times steering the decisions made in the design.

For a typical cross-country pipeline project, the cost of pipe and its associated construction and installation costs can be as much as 80 percent of the capital investment; therefore, the selection of the pipe, with regard to type of material, size, et cetera is very important. Trade-offs can be made during the design process with regard to diameter and wall thickness, grade of steel, and method of manufacture, as discussed in various earlier sections of this chapter. The cost of the pipe itself generally represents 25–50 percent of the total line cost, and the use of a reliable cost, based on current industry information, is significant. Annual cost indexes are published in a number of trade periodicals. Another source of costs

for line pipe, as well as component fittings, valves, and installation factors are manufacturing associations and the construction industry publications.

Using the information developed through the earlier example, a comparison of system designs can be made, as shown in Tables C5.7, C5.7M, C5.8, and C5.8M. These tables illustrate the general procedure for selecting an appropriate pipeline system for a specific route. The same comparisons can be made for different routes.

TABLE C5.7   Isothermal Crude Oil System

Comparison of alternative diameters			
188,700 BPOD			
Pipe OD × wall thickness, in	16 × 0.250	20 × 0.250	24 × 0.250
Unit friction loss, ft/mile	132.1	44.1	18.1
Length, miles	248	248	248
Pipe friction loss, ft	32,756	10,934	4,486
Static head, ft	50	50	50
Total head, ft	32,806	10,984	4,536
Total pressure, psi	12,357	4,137	1,709
MAOH, ft	3,580	2,864	2,387
MAOP, psi	1,350	1,080	900
Number of pump stations	9.15	3.83	1.90
Operating horsepower @ 82% efficiency	48,382	16,200	6,690

Preliminary comparative cost comparison			
Capital cost ($1,000)			
Pipeline	16 × 0.250	20 × 0.250	24 × 0.250
Pipe unit weight, tons/mile	111.0	139.2	161.4
Pipe weight, tons	27,528	34,522	40,027
Pipe cost @ $700/ton	19,270	24,165	28,019
Unit installation cost, $/ft	35	40	45
Pipeline installation	45,830	52,378	58,925
Total pipeline cost	65,100	76,543	86,944
Pump stations			
Installed horsepower per station	5,000	4,250	3,500
Base cost per station	1,000	1,000	1,000
Installed horsepower @ $750/hp	3,750	3,188	2,625

These comparisons also illustrate that consideration should be given to the method of financing and appropriate economic factors, such as system growth and annual operating costs.

The reader should refer to a handbook on financial decision making to learn more about the process of optimum system selection on economic grounds, including the processes of discounted cash-flow analysis.[22]

SPECIAL OIL PIPELINE DESIGN TOPICS

Special Hydraulic Conditions

Pipeline systems which fall under the scope of the Code have a wide variety of physical properties, as was shown in Table C5.1. Furthermore, two of the most important properties—viscosity and vapor pressure—vary with temperature. Earlier sections have discussed pipeline systems having no fluctuation in temperature, therefore the hydraulic system design was simplified. Hydraulic design of nonisothermal systems for heavier commodities, such as heavy crude and residual fuel oils are influenced by the effect of temperature on viscosity and related friction losses. Hydraulic design for the lighter commodities, such as gasoline and natural gas liquids (NGL), is relatively independent of viscosity, but more dependent on vapor pressure considerations.

This section summarizes the special considerations which will arise in the design of multiproduct, high-vapor pressure, hot oil, and non-Newtonian fluid pipeline systems, without attempting to be comprehensive. The reader is encouraged to consult specialists and specific references for more detailed discussions of the design of these systems than can be described here.

Multi-product Pipelines. If the pipeline system is to transport fluids of differing properties such as in a batch-type operation of a multiproduct system, the design fluid should be considered as the fluid producing the greatest friction loss, i.e., with the greatest viscosity at the design operating temperature. Using this fluid assures that all pumping stations have adequate power and all sections between stations have adequate wall thickness to sustain the design pressure and flow rate. Furthermore, multiproduct systems may have intermediate deliveries to the system and discharges from the system, i.e., different flow rates for each pipeline section may need to be considered.

To avoid excessive mixing of products, the system should be designed for flow in the turbulent region. Batching pigs can be used to minimize interface mixing at low flow rates.

A special pipeline application uses a batch-flow technique to transport unlike petroleum products sequentially in a single pipe without significant deterioration of the quality of the products by contamination. An explanation of the principle involves a discussion of laminar and turbulent flow regimes, as given in Chap. B8, Flow of Fluids.

In laminar flow, the molecules travel forward in parallel. Velocity is maximum at the center of the pipe, with decreasing velocity to zero at the pipe wall caused by viscous drag among the molecules and friction at the pipe wall. The standard velocity profile is parabolic over the cross-section of the pipe. Therefore, in the laminar flow region, an interfacial plane between adjacent products would rapidly

deteriorate into a bulge, and the trailing product would tend to push through the leading product travelling more slowly near the pipe wall.

In turbulent flow, however, the molecules are in random motion, bouncing off other molecules as well as the pipe wall, and tend to remain in relative position. Therefore the profile of velocity is almost constant over the cross-section of the pipe and the fluid flows more like a ''plug.'' The interfacial plane between adjacent batches in the pipeline tends to remain in place as the products proceed down the pipeline. Some mixing occurs, principally by diffusion, and is more a function of length (time) of transport than velocity. The amount of contamination of the leading product by the trailing is the same as the contamination of the following by the leading. The transition from one product to another, as the interfacial zone passes a point, takes the shape of a sine wave. At some point as the interface wave passes the switching manifold, the flow is diverted to separate storage or distribution facilities. The contamination of one product in another is controlled by timing the *cut* or diversion. One way this is done is to place a gravitometer some distance upstream of the receiving terminal and to record its signal at the terminal so that the receiving operator has a preview of exactly what the interface will look like on arrival. From a design point, a batch flow pipeline has several hydraulic gradients, at least one for each product, as well as for the mixing zone.

High Vapor-Pressure Pipelines. High vapor-pressure systems are characterized by low density, low viscosity, and the necessity to operate the system at elevated pressure to maintain the fluid as a single phase in the pipeline. Single phase is maintained throughout the pipeline by maintaining the elevation of the hydraulic gradient above the ground profile by more than the head equivalent of the local vapor pressure. Back-pressure regulators may be installed in terminals to maintain the required elevated gradient. In this sense, the design of high vapor-pressure lines differs from crude-oil pipelines in that the parameter governing design is the vapor pressure, directly related to temperature, rather than viscosity, which is on maximum temperature, where maximum vapor pressure occurs, versus the maximum viscosity or minimum temperature point which is the design basis of highly viscous fluid systems.

Waxy and Heavy Crude Oils. One treatment for waxy and heavy crude oils is to heat the commodity as part of the transport operation. This concept was discussed earlier under nonisothermal hydraulics.

Chemical additives have also been used in oil pipeline systems to improve flow, i.e., reduce the drag of heavy and waxy crudes. Initially developed to enhance oil-well fracturing, these additives are hydrocarbon-based polymers. The additives are solutions of a high molecular–weight copolymer or polyolefin in a hydrocarbon solvent. Being a hydrocarbon, it distills according to the volatility of its fractions and is not distinguishable from the hydrocarbons originally present in crude oil. The additive reduces the turbulent flow, effectively expanding the transition flow region. It is injected into the flowing pipeline stream by a compact, skid-mounted chemical injection module consisting of injection pumps, positive displacement flowmeters with totalizers, and miscellaneous instrumentation. The polymer itself is so viscous that an inert gas, such as nitrogen, is used to help transfer the material from tank to pumps.

Injection of the additive must be at every station on a system, because the polymer is degraded by the action of centrifugal pumps. Initially it was thought that only very large diameter pipelines could benefit from the use of drag reducers.

Widespread tests have demonstrated that smaller crude and product lines can also benefit.

Multiphased Flow.   The presence of gas and liquid phases of a product in sections or in the entire pipeline length has been mentioned in the discussion of slack flow. Multiphased flow is particularly a factor in flow lines used to gather the produced gas-oil-water mixture from wells in a production field and transport it to separation facilities. Detailed knowledge of phase-equilibrium conditions and related product properties as well as specific multiphased flow energy and hydraulic conditions is required for the design of these systems. Computer programs have been developed to include the possibility of multiphased flow and are commonly employed for the solution of the hydraulic design of this type of system.

Seismic Considerations

The entire topic of designing facilities and systems, including pipeline systems for earthquakes, is of major importance in many parts of the world. With consideration to pipeline design, three major seismic hazards for buried pipelines are landslides, liquefaction of soil under and around the pipe, and differential fault movement and ground rupture. Ground motion (shaking) itself is a major consideration in the design of stations and terminal facilities and aboveground supports of a pipeline, but has less effect on buried pipelines.[24,25] Differential settlement and faultline shifts with vertical and horizontal displacement will impose additional longitudinal stresses on the pipe material.

In route selection, a survey of alternate routes should consider evidence of past landslides, i.e., movement of the ground triggered by a seismic occurrence. Slopes showing signs of recent instability or movement may be candidates for further disturbance in event of an earthquake. If slope instability involves deep translations and rotational displacement, the potential ground movements in the area may be large, and relocation of the pipeline may be more cost beneficial than expensive stabilization measures. If instability involves slumps and shallow slides, slope stabilization may be effective. In any case, seismic and geologic specialists should be consulted.

In saturated, cohesionless soils, for example, nonplastic silts and medium-dense sands, liquefaction may be the major hazard wherein the soil temporarily is transformed into a liquid state, losing shear strength and bearing capacity. Liquefaction leads to lateral spreading, loss of bearing capacity, and uplift of buried pipe due to increased buoyancy. Several measures can be taken to design a pipeline system crossing areas susceptible to liquefaction, including designing for moderate deformations as a result of uplift during an event, limited burial in the area, and adding weight coatings, thereby limiting uplift. Operationally, additional line block valves for shut-off in case of a failure following an earthquake may need to be provided.

Fault movement is the most dramatic earthquake occurrence, and potentially catastrophic for a pipeline. Pipeline alignment in fault zones should be such that the expected fault movement will produce tensile stresses in the pipe. If compressive stresses result, buckling may occur. The line should be laid in relatively straight sections, crossing the fault at an angle of 60 to 90° and without abrupt changes in direction or elevation, a procedure which might serve as an anchor during an earthquake. Depth of cover should be minimal, thereby reducing soil restraint, and the backfill material should be granular, medium-range soft sand without large stones, placed well around the pipe to allow relatively free movement.

Two of the references, ''Guidelines for the Seismic Design of Oil and Gas Pipeline Systems,''[24] and ''Seismic Design of Oil Pipeline Systems''[25] have additional material on the location and operation of pipelines across earthquake fault zones.

Underwater Pipeline Design[26,27]

The subject of underwater pipeline design, in particular ocean or deepwater pipelines, is worthy of a separate chapter. Yet it is important to reference some of the related topics here, particularly about the section of a pipeline system that may cross a river or lake, requiring placement underwater. There are generally two types of underwater pipelines—those that cross a relatively short distance and represent a minimal portion of the entire system design, e.g., a river crossing; and the submarine pipeline, which is primarily underwater. River crossings of a pipeline can be made by pulling the pipe string previously welded onshore, or by laying the pipeline into a trench beneath the depth of scour, then covering with protective backfill. Directional drilling techniques to drill under the riverbed are available where soil conditions, distance, construction space, and pipe properties are amenable. However, the design of an underwater, or submarine, pipeline has several special considerations, which may or may not also be major considerations in river crossings of terrain pipeline systems. The reader is referred to specific handbooks on the design of ocean pipelines for more specific information on this topic.

If a body of water is to be crossed as part of a terrain pipeline and the decision is made to place the line underwater, a hydrographic survey of the area should be initiated. In addition to as much information as possible about the potential route, other hydrographic data are required, such as current and tidal data, weather records, wave height and patterns, possible underwater obstructions along the route, and sources of impact such as dragging anchors. Selection of the landfall location is also an important element in the route selection.

External pressure, discussed earlier, will be greatest on the empty pipeline after placement. The tendency of the pipe to buckle under external pressure should always be checked and design of buckle arresters, i.e., stiffer sections, included in the design to limit buckle propagation.

Selection of the material for the pipeline should take into consideration that the stresses during the laying operation may govern the mechanical design. Note that these stresses do not occur in conjunction with internal pressure. The laying

TABLE C5.9 Conversion Factors, Length

To obtain → Multiply ↓ by ↘	mm	in	ft	m	mi	km

meter$_{hd}$ per kilometer	0.10*rd	9.8067*rd	2.2879*rd	5.280	1

rd = relative density: absolute density of fluid divided by density of water @15°C and 101.325 kPa, where density of water is taken as 1000 kg/m^3. Subscript hd = head in column of liquid at the density of the fluid.[6,7]

stresses can be categorized as direct pulling stresses, from welding onshore and pulling into location or from the tension of laying from a laybarge; bending stresses as the pipe is lowered to the riverbed or seabed; torsional stresses induced during the laying operation; and current and wave stresses during tow and placement.

Pipeline stability, once in place, is another consideration to ensure security of the pipeline. If additional weight is required, it can be provided by weights or anchors placed at intervals or by continuous weight coating. Placement of the pipeline in a trench and covering with protective backfill is another alternative.

CHAPTER C6
GAS SYSTEMS PIPING

Peter H.O. Fischer
Pipeline Project Manager
Bechtel Corporation
San Francisco, California

INTRODUCTION

General

Natural gas is the cleanest of all fossil fuels. Plentiful supply, competitive cost, and versatility continue to support an upward trend in the consumption of natural gas on a worldwide scale. In addition to its traditional industrial and residential uses, natural gas has made inroads as a motor fuel for fleet and private vehicles, and as a supply for gas-fired cogeneration power plants and for use in fuel cells.

Increasingly, gas fields are being discovered in the remotest regions of the world. Gas transportation and distribution to and within the industrial and/or populated areas where it is needed is a significant factor in its development as an energy resource. Over long distances, gas can be transported by pipelines or in liquid form in ships. For local distribution, the gas can be delivered through piping distribution networks or in trucks in liquid form.

This chapter addresses the transport and distribution of gas by pipelines and piping systems. Throughout the chapter, reference will be made to Section B31.8 of the American Society of Mechanical Engineers (ASME) Code for Pressure Piping, Gas Transmission and Distribution Piping Systems. This is for convenience only as it is beyond the scope of this endeavor to reference, cross-reference, or compare the many excellent codes and standards that have been developed and that are in use in other countries.

Definitions

Section B31.8 of the ASME Code for Pressure Piping, Gas Transmission and Distribution Piping Systems, defines *gas* as follows:

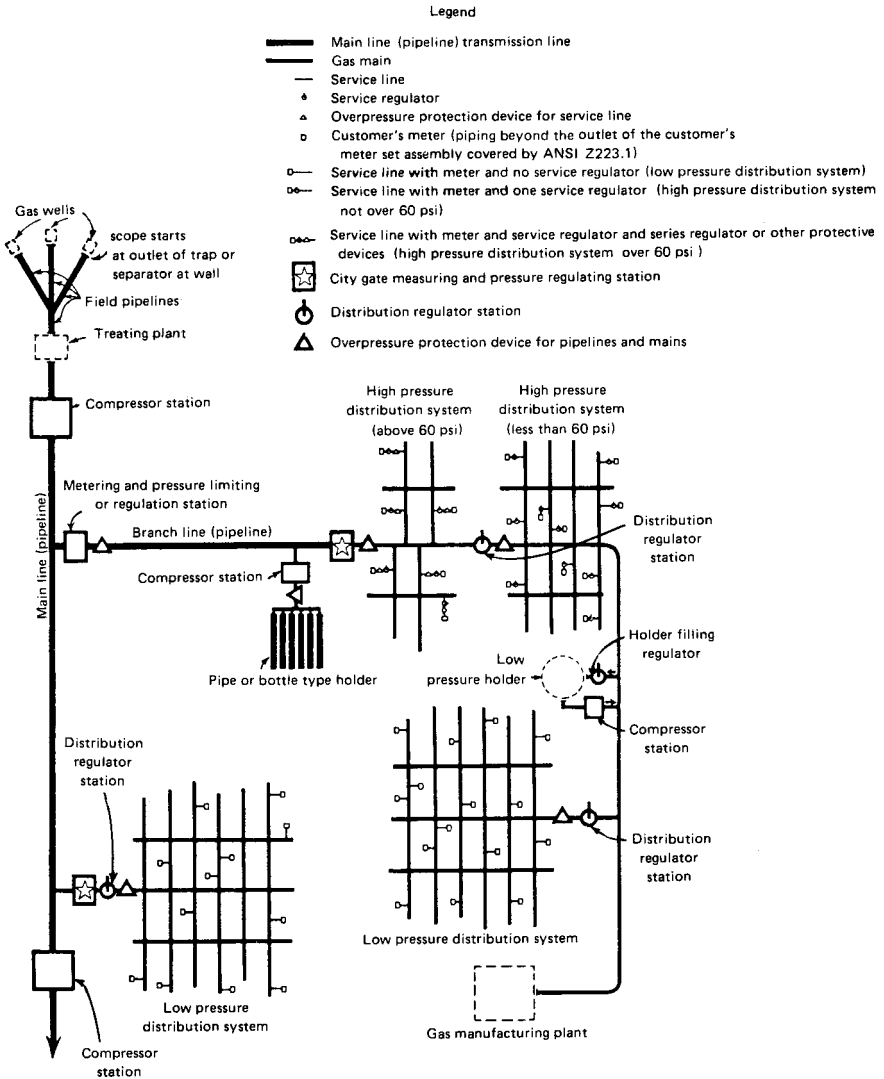
Legend


FIGURE C6.1   Gas transmission and distribution piping systems.[2] (Ref. 8.)

Gas, as used in this Code, is any gas or mixture of gases suitable for domestic or industrial fuel and transmitted or distributed to the user through a piping system. The common types are natural gas, manufactured gas, and liquefied petroleum gas distributed as a vapor, with or without the admixture of air. (Ref. 8.)

A comprehensive listing of the definitions of general terms used in the gas transmission industry is provided in Secs. 803 through 806 of ASME B31.8.

Types of Systems

Figure C6.1, abstracted from ASME B31.8, gives an overview of the piping and facilities (indicated by solid lines) considered to be part of gas transmission and distribution piping systems.

Gas Gathering System.   The gas gathering system consists of field pipelines transporting dry or wet gas from the wellheads to a central treating facility, where initial separation of gas and liquids takes place.

Mainline (Pipeline) Transmission Lines.   Main transmission pipelines transport gas from a source or sources of supply to one or more distribution centers or to one or more large-volume customers, or may interconnect sources of supply. Main transmission pipelines are usually characterized by larger-diameter pipe installed over longer distances with intermediate compressor stations.

Gas Distribution System.   The gas distribution system is a piping system installed within a community to convey gas to individual service lines or other gas mains.

REFERENCE DOCUMENTS

Codes and Standards

In the United States as well as many other countries the need for a national code for pressure piping became evident in the early stages of the pipeline industry. To meet this need, codes and standards were developed, and reviewed and revised over the years as needed, to meet the requisites of the industry and of government regulatory agencies. The process is ongoing.

In some instances the codes and standards have become law, as is the case with The Pipeline Safety Act in the United States in the form of Title 49 Part 192 and 195 of the Code of Federal Regulations, ''Transportation of Natural and Other Gas by Pipeline'' and ''Transportation of Liquids by Pipeline.''

Needless to say, whether enacted into law or not, it is not the intent of codes and standards to provide a set of rigid rules and formulas, which if followed diligently, will always result in the design and construction of a perfect pipeline system. The great number of variables involved, the unknown circumstances that can be encountered, and the random eventualities which may occur preclude such an approach. Codes and standards do, however, provide a framework within which the experienced and competent designer or engineer can develop a safe, reliable, and economic pipeline.

The following is a listing of codes and standards referenced in this chapter:

Other Reference Documents

Many countries other than the United States have pipeline regulations of their own, and in many cases these are more stringent than the U.S. codes, especially where licensing and leak testing are concerned. These must always be researched before starting design intended for the installation of pipelines in other countries. Countries known to have codes include:

Algeria	Germany
Austria	Great Britain
Australia	Japan
Belgium	Italy
Canada	Russia
France	

Table C6.1 provides a synopsis of *some* of these pipeline codes.

DESIGN

The specific identification of types of pipe generally used for high-pressure gas lines is given in the latest edition of the ASME Code for Pressure Piping, ASME B31.8. Special fittings for gas systems, together with typical details and design recommendations, are included in this chapter.

Basic Flow Equations

Rational Gas Flow Formula. Many equations for calculations involving isothermal gas flow in horizontal gas pipelines have been used by the pipeline industry

with varying degrees of success over the years. One of the more common is the rational gas flow formula:

$$P_1^2 - P_2^2 = Bf(ZTGQ^2/D^5)L \qquad\qquad (C6.1)$$

			Units	
			Imperial	*Metric*
where	$B =$	dimensional constant	76.86	5608
	$D =$	internal diameter	in	mm
	$f =$	friction factor	dimensionless	
	$L =$	length	mi	km
	$G =$	gas gravity	(air $=$ 1)	
	$P_1 =$	initial line pressure	psia	kg/cm^2
	$P_2 =$	final line pressure	psia	kg/cm^2
	$Q =$	flow rate	1000 ft^3/hr (MCF/hr)	m^3/hr
	$T =$	absolute gas temperature	°R (°F+460)	K (°C+273)
	$Z =$	compressibility factor, at average flow conditions	dimensionless	

To take into account differences in elevation, the pressure profile for flow in gas pipelines is determined using the rational gas flow formula modified with J. William Ferguson's elevation correction method as follows:

$$P_1^2 - e^S P_2^2 = Bf\,(ZTGQ^2/D^5)L_e \qquad\qquad (C6.2)$$

			Units	
			Imperial	*Metric*
where	$B =$	dimensional constant	76.86	5608
	$P_1 =$	initial line pressure	psia	kg/cm^2
	$P_2 =$	final line pressure	psia	kg/cm^2
	$e =$	natural logarithmic	base, 2.71828	
	$f =$	friction factor	dimensionless	
	$G =$	gas gravity	(air $=$ 1)	

$T =$	absolute gas temperature	°R	K
$Q =$	flow rate	1000 ft³/hr (MCF/hr)	m³/hr
$Z =$	compressibility factor, at average flow conditions	dimensionless	
$L =$	length of pipe segment	mi	km
$H =$	elevation difference over the segment (positive uphill, negative downhill)	ft	m
$A =$	dimensional constant	26.647	14.637
$s =$	GH/(ATZ)	dimensionless	
$L_e =$	effective length $(e^s - 1)$ L/s	mi	km
$D =$	pipe internal diameter	in	mm
$e^s =$	elevation correction factor	dimensionless	

Pipe Design Formula. The design pressure for steel gas piping systems or the nominal wall thickness for a given design pressure is determined by the following formula:

$$P = 2St\,FET/D \qquad (C6.3)$$

		Units	
		Imperial	*Metric*
$P =$	permissible design pressure	psig	kg/cm²
$S =$	yield strength	psig	kg/cm²
$D =$	nominal outside pipe diameter	in	mm
$t =$	nominal pipe wall thickness	in	mm
$F =$	design factor. Value depends on location class. (See Table C6.2). Exceptions are given in Table C6.3.	dimensionless	
$E =$	longitudinal pipe joint factor. This is a function of the type of pipe manufacture. (See Table C6.4).	dimensionless	

where appears to the left of the lower table.

$T =$	temperature derating factor. (See Table C6.5)	dimensionless

Location Classes for Design.   The possibility of damage to a gas pipeline increases with greater concentrations of people and buildings. One method of providing added protection is to lower the pipe stress level as a function of public activity.

TABLE C6.2   Basic Design Factor F (Ref. 8)

Location class	Design factor F
Location Class 1, Division 1	0.80
Location Class 1, Division 2	0.72
Location Class 2	0.60
Location Class 3	0.50
Location Class 4	0.40

ASME B31.8 quantifies this activity by determining location class and relating the design of the pipeline to the appropriate design factor.

ASME B31.8 has defined *location classes* as follows:

Location Class 1.   A Location Class 1 is any 1 mile section that has 10 or fewer buildings intended for human occupancy. A Location Class 1 is intended to reflect areas such as wasteland, deserts, mountains, grazing land, farmland, and sparsely populated areas.

Division 1.   A Class 1 location where the design factor of the pipe is greater than 0.72, but equal to or less than 0.80, and which has been hydrostatically tested to 1.25 times the maximum operating pressure.

Division 2.   A Class 1 location where the design factor of the pipe is equal to or less than 0.72, and which has been tested to 1.1 times the maximum operating pressure.

Location Class 2.   A Location Class 2 is any 1 mile section that has more than 10 but fewer than 46 buildings intended for human occupancy. A Location Class 2 is intended to reflect areas where the degree of population is intermediate between Location Class 1 and Location Class 3 such as fringe areas around cities and towns, industrial areas, ranch or country estates, etc.

Location Class 3.   A Location Class 3 is any 1 mile section that has 46 or more buildings intended for human occupancy except when a Location Class 4 prevails. A Location Class 3 is intended to reflect areas such as suburban housing developments, shopping centers, residential areas, industrial areas, and other populated areas not meeting Location Class 4 requirements.

Location Class 4.   Location Class 4 includes areas where multistory buildings are prevalent, and where traffic is heavy or dense and where there may be numerous other utilities underground. Multistory means 4 or more floors above ground including the first or ground floor.

The design factor for pipelines or mains supported by railroad, vehicular, pedestrian, or pipeline bridges must be determined in accordance with the location class

TABLE C6.3 Design Factors for Steel Pipe Construction (Ref. 8)

Facility	Location class				
	1		2	3	4
	Div. 1	Div. 2			
Pipelines, mains, and service lines	0.80	0.72	0.60	0.50	0.40
Crossings of roads, railroads without casing:					
(a) Private roads	0.80	0.72	0.60	0.50	0.40
(b) Unimproved public roads	0.60	0.60	0.60	0.50	0.40
(c) Roads, highways, or public streets, with hard surface and railroads	0.60	0.60	0.50	0.50	0.40
Crossings of roads, railroads with casing:					
(a) Private roads	0.80	0.72	0.60	0.50	0.40
(b) Unimproved public roads	0.72	0.72	0.60	0.50	0.40
(c) Roads, highways, or public streets, with hard surface and railroads	0.70	0.72	0.60	0.50	0.40
Parallel encroachment of pipelines and mains on roads and railroads:					
(a) Private roads	0.80	0.72	0.60	0.50	0.40
(b) Unimproved public roads	0.80	0.72	0.60	0.50	0.40
(c) Roads, highways, or public streets, with hard surface and railroads	0.60	0.60	0.60	0.50	0.40
Fabricated assemblies	0.60	0.60	0.60	0.50	0.40
Pipelines on bridges	0.60	0.60	0.60	0.50	0.40
Compressor station piping	0.50	0.50	0.50	0.50	0.40
Near concentration of people in Location Classes 1 and 2	0.50	0.50	0.50	0.50	0.40

TABLE C6.4 Longitudinal Joint Factor E (Ref. 8)

Spec. No.	Pipe class	E factor	Spec No.	Pipe class	E factor

				Submerged arc welded	1.00

General note:
Definitions for the various classes of welded pipe are given in ASME B31.8.

TABLE C6.5   Temperature Derating Factor T for Steel Pipe (Ref. 2)

Temperature		Temperature derating factor T
°F	°C	
250 or less	121 or less	1.000
300	149	0.967
350	177	0.033
400	204	0.900
450	232	0.867
General note: For intermediate temperatures, interpolate for derating factor.		

prescribed for the area in which the bridge is located, except that in Location Class 1, a design factor of 0.6 must be used.

Flowing Temperature.   The original equation developed to predict with reasonable accuracy the temperature of gas at any point along a transmission line was derived by Charles E. Schorre and presented in 1954 (Schorre, C.E., "Flow Temperature in a Gas Pipeline," *OGJ*, Sept. 27, 1954).

However, with Schorre's equation, flowing gas temperatures continuously decrease with downstream distance, never reaching an equilibrium value as would be expected when the Joule-Thompson cooling effect is offset by heat gain from warmer surrounding soil.

In 1979, D.M. Coulter and M.F. Bardon developed the following equation which gives a logarithmically decreasing flowing gas temperature which asymptotically approaches a value below that of the ground temperature. Using the same nomenclature as Schorre (and P = pressure):

$$T_2 = (T_1 - (T_g + (\mu/a)(dP/dX))) \, e^{(-aX)} + (T_g + (\mu/a)(dP/dX)) \quad \text{(C6.4)}$$

where

			Units	
			Imperial	*Metric*
$\mu =$	Joule-Thompson coefficient		°F/psi	°C/kg/cm²
$\mu(dP/dX) = J =$	Joule-Thompson effect		°F/ft of pipe	°C/m of pipe
$X_1 =$	distance to T_1 from initial point		ft	m
$X_2 =$	distance to T_2 from initial point		ft	m
$X = X_2 - X_1$			ft	m
$J/a =$	temperature difference between the ground and gas which would be necessary to hold the gas temperature constant		°F	°C

$T_1 =$	initial gas temperature at point X_1	°F	°C
$T_2 =$	gas temperature at point X_2	°F	°C
$T_g =$	average ground temperature	°F	°C

$$a = 2\pi RU/(qC_p) \tag{C6.5}$$

		Units	
		Imperial	*Metric*
where			
$\pi =$	Pi	3.1416	3.1416
$R =$	pipe radius	ft	m
$U =$	heat-transfer coefficient	Btu/hour/ °F/sq.ft.	Joules/hour/ °C/cm²
$q =$	gas flowing	1000 ft³/hr (MCF/hr)	m³/hr
$C_p =$	specific heat of gas at constant pressure	Btu/°F/ MCF	Joules/°C/ m³

(Coulter, D.M., Bardon, M.F.,[5] "Revised equation improves flowing gas temperature prediction," *OGJ*, Feb. 26, 1979)

Transmission Factor. The transmission factor, $(1/f)^{0.5}$, is one of the most difficult values to determine. The following equations have proven to be reasonably reliable for use with the rational gas flow formula.
For laminar flow:

$$(1/f)^{0.5} = 0.5(4 \log_{10}(f^{0.5}R_e) - 0.6) \tag{C6.6}$$

For fully turbulent flow:

$$(1/f)^{0.5} = 0.5(4 \log_{10}(3.7D/k_e)) \tag{C6.7}$$

For fully turbulent flow using Colebrook's[9] equation:

$$(1/f)^{0.5} = 1.74 - 2 \, \text{Log}_{10}(2\varepsilon/D + 18.7/(R_e f^{0.5})) \tag{C6.8}$$

The Colebrook equation requires an iterative procedure to solve for f.

		Units	
		Imperial	*Metric*
where	$f =$	friction coefficient	dimensionless	
	$D =$	inside diameter of pipe	in	mm
	ke	effective roughness	in	mm

$\varepsilon =$	absolute roughness	in	mm
$R_e =$	Reynolds number	dimensionless	

The Reynolds number for flowing gas is determined by the following:

$$R_e = C Q_b \, G P_b / (\mu D \, T_b) \qquad\qquad (C6.9)$$

			Units	
			Imperial	*Metric*
where	$C =$	Dimensional constant	0.7099	12.3039
	$Q_b =$	flow rate at P_b, T_b	ft³/day	m³/hr
	$G =$	gas specific gravity	(Air = 1.0)	
	$P_b =$	base pressure	psia	kg/cm²
	$\mu =$	viscosity	centipoise	kgf s/m²
	$D =$	internal diameter	in	mm
	$T_b =$	base temperature	°R	K

Compressibility Factor.　The compressibility factor, Z, may be obtained from the standard gas compressibility factor chart, Fig. C6.2.

$$\text{Pseudo-reduced temperature,} \qquad T_r = T/T_c \qquad (C6.10)$$

$$\text{Pseudo-reduced pressure,} \qquad P_r = P/P_c \qquad (C6.11)$$

			Units	
			Imperial	*Metric*
where	$T_c =$	absolute pseudo-critical temperature	°R	K
	$P_c =$	absolute pseudo-critical pressure	psia	kg/cm²
	$P =$	absolute pressure at which the gas exists	psia	kg/cm²
	$T =$	absolute temperature at which the gas exists	°R	K

Figure C6.3 provides convenient approximations for determining the pseudo-critical pressure and pseudo-critical temperature of gases when only the specific gravity of the gas is known. Otherwise, these values should be calculated based on actual gas composition.
FIGURE C6.2 Compressibility factors for natural gas. *(Gas Processor Suppliers Association Engineering Data Book.)*
FIGURE C6.3 Pseudocritical properties of natural gases. *(Gas Processors Suppliers Association Engineering Data Book.)*

Gas Gathering Systems

Condensate Formation. Liquids are created in gas pipelines when the temperature of the gas flowing through the pipeline drops below the dewpoint of the gas. As the gas has both a hydrocarbon dewpoint and a water dewpoint, both hydrocarbons and water may condense and accumulate at low points in the pipeline to obstruct the flow of gas. In addition to the reduction in the capacity of the pipeline, the arrival of large volumes of liquid at downstream gas treatment facilities can result in severe damage to equipment or, at the least, cause erratic plant operation.

Two-Phase Flow.   Accurate determination of pressures along the route of a wet gas pipeline operating in two-phase flow is difficult because the flow regimes associated with two-phase flow are numerous, complex, and difficult to define. Consideration must be given to gas and liquid fluid properties, flow regimes, pressure drop, and liquid holdup.

The major complication with two-phase flow is the variety of flow patterns that can be produced in a gas-liquid system. The type of flow pattern encountered depends upon the flow rates and properties (density and viscosity) of each of the gas and liquid components, surface tension between the two phases, pipe size, and pipe configuration, and terrain. These factors have rendered the derivation of general flow correlations difficult.

New correlations for pressure loss and liquid holdup in gas/liquid pipelines are continuously being developed and are showing consistently reliable predictions for both holdup and pressure loss when compared to actual field operating data.

The very number, complexity, and application specific limitations of many of these correlations precludes the presentation and discussion of any particular correlation in this chapter. The reader is referred to current literature to obtain the latest information and formulas, and to proprietary computer software available on the market.

Hydrate Considerations.   Under unfavorable conditions, the low molecular weight hydrocarbons such as methane, propane, or butane form insoluble hydrate deposits in conjunction with water molecules. These hydrate crystals, which resemble ice or wet snow, have been known to virtually plug and stop gas transmission lines.

Hydrates may also occur in equipment as a result of cooling due to pressure reduction. This can be a problem particularly in pressure-control valves and pressure regulators, which can literally freeze up.

The methods for determining the hydrate temperature/pressure are covered in detail in Sec. 15 of the Gas Processors Suppliers Association (GPSA) Engineering Data Book.

Hydrate formation can be prevented by maintaining the gas at a higher temperature, by dehydrating the gas, or by the injection of glycol or methanol. Where hydrate problems occur at pressure-control valves or other equipment, localized heating of the equipment may provide an efficient solution.

Gas Transmission Systems

Route Selection.   The most logical pipeline route is a straight line between the point of supply and the point of delivery. However, in practice this tends to be the exception and not the rule. Physical terrain, soil conditions, built-up areas, population densities, and both natural and man-made obstacles together with the requirements of codes and standards will force deviations from a straight line route.

Normally, the best route from a number of alternates will be that which results in the lowest overall project cost for the life of the project, considering material and equipment, construction, and operation and maintenance costs.

In evaluating possible pipeline routes, consideration must be given to the following:

Location of Facilities.   Although the locations of supply and delivery points are usually fixed, the siting of these facilities should take into account the availability of suitable pipeline routes whenever possible.

On long transmission lines, the availability of suitable sites for intermediate compressor stations will also have an impact on the selection of the final route.

And finally, the location of possible future supply and delivery connections to the mainline may play a role in the alignment of the mainline.

Environment.   Impact on the environment of pipeline construction, maintenance, and operation must be considered and mitigated, or avoided altogether by rerouting. Special attention must be given to the habitats of endangered species of plant and animal life. In many instances severe restrictions will be imposed on the construction of the pipeline and related facilities.

Cultural and Historical Heritage.   Sensitivity to the significance of local cultural and historical areas to the local peoples must be exercised in developing the pipeline route. Gaining the trust and respect of the people who will be affected by the installation and operation of the pipeline will reap substantial benefits for construction and future operation.

Terrain.   The terrain which a pipeline traverses has a significant impact on construction costs and in some cases maintenance costs. For instance, the amount of rock along the pipeline route has a major impact on the cost of installation, but little or none on operating or maintenance costs. However, areas of soil erosion, landslide areas, swamps, and river crossings increase both the cost of installation and the cost of maintenance. Such areas usually require special construction methods and in many cases require stabilization measures after installation which become a continuing maintenance item.

Man-Made Infrastructure.   The pipeline route must normally also cross roads, highways, railroads, canals, and irrigation structures. Such crossings increase the installation costs as additional depth of burial, and in some instances, the installation of casing is required. The costs of crossing such obstacles must be weighed against the costs of alternate routes, if available.

Populated Areas.   The pipeline route should avoid populated areas to reduce the exposure of the population to hazards associated with the pipeline. Also, by avoiding populated areas, the possibility of damage to or interference with the pipeline is reduced.

There is also an economic penalty in crossing populated areas. Most codes will require the use of a lower pipe design factor, resulting in the installation of heavier-wall pipe. More expensive construction methods may also be required and ready access to the pipeline for operation and maintenance may be reduced.

The area defined by Section 840 of ASME B31.8 in which the design of the pipeline is affected by the density of the population extends 200 meters (1/8 mile) on either side of the pipeline. As future increases in population density can force the upgrading of an existing pipeline, the rate of development and probable direction of future population growth must be considered in selecting the pipeline route.

Diameter Selection/Station Spacing.   Investment in pipe invariably represents the largest single expenditure for a transmission line. It is therefore imperative to find the size of pipe that will most cost-effectively handle the required gas volumes. To do so, horsepower and compressor station spacing must be considered. While pipe tonnage represents a high first cost in investment compared to the installation of horsepower, the operating charges for pipe are relatively negligible, while fuel and maintenance costs of compressor facilities are high. The savings realized by decreasing pipe tonnage can eventually be offset by the costs associated with the increased horsepower required.
FIGURE C6.4   Effect of pipeline diameter on gas transmission costs.

An estimate of the pipe size required can be made from charts similar to Fig. C6.4, which plot gas transmission costs against throughput volume for varying pipe diameters. With the approximate pipe size(s) determined, a preliminary economic analysis can be performed using computer programs developed for economic studies of gas pipeline systems. These programs allow for the rapid comparison of a number of alternatives, allowing the selection of the one apparently offering most economic advantages.

With an optimum pipe size determined, a more precise design of the selected system can be undertaken.

Mainline Valves.   Mainline valves are installed in gas transmission lines for both safety and economic reasons. The basic concern is the loss of gas and the associated hazards in the event of a break in the pipe. Factors which must be considered in determining the spacing of mainline valves include:

- The availability of continuous access to the valves
- The conservation of gas
- The time required to blow down any given section of pipe in case of emergency or maintenance
- Continuity of gas service
- Operating flexibility
- Future development within the pipe section
- Any significant natural conditions which could adversely affect the operation and security of the pipeline

The maximum spacing between valves is specified in Sec. 846 of ASME B31.8 and varies with the population density along the pipeline. Spacing on new transmission lines may not exceed the following:

Location	Spacing	
Class 1	20 miles	(32 km)
Class 2	15 mile	(24 km)
Class 3	10 miles	(16 km)
Class 4	5 miles	(8 km)

The mainline valves should be of the full-opening, through-conduit type to allow for the passage of scrapers and inspection pigs. Either ball or gate valves are suitable, preferably weld-end (avoids flange leaks) with shop-welded transition pieces. Valves for underground service should have stem extensions to elevate the valve operators above grade and should also have lubricant and bleed lines extended for ease of access.

Blowdown Assemblies. Blowdown assemblies allow for the evacuation of gas from sections of pipeline under emergency conditions or for scheduled maintenance operations. A typical mainline valve and blowdown assembly is shown in Fig. C6.5.

The primary consideration in sizing the piping for the assembly is the time required to blow down the section between two mainline valves.

The following formula, found in the American Gas Association Manual, provides a means of determining venting time and blowdown valve size:

$$T_m = B P_1^{1/3} G^{1/2} D^2 L F_c / d^2 \qquad (C6.12)$$

where

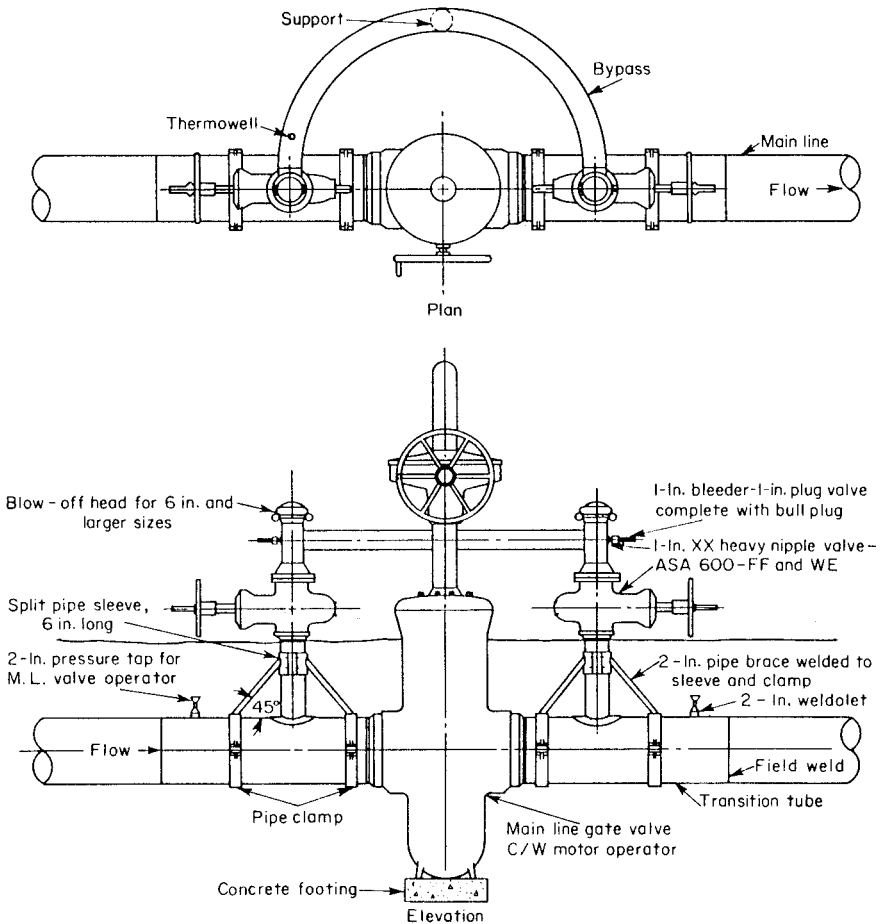
			Units	
			Imperial	*Metric*
$T_m =$	blowdown time		min	min
$B =$	dimensional constant		0.0588	0.0886
$P_1 =$	initial line pressure, abs		psia	kg/cm^2
$G =$	specific gravity		(Air = 1.0)	
$D =$	inside diameter of pipe		in	mm
$L =$	length of pipeline section		mi	km
$d =$	inside diameter of blowdown		in	mm
$F_c =$	choke factor:			
	ideal nozzle	= 1.0		
	through gate	= 1.6		
	regular gate	= 1.8		
	regular lube plug	= 2.0		
	venturi lube plug	= 3.2		


FIGURE C6.5 Mainline gate valve equipped with bypass and blowoff arrangement. *(Piping Handbook, fifth edition.)*

Supports for the blowdown assembly must be designed to not only carry the weight of valves and piping but also the thrust loads which will occur during venting.

Gas Distribution Systems

Although the service pipe that connects the street main to the customer's meter is usually installed by the gas supplying company, the actual ownership (and hence, responsibility) of the pipe varies. In some areas, the gas company owns the pipe all the way to the meter set assembly, but in others the customer owns the pipe from the property line.

Sizing of services may be facilitated by reference to published tables and charts,
FIGURE C6.6 Total gas flow through LP services, 0.5 in (12.7 mm) water column total drop.
FIGURE C6.7 Total gas flow through LP services, 0.3 in (7.6 mm) water column total drop.

or now, more than likely through the use of either proprietary gas company or marketed computer software. Regardless of the tools used, the following discussion still provides an overview of the thought processes involved, and the charts and tables allow for a simplified means of determining pressure drop and flow rate.

Many different bases are available and used in selecting the proper size. Some use a maximum pressure drop; some use a maximum size for all services; others make a detailed pressure drop calculation for each installation. A brief description of the methods followed by a majority of the companies will be of interest. Consideration of connected load, length of service, and main pressure are made in selecting service pipe size. Generally this combination of variables is handled by means of selecting an allowable pressure drop for a particular main pressure and then selecting the pipe size based upon length of service and anticipated load, which will result in a calculated pressure drop of less than the allowable. Since it is usually the easiest to determine the connected load on a gas service, this flow is used to size the service pipe. Some companies refine the principle by introducing a diversity factor based upon the assumption that all of the appliances will not be in use at the same time. Others assume that the service will ultimately supply a piece of gas space heating equipment and size the service for this load even if no house heating load is installed at present.

The pressure drop allowed on a gas service is primarily a function of the pressure being carried on the mains during the time the mains are supplying the peak demand. In a low-pressure system which operates at a nominal main pressure of from 6 to 8 in (152.4 to 203.2 mm) of water column, most of the companies consider the maximum allowable pressure drop on a gas service to be either 0.3 or 0.5 in (7.6 or 12.7 mm) of water column (see Figs. C6.6 and C6.7). An intermediate-pressure system operating at a main pressure of from 1 to 15 psig (0.07 to 1.05 kg/cm^2) will generally permit an allowable pressure drop of about 0.5 psig (0.035 kg/cm^2). High-pressure distribution systems permit allowable pressure drops of 0.5 to 3 psig (0.035 to 0.21 kg/cm^2). Another method of selecting the allowable pressure drop is to specify that it be some percentage of the main pressure during the maximum hour. One company selects a 20 percent drop, and another a 10 percent drop. Still another method is to specify a value of 10 for the difference in squares of the absolute inlet and outlet pressures.

Flow Characteristics of Low-Pressure Services.   Experiments in 1960 showed that the widely used Spitzglass equation for low-pressure gas flow required new resistance values. This flow is a function of inside diameter rather than surface smoothness. Thus, tubing of smaller diameter does not have a capacity equal to that of a larger steel pipe through which it may be drawn for replacement purposes.

The flow equation for either copper or steel services from ¾ in copper tubing size (CTS) copper to NPS 1½ (DN 40) steel pipe was found to follow the form:

$$Q = C \left[\frac{\text{total pressure drop in service, } P}{(K_p)(S/S')(L + L_{ef})} \right]^{0.54} \quad (C6.13)$$

NPS 1½ (DN 40) steel	22.0	6.71

PIPE AND FITTINGS

Primary Materials

Most pipe for transmission pipelines worldwide is made to American Petroleum Institute (API) Specification 5L, Specification for Line Pipe, and virtually all the

major pipe mills in the world qualify for the API stamp. The API specification covers:

- Pipe made from mild steel, Grades A and B (specified minimum yield strengths up to 35,000 psi)
- Pipe made from high-strength steels (i.e., X42, X46, X52 etc., the number following the "X" being the specified minimum yield strength expressed in thousands of psi)
- Pipe made by welding coiled skelp into a helix (spiral) and welding the abutted edges

Refer to App. E5 and App. E6.

Line pipe comes in a variety of sizes from NPS 3 to NPS 60 (DN 80 to DN 1500) in outside diameter. Special production runs of pipe up to NPS 100 (DN 2500) in diameter have been made. Wall thickness is usually specified in $\frac{1}{32}$ in (0.8 mm) in intervals, from $\frac{3}{16}$ in in small pipe sizes to 1¼ in (31.75 mm) in the larger diameters. American engineers use the decimal equivalent of $\frac{1}{32}$ in to express wall thickness (.219 for $\frac{7}{32}$ in, .250 for ¼ in, etc.). Engineers in metric countries express the same wall thickness in millimeters (.219 in = 5.56 mm, .250 in = 6.35 mm, etc.). Pipe sizes in the metric system tend to be expressed in multiples of 25 mm nominal (NPS 14 = DN 350, NPS 24 = DN 600, etc.). Refer to Chap. A1.

Pipe flanges and flanged fittings are manufactured according to the American Society of Mechanical Engineers Standard, ASME B16.5, Steel Pipe Flanges and Flanged Fittings, which establishes pressure ratings for eight classes of flanges and fittings. ASME B16.5 details the standard physical dimensions, number and size of bolt holes, etc. for each size fitting. The exact pressure rating of each class of fitting varies with type of steel and the design temperature.

Other Materials

Other materials which have been used in gas service include ductile-iron, plastic, and copper. Cast-iron, because of its brittleness, is quickly being replaced by plastic pipe. These are generally limited to use in mains and service lines in distribution systems. A brief summary of the limitations and restrictions on their use is given below.

Ductile-Iron. Ductile-iron pipe must be manufactured in accordance with ANSI A21.51/AWWA C151 Ductile Iron Pipe, Centrifugally Cast, in Metal Molds or Sand Lined Molds for Gas.

Plastic. Plastic pipe and components must be manufactured in accordance with the following American Society for Testing and Materials (ASTM) standards:

ASTM D 2513	Thermoplastic Gas Pressure Pipe, Tubing, and Fittings
ASTM D 2517	Reinforced Epoxy Resin Gas Pressure Pipe and Fittings

Copper. Copper tubing or pipe for use in gas mains is limited to pressures of 100 psi (7 kg/cm²) or less, must have a minimum wall thickness of 0.065 in (1.65 mm), and must be hard-drawn.

Where the gas being transported contains more than an average of 0.3 grains

of hydrogen sulfide per 100 standard cubic feet (2.83 standard cubic meters) of gas, copper may not be used.

COMPRESSOR STATIONS

Types and Function

The compressor station is the equivalent of the pump station on a liquid transportation pipeline system. Whenever a gas has insufficient energy for transport, a compressor station is installed. The types of compressor stations that are in general use can be categorized as follows:

Field or Gathering Stations.   These stations gather gas from wells in which pressure is not sufficient to produce a desired flow rate into transmission or distribution systems. Such stations may handle suction pressures from below atmospheric pressure up to 750 psig (53 kg/cm^2), and volumes from a few thousand to many million standard cubic feet (30 to 30,000 m^3) per day.

Repressurizing or Recycling Stations.   This type of station is an integral part of a processing or secondary recovery facility, which may or may not involve transportation of natural gas to a consumer. All or a percentage of the gas is reinjected into the reservoir for reservoir maintenance, or for storage for future use. Discharge pressures can exceed 6000 psig (420 kg/cm^2).

Storage Field Stations.   These stations compress trunk line gas for injection into designated storage wells. Discharge pressures may range up to 4000 psig (280 kg/cm^2) with compression ratios as high as 1 to 4. Some storage stations are designed to also permit the withdrawal of gas from storage as well, and to inject the gas into high-pressure pipe lines. These field stations require precise design engineering due to the wide range of pressure-volume operating conditions encountered.

Distribution Plant Stations.   Distribution plant stations compress gas from a holder supply to medium- or high-pressure distribution lines at about 20 to 100 psig (1.4 to 7 kg/cm^2), or compress gas into bottle storage at pressures up to 2500 psig (175 kg/cm^2).

Pipeline Booster Stations.   Stations of this type are used in gas transmission line service. The volume through these stations is usually quite large with compression ratios below 2. The pressure range is generally between 200 and 1000 psig (14 and 70 kg/cm^2), sometimes as high as 1200 psig (84 kg/cm^2). However, this upper limit is continuously being challenged and gas transmission systems with an ASME Class 900 pressure rating (150 kg/cm^2/2160 psi) are being considered.

Compressor Station Layout

A typical compressor station arrangement can be broken down into three principal systems:

- Main Gas System
- Unit Gas System
- Auxiliary Gas System

Main Gas System. The main gas system includes the main gas piping and equipment between the transmission pipeline and the compressor unit suction and discharge leads. Equipment encompasses:

• Station Block Valves
• Station Bypass Valve
• Station Purge Valve
• Gas Scrubbers
• Orifice Fitting
• Station Surge Valve
• Station Relief Valves
• Station Blowdown Valve

Unit Gas System. The unit gas system includes the suction and discharge leads from the main gas header to the compressor and back to the main gas header. Equipment basically consists of:

• Unit Block Valves
• Unit Bypass Valve
• Unit Purge Valve
• Unit Vent Valve

Auxiliary Gas System. The auxiliary gas system supplies the gas needed for compressor start-up and operation and for other facilities (such as power generation and valve actuation) within the compressor station which require gas. The subsystems include:

• Fuel Gas System
• Starting Gas System
• Utility Gas System

Gas enters the station through the station block valve, passes through the scrubber, orifice meter, and unit suction block valve to the compressors where it is compressed, and is then discharged through a unit discharge block valve to the station discharge piping and block valve back to the transmission line.

Piping

In the United States, compressor station piping design is governed by the minimum requirements of the Federal Safety Standard "DOT Title 49 Part 192 Transportation of Natural and Other Gas by Pipeline."

For high-pressure transmission service, the law specifies certain types of pipe materials. According to ASME B31.8, compressor station piping must be Class 3 construction. A design factor of 0.5 (Table C6.2) must be used in the steel pipe design formula.

After possible pipe sizes are determined and preliminary station layouts are prepared, pressure-drop studies and thermal piping stress studies must follow. The thermal piping stress analysis determines that stresses in station piping in general

stays within allowable limits, and that, in particular, forces and moments on compressor flanges do not exceed allowable values set by the compressor manufacturer. Pipe stresses are caused by the temperature increase when gas is being compressed. The temperature rise across a compressor can range from 0.2 to 4°F (0.1 to 2°C) per 1.5 psi (0.1 kg/cm^2) increase in pressure, depending on the specific gas and pressure involved.

Noise is defined as airborne sound energy within a broad range of frequencies that has the potential to cause either physical or psychological discomfort, or injury to personnel. In order to keep noise levels in station piping within acceptable limits (on the order of 80 decibels), the following gas velocities should not be exceeded:

- Station Main Gas Piping   40 fps (12 m/s)
- Unit Main Gas Piping   25 fps (7.5 m/s)
- Fuel Gas Piping   25 fps (7.5 m/s)

The selection of maximum allowable velocities requires an engineering study for each specific application.

In designing compressor station piping, consideration must also be given to installing piping above ground, or below ground. It should be noted that above-ground piping is easier to monitor for gas leaks and to maintain; however, station yard access may be impeded. For buried piping, the reverse applies.

An additional item often overlooked in station piping design is the installation and placement of drain connections to properly drain the water out of piping after hydrostatic testing.

Components and Equipment

Buildings.   Types of compressor station buildings will vary depending on geographic location and climate, whether the station is manned or unmanned, and whether it is located in a rural or a populated area. Structures can vary from a simple shelter to provide some protection from sun and rain, to site-constructed or prefabricated buildings, to totally enclosed prepackaged units ready for installation.

Station Valves—Operators.   Main station valves, normally ball, plug, or gate, are actuated by gas or electric motors for ease and speed of operation. Use of motor operators for valves is a function of the availability and cost of power. Gas actuators usually utilize the energy inherent in the pressurized gas of the main line. However, gas actuators will vent spent gas to the atmosphere, so the frequency of valve operation and the quantity of gas needed per operation must be evaluated.

Scrubbers.   Gas scrubbers are installed in upstream station piping to remove any liquids or solid particles which may damage the compressors. They tend to be of two types as follows:

Horizontal Inline Type.   Horizontal inline scrubbers take advantage of the effect of the helicoid tuyere. The gas, after entering the vessel, is subjected to an extended centrifugal motion which throws the heavier particles to the periphery of the vessel. Here the particles are forced into an annular space, at which point all solid particles are trapped and ejected through the drain. The inlet stream, freed from entrained particles, continues through to the outlet of the separator.

A secondary vortex breaker prevents reentrainment, thereby extending flow range. General scrubber characteristics are as follows:

Efficiency:	99.5 percent of all solids or liquids
Pressure drop:	Low
Cost:	Medium
Flow Range:	Relatively wide
Installation:	Simple and straightforward

Vertical Tube Type.   In vertical tube type gas scrubbers, dust-laden gas enters the tube tangentially, creating a high centrifugal force that projects solids and liquid droplets to the walls of the tube. Clean gas reverses flow at the vortex and passes through a concentric outlet tube to an outlet plenum. Impurities continue downward to a storage area for disposal.

Flowmeters.   (see Gas Metering.)

Purge, Relief, Surge, and Blowdown.   (see Pressure Relief.)

OTHER FACILITIES

Pressure Relief

The following discussion on pressure-relief valves was abstracted from an article by Gary B. Emerson in the February 1987 issue of *Pipe Line Industry*.[1]
A *safety relief valve* is an essential and important piece of equipment on virtually any pressured system. Required by the ASME Boiler and Pressure Vessel Code, Sec. VIII, Pressure Vessels, among others, it must be carefully sized to pass the maximum flow produced by emergency conditions.

Sizing.   The sizing formulas for vapors and gases fall into two general categories:

- Based on the flowing pressure with respect to the general categories
- Based on the flowing pressure with respect to the discharge pressure

When the ratio of P_1 (set pressure plus allowable accumulation) to P_2 (outlet pressure) is greater than two, the flow through the relief valve is sonic; the flow reaches the speed of sound for the particular flowing medium. Once the flow becomes sonic, the velocity remains constant; it cannot go supersonic. No decrease of P_2 will increase the flow rate.

Sonic Flow.   In accordance with API RP 520, Part 1, Sec. 4.3.2, the formulas used for calculating orifice areas for sonic flow are:

$$A = B_w W (T Z / M)^{0.5} / C K P_1 \qquad (C6.14)$$

TABLE C6.8   Gas Constant Based on Ratio of Heats

Gas	Mol. wt.	C_p/C_v	C
Acetylene	26	1.26	343
Air	29	1.40	356
Ammonia	17	1.31	348

Sulfur dioxide	64	1.29	346

$$A = B_q Q (T Z M)^{0.5} / (6.32 C K P_1) \qquad\qquad (C6.15)$$

			Units	
			Imperial	*Metric*
where	$A =$	calculated orifice area	in^2	cm^2
	$B_w =$	dimensional constant	1	1.3387
	$B_q =$	dimensional constant	1	21.4881
	$W =$	flow capacity	lb/h	kg/h
	$Q =$	flow capacity	scfm	m^3/min
	$M =$	molecular weight of flowing media	dimensionless	
	$T =$	inlet temperature, absolute	°F + 460	°C + 273

$Z =$	compressibility factor	dimensionless	
$C =$	gas constant based on ratio of specific heats (Table C6.8)	dimensionless	
$K =$	valve coefficient of discharge	dimensionless	
$P_1 =$	inlet pressure (set pressure + accumulation + atmospheric pressure)	psia	kg/cm^2

Subsonic Flow. The second general category for vapor or gas sizing is generally when P_2 is greater than half of P_1 (back pressure greater than half of inlet pressure).

Using k (ratio of specific heats) and P_1/P_2 (absolute), confirm from Fig. C6.8 that the subsonic ("low pressure") flow formula is required. If so, then determine F factor. If not, use sonic flow formula.
FIGURE C6.8 Low-pressure and high-pressure flow formulas.

$$A = BQ(GTZ)^{0.5}/[863KF((P_1 - P_2)P_2)^{0.5}] \qquad (C6.16)$$

where			Imperial	Metric
			\multicolumn{2}{c}{Units}	
$A =$	calculated orifice area		in^2	cm^2
$B =$	dimensional constant		1	21.4881
$Q =$	flow capacity		scfm	m^3/min
$G =$	specific gravity		dimensionless	
$T =$	inlet temperature, absolute		°F + 460	°C + 273
$Z =$	compressibility factor		dimensionless	
$F =$	factor obtained from Figure C6.8		dimensionless	
$K =$	valve coefficient of discharge		dimensionless	
$P_1 =$	inlet pressure (set pressure + accumulation + atmospheric pressure)		psia	kg/cm^2
$P_2 =$	outlet pressure (back pressure + atmospheric pressure)		psia	kg/cm^2

After determining the calculated orifice area, select the next-largest standard orifice size from the relief valve manufacturer's catalog.

Selection. The fundamental selection of a relief valve involves the consideration of the two basic types more commonly used.

Conventional spring-loaded relief valves embody the following advantages:

- Competitively priced at lower pressures and in smaller sizes
- Wide range of chemical compatibility
- Wide range of temperature compatibility, particularly at higher temperatures

The disadvantages of conventional spring-loaded relief valves are:

- Metal-to-metal seat not tight near set pressure and usually after valve relieves
- Sensitive to conditions that can cause chatter and/or rapid cycling
- Protection against effects of back pressure is expensive, pressure limited, and creates possible additional maintenance problems
- Testing of set pressure not easily accomplished

Advantages of pilot-operated type relief valves are:

- Seat tight to set pressure (Fig. C6.9)
- Ease of setting and changing set and blowdown pressures
- Can achieve short blowdown without chatter
- Pop or modulating action available
- Easy maintenance
- Easy verification of set pressure without removing relief valve from service
- Flexible—options for remote operation, back pressure protection, valve position indication
FIGURE C6.9 Setting seat pressure to set flow pressure.

The disadvantages of pilot-operated relief valves are:

- Maximum temperature limitations
- Should not be used in extremely dirty or polymerizing type service

Inlet Piping. The proper design of safety relief valve inlet piping is extremely important. Very often, safety relief valves are added to an installation at the most physically convenient location, with little regard to flow considerations. Pressure loss during flow in a pipe always occurs. Depending upon the size, geometry, and inside surface condition of the pipe, the pressure loss may be large (20, 30, or 40 percent) or small (less than 5 percent).

API RP 520, Part 2, recommends a maximum inlet pipe pressure loss to a safety relief valve of 3 percent. This pressure loss shall be the sum total of the inlet loss, line loss, and when a block valve is used, the loss through it. The loss should be calculated using the maximum rated flow through the pressure-relief valve.

The 3 percent maximum inlet loss is a commendable recommendation but often very difficult to achieve. If it cannot be achieved, then the effects of excessive inlet pressure should be known. These effects are rapid or short cycling with direct spring-operated valves or resonant chatter with pilot-operated relief valves. In addition, on pilot-operated relief valves, rapid or short cycling may occur when the pilot pressure sensing line is connected to the main valve inlet. Each of these conditions results in a loss of capacity.

Pilot-operated valves can tolerate higher inlet losses when the pilot senses the system pressure at a point not affected by inlet pipe pressure drop. However, even though the valve operates satisfactorily, reduced capacity will still occur because of inlet pipe pressure losses. The sizing procedure should consider the reduced flowing inlet pressure when required orifice area, A, is calculated.

A conservative guideline to follow is to keep the equivalent L/D ratio (length/diameter) of the inlet piping to the relief valve inlet to five or less.

Discharge Piping. Discharge piping for direct spring-operated valves is more critical than for pilot-operated valves. As with inlet piping, pressure losses occur in discharge headers with large equivalent L/D ratios. Excessive back pressure will reduce the lift of a direct spring-operated valve, and enough back pressure (15 to 25 percent of set + overpressure) will cause the valve to reclose. As soon as the

valve closes, the back pressure in the discharge header decreases and the valve opens again, with the result that rapid cycling can occur.

Pilot-operated relief valves with the pilot vented to the atmosphere or with a pilot balanced for back pressure are not affected by back pressure. However, if the discharge pressure can ever exceed the inlet pressure, a back-flow preventer must be used.

The valve-relieving capacity for either direct- or pilot-operated relief valves can be affected by back pressure if the flowing pressure with respect to the discharge pressure is below critical (subsonic flow).

Balanced bellows valves (direct spring-operated) have limitations on maximum permissible back pressure due to the collapse pressure rating of the bellows element. This limitation will in some cases be less than the back pressure limit of a conventional valve. Manufacturer's literature should be consulted in every case. If the bellows valve is used for systems with superimposed back pressure, the additional built-up back pressure under relieving conditions must be added to arrive at maximum back pressure.

Satisfactory performance of pressure-relief valves, both as to operation and flow capacity, can be achieved through the following good discharge piping practices:

- Discharge piping must be at least the same size as the valve outlet connection and may be increased when necessary to larger sizes.

- Flow direction changes should be minimized, but when necessary use long-radius elbows and gradual transitions.

- If the valve has a drain port on its outlet side, it should be vented to a safe area. Avoid low spots in discharge piping; preferably pitch piping away from valve outlet to avoid liquid trap at valve outlet.

- Proper pipe supports to overcome thermal effects, static loads due to pipe weight, and stresses that may be imposed due to reactive thrust forces must be considered.

Reactive Force. On large-orifice, high-pressure valves, the reactive forces during valve relief are substantial, and external bracing may be required (see Fig. C6.10).
FIGURE C6.10 Reactive forces during valve relief.

API RP 520, Part 2 gives the following formula for calculating this force.

$$F = [Q_h/366][(kT/(k + 1)M]^{0.5} \qquad (C6.17)$$

		Units	
		Imperial	*Metric*
where	$F =$ reactive force at valve outlet centerline	lb	kg
	$Q_h =$ flow capacity	lb/h	kg/h

$k =$	ratio of specific heats (C_p/C_v)	dimensionless	
$T =$	inlet temperature, absolute	°F + 460	°C + 273
$M =$	molecular weight of flowing media	dimensionless	

If bracing is not feasible, a dual-outlet valve (available in some pilot-operated safety relief valves) can be used. The reactive forces are equal but opposite, resulting in zero force on the valve outlet, but if redirected can still impose loads that must be reacted to in some manner.

Testing. Using DOT Title 49, Part 192.739 as a guideline, each valve should be inspected at least once a year to determine that it:

- Is in good mechanical condition
- Will operate at the correct set pressure
- Has adequate capacity and is operationally reliable
- Is properly installed and protected from dirt, liquids, or other conditions that might prevent proper operation.

The effectiveness of a safety relief valve installation depends greatly on proper sizing and selection of the valve type, suitable installation conditions, and proper and timely testing of the valve.

Pressure Regulation

Good regulation of high-pressure gas is important for two reasons:

- To protect low-pressure equipment from becoming overpressured and becoming a hazard.
- If located near an orifice meter station, a regulator station must operate smoothly or it will result in a chart record which is impossible to interpret accurately.

Types of Regulator. The type of load to be controlled usually dictates the type of regulator to be selected:

- *Globe Bodied*: The globe-bodied control valve has been the standard for the gas industry for many years and performs well in a wide range of applications. When properly sized and mated with a good controller, it is very well-suited for difficult applications such as pressure control on a plant where load changes rapidly. However, it becomes very large and difficult to maintain when sized to control large loads with low pressure drops. The globe-bodied regulator is also inherently noisy.
  With some relatively new designs, the disadvantages of the globe-bodied control valve are being overcome. Patented trim designs control flowing velocities by forcing the gas through a large number of very small flow paths with multiple 90° turns. The resulting reduced flowing velocities effectively minimize erosion, noise, and vibration, and result in enhanced process control.

- *Expansible Tube*:   The expansible tube regulator is extremely simple in its construction and principle of operation. On many applications it does not require a controller but operates with a pilot regulator.

    The expansible tube is by nature quieter than many regulators and it has good low-flow characteristics and tight shutoff. It does have a minimum differential pressure requirement of 10 to 50 psi (0.70 to 3.52 kg/cm^2), depending on size, which precludes its use in some applications.

- *Ball Valve*:   The ball valve is best suited to large loads where small pressure drops are required. This is often the case in flow control applications or where pipeline pressure varies from time to time. The ball valve can perform a double duty when used as a monitor regulator and as an isolating valve on one side of a primary regulator.

    Ball valves are inherently noisy and can give erratic control if not maintained properly. Due to their large capacity, it is often important to consider pressure losses through adjacent piping when sizing this type of regulator.

Influence on Station Design.   Whichever type regulator is selected, the way it is installed is important for successful operation. For most applications, it is best to have at least two parallel units. If the load varies widely, *split range* control is used, requiring two regulators, one to control low flows and a large-capacity unit to come in when required. For critical applications, it is desirable to have a standby regulator which would not normally be used but would open in an emergency.

When necessary to make a very large pressure reduction, it is best handled in two stages, with each regulator making about half the cut. Two-stage regulation can enhance measurement if one stage is placed on each side of the measuring station.

The upstream regulators should be used to control pressure in order to maintain a constant pressure at the measuring station. Downstream regulators can be used to control flow or to control customer pressure. As much volume as possible should be provided between the two regulator gauges; otherwise stable control may be difficult to achieve.

Overpressure Protection.   The most important part of designing a regulator station is being as sure as possible that the system downstream cannot be overpressed. The first step in protection is strict compliance with all safety regulations and, in particular, Part 192 of the Department of Transportation Safety Regulations (DOT 192).

Basically DOT requires secondary protection if it is possible for the pressure upstream of a regulator to reach a level which will be dangerous to the downstream system. Secondary protection may be provided either by a monitor regulator installed in series with the primary regulator or by a relief valve.

There are systems, however, where a safety/relief valve may be the best selection. If a regulator feeding a small-capacity system fails suddenly, a monitor may be too slow to prevent the system from being overpressed. A relief valve should be provided on small downstream systems to take off valve leakage if the load is cut off completely.

Gas Metering

Efficient measurement and control of high-pressure natural gas is vital. A measurement error of only 1 percent can cost thousands of dollars a day at a single large-volume station.

Measurement. Measurement requirements in the gas industry can be broken into two broad categories:

1. *Custody Transfer:* Most important and demanding is custody transfer at a station measuring gas flowing from one company to another. The orifice meter has dominated the field in measurement of large volumes of gas at high pressure. However, turbine meters and rotary meters are being used more and more where better accuracy is justified.

2. *Control.* Control, or check measurement, is used for routing gas toward a customer, control of compressor stations, and so forth. Repeatability is the most important feature of such measurement, and the complexity and expense of custody transfer type metering are not usually justified.

Gas industry meters operate on simple physical principals and have a long history of reliable and accurate performance. The commonly used meters fall into two categories: *displacement types* such as diaphragm, rotary-lobed impeller, and rotary vane shown in Fig. C6.11 and C6.12; and *rate-of-flow (velocity)* meters such as orifice meters and turbine meters shown in Fig. C6.13.

Tables C6.9 and C6.10 list factors which affect selection of the five meter types used in the gas industry. The tables are intended as a guide and should not be used without further study when selecting the best meter for a particular application. Capacity ranges given in Table C6.9 are shown graphically in Fig. C6.14 The ranges are representative and are intended to give preliminary information for specific problems. Since the chart reflects information from many manufacturers, individual model lines may not have the exact capacity shown.

A relatively recent addition to the long line of meters available to the gas industry is the ultrasonic gas flow meter. An array of ultrasonic transducers placed at angles across the bore of the meter tube measure the time it takes for sound to travel in a number of parallel planes. Sound transit times are measured with and against the flow through the meter. Given that travel time in the direction of flow is less than that against the flow, and the transducer locations are a known constant, the mean velocity of the gas can be calculated by averaging the measurements from each plane. The accuracy of the ultrasonic meter has evolved to the point now that it can determine gas flow rates to custody transfer standards.

The major advantage of the ultrasonic gas flow meter is its nonintrusive design. There are no parts in the gas stream to obstruct flow. There are also no moving parts requiring lubrication and maintenance.

Leak Detection

Leak detection for both gas and liquid pipelines, and especially for those fluids such as ethane and propane that are sometimes liquid and sometimes gas, has been an industry problem for many years. Public attention to the subject is now widespread.

The safety record of the pipeline industry is quite good. Measured in terms of accidents (defined by the U.S. Department of Transportation regulations in terms of dollars and fluid loss) per 1000 mi (1600 km) of pipeline, deaths per ton mile of cargo moved, or any other scale, the pipeline record is better than other means of transportation by at least an order of magnitude.

The causes of leaks are many and varied, but over 70 percent are accounted for by accidental damage from external sources, corrosion, and defective pipe.
FIGURE C6.11 Diaphragm displacement meters operate by alternately filling chambers of known volume.
FIGURE C6.12 Rotary displacement meters, like diaphragm meters, measure gas flow by alternate filling and emptying of fixed volume chambers. A counter or dial registers the total gas amount.

Historically, the number one source of leaks has been external corrosion, but modern pipe coatings and the almost universal application of cathodic protection system in the last 60 years has all but eliminated corrosion leaks on the newer pipelines. Modern mill practices and more conscientious hydrostatic testing have almost eliminated defective pipe as a cause of leaks on new lines. Of ever-increasing importance, however, is the problem of damage to pipelines by construction machinery. The problem is made worse by the fact that the very machine that does the damage comes equipped with a spark or hot exhaust to ignite the leaking fuel. It
FIGURE C6.13 Velocity flow meters pass a steady gas stream. Flow is detected as a differential pressure in the orifice meter and as rotor movement in the turbine meter.

is recommended that such protective measures as extra-depth burial, concrete slabs and/or warning tapes buried above pipe, and extra line markers be considered at major road crossings and in city growth areas.

One of the problems with leak detection is the frustration of knowing that when a leak has been detected a large part of the damage has already been done. It is well and good to say that early remedial action is needed. However, one must know what action to take—for example, to immediately slam a mainline valve shut would almost invariably be the wrong thing to do on a liquid line. Any action following a leak signal must be thought out very carefully. The other frustrating problem with leak detection is that it may be impossible to do at any reasonable cost.

Rudimentary leak detection was carried out for years by reporting hourly meter readings. Minor differences in reading time, temperature, line pack, and so forth made the result somewhat erratic, but a continuous shortage in delivery on a small pipeline was sufficient cause to assume a leak. Large leaks or *line breaks* were detected (sometimes automatically) by the combinations of suction and discharge pressure with flow at pump stations; that is, falling discharge pressure combined with increased flow meant a leak downstream; falling suction combined with decreased flow meant a leak upstream. The difference today is in the magnitude of the problem. The ± 2 percent deficiency detectable on an NPS 8 (DN 200) line transporting 25 million cubic feet per day (25 MMCFD; 708 Mm^3/D) was a 0.5 MMCFD (14 Mm^3/D) leak. Today, the ± 0.2 percent deficiency (may be) detectable by a sophisticated leak detection system on an NPS 42 (DN 1050) line transporting 1000 MMCFD (28 MMm^3/D) is a 2 MMCFD (57 Mm^3/D) leak.

Some new, patented devices which "listen" for the pressure wave which is generated by a suddenly occurring leak are state of the art leak detection. Today

TABLE C6.9 Summary of Gas Meter Selection Factors

Factor	Gas properties						Meter characteristics							
	Maximum pressure[1]		Flowing fluid temperature limits		Suitability for corrosive gas	Influence of condensate	Base maximum capacity range		Accuracy % of reading 10 50 90	Base rangeability	Type of scale	Common construction materials[2]	Pressure loss at base maximum capacity	
Meter type	psig	kg/cm²	°F	°C			Mcfh	m³/h					psi	kg/cm²
Diaphragm displacement	1000	70.3	−30 to +140	−34 to +60	No	Potential	0.2 to 12	5.7 to 339.8	±1	200:1	Uniform	Al/Cl/Brass/ Plastic/Zinc alloy	0.02 to 0.07	0.001 to 0.005
Rotary rotating vane	1440	101.2	−40 to +145	−40 to +63	Yes (with special bearings & materials)	None	3 to 38	85 to 1076	±1	25:1	Uniform	Anod. AL/300/SS /Steel/Bronze	0.04	0.003
Rotary lobed impeller	1440	101.2	−40 to +140	−40 to +60	Yes (with special bearings & materials)	None	1.5 to 102	42.5 to 2888	±1	20:1	Uniform	AL/CI/Steel	0.7	0.005
Gas turbine	1440	101.2	−40 to +145	−40 to +63	Yes (with special materials)	None	4 to 150	113.3 to 4248	±1	5:1 to 25:1	Uniform	AL/DU/CS	0.04	0.003
Orifice	5000	351.5	−65 to +500	−54 to +260	Yes	Potential	22 to 1500	623 to 42477	±1½	3:1 to 4½:1	Square root	FS/SS/CS	2.5	0.176

[1] Refer to manufacturer's published literature for the maximum pressure rating of a specific meter size.
[2] Common construction materials: AL = Aluminum, CI = Cast iron; CS = Cast steel; DU = Ductile iron; FS = Forged steel; SS = Stainless steel.

TABLE C6.10 Summary of Gas Meter Selection Factors

Factor	Installation factors						Economic factors				
	Normal line size		Straight pipe reqmts (no. of pipe diameter)	Ambient temperature range			Approx. first cost[3]	Life expectancy		Maintenance cost[4]	Installation cost[4]
Meter type	NPS	DN		°F	°C	Limitations		Between repairs (years)	Total (years)		
Diaphragm displacement	¼ to 4	8 to 100	None	−30 to +40	−34 to +60	Horizontal	220	8 to 10	30 to 40	L	M
Rotary rotating vane	2 to 6	50 to 150	None	−40 to +145	−40 to +63	Not critical	130	3 to 6	10 to 25	M	L
Rotary lobed impeller	1.5 to 10	40 to 250	None	−40 to +140	−40 to +60	Horizontal and leveled	150	3 to 6	10 to 25	M	L
Gas turbine	2 to 12	50 to 300	4 to 10	−40 to +145	−40 to +63	Horizontal	125	3 to 6	10 to 25	M	L
Orifice	2 to 16	50 to 400	3 to 40	−40 to +170	−40 to +77	Horizontal	100	1 to 3	10 to 15	H	M

[3] First cost ratio is based upon a NPS 2 (DN 50) orifice meter sized to measure approximately 5 Mcfh (141.6 m³/h) at atmospheric pressure.

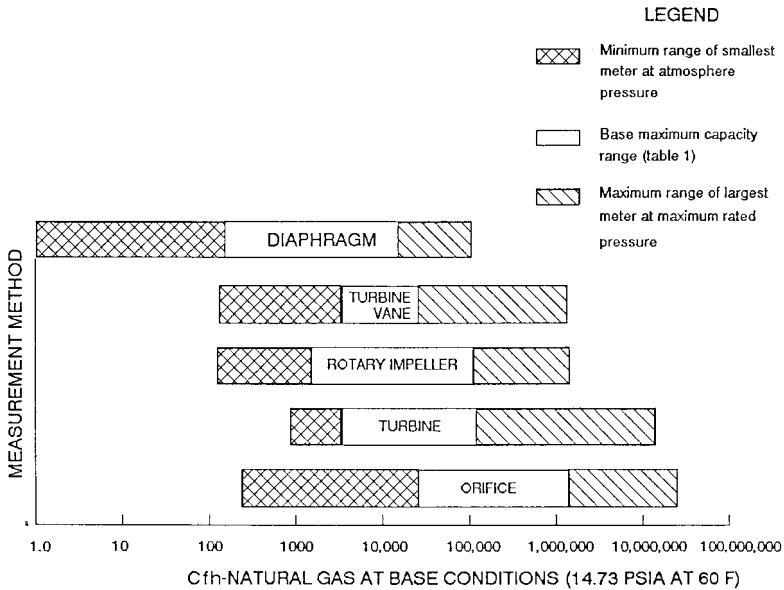
[4] Maintenance and installation costs: H = High; M = Medium; L = Low.


FIGURE C6.14   Gas measurement meter capacities.

a leak is defined as "the loss that can be measured with existing instrumentation" (probably about 0.1 percent of steady state flow).

Real-time computer modeling techniques have been developed which have already improved the sensitivity of old-fashioned "meter in-meter out" techniques even under transient flow conditions. Accuracy is achieved by the use of remote terminal units (RTUs), high-precision instrumentation, and an on-line computer.

Scrapers and Scraper Handling

Purpose of Scrapers and Spheres.   At various times throughout the life of a pipeline a need is found to send a *scraper* (pig) or *sphere* through the line. This may be for any one or combination of the following:

- *Initial Cleaning*:   On completion of a section of pipeline, at least one scraper is run to push out air as well as trash, rocks, weld slag, and so forth preparatory to hydrostatic testing.

- *Sizing Run*:   Before a line is put in service, usually before hydrostatic testing, a scraper with a steel plate, or a "caliper" pig, is run in order to make sure the pipe was not damaged during construction and that all future pigs will pass unrestricted.

- *Dewatering Scrapers/Spheres*:   During commissioning of the pipeline, a number of scrapers are used to displace the water left after hydrostatic testing.
FIGURE C6.15   Launching and receiving scraper traps for gas service. *(T.D. Williamson.)*

- *In-Service Cleaning*:   During normal pipeline operation pipelines accumulate water, corrosion products (rust, scale), condensate and compressor oil, sand, and dust which must be cleaned out on a regular basis to maintain efficiency of operation.
- *Deslugging*:   On some two-phase pipelines, spheres are run on a scheduled basis to push condensate into the slug catchers.

• *Inspection*:   Special instrumented "smart" pigs may be run from time to time to check corrosion, listen for leaks, or check damage after an accident.

   Some of these uses require special scrapers with knives (for cutting waxy deposits) or brushes (for cleaning rust/scale) or noise making devices, and so forth.

Scraper Handling Devices.   Because of the variety of uses for which scrapers are employed, a wide rang of scraper-handling equipment is required. The basic horizontal scraper trap has proved to be convenient for general services (see Fig. C6.15). There are two types of scraper traps, one for launching and one for receiving. The difference between the two is the point of entry of the bypass (kicker/equalizer) lines into the barrel, and sometimes the barrel length.

   The traps are equipped with a barrel that has an internal diameter 2 to 4 in (50 to 100 mm) larger than that of the mainline, a hinged closure, a full-opening (through conduit) trap valve, side-entering barred tee, and a bypass line with a valve. The trap assembly launches or receives a scraper by pinching the station valve with the trap and the bypass valves both open. This controls the movement of the pig out of the launcher or into the receiver.

   Scraper traps are placed at the initial and terminal points of the pipeline and at any other point where it is required to start or receive a scraper. It is not always necessary to put traps at a change in pipe size as multisized scrapers are available (within limits), nor is it necessary to put scraper traps at every compressor station. Usually it is the length of the pipeline section and the expected wear on the scraper that will indicate where scraper traps are required. Figure C6.16 is a simple piping diagram of the essential piping and valves in a booster station.
FIGURE C6.16   Piping arrangement for a station (*a*) with scraper traps, (*b*) without traps, where a scraper is passed by shutting down, and (*c*) with pipe and valving for bypass without shutdowns.

Pin Ball Machines.   On some pipelines where spheres are used frequently for cleaning condensate or for separating product batches, a special adaptation of the basic scraper trap allows for loading of several spheres in the launcher and releasing them on signal or by timer. The receiver is long enough to receive as many spheres as can be launched. Both launcher and receiver are sloped so that gravity aids in the operation.

Layout.   Scrapers and spheres are heavy, especially in the larger sizes, and may require davits or cranes to maneuver them into and out of the trap. Traps should also be located with truck and machinery access in mind. Gravity drainage to a sump tank should be provided to collect liquid from the trap drain connection and from spillage at the trap door.

CORROSION PROTECTION

Gas system pipelines are subject to both external and internal corrosion. In general, external corrosion is more serious in that it can drastically reduce the life of the pipeline and impair its safety. Internal corrosion, apart from exceptional cases of corrosive fluid components such as H_2S and CO_2, is usually a much more gradual process resulting in a lowering of pipeline efficiency. Regular line cleaning, as discussed in ''Scrapers and Scraper Handling,'' can be utilized to take care of the pipe internally for most installations. However, with an unusually corrosive fluid, internal coatings or inhibition might also be needed.

The corrosion rate of steel is higher in low-resistance soils or seawater that it is in high-resistance soils such as dry sands. Corrosion rates are also higher in turbulent waters than when the water is stagnant.

The two principal parts of corrosion protection are *pipe coating* (or insulation) to increase the pipe to soil resistance and *cathodic protection* (impressed current or galvanic anodes) to make the pipe always cathodic.

Coatings

For many years pipelines were coated with processed natural substances such as asphalt or coal-tar enamels, usually reinforced with fiberglass mesh, and over-wrapped with felt sheeting. Synthetic organic plastic materials have been developed relatively recently for external coatings and these are now in common use.

Coal Tar and Asphalt Enamels.   These coatings are applied hot over a cold primer and usually reinforced with a fiberglass inner wrap and protected with a felt outer wrap. They were often applied ''over the ditch'' by special ''coat and wrap'' machines. Well-founded environmental concerns over the toxicity of the fumes from the hot coal tar and asphalt enamels have curbed their use. However, these coatings are still being plant-applied under strict controls.

Asphalt Mastics.   This coating is commonly applied in a shop. It forms a thick ½ to ⅝ in (12.7 to 15.9 mm) layer around the pipe, and has mineral fillers which provide built-in reinforcement. Generally, it does not require an outer wrap.

Mastics have been extensively used for submarine lines, for swamp crossings, and for some land lines. They are not in common use today.

Extruded Plastic Coatings.   These coatings are usually applied in a shop, after sandblast cleaning of the pipe and priming with a thin layer of mastic. They afford good protection because the mastic exudes through nicks or scratches and heals breaks in the coating. Other systems include a bonded polyethylene jacket with a nonbonded PVC (polyvinylchloride) outer rock-guard. Extruded coatings are often used where long-term dependability is required for city service or for swamp service. They are also used on submarine lines.

Tape Coatings.   These coatings usually have an adhesive backing, and may be applied in a shop or yard, or over the ditch. Polyethylene and polyvinylchloride tapes are readily available. Polyethylene may be favored for its chemical, thermal, and physical stability.

Fusion-Bonded Epoxies. These are very thin coatings applied in a shop. The pipe is degreased, sandblasted, and heated to the fusion temperature. Epoxy powder is applied electrostatically and fuses to a uniform coat on the heated surface. Pinholes and other defects may be repaired with hot stock or with a liquid epoxy resin and catalyst compound. Refer to Chap. B10.

The coating is tough and easy to repair. However, it must not be too thick or it may crack during bending, and is subject to cathodic disbonding.

Field Joint Coatings. When each length of pipe has been coated individually, the field joint must still be protected after it is welded. Generally, the field joint coating material should be similar to the main pipe coating, and suitable for application in relatively uncontrolled field conditions.

Asphalt and coal tar enamels are usually applied by hand, along with the appropriate inner and outer wraps. Plastic tapes are also applied by hand.

For extruded plastic coatings, plastic shrink sleeves with mastic backing may be used. They are slipped over the pipe before the joint is welded, and are moved to cover the joint afterwards. Shrink sleeve wraps, which can be applied over the completed weld at any time, are also available. Application of heat then causes the plastic to shrink tightly down on the joint and on the coating to either side.

Mastic is usually made up by surrounding the joint with a thin metal shield and pouring hot mastic into the shielded space. This usually bonds well with the mastic to either side and makes a satisfactory tight joint.

Fusion-bonded epoxy coatings may be made up by heating the joint with a preheat coil and applying the resin powder. The pipe surfaces must be sandblasted before the powder is applied.

Liquid epoxy resin and catalyst compound, applied by hand, may also be used for field joint protection.

Internal Coatings. Where corrosive components are encountered in the gas being transported, the pipe can be protected internally by adding inhibitors to the fluid or by coating the pipe internal wall. An economic comparison can assist in making a choice. Continued use of inhibitors tends to be costly and introduces complications both in injection equipment and in the resultant effect on delivered gas analysis.

Coal tar and asphaltic components for internal coating are not difficult to apply, but if deterioration occurs during the life of the pipeline it can seriously affect the pipeline efficiency.

Epoxy coatings give good protection, long life, and a low friction factor. The main problem is to get a satisfactory bond between the shop-applied internal coating and the machine- or hand-applied coating on the joints after welding. This involves special application procedures which must be conscientiously followed in the field.

Cathodic Protection

Cathodic protection is a method of inhibiting corrosion that has been used for over a century. It is applicable to all types of pipe metals, although it is used mainly for steel pipe. The technique is to connect the pipeline to an anode bed and to make the pipe behave as a cathode by impressing a direct current voltage so that the anode bed corrodes and not the pipe. Where this is not practicable (as on long
FIGURE C6.17   Magnesium anode protects coated steel pipe; current flows from anode through earth to pipe. *(Pipeline & Gas Journal, February 1984.)*

water crossings), passive protection may be attained by attaching sacrificial anodes directly to the pipe (see Fig. C6.17).

Cathodic protection is particularly important for coated pipe, to overcome the effect of pinholes or accidental breaks in the coating, which would otherwise permit local corrosion cells to form. Being localized, these cells are highly active and can rapidly penetrate the pipe wall.

Insulating flanges are necessary to ensure the integrity of the section of pipeline to be protected. Test leads installed at intervals along the length of the line during construction are used to monitor the voltage levels during the life of the pipeline. Regular measurements and maintenance, as required, ensure the continued effectiveness of the cathodic protection system.

Impressed Current Systems. Impressed current systems are generally installed where alternating current is available for the rectifier units (see Fig. C16.18). Since the units can be obtained in a wide range of output voltage and current combinations, they are used (1) where soil or water electrical resistivities are high and (2) where total current requirements are large.
FIGURE C6.18   Additional current for cathodic protection requires use of a rectifier. *(Pipeline & Gas Journal, February 1984.)*

Direct current for cathodic protection is provided by a transformer-rectifier combination. Where alternating current is not available for standard rectifier units, alternative direct current sources that can be used are thermoelectric generators, diesel generators, and solar power systems.

Typical anode materials for impressed current systems are graphite, high-silicon iron, lead-silver alloys, and platinum on a titanium or columbium substrate. On occasion scrap steel is used, but usually only because of its availability. As an anode material, steel is consumed at a rate of about 20 lb (9.1 kg) per ampere year. Consumption for graphite and silicon iron is approximately 1 lb (0.45 kg) per ampere year, for lead-silver about 0.1 lb (0.045 kg) per ampere year, and for platinum about 6 to 20 milligrams per ampere year.

Galvanic Protection.   Galvanic protection is a passive system which depends on the principle that coupling two dissimilar metals in the same electrolytic environment causes accelerated corrosion of the more active metal and protection of the less active metal. The more active metal is preferentially consumed and is, therefore, called a *sacrificial anode.*

Galvanic protection is often used in preference to an impressed current installation as a temporary measure during construction or when the current requirements are low and the electrolyte has relatively low resistivity (less than 10,000 ohm-centimeters). Clearly, it has an advantage when there is no source of electrical power, or when a completely underground system is desired. Capital investment will generally be lower and is often the most economical method for short-life protection.

Insulating Joints

Insulating joints are required for electrical isolation of the cathodically protected section of the pipe from those sections not protected. In their simplest form, the joints may be flange connections with special arrangements of insulating gaskets, washers, and sleeves to prevent electrical contact between the bolts and the flanges. Preferably, they may be special unitized couplings in which the insulating features are factory-assembled, and the entire assembly can be welded into the pipeline (see Figs. C6.19 and C6.20).
FIGURE C6.19   Insulating flange connection for laying in the ground. *(Eisenbau Albert Ziefle KG.)*
FIGURE C6.20   Monobloc insulating coupling ready for erection by welding in. *(Eisenbau Albert Ziefle KG.)*

Insulating flange connections are made above ground whenever possible. This simplifies installation, makes periodic inspection easier, and minimizes the possibility of a short circuit across the joint.

For underground installation an external application of bitumen or compound molding, covering the whole insulated flange connection, protects it against corrosion and dirt and is absolutely necessary for maintaining the insulating properties of the joint.

INSPECTION AND TESTING

Inspection

ASME B31.8 requires that for piping systems that will operate at 20 percent or more of the specified minimum yield strength of the pipe, the quality of welding must be checked by nondestructive inspection. Such inspection may consist of radiographic examination, magnetic particle testing, or other acceptable methods. The trepanning method of nondestructive testing is specifically prohibited.

ASME B31.8 further specifies that the minimum number of field butt welds to be selected on a random basis from each day's construction for examination must be as noted below. Each weld so selected must be examined over its entire circumference, or as an alternative, the equivalent length of weld must be examined if only a section of the circumference of each weld is examined.

1. 10 percent of welds in Class 1 locations.

2. 15 percent of welds in Class 2 locations.

3. 40 percent of welds in Class 3 locations.

4. 75 percent of welds in Class 4 locations.

5. 100 percent of welds in offshore pipelines, in compressor stations, and at major or navigable river crossings, major highway crossings, and railroad crossings, if practical, but in no case less than 90 percent. All tie-in welds not subjected to a pressure proof test must be examined.

All welds which are inspected must meet the standards of acceptability of the American Petroleum Institute Standard API 1104. If a weld does not, it must be repaired and reinspected.

TABLE C6.11 Test Requirements for Pipelines and Mains to Operate at Hoop Stresses of 30% or More of the Specified Minimum Yield Strength of the Pipe

1	2	3	4	5
		Pressure test prescribed		Maximum allowable operating pressure, the lesser of
Location class	Permissible test fluid	Minimum	Maximum	
1 Division 1	Water	1.25 × m.o.p.	None	t.p., 1.25
1 Division 2	Water	1.1 × m.o.p.	None	t.p., 1.1
	Air	1.1 × m.o.p.	1.1 × d.p.	or d.p.
	Gas	1.1 × m.o.p.	1.1 × d.p.	
2	Water	1.25 × m.o.p.	None	t.p., 1.25
	Air	1.25 × m.o.p.	1.25 × d.p.	or d.p.
3&4 [Note (1)]	Water	1.40 × m.o.p.	None or d.p.	t.p., 1.40 or d.p.

m.o.p. = maximum operating pressure (not necessarily the maximum allowable operating pressure); d.p. = design pressure; t.p. = test pressure.

General note: This table brings out the relationship between test pressures and maximum allowable operating pressures subsequent to the test. If an operating company decides that the maximum operating pressure will be less than the design pressure, a corresponding reduction in prescribed test pressure may be made as indicated in the Pressure Test Prescribed, Minimum, column. However, if this reduced test pressure is used, the maximum operating pressure cannot later be raised to the design pressure without retesting the line to the test pressure prescribed in the Pressure Test Prescribed, Maximum, column. See paras. 805.214, 845.213, and 845.214 of ASME B31.8.

Note: (1) For exceptions, see para. 841.322(d) of ASME B31.8.

If the pipe is intended to operate at 40 percent or less of the specified minimum yield strength, and pipe size is less than NPS 6 (DN 150), or the number of welds to be inspected is small enough to make nondestructive testing impractical, welding may be inspected visually and approved by a qualified welding inspector.

Testing

ASME B31.8 requires that all pipelines and mains which will be operated at a hoop stress of 30 percent or more of the specified minimum yield strength of the pipe must be given a test for at least 2 hours to prove strength after construction and before being placed in operation. The test requirements are summarized in Table C6.11.

Pipelines and mains operating at less than 30 percent of the specified minimum yield strength of the pipe, but greater than 100 psi (7 kg/cm^2), must be tested as follows:

• In Class 1 locations, a leak test must be made at a pressure in the range from 100 psi (7 kg/cm^2) to that pressure required to produce a hoop stress of 20 percent of the specified minimum yield strength, in all cases where the line is to be stressed to 20 percent or more of the specified minimum yield strength of the pipe and gas or air is the test medium.

- In Class 2, 3, and 4 locations, at the least in accordance with the requirements listed in Table C6.11, except that gas or air may be used as the test medium within the maximum limits sent in Table C6.12.

TABLE C6.12 Maximum Hoop Stress Permissible During Test, % of Specified Minimum Yield Strength

	Class location		
Test medium	2	3	4
Air	75%	50%	40%
Gas	30%	30%	30%

For pipelines and mains that will operate at less than 100 psi (7 kg/cm^2), gas may be used as the test medium at the maximum pressure available in the distribution system at the time of the test.

OPERATION AND MAINTENANCE

The ASME B31.8 Code has established comprehensive guidelines for the operation and maintenance of gas transmission systems. Pertinent sections are paraphrased here.

Pipeline Maintenance

Continuing Surveillance of Pipelines. To maintain the integrity of a pipeline system, procedures for the continuing surveillance of its facilities must be established and implemented. Where unusual operating and maintenance conditions occur, such as failures, leakage history, drop in flow efficiency due to internal corrosion, or substantial changes in cathodic protection requirements, appropriate action must be taken.

When a facility is in unsatisfactory condition, a planned program must be initiated to abandon, replace, or recondition and proof test the facility. If the facility cannot be reconditioned or phased out, the maximum allowable operating pressure must be reduced in accordance with code requirements.

Pipeline Patrolling. A periodic pipeline program must be implemented to observe surface conditions on and adjacent to the pipeline right-of-way, indications of leaks, construction activity other than that performed by the company, and any other factors affecting the safety and operation of the pipeline. Patrols must be performed:

- At least once each year in Class 1 and 2 locations
- At least once each 6 months in Class 3 locations
- At least once each 3 months in Class 4 locations

Weather, terrain, size of line, operating pressure, and other conditions will be factors in determining the need for more frequent patrol. Main highways and railroad crossings must be inspected with greater frequency and more closely than pipelines in open country.

Maintenance of Cover at Road Crossings and Drainage Ditches. If the cover over the pipeline at road crossings and drainage ditches has been reduced below the requirements of the original design and is found to be unacceptable, additional protection such as barriers, culverts, concrete pads, casing, lowering of the line, or other suitable means must be provided.

Maintenance of Cover in Cross-Country Terrain. Where the cover over the pipeline in cross-country terrain does not meet the original design, and it is determined to be at an unacceptable level, additional protection must be provided by replacing cover, lowering the line, or other suitable means.

Leakage Surveys. Periodic leakage surveys on the line must be a part of any company's operating and maintenance plan. The type of surveys selected must be effective for determining if potentially hazardous leakage exists. The extent and frequency of such surveys must be determined by the operating pressure, piping age, class location, and whether the transmission line transports gas without an odorant.

Pipeline Markers. Signs or markers must be installed where necessary to indicate the presence of a pipeline at road, highway, railroad, and stream crossings. Additional signs and markers must be installed along the remainder of the pipeline at locations where there is a probability of damage or interference.

The signs or markers must include the words "Gas (or name of gas transported) Pipeline," the name of the operating company, and the telephone number (including area code) where the operating company can be contacted.

Distribution Piping Maintenance

Patrolling. Distribution mains must be patrolled in areas where construction activity, physical deterioration of exposed piping and supports, or any natural causes could result in damage to the pipe. The frequency of the patrolling must be a function of the severity of the conditions which could cause failure or leakage and the subsequent hazards to public safety.

Leakage Surveys. The type or types of surveys selected for the operating and maintenance plan of a company's gas distribution system must be effective for determining if potentially hazardous leakage exists. Some procedures which may be employed are:

- Surface gas detection surveys
- Subsurface gas detector survey (including bar hole surveys)
- Vegetation surveys
- Pressure-drop test
- Bubble leakage test
- Ultrasonic leakage test

Miscellaneous Facilities Maintenance

Compressor Station Maintenance.   The starting, operating, and shutdown proce-dures for all gas compressor units must be established by the operating company and appropriate steps taken to see that the approved practices are followed.

   Inspection and Testing of Relief Valves.   All pressure-relieving devices in com-pressor stations must be inspected or tested or both, and all devices except rupture disks must be operated periodically to determine that they open at the correct set pressure. Any defective or inadequate equipment found must be promptly repaired or replaced. All remote-control shutdown devices must be inspected and tested at least annually to determine that they function properly.

   Isolation of Equipment for Maintenance or Alterations.   Procedures must be established and followed for the isolation of units or sections of piping for mainte-nance, and for purging prior to returning units to service.

   Storage of Combustible Materials.   All flammable or combustible materials in quantities beyond those required for everyday use or other than those normally used in compressor buildings must be stored in a separate structure built of noncom-bustible material located a suitable distance from the compressor building. All above-ground oil or gasoline storage tanks must be protected in accordance with NFPA 30.

Maintenance of Pressure-Limiting and Pressure-Regulating Stations.   All pres-sure-limiting stations, relief devices, and other pressure-regulating stations and equipment must be subject to systematic, periodic inspections and suitable tests, or reviewed to determine that they are:

1. In good mechanical condition. Visual inspections must be made to determine that equipment is properly installed and protected from dirt, liquids, or other conditions that might prevent proper operation. The following must be included in the inspection where appropriate:
   a. Station piping supports, pits, and vaults for general condition and indications of ground settlement.
   b. Station doors and gates and pit vault covers to ensure that they are functioning properly and that access is adequate and free from obstructions
   c. Ventilating equipment installed in station buildings or vaults for proper opera-tion and for evidence of accumulation of water, ice, snow, or other obstructions
   d. Control, sensing, and supply lines for conditions which could result in a failure
   e. All locking devices for proper operation
   f. Station schematics for correctness
2. Adequate from the standpoint of capacity and reliability of operation for the service in which they are employed and set to function at the correct pressure.
   a. If acceptable operation is not obtained during the operational check, the cause of the malfunction must be determined and the appropriate components must be adjusted, repaired, or replaced as required. After repair, the compo-nents must again be checked for proper operation.
   b. At least once each calendar year, relief valves must be reviewed for sufficient capacity. If it is determined that the relieving equipment is of insufficient capacity, new or additional equipment must be installed to provide ade-quate capacity.

   Whenever abnormal conditions are imposed on pressure or flow control devices, the incident must be investigated, and the device inspected and/or repaired. Abnor-

mal conditions may include regulator bodies which are subjected to erosive service conditions or contaminants from upstream construction and hydrostatic testing.

1. An inspection or test, or both, of stop valves must be made to ensure that the valves will operate and are correctly positioned. The following must be included:
   a. Station inlet, outlet, and bypass valves
   b. Relief device isolating valves
   c. Control, sensing, and supply line valves
2. The final inspection procedure must include the following:
   a. A check for proper position of all valves with special attention given to regulator station bypass valves, relief device isolating valves, and valves in control, sensing, and supply lines
   b. Restoration of all locking and security devices to proper position

Valve Maintenance

Pipeline Valves. Pipeline valves required to operate during an emergency must be inspected periodically and partially operated at least once a year to provide safe and proper operating conditions.

1. Routine valve maintenance procedures must at the least include the following:
   a. Servicing in accordance with written procedures by adequately trained personnel
   b. Accurate system maps for use during routine or emergency conditions
   c. Valve security to prevent service interruptions, tampering, etc., as required
   d. Employee training programs to familiarize personnel with the correct valve maintenance procedures
2. Emergency valve maintenance procedures include:
   a. Written contingency plans to be followed during any type emergency
   b. Training personnel to anticipate all potential hazards
   c. Furnishing tools and equipment as required, including auxiliary breathing equipment, to meet anticipated emergency valve servicing and/or maintenance requirements

Distribution System Valves. Valves used for the safe operation of a gas distribution system must be checked and serviced, including lubrication where necessary, at sufficient frequent intervals to assure their satisfactory operation. Inspection must include checking of alignment to permit use of a key or wrench and clearing from the valve box or vault any debris which would interfere with or delay the operation of the valve. System maps showing valve location should be available.

Service Line Valves. Outside shutoff valves installed in service lines supplying places of public assembly, such as theaters, churches, schools, and hospitals, must be inspected and lubricated where required at sufficiently frequent intervals to assure their satisfactory operation. The inspection must determine if the valve is accessible, if the alignment is satisfactory, and if the valve box or vault, if used, contains debris which would interfere with or delay the operation of the valve. Unsatisfactory conditions encountered must be corrected.

Valve Records. A record must be maintained for locating all pipeline valves and distribution system valves which are needed for safe system operation or may need to be operated under emergency conditions. These records may be maintained on operating maps, separate files, or summary sheets, and must be readily accessible to personnel required to respond to emergencies.

Prevention of Accidental Operation. To prevent accidental operation of any of the valves covered above, certain precautions must be taken. Some recommended actions are as follows:

- Lock valves in above-ground settings readily accessible to the general public, that are not enclosed by a building or fence.
- Lock valves located in vaults, if accessible to the general public.
- Identify the valve by tagging, color coding, or any other suitable means of identification.

DECOMMISSIONING/ABANDONMENT

Guidelines for decommissioning or abandoning gas transmission facilities are given in the ASME B31.8 Code. Pertinent sections are paraphrased here for reference.

Abandoning of Transmission Facilities

Any plan for abandoning transmission facilities must include the following provisions.

- Facilities to be abandoned must be disconnected from all sources and supplies of gas such as other pipelines, mains, crossover piping, meter stations, control lines, and other appurtenances.
- Facilities to be abandoned in place must be purged of gas with an inert material and the ends sealed, except that:
- if precautions are taken to ensure that no liquid hydrocarbons remain in the facilities to be abandoned, the facilities may be purged with air. If the facilities are purged with air, precautions must be taken to ensure that a combustible mixture is not present after purging.

Abandoning of Distribution Facilities

To abandon inactive facilities, such as service lines, mains, control lines, equipment, and appurtenances for which there is no further planned use, the following provisions must be addressed:

- If the facilities are abandoned in place, they must be physically disconnected from the piping system. The open ends of all abandoned facilities must be capped, plugged, or otherwise effectively sealed. The need for purging the abandoned facility to prevent the development of a potential combustion hazard must be considered and appropriate measures taken. Abandonment is not complete unless the volume of gas or liquid hydrocarbons contained within the abandoned section has been determined to pose no potential hazard. Air or inert gas may be used for purging, or the facility may be filled with water or other inert material. If air is used for purging, the facility must be checked to ensure that a combustible mixture is not present after purging. Consideration must also be given to any

effects the abandonment may have on an active cathodic protection system and appropriate action taken.

- In cases where a main is abandoned, together with the service lines connected to it, insofar as service lines are concerned, only the customer's end of such service lines need be sealed as stipulated above.
- Service lines abandoned from the active mains should be disconnected as close to the main as practicable.
- All valves left in the abandoned segment should be closed. If the segment is long and there are few line valves, consideration should be given to plugging the segment at intervals.
- All above-grade valves, risers, and vault and valve box covers must be removed. Vault and valve box voids must be filled with suitable compacted backfill material.

Temporarily Disconnected Facilities

Whenever service to a customer is discontinued, one of the following actions must be taken:

- The valve that is closed to prevent the flow of gas to the customer must be provided with a locking device or other means designed to prevent the opening of the valve by unauthorized persons.
- A mechanical service or fitting that will prevent the flow of gas must be installed in the service line or in the meter assembly.
- The customer's piping must be physically disconnected from the gas supply and the open pipe ends sealed.

CHAPTER C7
PROCESS PIPING SYSTEMS

Rod T. Mueller, P.E.
Engineering Associate
Exxon Research & Engineering Co.
Florham Park, New Jersey

INTRODUCTION

General Description

Piping is indispensable to petroleum refineries, chemical plants, and other process units. Piping for most process units represents the major item of unit investment. Typical total erected piping cost ranges from 25 to 50 percent of the total cost of a unit. Consequently, the piping engineer often faces the necessity of making careful and realistic compromises between design features and cost without sacrificing minimum safety standards.

This chapter provides a basic guide to the design of *process piping,* with specific emphasis on petroleum refineries, chemical, and other related processing plants. It attempts to provide an overview of the fundamental design principles used by the ASME Pressure Piping Code, Section B31.3, Process Piping. This Code prescribes requirements for materials and components, design, fabrication, assembly, erection, examination, inspection, and testing of piping. References will be made to other chapters within this handbook where more detailed coverage of design analyses and acceptance criteria are provided that relate to the ASME B31.3 Code.[1] This chapter will also provide guidelines for the design and layout of specific systems typically found in petroleum refineries and related petrochemical processing plants.

Prior to the 1976 edition of ANSI B31.3, this Code was titled "Petroleum Refinery Piping," with direct application to the petroleum refinery industry; by inference it also served as the guiding document for the chemical process industry. The Code then expanded its scope to include areas where it previously had been used as reference, and B31.3 was retitled "Chemical Plant and Petroleum Refinery Piping." With its current 1996 edition, the title of B31.3 was revised to "Process Piping" to reflect its further expanded scope of including piping typically found in petroleum refineries; in chemical, pharmaceutical, textile, paper, semiconductor, and cryogenic plants; and in related processing plants and terminals. Figure C7.1 provides a schematic diagram illustrating the scope of ASME B31.3 (from the 1996 edition) for
FIGURE C7.1   Scope of ASME B31.3 applicability for process piping (1996 edition). (*Reprinted from ASME B31.3 by permission of the American Society of Mechanical Engineers. All rights reserved.*)

process piping of a typical refinery or chemical plant. Included in this scope are piping systems which convey:

1. Petroleum products
2. Raw, intermediate, and finished chemicals
3. Gas, steam, air, and water
4. Fluidized solids
5. Refrigerants
6. Cryogenic fluids

Some fluid services are further categorized by the Code according to the following category services, which need to consider the combination of fluid properties, operating conditions, and other factors which establish the design basis of the piping systems involved:

Category D Fluid Service—a service in which the fluid handled is nonflammable, nontoxic, and not damaging to human tissue, and the design pressure does not exceed 150 psi (1035 kPa) and the design temperature is between −20 and 366°F (−29 and 186°C). Part 3 (starting with Section 305) of the Piping Code covers specific design and fabrication requirements permitted for piping of Category D fluid services to reflect the less than severe conditions involved for these systems.

Category M Fluid Service—a service in which the potential for personnel exposure is judged to be significant and in which a single exposure to a very small quantity of a toxic fluid, caused by leakage, can produce serious irreversible harm to persons on breathing or bodily contact, even when prompt restorative measures are taken. Chapter VIII (starting with Section M300) of the Piping Code pertains to piping designated by the user as being in Category M fluid service.

High-Pressure Fluid Service—a service in which the user specifies the application of Chapter IX of B31.3 for piping design and construction for fluid services with high design pressures. High pressure is considered by the Code to be pressure in excess of that allowed by the ASME B16.5 Class 2500 rating for the specified design temperature and material group.[2] However, there are no specified pressure limitations for the application of these rules.

Normal Fluid Service—a fluid service pertaining to most piping covered by B31.3, i.e., not subject to the rules for Category D, Category M, or High Pressure Fluid service, and not subject to severe cyclic conditions.

The flow chart given by Fig. C7.2 has been taken from Appendix M of the Piping Code B31.3 to help the user determine the applicability of Category D and Category M Fluid services as distinguished from Normal services (and high-pressure services covered by Chapter IX of the Code).

Types of Systems

As applied to this section, *process piping* refers, except as excluded below, to all piping within the property limits of a chemical or petroleum processing plant installation. In addition to the main process units, this will typically include feed and product loading terminals, fuel oil and gas processing facilities, utility systems, waste and water treatment units, and bulk and atmospheric storage tank farms.

FIGURE C7.2 Determination of ASME B31.3 category M and D fluid services. (*Reprinted from ASME B31.3 by permission of the American Society of Mechanical Engineers. All rights reserved.*)

The flowchart contains the following elements:

Col. 1 — Fluid Service to be classified

Col. 2 — High Pressure Fluid Service designated by owner? See paras. 300(e) & K300(a).

Col. 3 — Is the fluid toxic?

Col. 4 — Is the fluid flammable? See definition in para. 300.2

Col. 5 — Can exposure to the fluid, caused by leakage, be damaging to human tissues, as defined in para. 300.2?

Is the fluid toxic? (Col. 2 branch, Yes)

Review the criteria in Col. 3. Do the conditions for Category M Fluid Service apply? See para. K300.1.4.

Design and construct per Chapter IX rules for High Pressure Fluid Service.

The Code makes no provision for this Fluid Service; see para. K300.1.4.

Can a single exposure, caused by leakage, to a very small quantity of the fluid, produce serious irreversible harm as defined under Category M Fluid Service? (See fluid service, para. 300.2.)

Considering experience, service conditions, and location involved, will design per Base Code or Chapter VII sufficiently protect personnel from exposure to very small quantities of the fluid in the environment.

Category M Fluid Service, subject to the owner's designation. See para. 300(d)(f).

Can occurrence of severe cyclic conditions[3] be prevented by design? See para. M300(e).

Design and construct per Chapter VIII rules for Category M Fluid Service.

Is the design gage pressure 1035 kPa (150 psi) or less, with design temperature between −29°C and 166°C (−20°F and 366°F), inclusive?

Base Code (Chaps. I–VI) applies to metallic piping; Chapter VII applies to nonmetallic and nonmetallic-lined piping.

Design and construct per Code rules for Normal Fluid Service.

If occurrence of severe cyclic conditions[3] cannot be prevented by design, then:
(a) for metallic piping, special requirements must be met;
(b) for nonmetal and nonmetal-lined piping, the Code makes no provision for such service. See para. A300(e).

Base Code (Chaps. I–VI) applies to metallic piping; Chapter VII applies to nonmetallic and nonmetallic-lined piping.

Category D Fluid Service designated by the owner?

Piping elements limited to Category D Fluid Service may be used. See para. 300(d)(5).

NOTES:
(1) See paras. 300(b)(1), 300(d)(4) and (5), and 300(e) for decisions the owner must make. Other decisions are the designer's responsibility; see para. 300(b)(2).
(2) The term "fluid service" is defined in para. 300.2
(3) Severe cyclic conditions are defined in para. 300.2. Requirements are found in Chapter II, Parts 3 and 4, and in paras. 323.4.2 and 341.4.3.

C.308

This is reflected in the scope of ASME B31.3 provided by Fig. C7.1. It should be noted that this figure was last published in the 1996 edition of the code and subsequently revised in a recent addenda. The earlier diagram as shown, however, provides a better illustration of the applicable process piping systems covered by the B31.3 Code for a typical refinery or chemical plant. Excluded from code jurisdiction are various low-pressure piping systems, plumbing, fired heater piping, and other special applications.

Petroleum Refinery Piping.   The wide range of piping typically found in a refinery complex can vary from small-diameter instrument takeoffs to very large-diameter product processing piping, constructed from a number of steel and alloy materials. Operating over a broad range of pressures, principally below 1000 psi (6900 kPa) and at elevated temperatures of up to 1300°F (705°C), most refinery piping is used for conveying hydrocarbons or is in close proximity of hydrocarbon-containing equipment.[3] Consequently, the potential for a fire is ever present. The piping layouts depicted in Fig. C7.3 provide a good example of the complex interconnections involved in a typical refinery.

FIGURE C7.3   Typical process plant piping.

Chemical Plant Piping.   As compared to refinery systems, typical chemical plant piping applications are usually smaller in size, mostly below NPS 8 (DN 200). Operating pressures for some services can be higher, but temperatures are generally lower and the presence of corrosive fluids is typical. The use of exotic alloy materials, thermoplastics, and thermoset resin materials in piping construction is common because of the highly corrosive nature of some chemicals. Many chemical plant piping systems convey flammable and/or toxic substances.

Other Related Processing Plants. Modern process facilities handle a myriad of chemical substances and compounds at various process temperatures and pressures. The piping systems specified to transport these fluids must be compatible with the intended service conditions. Since most of these facilities are one of a kind, the process piping materials selected for construction will be specific application driven. Today, numerous construction materials are available, both metallic and nonmetallic in nature. Installed cost variations may be as much as tenfold or even more, depending on the materials suitable for the application. Life cycle cost considerations must also be taken into account during the material selection phase to reflect subsequent repair and replacement requirements.

Whereas process piping material selection is specific application driven and will vary dramatically on a case by case basis, utility piping systems are basically the same across various process plants. Basic materials of construction and mode of construction will differ little from one plant to another for services such as air, water, and steam.

Table C7.1 is a hypothetical illustration of services and various piping material classes for a typical process facility. Note the material variations on the process side of the plant, compared to the relatively constant material types in the utility area of the facility.

Most metallic process piping is welded construction, except where flanged disas-

TABLE C7.1 Hypothetical Process Plant X, Y, Z Piping Service Index

Service	ASME Class	Temperature range °F	Temperature range °C	Piping material
Hydrocarbon processes				
Crude feed/Sour hydrocarbons	150	−20 to 200	−29 to 95	Carbon steel
Fractionation/Light hydrocarbons	150	−20 to 650	−29 to 343	Carbon steel
Catalytic cracking product	150	−20 to 900	−29 to 482	Type 316 SS or low alloy 5 Cr
Catalytic cracking regeneration	150	−20 to 1280	−29 to 693	Refractory lined CS or type 316 SS
Flare header	150	−50 to 750	−45 to 400	Killed carbon steel (low temp grade)
Fuel gas	150	−20 to 500	−29 to 260	Carbon steel
Hydrofiner feed product	300	−20 to 800	−29 to 427	Low alloy (1¼ Cr) or type 316 L SS
Propane	300	−50 to 250	−45 to 120	Killed carbon steel (low temp grade)
Methane feed	300	−20 to 925	−29 to 496	Low alloy (1¼ Cr)
Catalytic reformer/Hydrogen	600	−20 to 1100	−29 to 595	Low-alloy (1¼ or 2¼ Cr)
Ethane	600	−300 to 500	−184 to 260	Type 304L SS
Hot oil heating	600	−20 to 750	−29 to 399	Type 304 SS
Hydrocracker/Hydrocarbon	1500	−20 to 850	−29 to 454	Low alloy (1¼ Cr to 2¼ Cr)
Other Systems				
Acetic acid	150	−50 to 160	−45 to 70	Type 304 stainless steel
Caustic (15% by weight)	150	−20 to 150	−29 to 65	Monel
Chloride/Chlorine (Dry)	150	−20 to 125	−29 to 50	Carbon steel
Hydrochloric acid	150	−50 to 150	−45 to 65	Hastelloy
Liquid sulfur	150	−20 to 500	−29 to 260	Carbon steel jacketed or traced pipe
Hydrocarbons/Wet chlorine	300	−20 to 500	−29 to 260	Inconel or plastic-lined steel
Utilities				
Instrument air	150	−20 to 150	−29 to 65	Carbon steel galvanized/ SS tubing
Nitrogen/Utility air	150	−20 to 300	−29 to 149	Carbon steel
Potable water	150	−20 to 120	−29 to 50	Carbon steel—galvanized
Firewater	150	−20 to 500	−29 to 260	Carbon steel
Low-pressure steam/ condensate	150	−20 to 500	−29 to 260	Carbon steel
Boiler feed water	300	−20 to 500	−29 to 260	Carbon steel
High-pressure steam	600	−20 to 750	−29 to 399	Carbon steel

sembly is required, typically at equipment and valve connections. Due to the high value added cost of the process fluid and its potential for damage to personnel or the environment upon release, integrally welded joints for all size ranges are common.

Energy costs have made integrally welded joints for steam and other utility services more attractive when evaluated against conventional threaded joints and their potential for leakage. Threaded joint construction is still used for low-severity service, but it is typically limited to NPS 2 (DN 50) and smaller sizes, and to services that offer little or no threat to personnel safety or environmental harm.

REFERENCE CODES AND STANDARDS

Code application, jurisdiction, and specific scopes are covered in detail in Chap. A4, ''Piping Codes and Standards,'' in this handbook. This chapter closely parallels the requirements as outlined in ASME B31.3, ''Process Piping,'' 1996 Edition. Codes and standards referenced in this chapter are provided by Table C7.2. Refer to App. E10 for international codes and standards.

DESIGN CONDITIONS

The definitions in this section have been extracted from Process Piping Code, ASME B31.3.

Design Pressure

The design pressure of each component in a piping system shall not be less than the pressure at the most severe condition of coincident internal or external pressure and temperature (minimum or maximum) expected during service. The most severe condition of coincident pressure and temperature is that which results in the greatest required pipe thickness and the highest flange rating. When more than one set of pressure-temperature conditions exist for a piping system, the conditions governing the rating of components conforming to applicable standards may differ from the conditions governing the rating of components in accordance with ASME Code B31.3 pressure design criteria.

Design Temperature

The design temperature is the temperature at which, under coincident pressure, the greatest wall thickness or highest component ratings is required as explained above and shall be determined as follows:

1. *For fluid temperatures below 150°F (65°C),* the metal temperature shall be taken as the fluid temperature unless solar radiation or other effects result in a higher temperature.
2. *For fluid temperatures 150°F (65°C) and above,* the metal temperature for uninsulated components shall be no less than the following values, unless a lower average wall temperature is determined by test or heat transfer calculations:

Note: (1) Refer to Appendix A and Table 326.1 of ASME B31.3 for a more complete listing of ASTM Standard and Specifications.

- Threaded and welding end valves, pipe, welding fittings, and other components having wall thickness comparable to that of pipe: 95 percent of the fluid temperature
- Flanged valves, flanged fittings, and flanges (except lap joints): 90 percent of the fluid temperature
- Lap joint flanges: 85 percent of the fluid temperature
- Bolting: 80 percent of the fluid temperature

3. *Externally insulated piping:* The fluid temperature shall be used unless calculations, previous tests, or service experience based on measurements support the use of other temperatures. Where piping is heated by heat tracing or jacketing, the effect of such heating or cooling shall be incorporated in the establishment of the design temperature.

4. *Internally insulated piping:* The design metal temperature shall be based on heat transfer calculations or tests.

Design Minimum Temperature

The design minimum temperature is the lowest component temperature expected in service. This temperature may establish special design requirements and material qualification requirements, as required for low-temperature toughness testing of metals per Para. 323.2.2 of ASME B31.3.

Cooling Effects on Pressure

The cooling of a gas or vapor in a piping component may reduce the pressure sufficiently to create an internal vacuum. In such a case, the piping component must be capable of withstanding the external pressure at the lower temperature, or provisions must be made to break the vacuum.

Ambient Effects

Consideration needs to be given to low ambient temperature conditions for displacement stress analysis, and for possibly setting the design minimum temperature just discussed. Where the design minimum temperature of a piping system is below 32°F (0°C), the possibility of moisture condensation and buildup of ice shall be considered and provisions made in the design to avoid resultant malfunctions. This applies to surfaces of moving parts of shutoff valves, control valves, pressure-relief devices including discharge piping, and other components.

DESIGN LOADING CONSIDERATIONS

This section will discuss some of the more common loading conditions which need to be considered in the design of a piping system.

Imposed Pressure Including Transient Effects

In determining the system design pressure, it is important to consider the maximum differential operating pressure that can exist between the interior and exterior portions of the system. This needs to reflect the full range of anticipated operating conditions imposed of the system, including normal operation, startup, and shutdown conditions. All pressure sources need to be considered in determining the governing design pressure, including the following effects additive to the maximum operating pressure:

- Hydrostatic head effects due to differences in elevation between high and low points in the system
- Friction losses and back-pressure effects
- Pump shutoff heads
- Variations in system controls and other operating pressure surges

It is realistic to expect that short-duration transient system pressure excursions will occur during normal system operation. Provisions of ASME B31.3 allow for some acceptable level of overpressure transients for metallic and not brittle materials provided that the amount of time that the transient condition occurs does not exceed a specified percentage of the total system operating time per the following:

1. When the increased operating condition will not exceed 10 hours at any one time, or 100 hours per year, it is permissible to increase the pressure rating or the allowable stress for pressure design at the temperature existing during the increased operating condition by a maximum of 33 percent.
2. When the increased operating condition will not exceed 50 hours at any one time, or 500 hours per year, it is permissible to increase the pressure rating or the allowable stress for pressure design at the temperature existing during the increased operating condition by a maximum of 20 percent.

Some of the conditions which should be investigated for the short time period are the centrifugal pump shutoff pressure, or the pressure at the maximum point of the pump characteristic curve, centrifugal compressor surge-point pressure, stalling pressure of reciprocating pumps and reciprocating compressors, and the set pressure of relief valves which limit pressure in the piping.

Fluid Expansion Effects

The Code states that provision shall be made in the piping design either to withstand or to relieve increased pressure caused by the heating of static fluid in a piping component. Most operators, however, have found it unnecessary to provide a relief valve on piping components which may be blocked in. The reason for this is that leaks through valve seating surfaces relieve the pressure before it becomes excessive as the result of the heating of the blocked-in fluid. Valves utilizing resilient seating materials have made this more of a problem, however, because of their ability to seal even more tightly as the pressure increases. Consequently, when such valves are used, greater consideration should be given to the problem of possible pressure buildup in the valve body cavity. A similar problem can be created in a blocked-in section of process piping by the increase in pressure which can result from the

evolution of gas caused either by an increase in fluid temperature or by a chemical reaction (e.g., hydrogen release as a product of corrosion).

Weight Effects

In the design of piping and its supports, it is required that live loads, dead loads, and loads and forces from other causes be taken into account. *Live load,* as used here, is taken as the weight of fluid transported plus snow and ice loads in localities where such conditions exist. *Dead load* is the weight of the piping components and insulation and other superimposed permanent loads. Reference is made to Chap. B2 of this handbook for more details in considering weight effects.

Other Mechanical Loads

The pipe wall must be sufficiently thick to prevent overstress, damage, collapse, or buckling due to superimposed loads from supports, ice formation, backfill, and other causes. In those cases where it is impractical to increase the thickness or if a thickness increase would cause excessive local stresses, the factors that would contribute to the damage of the piping are required to be corrected by other design methods. Examples of these considerations would be pipelines that run under railroad tracks or roadways, where steel pipe sleeves may be required to preclude excessive local bearing stresses being imposed on the pipe wall.

Dynamic Effects

The Code requires that the piping designer take into account wind and earthquake forces, although not concurrently, in design of his piping. It also requires that the designer consider impact forces (including hydraulic shock) and vibration. Vibration and impact forces create complex design problems. This is especially true in the case of vibration because difficult-to-detect low-amplitude high-frequency vibrations often produce the most dangerous stresses. Refer to Chap. B4 of this handbook for stress analysis of piping systems.

Most piping systems will vibrate to some extent. Vibration in piping may be generated by the following exciting forces:

1. Mechanical vibration of connected equipment, such as compressors, pumps, and vessels.[4]
2. Wind-produced vortices that form alternately on opposite sides of cylindrical surfaces.
3. Internal pulsations in flowing fluids, such as those set up by reciprocating pumps and compressors. Vibration from this latter cause can generally be kept within controllable limits by limiting pressure pulsations to 1 to 3 percent of line pressure.
4. Hydraulic transient effects, such as those caused by water hammer impact effects and relief valve discharge. Of all the loading conditions that a piping system may experience in service, hydraulic transients are among the most damaging. Typical damage could be the failure of pipe supports, restraints, and/or supporting structures. Breaches of pressure integrity can also be experienced, especially where large-diameter thin-walled piping is involved.

Where vibration is expected, good design should include the following:

- Adequate foundations, especially for reciprocating pumps and compressors.
- Strategic location of pipe guides and supports to reduce vibration. They should be installed so as to cause minimum restraint to normal thermal movements. The use of sway braces of the energy-absorbing or instant-counterforce-acting type is recommended for control of undesirable pipeline movement. Rigid braces are also effective in controlling movement, provided their restraining effect is taken into account in the piping flexibility design. Where pulsating flow exists, piping should be supported at all changes in direction, and cantilever sections should be avoided.
- Avoidance of small branch connections. Additional supports, such as gusset plates, to stiffen piping may help reduce certain vibration problems.
- An acoustical study to determine whether dampening equipment is needed. Failure can be caused by resonance of some part of the system with the pulsation frequency. Pressure pulsations can be minimized by the use of hydra-pneumatic accumulators, snubbers, or surge drums. These pulsation-reducing devices should be installed as close as possible to the pulsation-producing equipment.
- Any sudden change in the flow velocity or pressure in a liquid line will produce hydraulic shock (water hammer). Typical water hammer problems can be attributed to the rapid closure of a valve that results in hydraulic shock waves in the piping system upstream of the valve.

Water hammer requires careful consideration because it can damage equipment associated with piping and instrumentation even though the permissible pressures for piping components may not be exceeded. In addition to the utilization of slow-closing valves, the installation of surge tanks, pneumatic chambers, spring-operated relief valves, or shock absorbers are sometimes used to help control this phenomenon. Refer to Chap. B8 of this handbook for more details in dealing with this type of dynamic loading.

Another particular type of flow-induced pulsation warranting specific attention is associated with gaseous-flow pressure regulators and flow control valves.[5] These may produce high acoustic energies associated with both turbulence and flow separation. When operating with a severe pressure drop, such valves have high flow velocities that generate significant turbulence. This acoustic energy can couple with the acoustic and natural frequencies of the system to create severe vibration problems. Experience in the gas, petrochemical, power generation, and aerospace industries has shown that high-capacity pressure-reducing systems are prone to severe vibrations, which have caused piping fatigue failures in as short a period as 12 hours after initial commissioning of the system. Piping systems of particular concern include high capacity {>200,000 lb/hr (91,000 kg/hr) flow rate} and/or high pressure drop (>3.0 upstream to downstream pressure ratio) systems. Reference No. 5 provides more details on this type of vibration and considerations for mitigation, which is limited to low-noise-producing valve designs to avoid excessive acoustic energy generation.

Thermal Expansion and Contraction Effects

The following thermal effects, combined with loads and forces from other causes, need to be taken into account in the design of piping:

Thermal loads due to restraints. These loads consist of thrusts and moments that arise when free thermal expansion and contraction of the piping are prevented by restraints or anchors, including connections to fixed equipment.

Loads due to temperature gradients. These loads arise from stresses in pipe walls resulting from large rapid temperature changes or from unequal temperature distribution as may result from a high heat flux through a comparatively thick pipe or stratified two-phase flow causing bowing of the line.

Loads due to differences in expansion characteristics. These loads result from differences in thermal expansion where materials with different thermal expansion coefficients are combined, as in bimetallic, lined, or jacketed piping, or with metallic-nonmetallic composite piping systems.

Corrosion and Erosion Allowances

A commonly used nominal value for corrosion allowance is ¹⁄₁₆ in (1.5 mm) for carbon steel and low-alloy steel piping in hydrocarbon service. Larger corrosion allowances [typically up to ¼ in (6 mm)] for these materials may be required to allow for severe corrosion and/or erosion anticipated for the fluid service involved. Higher-alloy materials, including austenitic steels, are typically required for very corrosive service environment. The allowance for corrosion or erosion should be considered for all surfaces exposed to the process fluid. Determinations for recommended corrosion/erosion allowances are typically based on corrosion monitoring techniques and representative process experience. In addition, the possibility of external corrosion should be considered for piping systems located in aggressive environments such as at marine terminals off coastal waters.

Threading and Grooving Allowances

Calculations for the thickness of piping components which are to be threaded or grooved are required to include a dimensional allowance equal to the depth of the cut plus the required tolerance. For threaded components, the nominal thread depth (dimension *h* of ASME B1.20.1, or equivalent) should apply.[6] For machined surfaces or grooves where the tolerance is not specified, the tolerance is taken as 0.02 in (0.5 mm) plus the depth of cut. Threading and grooving allowances, weld joint factors, and other mechanical strength factors shall be as required by the applicable Code.

Allowable Stresses

Allowable stress values (*S*) are provided by Table A-1, and Table A-2 for bolting, of the Process Piping Code ASME B31.3, which are used in principal design calculations within this Code. The stress values in these tables are basic allowable stresses in tension which are grouped by material specifications and product forms, and are for stated temperatures up to specified maximum limits. Design equations within the code often stipulate the product of *S* and *E,* where:

$$S = \text{Material allowable stress}$$
$$E = \text{Quality factor}$$

The factor E (formerly defined by the code as *joint efficiency factor*) represents one of the following quality factors:

- Casting quality factor E_c is provided by Table A-1A of the Code based on the listed material specification and the type of casting inspection examinations. The code also describes various supplementary inspections which permit the allowable stresses and casting quality factors to be increased. The casting quality factors, however, do not apply to valves, flanges, and fittings that conform to the standards listed in Table 326.1 of the code.

- Weld joint quality factors E_j is tabulated in Table A-1B of the Code for straight or spiral welded joints for pressure-containing components. This is further defined by Table 302.3.4 of the Code. As in the case of casting quality factors, the Code allows for increased joint quality factors for certain kinds of welds if additional examination is performed beyond that required by the product specification.

If a component is made of castings joined by longitudinal welds, both a casting and a weld joint quality factor applies to reduce the material allowable stress in accordance with the Code.

The bases for establishing the basic allowable stress values for ferrous, nonferrous, and nonmetallic materials are described in the Code. The Code user will need to refer to this only in those cases where he or she desires to establish allowable stresses for an unlisted material.

The allowable stress values in shear and bearing are 0.80 and 1.60, respectively, times the values contained in the Code.

For other than normal operations, the allowable adjustments in pressure-temperature ratings as just set forth are applicable to allowable stress values in calculations concerning components, such as pipe, which do not have established pressure-temperature ratings.

The designer should remember that a more severe operating condition may be caused by increased contents load than by increased temperature or pressure. For example, a pipeline may have been designed for gaseous service. Subsequent process changes required the pipeline to see liquid service at nominally the same pressure and temperature as the previous gas service. The basic pipe spans would need to be reevaluated due to the increase in the dead-weight bending loads caused by the added weight of the liquid contents.

Limits on Calculated Stresses Due to Sustained Loads and Thermal Expansion

This subject is covered in detail in Chap. B4 of this handbook. Design considerations in the application of these criteria to process system piping will be covered in subsequent sections of this chapter.

Pressure-Temperature Ratings for Piping Components

Pressure-temperature ratings have been established for certain piping components. Those that have been accepted by ASME B31.3 are maintained in the standards listed in Table 326.1 of this Code. These established ratings should not be exceeded by the expected normal operating conditions. However, during shutdown, startup, or an interruption in the normal operation of a process unit, conditions more severe

than normal may be characteristic of a service. Depending on the frequency and duration of these more severe conditions, the Code permits adjustment of the pressure ratings as previously discussed on transient pressure effects. Extrapolation of accepted pressure-temperature ratings is permitted when these ratings do not extend to the upper material temperature limits allowed by the code, provided this is done in accordance with the applicable rules of the standard involved.

PRESSURE DESIGN OF PIPING COMPONENTS

Straight Pipe

The equations given in the Code consider pressure, mechanical, corrosion, and erosion allowances. In addition to these factors, the Code requires that all designs (not only those for straight pipe) be checked for adequacy of mechanical strength under the applicable loadings discussed previously. The Code gives equations for determining the thickness of straight pipe for the outside diameter/thickness ratios D_o/t greater than 6. The pressure design of piping having a diameter/thickness ratio of 6 or less requires special considerations which encompass design and material factors, such as theory of failure, fatigue, and thermal stress. These considerations are addressed in Chap. IX of the Code for High Pressure Piping. Refer to Chap. B2 of this handbook for the calculation of the required minimum wall thickness of the pipe.

    Piping lengths subjected to external pressures will also need to be sufficiently stiff to resist buckling. The Piping Code refers to the procedures of the ASME Boiler and Pressure Vessel (BPV) Code, Section VIII, Div. 1, for piping subjected to external pressure, which should be specifically reviewed in case of relatively large-diameter and thin-walled piping systems.[7] This may require the addition of external stiffening rings or thicker pipe walls to resist buckling. Refer to Chap. B2 of this handbook for calculating pipe wall thickness when piping is subjected to external pressure.

Bends and Elbows

The minimum required wall thickness at a pipe bend after bending should be determined as for straight pipe, provided the bending operation does not produce a difference between the maximum and minimum diameters greater than 8 percent for internal pressure service and 3 percent for external pressure. The centerline radius of pipe bends should typically be a minimum of 3 times the nominal pipe diameter. Smaller radius bends as tight as 1½ D are possible, such as that obtained with induction bending methods with appropriate heat treatment. Specific manufacturing experience and process procedures in these circumstances should be reviewed by the process plant owner in assessing cost incentives over more conventional pipe bends or elbows.

    Elbows that are manufactured in accordance with any of the standards listed in Table 326.1 of the ASME B31.3 Code are considered to be suitable for use at the pressure-temperature rating specified in the listed standard. In the case of standards under which elbows are made to a nominal pipe thickness, such as ASME B16.9, the elbows are considered suitable for use with pipe of the same nominal thickness.[8]

Miters

The thickness of each segment of a miter must be designed in the same manner as straight pipe. The thickness, however, does not allow for the discontinuity stresses that exist at junctions between the segments of a miter. These stresses are reduced for a given miter as the number of segments is increased. An angular offset of 3° or less does not require design considerations as a miter bend, and the same design basis applies as is used for straight pipe. The Code requires multiple miter bends with miter angle cuts not greater than 22.5°, which requires a minimum of 2 miter cuts to achieve a short-pattern full 90° bend. Single miter bends are allowed with a miter cut angle greater than 22.5°, but different design rules apply. Miters in process plants are typically limited to relatively large diameter and low-pressure [50 psig (345 kPa) or less] piping systems, especially where elbow fittings are not readily available. Even for these services, 90° miter bends should have three or more segments. Refer to Fig. C7.4.

The wall thickness of mitered segments of pipe subjected to external pressure must be designed in the same manner as required for straight pipe.

Branch Connections

Branch connections may be made by the use of integrally reinforced fittings (e.g., tees, extruded outlets, branch outlet fittings, laterals, and crosses), welding outlet fittings or by welding the branch pipe directly to the run pipe, with or without added reinforcement as covered by the Code. The Code gives rules governing the design of pipe-to-pipe branch connections to sustain internal and external pressure in those cases where the angle between the axis of the branch and of the run is between 45° and 90°. Branch connections in which the smaller angle between the axis of the branch and the run is less than 45° impose special design and fabrication problems. The rules given in the Code for angles between 45° to 90° may be used as a guide, but sufficient additional strength must be provided to ensure safe and satisfactory service, and the design must be substantiated by the provisions of the Code for nonstandard piping components.

Branches at angles other than 90°, such as laterals, should be avoided except when flow and pressure drop considerations greatly outweigh the difficulty in obtaining satisfactory welds and the greater difficulty in adequately reinforcing such connections.

For welded pipe-to-pipe branch connections, the stress concentration at the junction increases rapidly as the size of the branch approaches the size of the run. This is also true with most welding outlet fittings. Consequently in services which involve considerable cycling due to pressure or temperature or both, it is usually good practice to make the branch connections with butt-welding tee fittings, or socket-welding fittings in the case of small-diameter piping. The use of butt-welding tees is also considered good practice for full-sized branches in most process services. If there is at least one size reduction in the branch, fabricated pipe-to-pipe branch connections should, as a rule, be acceptable for all services except those with severe cycling. The use of reinforcing pads for fabricated branch connections should also be avoided for elevated temperature services greater than 800°F (426°C) due to concerns for high differential thermal expansion strains.

Strength of Branch Connections. The opening made in a pipe for a branch connection weakens the pipe, and unless the wall thickness of the pipe is sufficiently in
Where:

D = outside diameter of pipe

r_2 = mean radius of pipe using nominal wall T

T = miter pipe wall thickness (measured or minimum per purchase specification)

C = sum of mechanical and corrosion/erosion allowances

θ = angle of miter cut

α = angle of change in direction at miter joint
= 2θ

R_1 = effective radius of miter bend, defined as the shortest distance from the pipe center line to the intersection of the planes of adjacent miter joints

The ASME piping Code, B31.3, requires that the value of R_1 shall not be less than:

$$R_1 \geq \frac{A}{\tan \theta} + \frac{D}{2}$$

Where:

A = an empirical value defined by Section 304.2.3 of this code.

FIGURE C7.4 Nomenclature for miter bends.

excess of that required to sustain the pressure, it may be necessary to provide reinforcement. Typical welded branch connections permitted by the Code are illustrated in Fig. C7.5 shown with and without added reinforcement. The amounts of reinforcement required to sustain the pressure in welded pipe-to-pipe branches are outlined in Sec. 304.3 of ASME B31.3. Certain branch connections may be made without the necessity of their use being supported by engineering calculations. This includes, for example, branch connections made by welding a threaded or socket welding coupling or half-coupling directly to the pipe run, provided the size of the

(a) Set-on

(b) Set-through

(d) Set-through with Reinforcing Pad
FIGURE C7.5 Fabricated branch connections.

branch does not exceed NPS 2 (DN 50), and the coupling has a minimum rating of Class 2000 per ASME B16.11.[9]

Other Design Considerations for Branch Connections.   In addition to pressure loadings, external forces and movements are applied to a branch connection by thermal expansion and contraction, dead and live loads, and movement of piping terminals and supports. Due consideration must be given to the design of a branch connection to withstand these forces and movements. Fabricated branch connections made by welding the branch pipe directly to the run pipe also should be avoided when the branch size exceeds 0.8 times the run size or where repetitive stresses may be imposed on the connection by vibration, pulsating pressure, temperature cycles, and so forth. In such cases, it is recommended that the design be conservative and that considerations be given to the use of tee fittings or complete encirclement types of reinforcement.

Closures

The design of welded flat closures, ellipsoidal, spherically dished, hemispherical, and conical closures is encountered relatively infrequently. Closure fittings manufac-

tured in accordance with ASME B16.9 and B16.11 are considered suitable for use at the pressure-temperature ratings specified by such standards. In the case of standards under which closure fittings are made to nominal pipe thickness, the closure fittings shall be considered suitable for use with pipe of the same nominal thickness. In process plant piping the most commonly used closure is probably the butt-welding cap. Bolted flanged covers are used where access is needed.

Openings in Closures.   Code rules govern the design of openings in closures when the size of the opening is not greater than one-half of the inside diameter of the closure. The basis for the design of these openings in closures is the same as it is for branch connections. Closures with larger openings must be designed as reducers, except that flat closures must be designed as flanges.

Reducers

Reducers, either concentric or eccentric, are typically provided as forged or wrought fittings in accordance with an accepted standard (e.g., ASME B16.9 in the case of wrought steel butt welding fittings). Concentric reducers are typically made in conical or reversed curve sections, or a combination of such sections, and the design requirements of the Code for conical and toriconical closures apply.

Flanges

Flanges manufactured in accordance with ASME Standards B16.5, B16.36, B16.1, B16.24, B16.42, and B16.47 are considered suitable for use at the pressure-temperature ratings specified by such standards. Flanges not made in accordance with the standards listed shall be designed in accordance with Sec. VIII Div. 1 of the ASME Boiler and Pressure Vessel Code, except that the requirements for fabrication, assembly, inspection, and testing, and the pressure and temperature limits for materials of ASME B31.3 shall govern. ASME Section VIII, Division 1, design requirements with allowable stresses from B31.3 are also referenced for the design of blind flanges.

Blanks

The Piping Code provides design bases for determining the minimum pressure design thickness for permanent blanks, which are used to isolate or dead-end piping systems. Corrosion or erosion allowances and manufacturer's minus tolerance must be added to the thickness thus determined. Standard dimensions for permanent blanks and figure 8 blinds are provided by ASME B16.48 (formerly covered by API 590), Steel Line Blanks, which are typically used for most process refinery applications.[10]

In the design of temporary blanks which are not to be used during operation of the piping (e.g., during shutdowns or during testing), an allowable stress equal to 90 percent of the material's yield strength is sometimes used. It is suggested, however, that ¼ in (6.0 mm) is a practical minimum thickness for carbon-steel blanks.

Expansion Joints

Thermal expansion of piping systems within process plants is normally accommodated with the inherent flexibility achieved with elbows, bends, and pipe expansion loops. There are some special cases, however, where the layout requirements of the piping require the use of expansion joints. This may be the case, for example, if the system cannot tolerate appreciable pressure losses with the addition of elbows or bends. Instead, system thermal expansion or contraction requirements can be accommodated using a suitably designed expansion joint. Since expansion joints are comparably more vulnerable to potential damage and fatigue failures, they should only be considered after all other normal flexibility alternatives have been explored.

Several different types of expansion joints are available, ranging from rubber hose to metal bellows, which are covered in Chap. A2 of this handbook. If used in process plants, expansion joints are typically the metal bellows type, using U-shaped convolutions. The design of metal bellows type expansion joints is covered by App. X of the Process Piping Code, ASME B31.3. In addition to the pressure and thermal expansion design of the bellows, it is important to ensure that piping movements and external bending loads will not be beyond the limits of the joint design. Potential problems caused by pressure thrust must be considered. Refer to Chap. A2 for more details.

Attachments

Attachments to piping, both external and internal, are required to be designed so that they will not cause flattening of the pipe, excessive localized bending stresses, or detrimental thermal gradients in the pipe wall. It is important that such attachments be designed to minimize stress concentrations, particularly in cyclic services or systems prone to imposed vibrations. Gusseting of small piping connections ($\leq$ NPS 1½, or $\leq$ DN 40) should be considered for equipment and piping in vibrating services to provide proper bracing of these appurtenances against potential fatigue failures.

Pressure Design of Non-standard Components

In general, all pressure-containing components need to satisfy code requirements. However, if the design of similarly shaped or proportioned components has been proven successful by performance under comparable service conditions, provision for the use of such components is allowed by the Code. Alternatively, the Process Piping Code, Sec. 304.7.2, permits the pressure design of the non-standard component to be proven either by an experimental stress analysis or by tests made in accordance with the ASME Boiler and Pressure Vessel Code, Sec. VIII.

SELECTION AND LIMITATIONS OF PIPING COMPONENTS

Pipe and Fittings

Table C7.3 lists typical piping materials for commonly used pipe found in process plants. It includes both welded and seamless pipe per the applicable specification.

TABLE C7.3 Piping Material Specifications

Material	Requirements
Cast iron	ANSI/AWWA C115 (Centrifugally Cast)
Ductile iron	ANSI/AWWA C151
Carbon steel	API 5L; ASTM A53, A106, A333/A333M, A671, A672, A691
Ferritic alloy steel	ASTM A335/A335M, A426, A671, A672, or A691: Classes 11, 22, 32, or 42
Austenitic Cr-Ni steel	ASTM A312/A312M, A358/A358M, A451
Monel	ASTM B165
3½ Ni or 9 Ni	ASTM A333/A333M
Inconel	ASTM B167
Aluminum	ASTM B241/B241M
Incoloy	ASTM B407, B423, B705

The majority of process plant piping is carbon steel, either longitudinally welded or seamless.

Cast-iron and ductile-iron pipe materials are usually limited to Category D water services not subject to freezing for most process plants, and typically are specified as centrifugally cast material. Low-melting-point alloys, such as aluminum, brass, and bronze should not be used in flammable or combustible fluid services.

The following list provides some guidelines on the application of welded pipe as typically used within hydrocarbon processing plants:

1. All longitudinally or spiral-welded pipe should be hydrostatically tested, and inspected by either ultrasonic or electromagnetic means by the manufacturer.

2. The use of furnace butt-welded pipe in typical process plants is usually limited to a maximum size of NPS 4 (DN 100) and restricted to water service per Category D of the B31.3 Piping Code.

3. Longitudinally welded carbon steel pipe is usually supplied to either electric-welded or fusion-welded specifications and typically acceptable for most applications requiring carbon steel pipe.

4. Spiral-welded pipe, as specified by API 5L, is primarily used outside of normal process units, typically for carbon steel offsite piping, including tank farms and terminal transfer piping. The spiral seams should be double-submerged arc-butt-welded.

Applicable standards and sizes of fittings are summarized in Table C7.4.

TABLE C7.4 Recognized Standards for Fittings

Fittings	Size range	Applicable Standards
Steel buttwelding fittings	NPS ½ thru 24 (DN 15 thru 600) Over NPS 24 (>DN 600)	ASME B16.9 ASME B31.3
Steel socket welding and threaded fittings	NPS ½ thru 2 (DN 15 thru 50)[1]	ASME B16.11[2]
Malleable iron threaded fittings[3]	NPS ½ thru 2 (DN 15 thru 50)	ASME B16.3
Gray iron and ductile iron fittings[4]	NPS 2 thru 48 (DN 50 thru 1200)	ANSI/AWWA C110
Flanged fittings	NPS ½ thru 24 (DN 15 thru 600)	ASME B16.5

Notes:
   (1) Normally used sizes.
   (2) Covers NPS ⅛ (DN 6) through NPS 4 (DN 100) fittings.
   (3) Limited to air, inert gas, and water service.
   (4) Gray iron limited to water service. Ductile iron limited to nonhydrocarbon service.

There are many Code mandated restrictions for the use of fittings, bends, and other related components which are not universally applicable to all process plant services. Some guidelines, however, are of value to the designer and are listed in the following paragraphs.

- In typical process complexes, flanged connections should be limited to locations where their use is considered essential to the operation and maintenance of the unit. This is particularly the case for critical services where welded fittings and connections should be used to reduce the potential for leakage associated with flanged connections.

- Butt-welding elbows are typically of the long-radius type unless specific layout restrictions require the special application of short-pattern elbows.

- In services with very high corrosion rates, butt-welding fittings are preferred to threaded and socket-welding fittings.

- Pipe couplings or threaded fittings made of cast, malleable, or wrought-iron are not permitted for flammable fluids within process limits or hazardous fluids in any area.

- Large-radius pipe bends are preferred to butt-welding elbows for reciprocating compressor suction and discharge piping, vapor relief-valve discharge piping, and piping conveying corrosive fluids (such as acid) where turbulence in a fitting may cause excessive corrosion.

- Threaded plugs are preferred to pipe caps for threaded end closures to reduce dead-end corrosion problems caused by inadequate draining of trapped corrosive fluids.

- The use of bell-and-spigot fittings is limited to water and drainage service.

Special Considerations for Fittings in Abrasive Fluidized Solid Services. The following additional guidelines are offered for fittings and other pipe components in fluidized solids services where internal erosion concerns exist:

- Long radius bends should be used for dense-phase flow of pulverized abrasive solids and for all piping which handles either pulverized or granular solids suspended in liquids or granular solids suspended in gases.

- Long radius bends or dead-end tees should be used for piping which conveys pulverized abrasive solids suspended in gas in the dilute phase. Dead-end tees (so arranged that the flow will impinge against the dead end) have a longer life than bends in abrasive service and should be used if the system can be designed to accommodate the resulting increase in pressure drop.

- Similarly, if the flow is through a branch into a header (or run pipe) in a piping system which transports pulverized abrasive solids suspended in gas in the dilute phase, a dead-end cross (so arranged that the flow will impinge against the dead end) should be considered.

Piping Joints

The type of piping joint used must be suitable for the pressure-temperature conditions and should be selected by giving consideration to joint tightness and mechanical strength under the service conditions (including thermal expansion), and to the nature of the fluid handled with respect to corrosion, erosion, flammability, and toxicity. In general, the number of disassembly joints is minimized; most joints are welded if the material is weldable.

Welded piping is used almost exclusively for transporting hydrocarbons and other flammable fluids. This includes bypass piping, alternate process connections, and auxillary piping systems such as gland oil, seal oil, lubricating oil, fuel gas, fuel oil, heating or cooling oil, flushing oil, flue gas, blowdown piping and the like. Welded construction is also used for all piping outside process unit limits which is used for the transfer of hydrocarbons or most other process fluids.

Welded Joints. The Code permits welded joints in all instances in which it is possible to qualify welding procedures, welders, and welding operators in conformance with the rules of the Code. There are, however, a few minor additional considerations for seal-welded (threaded) and socket-welded joints, which are typically limited to pipe sizes NPS 2 (DN 50) and smaller, except for air or water below 250°F (121°C). For example, the Code cautions against the use of socket-welded construction in cases where severe crevice corrosion or erosion could occur. The Code also states that seal welds may be used to avoid joint leakage but that they shall not be considered as contributing any strength to the joint.

Flanged Joints. The number of bolted flanged joint connections in a piping system is usually determined by maintenance and erection considerations, including flanged joints needed for the insertion of blanks during shutdown and for system isolations during initial hydrostatic testing. Where flanges of different ratings are bolted together, the rating of the joint must not exceed the lower rated flange. The selection of flanges is a topic within itself, which will be discussed in more detail in a subsequent section.

Threaded Joints. Economics will limit the use of threaded piping to small pipe sizes, NPS 2 (DN 50) and smaller, for most services. It is also used for most galvanized piping connections. The threading of pipe with a wall thickness less than ASME B36.10M standard wall is not permitted.[11] The use of threaded joints also should be avoided where crevice corrosion, severe erosion, or cyclic loading may occur.

All pipe threads on piping components must be taper pipe threads in accordance with ASME B1.20.1, except that:

- Pipe threads other than taper pipe threads may be used for piping components where tightness of the joint depends upon a sealing surface other than the threads (e.g., a union comprising of male and female ends joined with a threaded union nut), and where experience or tests have demonstrated that such threads are suitable for the condition.

- Couplings, NPS 2 (DN 50) and smaller, with straight threads may be used only for Category D Fluid Service, and only with taper-threaded mating components.

Seal welding of threaded joints is recommended for all services except for Category D fluid services. Threaded joints also do not need to be seal welded if the joint is for instrument connections or for piping components that require periodic removal for maintenance. Similarly, seal welding is typically not required for plugs and caps for drain and vent valves, and for union ring threads.

Expanded Joints. This type of joint is more commonly used on the piping and tubes for refinery heaters or steam generators. Expanded joints are excluded for use in hazardous and/or toxic services and under severe cyclic conditions. Adequate means must be provided to prevent separation of the joint if used. Expanded joints are not typically used in process applications, and if they are used, considerations must be given to the tightness of the expanded joint when subjected to vibration, or differential expansion or contraction due to temperature cycling or external mechanical loads.

Flared, Flareless, and Compression Joints. The use of flared, flareless, or compression type tubing fittings may be considered for tubing connections, as may be required for instruments or other similar devices, within the limitations of applicable component standards or specifications. In the absence of such standards or specifications, the adequacy of the fitting should consider the following:

- The pressure design must meet the requirements of the Code.
- A suitable quantity of the type and size of fitting to be used should meet successful performance tests to determine the safety of the joint under simulated or similar service conditions.
- Fittings and their joints must be suitable for the tubing with which they are to be used.
- Fittings must not be used in services which exceed the manufacturer's maximum pressure and temperature limits and recommendations.

Caulked Joints. The term *caulked joints* applies to joints of the bell-and-spigot type which are permitted only for Category D water service and to a temperature of not over 200°F (93°C). They also must be used within the pressure-temperature limitations of the pipe to which they are applied. Provisions must be made to

prevent disengagement of the joints at bends and dead ends and to support lateral reactions produced by branch connections or other causes. Further details on this type joint are covered in Joining Cast-Iron Pipe in Chap. A2 of this handbook.

Brazed and Soldered Joints.   Fillet-brazed or fillet-soldered joints may not be used in process piping, but the use of soldered and silver-brazed socket-type joints is permitted in nonflammable nontoxic service. The melting point of brazing alloys should be considered where possible exposure to fire is involved.

Other Proprietary Joints.   Coupling-type, mechanical-gland type, and other proprietary-type joints are available and may be considered for use provided adequate provision is made to prevent separation of the joints. The design should be verified according to the procedures of ASME B31.3 for special fittings, which should include the performance testing of a prototype joint to confirm the safety of the joint under simulated service conditions. These tests should incorporate anticipated loading conditions, including the simulation of vibration, fatigue, cyclic conditions, low temperature, thermal expansion, or hydraulic shock.

Selection and Limitations of Flanges

Flange components used in most process plants follow the design and material requirements of the standards listed in Table C7.5. It is important to note that large-diameter flanges specified by ASME B16.47 "Large Diameter Steel Flanges" are available in 2 different size categories: Series A, which are dimensionally the

TABLE C7.5 Flange Material Specifications

Flange material	Size range	Applicable standard
Carbon steel Ferritic alloy steel Austenitic Cr-Ni steel 3½% Ni steel	NPS ½ thru 24 (DN 15 thru 600)	ASME B16.5
	NPS 26 thru 60 (DN 650 thru 1500)	ASME B16.47 Series A and B[1]
Cast-iron	NPS 1 thru 48 (DN 25 thru 1200)	ASME B16.1
Nickel Nickel copper (monel) Nickel-chromium-iron (inconel) Hastelloy B-2 and C-276	NPS ½ thru 24 (DN 15 thru 600)	ASME B16.5
	NPS 26 thru 60 (DN 650 thru 1500)	ASME B31.3[2]
Aluminum bronze	NPS ½ thru 24 (DN 15 thru 600)	ASME B31.3[3]
Aluminum alloy	NPS ½ thru 24 (DN 15 thru 600)	ASME B31.3, Appendix L[3]

Notes:
   (1) ASME B16.47 Series A flanges (previously specified by MSS SP-44) and Series B flanges (previously API-605 now withdrawn) specify different flange patterns for most sizes.
   (2) Dimensions including flange face finish per ASME B16.47, Series A or B as specified by the User.
   (3) Dimensions including flange face finish per ASME B16.5.

same as those covered by MSS SP-44, and Series B which are dimensionally the same as those previously covered by API-605 (withdrawn).[12] Most large flange installations in process piping are to Series B flange patterns, except where ASME B16.47 Series A flanges may be required to accommodate flangeless or lug type valves or other similar flangeless components, or to mate with existing equipment flanges.

Flanges of materials other than those listed in applicable standards or flanges with special dimension for mating to equipment should be in accordance with ASME B31.3 following the design requirements of the ASME BPV Code Sec. VIII, Div. 1.

Flange Types. Several different flange types are permitted by the standards listed in Table C7.5, as principally covered by ASME B16.5. These include different types of attachment to the pipe including threaded, lapped, and welded as covered in more detail by Chap. A2 of this handbook. Of the welded type, most flanges are the butt-welded, slip-on, or socket-welded types. The majority of flanges are butt-welded, which are more commonly referred to as the welding neck flange. Socket-welded flanges are typically limited to small-diameter connections less than NPS 2 (DN 50). Slip-on flanges fit over the outside diameter of the pipe and are attached with fillet welds at both the pipe end and off the hub end of the flange.

Typical restrictions on the use of slip-on flanges include:

- While available in most pressure classes, slip-on flanges are more typically limited to Class 300 or lower pressure rating in process plant piping. The available raised face gasket seating area can preclude commonly used gaskets in the case of slip-on flanges for higher class piping.
- They are limited to services with design temperatures below 750°F (400°C).
- They should not be used where the specified corrosion allowance exceeds 0.125 in (3 mm).

The Code restricts the use of threaded flanges as it does any threaded pipe joint. Some limits on the application of threaded flanges include:

- The use of cast, nodular, wrought and malleable iron threaded flanges should be avoided.
- Threaded steel flanges for steel pipe are usually limited to water or air (or other Category D) services for sizes NPS 6 (DN 150) or smaller and with design temperatures not exceeding 250°F (121°C).
- Threaded flanges on cast iron or ductile iron pipe should be steel material.

The following recommended limitations should be considered with the use of lap joint flanges for process plant applications:

- Lap joint flanges should not be used where the combined longitudinal stresses in the pipe at the lap-joint stub-end (resulting from pressure, weight, and thermal expansion) exceeds the ASME B31.3 basic allowable stress at the pipe design temperature.
- The flange may be of a material different from that of the pipe, provided the flanged joint will not be subject to galvanic corrosion (e.g., carbon steel flanges may be used on lap-joint stub-ended 18 Cr 8 Ni pipe in above ground services).
- Stub-ends for lap joint flanges, if fabricated by welding, should be made with full penetration welds

The following additional limitations on flanges are included for the designer's guidance.

- In services with very high corrosion rates, the bore of weld neck flanges should be the same inside diameter as the attached piping (if not the same, consider taper-boring the component with the smaller inside diameter).
- ASME Standard B16.47 ''Large Diameter Steel Flanges'' governs steel flanges in sizes NPS 26 through 60 (DN 650 through 1500). However, the designer must ensure that the flange drilling on such flanges will match that of the equipment to which it is to be attached. Use Series A for previous installations with MSS SP-44 ''Steel Pipe Line Flanges,'' and Series B for flanges mating to equipment with API 605 ''Large-Diameter Carbon Steel Flanges.''

Selection of Flange Facings

Several different types of flange faces are used as the contact surfaces to seat the sealing gasket material. In the case of Class 125 cast iron flanges, full faces are provided with a phonographic finish. ASME B16.5 and B16.47 define various types of flange facings, including the raised face, the lapped, and the large male and female facings which have identical dimensions to provide a relatively large contact area. Other flange facings covered by these standards include the large and small tongue-and-groove facings, and the ring joint facing specifically for ring joint type metal gaskets. Chapter A2 of this handbook provides detailed descriptions of the various flange faces and their uses.

When flat face (FF) Class 125 cast iron or nonmetallic flanges are bolted to Class 150 steel flanges, the 1/16 in (2 mm) raised face on the steel flanges should be removed to preclude possible damage to the mating flange.

The raised face (RF) flange face is the most common type used in process plant applications. This face type allows the use of a wide combination of gasket designs, including flat ring sheet types and metallic composites such as spiral wound and double jacketed types. The typical flange face finish for ASME B16.5 RF flanges is 125 to 250 μin Ra (3 to 6 μm Ra). The use of ring joint gaskets specifically requires the use of grooved ring joint (RJ) flanges. These are typically used in relatively high pressure (Class 600 and higher rating) and/or high temperature services above 800°F (427°C), and are usually the gasket of choice for highly cyclic temperature services.

Selection and Limitations of Gaskets

A considerable variety of gaskets is in common use for the flanges located within process plants. These can be nonmetallic or metallic, or a composite of nonmetallic and metallic materials.[13] The majority of nonmetallic gaskets are soft sheet materials such as rubber, vegetable, and other mineral fibers, cork, asbestos, PTFE (polytetra-fluoroethylene), and graphite. These sheet gaskets are manufactured to the dimensional standards of ASME B16.21.[14] The composite gasket types combine metal and a soft material, the metal to provide added strength to withstand higher pressures and temperatures of the confined fluid, and the soft material to provide resilience. Spiral wound (SW) gaskets with metal strip spirally wrapped with resilient filler material, and metallic double jacketed with soft material filler are two of the most common gaskets of this type. Metallic gasket types come in various shapes and

constructions, including flat and ring types. Ring joint gaskets typically of the oval cross section are used in some of the more critical fluid services.

Until the last decade, asbestos was without question the principal gasket material used in petroleum and petrochemical plants. While the importance of finding acceptable substitutes to asbestos is generally recognized within the industry, it is widely accepted that comparable gaskets with all of the same attributes of asbestos have yet to be identified. Due to its unique properties of chemical inertness, thermal behavior, and excellent sealability, asbestos has been a major ingredient of many gasket compositions for the past century.

In recent years, flexible graphite has become the leading gasket material to replace asbestos for many users. This is particularly the case for the petroleum and petrochemical industries, where a broad range of application is required, including services at elevated temperatures. Yet, even flexible graphite gaskets have some significant limitations and continue to be the subject of ongoing research to evaluate long-term service characteristics at elevated temperatures.[15]

Principal characteristics for the ideal gasket within the petroleum and petrochemical industry (and other related processing plants) should include the following performance factors and other attributes:[16]

- *Overall Mechanical Integrity.* The mechanical strength of a gasket is a primary consideration to ensure sufficient strength against crushing and possible in-service blowouts. *Gross leaks* occur because, for some reason, the bolt load has been reduced to the point where the hydrostatic end force at the joint is roughly equal to the total bolt load. *Gasket stiffness* is an important consideration in precluding gross leakage. Another important mechanical integrity consideration of a gasket is its ability to resist *gross instability* or *crushing* with gasket seating during initial boltup and subsequent in-service retightening.

  Some recent experience with spiral wound gaskets filled with flexible graphite has demonstrated the importance of ensuring sufficient crush strength resistance.[17] A significant percentage of installed SW gaskets for a refinery expansion were found during the final stages of precommissioning to have gross buckling of the inner windings. The gaskets were specified without inner retaining rings, which raised questions about current standards (ASME B16.20) requirements for inner rings. While this phenomena is the subject of industrywide evaluation, ASME B16.20 recommends the use of inner retaining rings with flexible graphite filled spiral wound (SW) gaskets where experience has demonstrated inward buckling to be a problem.[18] Considering the extent of buckling experience reported to date, and the potential for severe leakage and consequential damage due to entrained spiral fragments migrating into downstream equipment, some users specify inner rings for all NPS 4 (DN 100) and larger SW gaskets with flexible graphite filler.

- *Leak Tightness.* A gasket for elevated temperature service must have good creep and stress relaxation resistance, and leak tightness. When addressing the sealability of gasket materials all of the operating parameters for a specific service impose their influence, to some extent, on the overall performance of the gasket. These include, for example, the physical nature of the fluid (i.e., gas, liquid, molecular weight, aggressiveness of the fluid on the gasket material, and fluid temperature and pressure). *Gasket creep and stress relaxation* first occurs during boltup and may also occur during heatup and subsequent cyclic loading, leading to additional creep losses. *Gasket degradation* results in gasket thickness loss, which further reduces bolt preload over time and increases the vulnerability of the joint. Degradation is the result of pyrolysis, oxidation, and other chemical reactions because

of high-temperature exposure and interaction with the process fluid. *Aging effects* as the result of prolonged exposure to service environments and temperature can lead to further degradation, affecting the useful life and sealing performance of the gasket.

- *Fluid Service and Gasket Material Compatibility*.   Will the gaskets tolerate the chemicals with which they will be in contact; that is, are they compatible with the contained chemicals? The user should *not* assume that: (1) if a gasket is good at one concentration and/or temperature range, it will be acceptable for other concentrations and/or temperatures, or (2) if it is good for two or more chemicals alone, it will be good for a mixture of these chemicals. This also needs to be reviewed for all material components of composite gasket constructions. Industry experience is very valuable here in confirming the suitability of the gasket material for the intended service.

  Galvanic corrosion may be a problem if an electrically conducive fluid is present with a gasket material, such as flexible graphite, that is also electrically conductive. Graphite is near the cathodic end of the galvanic scale, between silver and gold. The wider the distance between the two materials, the more rapid the corrosive attack of the anodic material.

  As flexible graphite is a relatively fragile material, most process plant gaskets have metal inserts. These can suffer galvanic corrosion if coupled with the flexible graphite under certain electrochemical environments. Salt water service, for example, has proven to be a problem with composite flexible graphite gaskets, where galvanic attack can cause severe corrosion of the metallic insert.

  The manufacturer should be consulted if there is any doubt about the compatibility of a gasket for the intended service. This is also the case for any potential concerns for galvanic coupling between the gasket material and metal reinforcement of a proposed gasket for an electrolytic chemical environment.

- *Fire Safety*.   The integrity of gasketed flanged joints in flammable services, exposed to fires, is a key consideration in accepting substitutes for asbestos in petrochemical and refinery plants. Asbestos gaskets have been generally recognized as being inherently fire safe as demonstrated by the favorable service experience accumulated over the years. Of the numerous nonasbestos products now on the market, many would appear to have questionable fire integrity capabilities (e.g., sheets based on aramid, glass fibers, or on PTFE). This is a principal advantage for flexible graphite-based gaskets, which have demonstrated capabilities of being inherently fire safe.

- *Broad Range of Application*.   Prior to falling out of favor, asbestos-based gaskets represented about 95 percent of all refinery and chemical service gasket applications. Ideally, substitutes should also exhibit a wide range of service applications. The obvious advantage of standardizing on one or two gasket materials is that doing so helps to minimize the chances of misapplication. Standardization also simplifies procurement and stocking requirements, which could get out of hand if many different types of gasket materials were kept in the warehouse stores.

Adding to the merits of flexible graphite as a gasketing material is the wide spectrum of gasket styles that are commercially available. These styles include the more commonly used reinforced flexible graphite sheet (RFG) gaskets, and flexible graphite-filled spiral wound (SW) and double jacketed (DJ) gaskets. Other less conventional styles such as corrugated metal covered with flexible graphite (CMCG)

TABLE C7.6 Gasket Material Specifications

Gasket type	Standards	Design range	
		Class	Temperature
Compressed Asbestos Fiber (CAF) sheet	ASME B16.21	≤300	−50 to 750°F (−45–400°C)
Metal Reinforced Flexible Graphite (RFG) sheet	Dimensions per ASME B16.21	≤300	−250 to 750°F (−157–400°C)
Corrugated Metal Flexible Graphite Covered (CMGC)	Dimensions per ASME B16.21	≤300	−250 to 750°F (−157–400°C)
Grooved Metal profile flexible Graphite Covered (GMGC)	Manufacturer's standards	≤300	−250 to 750°F (−157–400°C)
Corrugated Double Jacketed (DJ) filled with flexible graphite	ASME B16.20 with corrugated jacket	≤300	up to 875°F (up to 468°C)
Spiral Wound (SW)—Flexible graphite filled			up to 875°F (up to 468°C)
—Asbestos filled	ASME B16.20	≤900	up to 1000°F (up to 538°C)
—PTFE filled			up to 400°F (up to 204°C)
Ring Joint (RJ)	ASME B16.20 for oval shape	≤2500	Any

Notes:
(1) Use of asbestos-based gaskets subject to local restrictions.
(2) Typical fill materials for SW and DJ gaskets can be asbestos, flexible graphite, and PTFE (for nonflammable services).
(3) Both inner and outer retaining rings are recommended for spiral wound (SW) flexible graphite filled gaskets for all sizes greater than NPS 4 (DN 100), or if gasket design temperatures exceed 800°F (427°C).

and grooved metal covered with flexible graphite (GMCG) have also evolved with good user experience.

Table C7.6 provides a listing of the more commonly used gaskets within refinery and chemical plant process units, and the applicable standards available for their design and construction.

The temperature ranges indicated by Table C7.6 are approximate and will vary according to the service involved. This is particularly the case with flexible-graphite based materials, where the extent of material degradation and oxidation will vary according to the fluid service involved. As discussed in the previous subsections, gasket material compatibility should be confirmed for the specific fluid service intended.

A more detailed list of gasket materials for specific services is provided in Chap. A2 of this handbook. These include various elastomeric nonasbestos gasket materials, which should be considered to have relatively low service temperatures and generally are all non-fire safe.

TABLE C7.7   Bolting Material Specifications

| Design metal temperature | | Flange rating | Bolts | | |
°F	°C	ANSI Class	Type	ASTM Std.	Grade
−20 to 400	−29 to 204	≤150	Bolt	A307	B
−20 to 800	−29 to 427	Any	Stud	A193/A193M	B7
800 to 1100	427 to 593	Any	Stud	A193/A193M	B16
1100 to 1200	593 to 650	Any	Stud	A193/A193M	B5
1100 to 1500	593 to 815	≤300	Stud	A193/A193M	B8M Class 1[1]
−150 to −20	−101 to −29	Any	Stud	A320/A320M	L7[2]
−325 to −20	−198 to −29	Any	Stud	A320/A320M[3]	B8 Class 2[4]

Notes:
(1) Class 1 (low yield) bolts should not be used for Class 400 or higher flanges nor for flanged joints using metallic gaskets unless supported by appropriate design calculations per ASME B31.3, Par. 309.2.1.
(2) Test temperature for impact testing of all L7 bolts, per ASTM A320/A320M, should be −150°F (−101°C).
(3) ASTM A 193/A193M Grade B8 Class 2 bolts with ASTM A194/A914M Grade 8 nuts may be used as an alternate.
(4) Grade B8 bolts must be strain hardened (i.e., Class 2 of designated ASTM material standard).

Selection and Limitations of Bolting

Bolting as typically used within the processing industry is threaded in accordance with ASME Standard B1.1 for Unified Screw Threads. In diameters 1 in (25 mm) and smaller, the threads conform to the coarse thread series. For larger bolt diameters, the eight-pitch thread series applies for bolting to this standard used in process plants.[19]

Table C7.7 lists typical bolting materials and recommended design pressure and temperature rating limits for flanges found in process plants. A more complete listing of permissible bolting materials allowed by ASME B16.5 for steel pipe flanges is provided in Chap. B2 of this handbook.

While carbon-steel machine bolts may be used to make flange connections for bolt metal temperatures from −20 to 400°F (−29 to 204°C) inclusive, they are considered to be low-strength bolts and should be limited to noncritical low-pressure (Class 150) services. However, ASME B16.5 permits the use of these bolts for flanges up to Class 300 with the use of nonmetallic gasketing material.

The most widely used bolting materials in process plants are ASTM A193 Grade B7 stud bolts with ASTM A194 Grade 2H heavy semifinished hexagonal nuts. A number of operating companies, in fact, use these low-alloy materials almost exclusively, to simplify inventories and to reduce the possible misapplication of low-strength carbon-steel bolting. While the code permits the use of Grade B7 bolts from −50 to 1000°F (−45 to 540°C), a more conservative temperature range is recommended, as indicated by Table C7.7. At the high end, the use of Grade B16 low-alloy bolting is recommended instead of Grade B7, since the latter has greater creep relaxation concerns at elevated temperatures, which could lead to in-service loosening of the flange. At the lower temperature range, A320 Grade L7 bolts are more typically used below −20°F (−29°C), consistent with the use of impact tested carbon steel and other low temperature flange materials.

With the exception of carbon-steel machine bolts, the materials listed in Table

C7.7 refer to stud bolts. These should be threaded full-length with continuous threads to minimize stress concentrations within the bolt. The use of hardened washers, typically to ASTM F436, also should be provided under the nuts for the larger-size bolts [typically 1½ in (38 mm) and larger bolts] to minimize galling of the flange back face.

Selection and Limitations of Blanks

In a process plant, blanks are usually required to isolate individual pieces of equipment at shutdown and to positively block off selected process lines at the process unit limits. They are also needed during operation wherever positive shutoff is required to prevent leakage of one fluid into another. Blanks, especially for larger-size flanges, are typically provided with a companion spacer which has a full-size opening consistent with the inside bore diameter of the flange. Figure-8 blinds (also called *spectacle blanks*) combine both the blank and spacer with a tie bar. Figure C7.6 provides typical details for handle-type blanks, spacers, and figure-8 blanks.

Typically, operating line blanks, spacers, and figure-8 blinds, if specified for installation between ASME B16.5 flanges, are designed in accordance with the requirements of ASME B16.48, Steel Line Blanks (API 590, withdrawn), to accommodate the full rating pressure of the flange class involved. Blanks can also be designed in accordance with ASME B31.3.

Blanks ideally should be located in horizontal lines to ease their installation and removal. Blanks should not be used in vertical water and steam lines in climates where danger of freezing exists.

The use of figure-8 blanks obviously ensures that the companion spacer is on hand when needed (and vice versa). However, these are difficult to handle in the larger sizes [i.e., above NPS 12 (DN 300)], and instead separate spacers and blanks are used. The paddle handle provided on these devices should make it clear at a glance whether a bank or a spacer is installed within mating flanges. An accepted convention is to provide a T-bar off the end of the paddle handle for blanks, and a drilled hole or formed eye in the handle-end of spacers, which allows the lifting of these respective devices yet clearly distinguishes them from each other.

Piping systems should be equipped with spacers, figure 8 blanks, or designed with sufficient flexibility and flanges to permit blinds to be readily installed for isolation of equipment in accordance with the following criteria:

- In the piping or at the nozzle of all process and utility connections to vessels where necessary to provide safe entry for inspection and maintenance personnel
- In the suction and discharge lines of all turbines and compressors, except atmospheric suction of air fans
- At the inlets and outlets of process piping to fired heaters
- All fuel and pilot gas headers to each fired heater
- Spared equipment capable of being bypassed for maintenance
- Safety valve bypass lines
- Process battery limits

Blanks should be made from a plate or forging specification, approved for use by ASME B31.3, of essentially the same chemical composition as the mating flanges and piping involved.

(a) Paddle Blank (with T-handle)

(b) Paddle Spacer
(c) Figure 8 Blank

NOTES:
(1) Hole size (where required due to bolt spacing) should be the same as the flange bolt hole.
(2) The thickness of the web (or tie bar) dimension W_t should be 0.25 in (6 mm) minimum, or equal to t if less than 0.25 in. (6 mm).

Selection of Strainers

Strainers are an important component of piping systems to protect equipment from potential damage due to dirt and other debris that may be carried by the process fluid. This includes the use of temporary strainers that may be placed upstream of mechanical equipment to protect it from construction debris left in the pipe. Permanent strainers are also provided for some inlet piping to protect equipment from in-service corrosion products and other product residues. Typical strainer designs and construction details are provided in Chap. A2 of this handbook.

Centrifugal and reciprocating pumps handling material containing solids should have permanent strainers provided in the suction lines to the pump or in the vessel

from which the pump takes suction. The free area of such strainers should be not less than three times the cross-sectional area of the suction line. The location of permanent strainers (as contrasted to the temporary cone type which is installed at a flanged joint) also merits attention.

Some typical strainer opening or mesh sizes are provided by Table C7.8 for various equipment. The mesh sizes (or openings) are the usual maximums for normal operation. These opening sizes vary with the application, but should not exceed the value recommended for the particular type of equipment. The available pressure differential usually determines the minimum clear opening for screens.

The material for the strainer body (including bolting) should be equal to the material specified for the valves in the same service. The screen material generally should be the same as the valve trim (e.g., 11 to 13 percent chrome or Type 316 stainless steel for most services).

Permanent strainers should have baskets that can be flushed clean during operation or easily removed for cleaning. If considerable clogging of strainers is anticipated the strainers should be of the self-cleaning or the duplex type to permit continual flow of clean liquid.

Valve Applications and Limitations on Use

The successful performance of any process plant piping system is dependent on the proper selection and location of the valves that control and direct the flow of the piped fluids. There are numerous valve types and intended applications within a typical process plant, and to cover them all is beyond the scope of this chapter. More justice, however, is given this topic in Chap. A10 of this handbook, which provides detailed descriptions of valves and their features. This section will overview the application of the more commonly used valves within process plants, which can be categorized according to their function.

Block (Isolation) Valves. Block valves, as the name implies, are used to stop flow or isolate a portion of a system. Basic design requirements of a block valve are to offer minimum resistance to flow when fully opened, and conversely to achieve tight shutoff (nil leakage) when fully closed. Principal block valve types include *gate, globe* (although used mostly to regulate flow), *ball, butterfly, plug, ram*, and *diaphragm* valves. These achieve the required objectives in varying degrees, so all types can typically be found in a large process complex. Of these, however, the gate valve is the most commonly used block valve for refinery and chemical plant applications.

Throttling (Regulating) Valves. Throttling valves are principally used to regulate the flow of fluid within a piping system. This is achieved by varying the valve's open position to impart the required pressure drop to regulate the volume of flow. In the case of process control valves, throttling valves are used to control flow, pressure, or temperature, and in all situations the task is achieved by increasing or decreasing the flow through the valve in response to a signal from a pressure, flow, or temperature controller. Typical throttle valves include *globe, needle, butterfly, ball, plug* and *diaphragm* valves, which as previously noted can also serve a dual function to block flow.

Backflow Protection. *Check valves* are used to prevent backflow. A principal requirement of all check valves is that they be self-actuating, with little resistance

TABLE C7.8 Strainer Screen Openings for Equipment Inlet Piping

Equipment	Service	Pipe or flange size, NPS (DN)	Strainer type (Temporary) (Permanent)	Mesh size or opening, in
Pumps Centrifugal:	Suction	3 (80) and under	TEMP	5 × 5
Horizontal single stage, Vertical inline		3 to 6 (80–150)		3 × 3
		Over 6 (150)		½
Horizontal multistage, Vertical deepwell	Suction	6 and under	TEMP	20 × 20
		Over 6		⅛
Reciprocating	Suction	All sizes	TEMP	5 × 5
Rotary, turbine	Suction	All sizes	TEMP	20 × 20
Compressors Centrifugal:	Air, Suction	All sizes	PERM	3 × 3
	Gas, Suction		TEMP	5 × 5
Reciprocating:	Air, Suction	All sizes	(PERM Filter)	—
	Gas, Suction		TEMP	20 × 20
Rotary screw:	Air, Suction	All sizes	PERM	20 × 20
	Gas, Suction		TEMP	20 × 20
Axial:	Air, Suction	All sizes	PERM Screen on Dry Filter	5 × 5
	Gas, Suction		TEMP	5 × 5
Turbines Gas:	Inlet Air	All sizes	PERM Screen on Dry Filter	5 × 5
Steam:	Inlet	All sizes	PERM	⅛
Other equipment Fuel-oil lines to burners	Inlet	All sizes	PERM	⅛
Air supply to pneumatically actuated equipment	Inlet	All sizes	PERM	40 × 40
Upstream of restriction orifices in bleed services	Inlet	All sizes	PERM	1⁄16
Energizing fluids to ejectors	Inlet	All sizes	PERM	¼

Acceptable Metric Equivalent Dimensions for Above Table

Screen							Perforated plate opening		Pipe size, NPS	
Meshes (per linear in)	Wire diam in	mm	Average opening width in	mm			in	mm	in	mm
100 × 100	0.004	0.102	0.006	0.15			1⁄16	1.5	3	80
80 × 80	0.0055	0.140	0.007	0.18			⅛	3	6	150
40 × 40	0.010	0.254	0.015	0.38			½	13		
20 × 20	0.016	0.406	0.033	0.85						
5 × 5	0.063	1.6	0.137	3.50						
3 × 3	0.063	1.6	0.272	6.90						

to forward flow and rapid closure triggered by reverse flow. The closing of the disk can be achieved with gravity effects or with the assistance of springs or pneumatic actuators to assist in the rapid closure of the valve. Typical check valves include the *swing disk, dual-disk butterfly, tilting disk, ball,* and *piston* types.

Pressure-Relief Devices. These devices are used to protect piping and equipment from being subjected to pressures that exceed their design pressures. Some pressure-relief or safety valves achieve this with a spring-retained disk which pops when sufficient pressure lifts it off a sealing seat. Another type incorporates a pilot valve which uses system pressure to control the movement of the relieving disk. Rupture discs, although not valves, can also achieve rapid pressure relief, which is accomplished by the disk bursting open at a predetermined pressure. These have the advantages of being leak-tight up to the rupture pressure and of being capable of relieving large rates of flow. However, they cannot adjust the set pressure, as can relief valves. Another major factor for considering relief valves versus rupture disks is that the rupture disks don't reseat when the pressure goes back below the set point.

Valve Standards/Specifications

Table C7.9 provides some of the specific standards used in the manufacture of block and check valves for process plants. Most valves conform to the standard pressure and temperature ratings specified by ASME B16.34.[20] The pressure-temperature ratings of B16.34 for standard-class valves parallels that of ASME B16.5 (for steel flanges) except B16.34 provides for higher pressure-temperature ratings for welding-end special-class valves that receive additional prescribed nondestructive examinations. As indicated by Table C7.9, several API Standards provide detailed design and manufacturing requirements for the specific valve types covered to supplement the principal design requirements stipulated by ASME B16.34. Refer to Chap. A10 for details. The points that follow will highlight several application

TABLE C7.9 Valve Standards for Process Plant Applications

ASME Standards	
B16.34	Valves—Flanged, Threaded, and Welding End
API Standards	
594	Wafer and Wafer-Lug Check Valves
598	Valve Inspection and Testing
599	Steel and Ductile Iron Plug Valves
600	Steel Gate Valves, Flanged and Buttwelding Ends
602	Compact Steel Gate Valves—Flanged, Threaded, Welding, and Extended-Body Ends
603	Class 150, Cast, Corrosion-Resistant, Flanged-End Gate Valves
607	Fire Test for Soft-Seated Quarter-Turn Valves
608	Metal Ball Valves, Flanged, Threaded, and Welding End
609	Butterfly Valves, Lug-Type and Wafer-Type
ASTM Standard	
A494/A494M	Castings, Nickel and Nickel Alloy
ANSI/AWWA Standard	
C504	Rubber Seated Butterfly Valves

considerations associated with some of the more commonly used valves covered by these standards.

Gate Valves. The majority of steel gate valves for use in refinery and chemical process plants are specified to API 600 covering Steel Gate Valves.[21] This standard provides for greater corrosion allowance and hence heavier wall thickness than ASME B16.34 for the same pressure rating. This allows the broader application of the same API 600 gate valve across multiple-service classes. API 600 also stipulates that the valve be of the Outside Screw and Yoke (OS&Y) type for the actuating stem works to minimize corrosion damage of this mechanism by locating the screw threads external to the valve.

Additional application considerations for gate valves include:

- The wedge design for gate valves should be the flexible type to allow for better sealing of both the upstream and downstream side of the gate to the valve body seats. It also compensates for differential thermal expansion effects that can occur between the valve body and the gate wedge. Solid wedges, however, may be used for small-diameter [NPS 2 (DN 50) or smaller] or lower-pressure-class valves ($\leq$ Class 150).

- Valve trim materials for the stem and gate/body seats are typically specified by the user for the intended service in accordance with the trim alternatives defined by API 600. For critical nonlubricating services, valve seats are hard-faced to minimize seat travel wear.

- If the pressure differential across a closed gate valve is approximately equal to the pressure rating of the valve, consideration should be given to providing a pressure-equalizing bypass around the valve. Consideration should also be given to bypasses for valves in steam lines for warm-up purposes. When bypasses are provided, they should be sized in accordance with MSS SP-45, *Bypass and Drain Connection Standard.*[22]

- Gate valves with soft-seal (e.g., PTFE) inserts in the seat rings can provide improved leak-tight performance. However, it is important to confirm that proper metal-to-metal seat contact is achieved between the gate and body seats prior to installing the soft seals. This is needed to obtain normal gate sealing as a secondary backup to the soft seals should they be damaged during a fire.

Other Block Valves. *Butterfly valves, ball valves, nonlubricated plug valves*, and *lubricated plug valves* may be considered as possible alternates to gate valves. The majority of these valves rely on soft-seal materials to effectively achieve leak-tight performance. Table C7.10 identifies recommended temperature limits for several of the more common soft-seal materials used with these block valves.

TABLE C7.10 Valve Soft Seal Material Temperature Limits

	Temperature limit	
Soft seal material	°F	°C
PTFE (Polytetrafluoroethylene)	450	230
FEP (Perfluoro (Ethylene-Propylene) Copolymer)	400	200
VITON-A	400	200
BUNA N	250	120
NEOPRENE	200	90

Other design considerations for soft-sealed block valves include the following:

- Fire-tested type ball, plug, or butterfly valves should be certified per the requirements of API Standard 607, *Fire Test for Soft-Seated Quarter-Turn Valves,* if intended for flammable or other dangerous material services.[23] These fire-tested valves are specifically designed with metal-to-metal secondary sealing to minimize leakage across the block should the primary soft seals be destroyed during exposure to a fire.

- Soft-seated valves in liquid service should be provided with pressure relief for the body cavities. The liquid is usually relieved to the upstream side. This is needed to relieve pressure buildup and possible valve damage due to liquid thermal expansion within the body cavity, which cannot escape because of the leak-tight soft seals.

Globe Valves. As a general rule, hand-operated throttling valves for services where fine control is not required, and those for control valve bypasses, should be globe valves (integral stem and plug preferred). For severe throttling service, and where close control is required, a conventional control valve with a hand operator should be used. The only other common application for globe valves in process service is for mixing purposes where relatively tight shutoff is required.

In most process plants, internal corrosion is a greater problem than external corrosion. Consequently, it is common practice that all NPS ¾ (DN 20) and larger steel and cast-iron [and all NPS 2½ (DN 65) and larger brass] gate, globe, and angle valves (located above grade) be of the outside screw and yoke type.

Check Valves. The following design considerations are offered in the specification of check valves for typical process plant applications:

- Do not use check valves in vertical lines in which the flow is downward.

- Dual- and single-plate wafer check valves should be designed to API-594, *Wafer and Wafer-lug Check Valves,* requirements.[24] These types of check valves are not recommended for reciprocating compressor or reciprocating pump services, which could otherwise lead to pulsation-induced fatigue failures of the valves' spring-assist closure mechanisms.

- Ball or piston check valves should be of the self-closing type (gravity or spring assisted) and should not depend on flow reversal, or only the spring, to effect closure.

- Lift check valves are not recommended for use in services subject to fouling, coking deposits, or erosion.

Double Block and Bleed Valves. Under certain conditions double block valves are needed to prevent product contamination or where it is necessary to remove essential equipment from service for cleaning or repairs while the unit continues in operation. Of course, such equipment must be provided with a spare or it must be possible to bypass it temporarily without shutting down the unit. The nature of the fluid, its pressure and temperature, and many other factors must be considered when determining the need for double block valves.

Generally, double block valves should be considered for the onstream isolation of equipment if the fluid is flammable or otherwise hazardous, or if the fluid is in high-pressure or high-temperature service. Where double block valves are used, a NPS ¾ (DN 20) or larger bleed valve should be installed between the block valves
FIGURE C7.7   Double block and bleed valves.

(see Fig. C7.7). The purpose of the bleed valve is twofold. First, the bleed ensures that the upstream valve is in fact tight before slipping in a blind off the downstream block valve. The bleed connection also permits the safe withdrawal of moderate leakage from the upstream valve to again assure the tight shutoff of the downstream valve.

Depending on the service conditions, it may be possible to use a single block valve with a body bleed to provide *double block and bleed* provisions for onstream isolation of equipment. Gate valves with flexible wedges and with body or bonnet bleed valve can serve this purpose if specifically tested in accordance with API-598 for double block and bleed quality valves.[25] Some ball valves and nonlubricated plug valves, when equipped with a valve body bleed between the seats, can also be satisfactory substitutes for double block valves. Testing for double block and bleed quality valves requires the pressure-testing of each seat, with leakage measured through the valve body bleed as a means of substantiating the independent leak tightness of both the upstream and downstream seats of the valve.

GENERAL PROCESS PIPING SYSTEM CONSIDERATIONS

In previous sections, emphasis was placed on individual piping components. This section will look at the composite of these components by highlighting some of the important considerations required in the overall system design of process piping.

Materials Related Considerations

Proper materials selection is a key parameter in determining the adequacy of the performance of a piping system to sustain the extremes of temperature, chemical attack, or erosion. Such materials related considerations include the specific chemical, metallurgical, and physical properties of a piping system's material constituents, which can ultimately determine its suitability for a particular service.[26] Chapters A3 and B2 of this handbook expand on some of the principal considerations involved in the selection of materials for a specific piping system, which would include:

- *Strength.* The strength of a piping component or system is usually determined by the Process Piping Code, ASME B31.3, as it relates to the allowable working stresses for the materials under consideration. These allowable stresses are typically based on specified percentages of the material's yield and tensile strengths. It also considers creep and rupture stress rate properties for any material operating in temperatures within its creep range.

- *Toughness, or Ductility.* Toughness is the ability of a material to resist impact or to absorb strain energy when stressed beyond the elastic limit. Steel piping materials are normally considered to be ductile. Under certain conditions, however, steel may behave in a brittle manner and shatter like glass. In piping, this behavior typically occurs only at low temperatures. Temperatures below the *transition temperature* for any steel represent temperatures at which it will behave in a predominantly brittle manner. Hence, steel with a high transition temperature is more likely to behave in a brittle manner during pressure testing or in service. It is important that the material's transition temperature be well below the design minimum temperature expected in service for the piping system involved.

- *Corrosion Resistance.* This material property is a measure of a piping system's material ability to resist chemical attack from a specific process fluid throughout the range of expected operating temperatures and fluid compositions, or from its exposure to environmental effects. All common piping system materials react with some process fluid corrodants at certain temperatures. When specifying a material for a particular application, it is important to select a material whose corrosion rate in the presence of expected corroding is acceptable over the design life of the piping system.

- *Other Material Considerations.* In addition to corrosion, it is also worth mentioning other materials related degradation phenomena which need to be considered in the selection of the piping system materials. These would include, for example, materials resistance to *hydrogen attack* at elevated temperature, which is a particular concern of many refinery processes, and is generally attributed to the formation of methane (CH_4). This can occur for carbon-steel materials exposed to fluids with a high concentration of hydrogen at elevated temperatures. It is usual practice to specify low-alloy ferritic steel materials, increasing the amount of chromium composition between 1 to 5 percent depending on the hydrogen concentration and fluid temperature involved, to preclude hydrogen attack. Another materials related concern is *stress corrosion cracking,* which can occur with certain grades of austenitic stainless steel materials under a broad range of services and fluids. *Erosion* of piping materials can be another factor limiting the life of components. This is a principal concern for systems with fluids with some solids contents or high flow velocities resulting in significant material loss.

Unfortunately, the list of other special materials-related concerns for process piping can be quite extensive and well beyond the scope of this chapter, but these are covered to some extent in Chap. A3 of this handbook. It is important for the designer to have an appreciation of the service experience of the proposed materials for the intended fluid media to confirm its overall compatibility for these fluid service conditions.

Refer to App. E5 for piping and tubing material specifications for use in B31.3 applications. App. E6 provides some international pipe specifications.

Pressure Integrity

The pressure integrity design of a piping system needs to first determine the minimum required pipe wall thickness. The second consideration is the determination of the pressure rating of all the piping components, such as fittings and valves, within the system. Thus, verification is required that all of the individual components of the piping system are specified with sufficient wall thickness to be acceptable for the imposed pressure-temperature design conditions.

The designer is cautioned that regardless of the combination of operating pressure and temperature which results in the most severe condition from a stress standpoint, the selection of materials will often be governed by the extremes of operating temperature and pressure. In designing piping systems, it is simpler to use fluid temperature than metal temperature. Substantial savings, however, can be realized by making appropriate thermal calculations or tests to determine the metal temperature, especially if the fluid temperatures are high or if the system is internally insulated. Not only can flange (and valve) ratings and pipe thicknesses often be reduced, but occasionally less expensive materials can be used.

In considering metal rather than fluid temperatures, any savings in the cost of piping components must be balanced against the present worth of the additional heat to be lost from the piping components if the insulation is omitted. Flanges and valves which are to be left bare should be clearly marked on the piping drawings so that they are not inadvertently insulated.

Operability, Maintenance, Safety, and Accessibility

The overall piping system design will need to consider the operability, maintenance, and accessibility of the principal components. These factors are very dependent upon each other, which also need to be considered in the context of assuring the overall safety of the piping system.

Operability. From the process unit operators' perspective, the layout of the piping system needs to provide easy access to key components that must be operated frequently. This typically includes accessible positioning of the more frequently used block and control valves, and readable instruments installed directly off the piping. It is not possible, however, to make every valve and instrument directly accessible. Instead, consideration should be given for the frequency of operation and the degree of physical effort needed to perform the required operation. Important operable valves and instruments should be reachable while standing at grade or from an elevated platform provided for that purpose. The position of any valve handwheel or instrument control device should be such that the force needed to operate it can be applied without excessive strain on or undue contortions by the operator. It is also important that adjacent valves, lines, or other equipment not interfere with these operations.

Maintainability. The piping system layout must consider the maintenance requirements, whether anticipated or not, of the piping and equipment involved. The arrangement of the piping should ensure that sufficient space is provided for the maintenance of equipment and for the piping system, and the maintenance of the components within it. This should include, as examples, sufficient space allocations for the pulling of exchanger bundles, major equipment laydown spaces, machinery rotor and furnace tube removals, and for the dismantling of equipment where required. Maintenance requirements will also dictate the location of isolation block

valves, especially those required for the onstream isolation of the key equipment and instruments. It is important to design the facilities so that the appropriate accessibility is provided to accomplish the required maintenance, including provision for any lifting equipment, such as davits, cranes, or trolley-beam hoists.

Safety Considerations. In laying out piping for operability and maintenance, it is important that equipment, valves, and other components are placed in locations where they do not create hazards to personnel. These could be tripping obstacles, head-knockers, or other obstructions which could lead to bodily injury. Safety design requirements for stairs, platforms, ladders, means of egress aisleways, and minimum headroom clearances, for example, need to be considered to provide a safe work environment. These requirements, obviously, should be reflected in the overall process unit design.[27]

Accessibility. This has already been discussed in some detail in terms of space and treatments to help workers do their job as related to the operability and maintenance of the piping system. Even for remote valve locations, the inclusion of a platform could be justified, considering the importance of the component involved and the associated possibility of personnel injuries if not provided.

Flexibility and Support of Process Plant Piping

The general challenge of flexibility and expansion of piping systems is treated in Chap. B4 of this handbook, and the support of piping systems is covered in Chap. B5. Techniques, methods, and procedures developed in those chapters are applicable to process plant piping. Appendix E9 lists the capabilities of piping related computer programs.

The need for detailed analyses of piping systems must reflect the acceptability of imposed reaction loads to equipment terminations and not just the thermal flexibility stressing of the pipe itself.[28] The determination and analysis of equipment reaction loads will in fact justify the need for detailed thermal flexibility and sustained longitudinal stress analyses for a considerable number of piping systems within a typical process plant. Recommendations in this regard would suggest that, as a minimum, *formal computer flexibility analyses* be performed for each of the following piping systems:

- Process, regeneration, and decoking lines to and from all fired heaters and steam generators
- Process lines to and from all compressors and all blowers
- All NPS 3 (DN 80) and larger lines connected to other rotating equipment, including pumps, steam or gas turbines, and mixers
- Main process and regeneration lines to and from all process reactors
- All lines NPS 4 (DN 100) and larger with a design temperature of 450°F (232°C) or more
- All lines NPS 8 (DN 200) and larger with a design temperature of 350°F (177°C) or more
- All lines NPS 12 (DN 300) and larger with a design temperature of 250°F (121°C) or more
- All lines NPS 20 (DN 500) and larger, regardless of design temperature
- All lines that contain expansion joints

- All lines with internal refractory lining
- All lines NPS 4 (DN 100) and larger connected to air-cooled heat exchangers
- All lines NPS 12 (DN 300) and larger connected to storage tanks

Other piping systems not covered by this list will still need to be evaluated using conventional thermal flexibility evaluation techniques to verify the acceptability of the planned layout and supporting arrangements.[29] Depending on the system, these screening evaluations may establish whether a more detailed computer flexibility analysis is required because of the complexity of the piping layout, and its interconnections with other piping or equipment involved. An example in this regard would be the tie-in of a new branch line to an existing piping system, where the thermal expansion effects of the new composite system need to be verified, and where the complexity of the system or the load sensitivity of the connecting equipment involved would justify a more detailed analysis.

Fabrication, Assembly, and Erection of Process Plant Piping

These topics are covered at length in Chap. A6 of this handbook. Detailed requirements which relate to fabrication, assembly, and erection of the process piping systems are given in ASME B31.3. Important phases of the Code treatment of these topics are covered briefly in this section.

Materials for Welding. All filler materials must comply with the requirements in Sec. IX of the ASME Boiler and Pressure Vessel Code.[30] If backing rings are used in services where their presence will result in severe corrosion or erosion, it is required that the backing ring be removed after welding and the internal joint ground smooth. When it is impractical to remove the backing ring in such a case, consideration should be given to welding without backing rings or to the use of consumable inserts or removable nonmetallic backing rings.

Welding End Preparation. ASME B16.25 provides dimensional standards for weld end bevels.[31] Preferably, the ends of pipe and the edges of plate used to form pipe should be shaped by machine. Other methods of shaping may be employed, provided that a reasonably smooth surface suitable for welding and free from tears, slag, scale, and grease is attained. Oxygen or arc cutting is acceptable only if the cut is reasonably smooth and true, and all slag is cleaned from the flame-cut surfaces.

If piping component ends are machined on the inside for backing rings, such machining must not result in a finished wall thickness, after welding, less than the minimum design thickness plus corrosion and erosion allowances.

Generally a root gap of ⅛ in (3 mm) is used for girth butt joints (including branch connections) without backing rings, except that where the pipe wall thickness is less than ³⁄₁₆ in (5 mm), a ¹⁄₁₆ in (1.5 mm) root gap is generally used.

Welding Alignment Considerations. The following requirements should be considered in the final alignment of the completed welded connection for the type indicated:

- Radial misalignment at the joining ends of piping components should be limited to ⅛ in (3 mm) or ¼ of the pipe wall thickness, whichever is less. Internal radial misalignment exceeding ¹⁄₁₆ in (1.5 mm) should be taper trimmed so that the adjoining internal surfaces are flush. However, the resulting thickness of the

welded joint should not be less than the minimum design thickness plus the specified corrosion allowance.

- Longitudinal seams in adjoining lengths of welded pipe should be staggered and located to clear openings and external attachments.

- Flange bolt holes should straddle the established centerlines unless other orientation is required to match the flange connections on equipment.

- Slip-on flanges should be positioned so that the distance from the face of the flange to the pipe end is about equal to the nominal pipe wall thickness plus ⅛ in (3 mm).

- Welding neck orifice flanges should be the same bore as the pipe to which they are attached and must be aligned accurately.

Welding Requirements/Procedures. Specific welding procedures are usually defined by the welding procedure specification (WPS). However, the following restrictions, limitations, or guidelines generally apply to the welding of process piping:

- Qualification of the welding procedures to be used and of the performance of welders and welding operators is required to comply with Sec. IX of the ASME Boiler and Pressure Vessel Code.

- Before welding, all surfaces must be cleaned and free from paint, oil, rust, scale, or other detrimental material. Furthermore, welding is prohibited if there is impingement of any rain, snow, sleet, or high wind on the weld area.

- Projection of weld metal into the pipe bore at welded butt joints should not exceed 1/16 in (1.5 mm) for pipe NPS 8 (DN 200) and smaller or ⅛ in (3 mm) for larger pipe. Excessive projections on accessible joints should be removed. Welds attaching welding neck orifice flanges to pipe should be ground smooth on the inside.

- The Code does not permit cracks in fillet or seal welds and limits undercutting to 1/32 in (0.8 mm) for these welds. Fillets welds may vary convex to concave.

- If *seal welding of threaded joints* is performed, the code requires that all exposed threads be covered by the seal weld and that the welding be done by qualified welders. In addition to the Code requirements, all threaded joints to be seal welded should be made without thread compound or PTFE tape. Seal welds should be at least two pass welds using a 3/32 or ⅛ in (2.4 or 3 mm) electrode, except a 5/32 in (4 mm) electrode is acceptable for NPS 2½ (DN 65) and larger pipe sizes.

The following Code requirements apply to *girth butt welds* and any *longitudinal butt welds* in piping components which are not made in accordance with a standard or specification.

- If the external surfaces of the two components are not aligned, the girth butt weld must be tapered between the two surfaces.

- Tack welds, if not made by a qualified welder using the same procedure as the completed weld, must be removed. Tack welds that are not removed should be made with an electrode which is the same as or equivalent to the electrode to be used for the first pass. Tack welds which have cracked must be removed.

- Peening (mechanical working) is prohibited on the root pass and final pass of a weld.

- No welding should be done if there is impingement on the weld area of rain, snow, sleet or excessive wind, or if the weld area is frosted or wet.

Preparation and Welding Procedure for Welded Branch Connections. Branch connections (including specially made integrally reinforced branch connection fittings) which abut the outside surface of the run wall or which are inserted through an opening cut in the run wall must be so arranged as to provide a good fit and attached by means of full penetration groove welds.

The recommendations for spacing and location of branch connections contained in Pipe Fabrication Institute (PFI) Standard ES7 should be followed.[32] A good fit must be provided between reinforcing rings and saddles and the parts to which they are attached. Reinforcing pads, when required, should be added as a subsequent fabrication step after visual inspection of the branch-to-header weld.

When rings or saddles are used, a drilled vent hole, minimum ⅛ in (3 mm), is provided at the side and not at the crotch of the ring of saddle to reveal leakage in the weld between branch and main run and to provide venting during welding and heat-treating operations. A pad or saddle may be made in more than one piece if joints between pieces have strength equivalent to the pad or saddle parent metal, and if each piece has a vent hole.

Defect Repairs. Weld defects that require repair must be removed. All repair welds must be made with the same welding procedure initially used for making the original weld.

Fabrication Tolerances for Welded Piping. A widely accepted tolerance on face-to-face and center-to-face dimensions of welding piping is ±⅛ in (3 mm). As for the location of the flanges, their lateral translation in any direction from the specified position should not exceed ⅟₁₆ in (1.5 mm). Also, the alignment of flanges should not deviate from the specified position, measured across any diameter, by more than ⅟₃₂ in (0.8 mm).

The tolerance for flange connections to rotating equipment or other load-sensitive equipment is typically specified to be much tighter, usually ⅟₃₂ to ⅟₆₄ in (0.8 to 0.4 mm) for the maximum translation or rotation of the flange, depending on the size of the nozzle connection.

Bending and Forming. Pipe may be bent by any hot or cold method consistent with material characteristics of the pipe being bent and the intended service. It may be bent to any radius that will result in a bend arc surface which is free of cracks and buckles. However, it is recommended that the centerline radius of pipe bends shall be equal to at least three times the nominal pipe diameter, and fabrication should be in accordance with ES-24, *Pipe Bending Methods, Tolerances, Process and Material Requirements*, of the Pipe Fabrication Institute.[33] Tighter bends approaching 1½ D are possible, such as that obtained with induction bending methods with appropriate heat treatment. Specific manufacturing experience and process procedures in these circumstances should be reviewed by the process plant owner, which is recommended in assessing cost incentives over more conventional pipe bends or elbows. Hot bending and forming must be done within a temperature range consistent with material characteristics, end use, or postweld heat treatment.

When pipe must be threaded before bending, forging, or heat treating, all exposed threaded surfaces should be protected during heat treatment.

Heat Treatment. Heat treatment is used to avert or relieve the detrimental effects of high temperature and severe temperature gradients inherent in welding, and to

relieve residual stresses created by bending and forming. The welding procedure qualification describes the necessity for preheating and postweld heat treatment of welds (and the temperatures and soaking period to be used) in order to restore or obtain the physical properties of the materials (such as strength, ductility, and corrosion resistance) needed to satisfy end-use requirements. Specific requirements for preheat and post weld heating are provided by Sec. 330 and 331, respectively, of ASME B31.3.

In the case of dissimilar materials, the heat treatment of welded joints between dissimilar ferritic metals or between ferritic metals using dissimilar ferritic filler metal should be at the higher of the heat treatment temperature ranges specified by the Code for the materials in the joint. Heat treatment of welded joints including both ferritic and austenitic components and filler metals should be as required for the ferritic material or materials.

Cleaning After Fabrication. Following fabrication, all loose scale, weld spatter, slag, sand, and other foreign material should be removed from the piping. Piping Fabrication Institute (PFI) Standard ES-5, *Cleaning of Fabricated Piping*, is an acceptable standard for cleaning fabricated piping.[34] Piping is typically painted, at least primed, before leaving the fabricating shop (i.e., before it has been erected and tested). However, it recommended that all welded joints for buried piping systems or for piping within environmentally sensitive areas be left unprimed and unpainted for examination during pressure testing.

Bolting Procedure for Flanged Joints. Proper assembly of bolted joints is as important as proper welding in assuring leak-free performance of piping systems. Chapter A7 of this handbook provides a detailed discussion of bolted joints. For the majority of flanges, it is recommended that specific *bolt-up procedures* be developed, and that field personnel be qualified by assembling one or more joints, in much the same way as welding procedures and welder qualifications are handled. The selection of the proper technique of tightening the bolts of a flange joint is a complex process requiring experience and good engineering judgment. In addition, the successful application of any technique requires qualification of the tools to be used and the crew.[35] The following steps are recommended as a general approach to flange makeup:

1. Check studs and nuts for proper specification stamp. Check bolts or studs, nut threads, and nut contact face for cleanliness and burrs. Bolts and nuts should be cleaned using a wire brush and visually examined after cleaning to ensure that they are free from burrs.

2. Lubricate the bolt and nut threads uniformly on all contact surfaces, including the nut-bearing surface contacting the flange, with an appropriate high temperature colloidal nickel compound. The use of hardened steel washers is recommended under the nuts of bolts 1½ inch in diameter and larger.

3. Clean gasket seating surface on flange face using a wire brush (use stainless steel bristles on alloy components). Ensure that the surface is free from scratches, dirt, scale, remnants of old gaskets, and other protrusions. Flange faces with radial scratches or tool marks that form leakage paths should be refaced.

4. Check the alignment of the two mating flanges in the field to verify that it is within accepted fabrication tolerances. Alignment should be achieved by cutting and rewelding the pipe where possible. Excessive force should not be used to

move flanges into alignment, particularly for piping attached to machinery or other load-sensitive equipment.

5. Visually examine the gasket prior to installation to ensure that it is free from defects. Make sure the gasket type, size, and materials of construction are in accordance with the specifications.

6. Insert the gasket between the flanges carefully to ensure proper placement (centering in the joint), taking care not to damage the gasket. If absolutely necessary to use something to hold the gasket in place, a light spray of adhesive can be used. Alternatively, thin cellophane or masking type tape may be used on the outside edges of gasket with enough material protruding to allow removal during the initial tightening process. Tape should be located with care to avoid infringing on the flange face/gasket seating surfaces.

7. Install bolts and hand-tighten. Tighten bolts with qualified tools, torque or hydraulic stud tensioners, and procedures. Tightening of the bolts should follow usual crisscross sequential pattern to approximate uniform preload seating of the gasket.

8. A multipass tightening procedure should be implemented to ultimately tighten the bolts to the target bolt-preload stress.

9. Increase torque or hydraulic pressure to 100 percent of the value necessary to achieve the desired residual stress level. The majority of flange joints in process plants are assembled based on 50 ksi average preload stress using ASTM A 193 Grade B7 bolts. However, there are some combinations of flange type, rating, and bolting material for which lower bolt stress values are appropriate.

10. Depending on the critical nature of the flange service, consideration should be given to measuring the elongation (stretch) achieved in the bolt to verify the target bolt preload has been obtained and relatively uniform for all bolts of the flange. The use of bolt elongation measurements should be specifically considered as part of the qualification procedures of the boltup methodology, tools, and the work crew in achieving the required target preload.

The completed bolt loading should exert a compressive force of at least twice that generated by the internal pressure to compensate for not only the internal pressure, but for other factors including bolt and gasket relaxation effects, and possible bending loads which are imposed on the flange pair during operation.

Steel-to-cast iron flanged joints must be assembled carefully in order to prevent damage to the cast iron flange. Both flanges in steel-to-cast iron flanged joints should be flat-faced and full face gaskets should be used. These joints should be made up with extreme care, taking up on bolts uniformly after fitting flanges into close parallel and lateral alignment. Flanges that connect piping to mechanical equipment, such as pumps, turbines, or compressors, should be fitted up in close parallel and lateral alignment prior to tightening the bolting.

Bell and Spigot Joints in Cast Iron Piping.   Bell and spigot joints in cast iron piping should be assembled using poured lead or other joint compound suitable for the service. Usually each cast-iron bell and spigot joint is packed with hemp, poured full of lead (with a minimum number of pours), and then caulked. The depression of lead below the face of the bell, after joint caulking, should not exceed ¼ in (6 mm). Lead wool can be used where it is not permissible to pour lead.

Threaded Piping.   Any compound or lubricant used on threads must be suitable for the service conditions and compatible with both the service fluid and the piping

materials. Threaded joints which are to be seal welded should be made up without any thread compound or PTFE tape.

Erection of Metal Bellows Expansion Joints. Metal bellows expansion joints should be installed as shipped from the manufacturer or compressed for the cold condition at erection depending on anticipated direction and magnitude of movement after the piping reaches operating temperature. The manufacturer's recommended total travel should preferably straddle the calculated travel. The bellows assembly of expansion joints in piping systems should be equipped with a removable external steel cover designed to protect the bellows from external mechanical damage. The cover should be designed so that it does not prevent the required thermal movement of the joint.

Erection of Valves. The manual operation of principal block and control valves should be checked to the extent practicable before they are fully installed within the system. In the case of gate valves, this should specifically check that the gate travel is in proper contact with the body seats when in the fully closed position. Similarly, the closure mechanisms of check valves should be checked to ensure good seat alignment and ease of operation. Valve packing glands should also be checked for the quality and quantity of packing, and lubricated plug valves should be provided with proper lubricant.

Erection of Pipe Supports and Springs Hangers. In addition to the major supports specified by the design drawings, minor supports as found necessary in the field should also be installed to prevent undesirable vibration, sag, lateral movement, or stresses. Spring hangers and pedestals, including the constant-support type, should be checked for proper adjustment of travel and be correctly positioned for the cold condition of erection. Springs should be provided with spring travel indicators and scales to allow the monitoring of these supports while in service from grade or nearby platforms.

Cleaning of Lines After Assembly and Erection. After the completion of erection, scale, dirt, welding electrodes, slag, and other foreign material should be removed from the lines. Particular attention should be given to the cleaning of air lines, equipment lubricating and seal-oil systems, and compressor, blower, pump, and turbine inlet piping.

All practical precautions should be taken to prevent the introduction of foreign matter into pumps, instruments, and other equipment. Cleaning may be accomplished by flushing out the lines. Temporary strainers should be used at pumps during the flushing operation unless spools or valves can be conveniently dropped out and suitable deflectors provided to prevent refuse from entering the pumps. Consideration should be given in dismantling those lines which cannot be adequately cleaned by flushing.

Examination, Inspection, and Testing

Prior to initial operation, a piping installation should be inspected to the extent necessary to assure compliance with the engineering design, and with the material, fabrication, assembly, and test requirements of the code. An employee representative of the owner should be responsible for this inspection. This examiner may delegate performance of any part of the inspection to inspectors who may be

employees of his own organization, of an engineering or scientific organization, or of a recognized insurance or inspection company.

A nondestructive examination (NDE) plan should be consistent with service severity, incorporating process and mechanical factors. The NDE plan focus should be on those pipelines where failure would produce the most harm to personnel or property. Some issues that the designer should consider when developing the NDE plan are:

- *Service factors*: The hazardous natures of flowing media including their degree of corrosivity, toxicity, and flammability are some considerations to which the designer would want to apply a sound NDE program in order to detect flaws in these dangerous streams.

- *Mechanical factors*: Temperature, pressure, cyclic conditions, thermal bending stresses, and vibration can contribute to fatigued and highly stressed lines, which are more likely to fail than low stressed lines. Detection and removal of flaws can provide additional service life.

Visual Examination. Visual examination consists of observations by the examiner of whatever portions of a component or welds that are exposed to such observation, either during or after manufacture, fabrication, assembly, or testing. Sufficient materials and components, selected at random, need to satisfy the examiner that they conform to specifications and are free from defects.

Types of Examination. The following types of examination are or may be specified by engineering either when required by the Code or considered necessary because of special service conditions requiring a high degree of freedom from imperfections. If such examination is specified for a weld, it is only required that the weld examined be repaired, if necessary, so that the weld imperfections comply with the limitations in the Code for the type of examination used. ASME B31.3 requires certain NDEs be performed in accordance with the methods described in ASME Sec. V, Nondestructive Examinations.[36] If supplementary types of examination are specified they should be performed after completion of any postheat treatment where required. If any of the following types of examination are specified by the engineering design, they should be performed to the extent that follows:

- *Magnetic Particle.* Magnetic particle examination is essentially a surface-type examination, although some imperfections just below the surface are detectable. This type of examination is limited to materials which can be magnetized (hence it is not appropriate for austenitic stainless steels). An area to be examined by magnetic particle examination can be completely examined or examined on a random sampling basis, as specified.

- *Liquid penetrant examination.* Penetrant-type examinations are suitable for surface examinations only but are very sensitive. The most common case is a red dye penetrant with a white developer.

- *Random Radiography.* X-ray or gamma ray method radiography may be used. The selection of the method should be dependent upon its adaptability to work being radiographed. When random radiography of welds is specified by the engineering design, it should be done on the number of welds designated. The engineering design shall specify the extent to which each examined weld should be radiographed. Random radiography may also be used for examination of piping components such as a valve or fitting to any extent specified by the engineering design.

- *100 percent Radiography.* If 100 percent radiography is specified for welds in piping, each weld in the piping shall be completely radiographed.
- *Ultrasonic Examination.* Ultrasonic examination is used in piping for the detection of defects in welds and materials as well as for determining material thickness. The ability of UT to detect discontinuities depends a great deal on the part geometry and defect orientation. Therefore, the search technique must be carefully chosen to assure that it will cover all possible defect orientations.

Hardness Tests. The extent of hardness testing required shall be as specified by Code or by the engineering design, considering the severity of the service, type of material, and other pertinent factors.

Pressure Tests. Prior to initial operation, piping must be pressure tested to assure leak tightness. If repairs or additions are made following the pressure tests, the affected piping is retested, except that in the case of minor repairs or additions the owner may waive retest requirements. The pressure test is maintained for a sufficient time to determine whether there are any leaks but not less than 10 minutes.

Water is commonly used as the test fluid, except when there is a possibility of damage due to freezing, or if the operating fluid or piping material would be adversely affected by water. If hydrostatic testing is not considered practical, a pneumatic test using air or another nonflammable gas may be substituted. However, pneumatic testing involves the hazard of released energy stored in compressed gas. Particular care must therefore be taken to minimize the chance of brittle failure during a pneumatic leak test. Test temperature is important in this regard and must be considered when the designer chooses the material of construction.

Hydrostatic Pressure Tests. Hydrostatic tests are conducted at 1.5 times nominal design pressure, adjusted for temperature, per the following equation from ASME B31.3:

$$P_T = 1.5P \frac{S_T}{S}$$

where P_T = minimum test gage pressure
$\quad\quad P$ = internal design gage pressure
$\quad\quad S_T$ = allowable stress value at test temperature
$\quad\quad S$ = allowable stress value at design temperature

If the test pressure as defined in the preceding equation would produce a stress in excess of the yield strength at test temperature, the test pressure may then be reduced to the maximum pressure that will not exceed the yield strength at test temperature.

Test Preparation. All joints, including welds, are to be left uninsulated and exposed for examination during the test. If a joint has been previously tested in accordance with the code it may be insulated or covered. Piping designed for vapor or gas shall be provided with additional temporary supports, if necessary, to support the weight of the test liquid.

Expansion joints shall be provided with temporary restraint, if required, for the additional pressure load under test or shall be isolated from the test.

Equipment which is not to be included in the test should be either disconnected from the piping or isolated by valves or blanks. If a pressure test is to be maintained for a period of time and the test liquid in the system is subject to thermal expansion, precautions must be taken to avoid excessive pressure buildup.

All pressure gages, gage glasses, flowmeter pots, liquid level float gages, and all other pressure parts of instruments, together with the piping connecting the instruments to the main piping, should be included in the hydrostatic test. Relief valves and rupture disks should not be subjected to the pressure test.

Pneumatic Testing.   If piping is tested pneumatically, the test pressure is set at 110 percent of the design pressure, which is considerably less than the test pressure required by ASME B31.3, if tested hydrostatically. Pneumatic tests include a preliminary check at the lesser one-half the test pressure or 25 psig (172 kPa), and the pressure is then increased gradually in steps providing sufficient time to allow the piping to equalize strains during the test and to check for leaks. Again, particular care must be taken to minimize the chance of brittle failure during a pneumatic leak test.

Test Records.   Records must be made of the tests, including date of test, identification of piping tested, test fluids, test pressure, and approval by inspector.

SPECIAL DESIGN PIPING SYSTEMS

Refractory Lined Pipe

Often elevated temperature pipelines or systems in erosive fluid solids service can be candidates for refractory lined piping systems. A principal application of refractory lined piping systems can be found in catalytic cracking units typical of most large refineries. A catalytic cracking (Cat) unit brings together a heavy feed and an active catalytic agent to produce lighter, more valuable petroleum products.[37] Catalytic cracking combines the action of heat and a catalyst to produce higher yields of motor fuels and other valuable products. In typical Cat units, the catalyst is fluidized and continuously circulated between a reactor vessel operating at around 1000°F (538°C) and a regenerator vessel where carbon is burned off the catalyst at about 1300°F (704°C). Operating pressures are usually well below 100 psig (690 kPa). The vessels and interconnecting reaction and regeneration piping are all refractory lined because of the economic material advantages that can be gained by applying thermal insulation on the inside of the vessel and pipeline rather than on the outside when very high operating temperatures are involved. Some of the immediate advantages include:

- Pipe wall (pressure boundary) temperature is considerably lower, thereby, allowing the use of lower alloy or carbon steel material at higher allowable stresses. In fact, process developments continue to push design temperatures to higher limits, upwards of 1300°F (704°C) and beyond, where refractory lined equipment and piping is the only feasible alternative to allow operation at these temperature extremes.

- Decreased thermal expansion will allow a tighter piping layout. However, as will be discussed in subsequent text, the refractory lining will significantly increase the stiffness of the pipe system, which needs to be considered in the thermal flexibility of the piping involved.

- Another advantage of refractory lined systems is the potential for improved erosion resistance, relative to bare steel, which is an important feature when fluidized solids processes are involved as in the case of Cat units.

These factors affect lower installed cost. The economic advantage becomes increasingly significant as temperatures, pressures, and pipe sizes increase.

The design of internally lined pipe entails a number of unique considerations. First, the effect of the process fluid on the thermal conductivity of the refractory needs to be considered. Low molecular weight gases, such as hydrogen, tend to permeate refractory linings. Influencing parameters include pressure, temperature, refractory density and composition, application techniques, and refractory cell structure. Empirical correction factors based on field experience have been developed for various processes and combinations of refractory types.

Selection of appropriate lining materials and design details are important to ensure a properly functioning system. Depending on service conditions, either a single layer or dual layer lining can be used. Some designs are depicted in Figs. C7.8, C7.9, and C7.10.
FIGURE C7.8   Single layer refractory lining for clean service.

An advantage of the dual layer is that the internal layer can be made of a relatively dense refractory with good strength and erosion-resistance properties without concern for insulating values. This thickness should be sufficient to prevent through-wall cracking and should reflect the minimum required for the anchoring detail specified.

The outer layer next to the pressure boundary pipe wall can be a light-weight
FIGURE C7.9   Dual layer refractory lining for erosive service.
FIGURE C7.10   Dual-layer refractory lining for hydrogen-bearing streams.

refractory with good insulating properties to provide maximum temperature reduction. Various schemes for refractory installation have been used for dual-layer linings. See Figs. C7.9 and C7.10.

While the advantages of refractory lined pipe are quite apparent, the lining will significantly increase the stiffness of the piping. The stresses in the pipe will be higher, but more important, there will be much higher reaction loads at all equipment connections and thermal expansion restraints. The thermal flexibility analysis of refractory lined pipe is relatively complex and will typically require the use of computer tools with experimentally determined influence factors to account for the increased stiffness and line weight attributed to the refractory lining.

Typical applications for refractory lined steel shell transfer lines are again found in process applications when high temperatures, greater than 1000°F (538°C), and significant flow rates (and corresponding large diameter pipelines) are concurrent design parameters. In addition to catalytic crackers, there are other refinery services where high temperature fluid solids are involved, such as fluidized cokers and catalytic reformer processes, which will use refractory lined equipment and piping. Many such lines, for example, can be found in large refinery operations with diameters of NPS 60 (DN 1500) and larger that typically carry flue gases from regeneration vessels, cokers, and crackers. Transfer lines from certain thermal cracking type heaters are also typically refractory lined.

Jacketed Pipe

Jacketed pipelines (see Fig. C7.11 for typical construction) are commonly employed for conveyance of certain fluids in process facilities where external heating (usually by steam or other heating fluids) is required to maintain process temperatures under very controlled conditions. Process fluids that require stringent temperature control (i.e., molten sulfur) are good candidates for jacketed pipe applications. Molten materials (i.e., polymers) where high temperature maintenance is required are also candidate applications for jacketed pipe construction.

The advantages afforded by jacketed pipeline construction over other (i.e., tracing) heat transfer methods can be briefly described as:

- Uniformity of heat input around circumference of process pipe
- Tighter temperature control over entire pipeline length
FIGURE C7.11   Heat transfer jacketed pipe.

- Elimination of ''cold spots'' that may cause process fluid degradation or localized freezing

Various heating media are used for temperature control of the process fluid. Liquid and vapor phase fluids are employed, each with their own specific advantages and design requirements.

Liquid Phase.   As shown by Fig. C7.12, liquid-phase jackets are considered as circuits each having its own valved supply and return connections from the pipe header. The number of jackets included in a circuit is a function of heating medium heat loss, pressure drop through the jacket circuit, and position and location of the piping. As indicated in Fig. C7.12, fluid supply is introduced at the lowest tapping of a jacketed part; passes through the jacket and exits at the highest jacket tapping. This method of piping continues for the length of the circuit. Jumpers, as shown by Fig. C7.13, are used to carry the liquid across flanged connections. The fluid is then returned to the heater via the return header and a new connection from the supply main feeds the next circuit. Temperature of any circuit is controlled by throttling the quantity of fluid flowing to the jackets.

Vapor Phase.   The number of jacket sections heated with a condensing vapor in any one circuit has the same considerations as liquid heating mediums. Unlike liquid phase heat transfer fluids, a jacketed pipeline heated with a condensing vapor (see Fig. C7.14) requires that the vapor inlet pipe be connected to the uppermost jacket tap rather than the lowest tap as in liquid heating. Jump overs, as shown by

Fig. C7.15, carry vapor to the top of each section or flanged joint. The condensate is drained from each section or flanged joint, collected, and piped to a trapped common return header. Low pressure steam is typically the heating media of choice for most vapor jacketed piping systems.

Jacketed pipeline construction details vary depending upon process factors. When maximum heat transfer is desired, a full jacket is used (where the jacket pipe is welded to the back of oversize flanges). This technique will minimize any potential cold spots. Partial jackets are used for those services where product contamination or danger of hazardous conditions could arise if product and heating media could mix, or where temperature control is not critical and localized cold spots would not be detrimental to pipeline performance.

The design of integral jacketed piping needs to consider the increased stiffness resulting from the addition of the external jacket. As previously discussed for refractory lined systems, this will require sophisticated piping flexibility analyses
FIGURE C7.13   Jumper—liquid phase jacketed pipe.
FIGURE C7.14 Jacket vapor phase—circuitry.

to properly determine piping thermal flexibility stresses and imposed equipment loads that account for the increased stiffness of the integral jacketing construction.

Nonintegral or strap-on jackets are usually employed to provide a means of heat transfer to a pipeline component that may not be adaptable to integral jacketing (e.g., valve bodies). In all cases, the heat transfer distribution circuitry must be properly designed and installed for satisfactory performance.

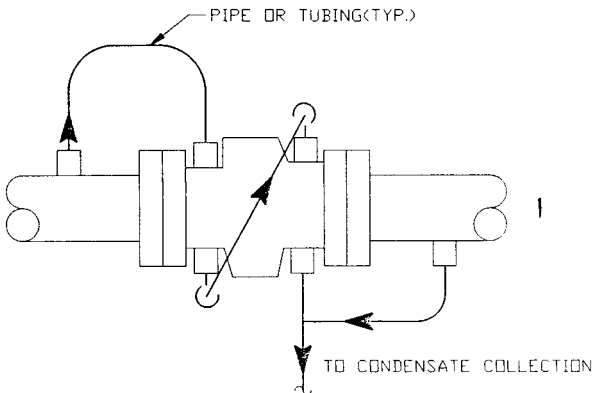
Vacuum jacketed piping systems are employed to transfer cryogenic temperature


FIGURE C7.15 Jumper—vapor phase jacketed pipe.

process fluids. The vacuum is established to minimize heat gain from the atmosphere to the cryogenic fluid. With the addition of external insulation little heat gain and resulting fluid vaporization will be realized. Cryogenic systems piping is covered in depth in Chap. C8 of this handbook.

Plastic Lined Pipe

Internal plastic liners are available in numerous materials that can be selected for use for a specific media. Some lining materials that are commonly used include PP (polypropylene), PVDC (polyvinylidene chloride), PTFE (polytetrafluoroethylene), FEP (perfluoro (ethylene-propylene) copolymer), ETFE (ethylene-tetrafluoroethylene), PFA (perfluoroalkoxy), and PVDF (polyvinylidene fluoride). Refer to Chap. B12 for details on plastic lined piping.

The properties of plastic-lined piping components permit these materials to be considered for the transportation of a variety of combinations and concentrations of fluids that are often very aggressive in normal steel piping systems.[38] Corrosion resistance is clearly a prime consideration for use of plastic-lined piping. However, there are other applications where plastic lined piping might be considered, including the following:

- Maintenance of process fluid purity, such as the processing of food products.
- Water treatment facilities and laboratory waste disposal systems.
- For secondary containment of dangerous, flammable, or environmentally damaging liquids. Because of its steel outer shell construction, the lined pipe will remain structurally self-supporting at higher temperatures and is less likely to rupture than solid plastic pipe.

Thermoplastic and thermoset resin piping systems are described in some detail in Part D, ''Nonmetallic Piping,'' of this handbook. Since these materials are not inherently fire safe, their application in typical refinery and chemical plant processes is very limited.

Glass and Glass-Lined Pipe

Borosilicate glass is used for specific piping services in the chemical and pharmaceutical industries. Some advantages afforded by glass piping are:

- Outstanding corrosion resistance for a variety of aggressive chemicals
- Smooth, pore-free surface
- Transparency
- Lack of product contamination effects, including those affecting taste, odor, and color
- Inertness

Glass lined piping components offer much of the same advantages afforded by solid glass piping and offer secondary containment, increased resistance to shock loads, and installed economics compared to other corrosion-resistant systems. The glass lining is extended from the pipe bore to cover the gasket seating areas of flanges. Gasket materials are typically limited to nonmetallic sheet gaskets suitable for the service to minimize compression seating forces exerted on the glass lined flange face.

SYSTEM LAYOUT CONSIDERATIONS

Piping arrangement and layout is discussed in depth in Chap. B3 of this handbook. This section will provide some important considerations in the design and layout of several of the more common types of piping systems found in process plants.

General Piping Arrangement

A general rule in piping layout is that lines should be located in as neat and orderly a manner (in groups or banks whenever practicable) as is consistent with economical design, pressure loss considerations, and satisfactory supporting arrangements. With the exceptions of water, drainage, and pumpout lines, the accepted practice on a process unit is to run the piping overhead, providing 7 ft (2.2 m) or more of clear headroom over walkways and platforms. Piping in a process unit should not be located at grade, especially in areas where frequent personnel traffic is likely.

All piping and equipment requiring regular attention of the operating and maintenance personnel should be readily accessible. Also, adequate clear working spaces, typically having a minimum width of 3 ft (1 m), should be maintained around equipment such as pumps, heat exchangers, control valves, instruments, and tower manways, which require frequent servicing. Consideration should be given to providing lateral and vertical clearance for the use of motorized materials-handling and crane equipment in maintenance work. To the extent practicable, principal valves should be located so they may be replaced and operated from grade, permanent platforms, or small portable platforms. If the bottoms of the handwheels are more than 6 ft above a platform or grade level, or if otherwise inaccessible, the valve should be equipped with extension stems or chain operators.

High temperature lines in a process plant pose problems for other piping and equipment. For example, hot lines, with temperature higher than 100°F (38°C), should be routed so as to avoid electrical conduits. Steam and condensate should not be discharged into the ground in the vicinity of electrical conduits. Lines containing corrosive chemicals should not be located near hot lines or other sources of heat.

Pressure Vessel (Reactors/Towers/Drums) Piping

The piping designer is cautioned that often limitations concerning piping connections at vessels are detailed in Sec. VIII of the ASME Boiler and Pressure Vessel Code. This would typically include piping between the vessels protected by the same relief valve, and piping between a vessel and its pressure relief safety valve. The piping designer should coordinate piping requirements with the vessel designer to achieve the optimum nozzle locations.

In the case of tall vertical reactors and most towers, the piping will be supported directly off the vessel as shown, for example, by Fig. C7.16. For economy and ease of support, piping in these situations should drop or rise immediately upon leaving the tower nozzle and run parallel along the side of the vessel as close as reasonably possible to limit wind-imposed loadings to the vessel nozzles. Thermal flexibility provisions will need to consider the differential thermal expansion between the vessel shell and the piping being supported.

Connections off the bottom head of skirt supported vertical vessels should locate the nozzle flange outside of the skirt. This minimizes the possibility of flange leakage within the confined spaces of the vessel skirt. Hence, bottom nozzles are usually
FIGURE C7.16 Typical tower piping layouts.

angled in these cases to locate the nozzle flange just outside of the skirt. Piping flange connections in general should be avoided within the vessel skirt.

The location of isolation valves should consider the possible rupture of a line connected below the vessel liquid level (or to the dense phase in a fluid-solids vessel), which could drain the vessel unless there was a valve to stop the drainage. In deciding whether these valves are needed, the likelihood of mechanical damage to the line will be the prime consideration. Small lines, NPS 2 (DN 50) and smaller, are obviously more susceptible to damage than large lines, and hence are most often supplied with suitable isolation valves.

Compressor Piping

Special precaution is necessary in the design and fabrication of the piping at or near compressors, especially for reciprocating compressors, to reduce fatigue failures. This piping should be designed to have the minimum of overhanging weight. This is mostly a problem with high pressure compressors, where valves are very heavy. Butt welding fittings should be used wherever practical, and fit-up should be accurate. Braces should be provided as needed to reduce vibration, and consideration should be given to grinding all welds to remove surface discontinuities.

Reciprocating Compressors. Means to reduce excessive surge and vibration should be provided as necessary in the suction and discharge lines of all reciprocating compressors, and located as close as practical to the compressor. In the case of most reciprocating process compressors, pulsation suppression devices are installed at the suction and discharge flanges of each compression stage. Pulsation suppressors are not typically required at the air intake suction of an air compressor, or at the interstage of an integral interstage cooler unless pulsations are expected to occur. Where surge chambers are provided, the connecting pipe should extend into the bottom of the chamber.

The need for detailed pressure pulsation analysis and for acoustic simulation and mechanical vibration analyses should be considered for reciprocating compressor systems to confirm the acceptability of proposed suction and discharge piping layouts and support/restraint locations needed to contain the pressure pulsation vibrations generated by the compressor. The composite compressor piping system needs to be designed so that it avoids acoustical natural frequencies in the system which coincide with the natural mechanical frequencies of the piping or the lower range of compressor harmonic frequencies. Special hold-down supports and thermal expansion restraints are typically required for reciprocating compressor piping systems even with pulsation bottles installed off the suction and discharge nozzles of the compressor.[39] Acceptance criteria for nozzle loads are provided by API Standard 618, *Reciprocating Compressors for Petroleum, Chemical, and Gas Industry Services*.[40]

Centrifugal and Rotary Compressors. A check valve should be installed in the discharge line from any centrifugal or rotary compressor discharge into a system from which the fluid may flow backward through the compressor. The check valve should be located as close as possible to the compressor.

When a compressor takes suction from a header, the suction lateral should preferably be connected to the top of the header. However, if the lateral is at least one pipe size smaller than the header, it is permissible to make a centerline connection to the side of the header. Temporary screens should be provided for initial

compressor start-up and should be located as close as possible to the compressor unless permanent screens or filters are installed immediately adjacent to the compressor.

The flow characteristics of centrifugal compressors should be investigated to determine whether devices are required to prevent surging during start-up. Knock-out drums should be provided upstream of all compressors except those which handle gases with no possibility of condensate being formed. That is, most air and nitrogen compressors do not require knockdown drums. Compressor suction lines between the knockdown drum and the compressor should be as short as possible, without pockets, horizontal, and sloped toward the compressor. Also, for wet gas compressors, this portion of the suction line should be insulated. It may require auxiliary heating in the form of heat tracing to prevent condensation. Where the line between the knockdown drum and the compressor is long, low points in compressor suction lines should be provided with drains to remove any possible accumulation of liquid. If the suction line normally operates under vacuum conditions, all drains between the knockdown drum and the compressor should discharge into the knock-down drum.

Compressor discharge piping should be analyzed for flexibility under thermal load resulting from the heat of compression. Flexibility analyses will be needed for all centrifugal compressors to confirm the acceptability of the combined loads imposed on the compressor nozzles in accordance with the requirements of API 617, *Centrifugal Compressors for Petroleum, Chemical and Gas Industry Services*.[41] This standard also provides acceptance criteria for axial compressor piping.

The fabrication of suction and discharge piping requires stringent flange alignment tolerances at the compressor nozzle connections to avoid excessive loads imposed on the machine. Maximum permissible flange rotations and lateral translation tolerances of 1/64 in (0.4 mm) is not uncommon for this purpose, which can represent a challenge for relatively large [equal to or greater than NPS 12 (DN 300)] suction and discharge piping.

Pump Piping

Permanent strainers should be provided upstream of pumps handling streams which are likely to contain foreign material such as sand and scale. Temporary strainers, preferably of the cone type, should be provided for initial unit start-up where permanent strainers are not provided, and should be located as close as possible to the pump suction nozzle. A block valve should be provided in the suction line of each pump and located upstream of the strainer. For dirty streams, where two or more pumps take suction from a single header, the block valves should be located as close as is practical to the header to minimize the collection of dirt upstream of the valve.

A block valve should be provided in the discharge line of each pump. A check valve should be installed in the discharge line of each centrifugal or rotary pump unless there is no possibility of a reversal of flow or pressure surge under any condition. The check valve should be located between the pump and the block valve with a drain between the block and the check valve.

Pump Piping Layout Considerations.   Most pump installations in process plants have spare units to assure continuous operations by switching to a standby pump if required for maintenance. Pump piping, especially for high temperature service, generally represents one of the more difficult systems to design for thermal flexibility.
FIGURE C7.17 Typical piping layout for spared pump service.

A typical piping layout for the suction of a 3 centrifugal pump system is shown in Fig. C7.17. The piping design needs to consider the various operating scenarios possible between operating and idle pumps, along with all pumps operating simultaneously. Thermal flexibility analyses of this system will need to consider all of these operating cases to confirm the acceptability of the worst scenario reaction loads imposed on the pumps. This needs to consider simultaneously acting operating or standby temperatures for each of the pump piping branches.

Nozzle load limits must be satisfied for combined thermal, dead weight, and friction loads. Spring supports are often needed near the pumps to reduce the dead weight loads on the nozzle connections. Directional restraints (e.g., axial limit stops

and lateral guides) are also typically needed to prevent excessive thermal and friction loads on the pumps to control thermal expansion loads imposed on the pumps. Recommended acceptance criteria for nozzle reaction loads imposed on centrifugal pumps is covered by API Standard 610, *Centrifugal Pumps for Petroleum, Heavy Duty Chemical, and Gas Industry Service*.[42] And, in the case of reciprocating pumps, acceptance criteria is provided by API Standard 674, *Positive Displacement Pumps—Reciprocating*.[43]

As in the case of compressors, flange alignment between mating pump nozzle and piping flanges is very important and must be achieved to close tolerances to avoid excessive loads imposed on the pump. Concerns in this regard can lead to coupling misalignments between the pump and its driver, which can result in operating and subsequent maintenance problems.

Warm-up of Standby Pumps. Pumps that may be idle during plant operations and need to be started quickly should be provided with warm-up lines if pump design temperature exceeds 450°F (232°C), or if the process fluid will solidify at ambient temperature. The purpose of these warm-up lines is to eliminate undesirable thermal effects on lines and equipment and plugging of idle pump and piping materials. A typical warm-up line consists of an NPS ¾ (DN 20) valved bypass around the pump discharge block and check valves. The standby pump should be kept near to operating temperatures by opening the warm-up lines and by providing a suitable bypass around the discharge block and check valves to permit a small flow back through the idle pumps.

If the process fluid will solidify at ambient temperature, and the suction and discharge lines are not heated and insulated, an additional NPS ¾ (DN 20) valved bypass should be provided from the discharge lateral to the suction lateral and the header side of the valves. When the pump is removed from service, these laterals should be kept at operating temperature by opening this bypass valve to permit a small flow. The above warm-up lines should be heat-traced if the process fluid will solidify at atmospheric temperature. Pump systems with warm-up lines should be checked for adequate flexibility for the differential expansion between the pump discharge line and the warm-up line.

Low-Flow Protection. When the discharge line contains a quick-closing valve, the necessity for shock-absorbing equipment should be investigated if the closing time of the valve cannot be increased to a safe level. Where a remotely located valve can be closed against the pump and the pump does not shut off automatically or cannot be shut off immediately, a recirculating line should be provided from the pump discharge back to the point of suction. The purpose of recirculating the fluid is to prevent damage to the pump due to overheating. A low-flow protection system should be installed for pumps expected to operate at a flow less than the minimum continuous stable flow or minimum continuous thermal flow as defined by API 610. The minimum size of the recirculating line should be NPS ¾ (DN 20). The line should be equipped with at least one gate valve and an orifice sized to restrict flow to the minimum pumping rate of the pump.

Fired Heater Piping

Piping of interest for fired heaters consists of the inlet feed and outlet transfer lines typically from the radiant section. It also includes piping to and from convection

section headers or cross-overs between the convection and radiant sections. Decoking piping systems and burner fuel lines are also of interest.

The design of principal inlet and outlet piping for large heaters usually needs to consider the thermal expansion, and restraints and supporting details, of the main inlet and outlet collection headers for the radiant section tubes. The thermal expansion movements of these components need to be reflected in the thermal flexibility analyses of the connecting piping, or better yet, to incorporate the headers in the analysis of the system. Spring supports are often required for this piping because of the relatively high operating temperatures and resulting thermal expansion.

Steam-Air Decoking. Permanent steam-air decoking methods for cleaning coke buildup from heater tube internal surface connections should be considered on heaters requiring frequent decoking and where installation of a temporary steam air header would necessitate considerable dismantling of the process piping. On heaters with parallel coils (passes), blanks are required to separate the coils for decoking connections. Dropout spools or blanks should be provided for all decoking operations which are also installed for steam out. The alternate to steam air decoking is to provide sufficient flanged fittings for mechanical decoking. Thermal flexibility analyses of furnace transfer lines should consider the decoking line connections if permanently piped and checked for both normal operation and decoking.

Fuel Gas Burner Piping. All fuel gas supplied to heaters should pass through a dry drum which is located as close as practical to the heaters. The supply main, the branch lines, and the distribution headers between the dry drum and the heater should be pitched downward in the direction of flow and be without pockets. If this is not possible, a condensate leg with a valved and plugged drain connection should be provided at the low point. Branch lines should be connected to the top of the header. A remotely controlled or a remotely located block valve should be provided in the supply line of each heater. Wherever heater outlet temperatures are controlled by regulation of the fuel supply, automatic fuel-regulator valves should be provided upstream of the distribution header. Each gas burner should be supplied with a steel shutoff valve installed in a position such that a person operating the valve will not be in close contact with the aspirator.

Fuel Oil Burner Piping. For heaters using fuel oil, the burner oil piping system generally consists of a burner oil storage tank, a burner oil pump and oil supply main with a strainer, branch line to each heater, a distribution header at the heater, and an oil return main back to the storage tank. Circulating fuel oil lines should be sized to carry 200 percent of the maximum design fuel load of the heater. A remotely controlled or a remotely located block valve should be provided in the supply main or in the branch lines to each heater, and shutoff valves should be provided between the firing valves and the headers. Fuel-oil lines should be sloped from the burner shutoff valves toward the burners to provide natural drainage. A pressure-reducing valve should be installed as close to the heater as practical and upstream of the burners to regulate the pressure at the burners. A recirculating bypass should be provided between the branch line to the distribution header and the return branch line from the distribution header.

The atomizing piping system used in conjunction with the burner oil consists of a branch line from a live steam main, and a distribution header around each burner. Branch lines should have a capacity of approximately twice the combined steam requirements of all burners supplied by the branch. Steam traps should be provided

on the atomizing steam header where necessary to prevent water from reaching the burners.

Heat Exchanger Piping

Shell and tube, double pipe, plate frame, and air-cooled type heat exchangers are all well utilized in most process plants. Piping systems for these exchangers, especially for air-fin coolers, require particular attention to confirm the acceptability of imposed nozzle loads.

Generally, bypass piping around exchangers is provided for temperature control and to allow cleaning during operation of the rest of the process unit. There may be cases when the increase in operating efficiency resulting from cleaning or repair during the operation of the rest of the process unit would justify the cost of installing a bypass. Block valves need not be provided on the process side of the exchanger except where the valve is needed for flow control or where the exchanger may be bypassed while the unit is running. Typically, streams which are to be heated should enter at the bottom of the exchanger, and streams to be cooled should enter at the top of the exchanger.

Air-Fin Cooler Exchangers.   The inlet and outlet piping to air-cooled exchangers can represent a significant design challenge, especially for large multibundle units operating at relatively high temperatures. Figure C7.18 shows two typical approaches for the design of piping manifolds for air-cooled heat exchangers, which use different layouts for the lateral connections (flexible versus stiff lateral designs) between the air-cooled header and the manifold headers. Both approaches need to satisfy the requirements of API Standard 661, *Air-Cooled Heat Exchangers for General Refinery Services*, for imposed reaction loads to the header nozzles.[44]

With flexible laterals, the differential thermal expansion between the individual air-cooled heat exchanger bundles and the connecting manifold header is accommodated by providing sufficient flexibility in each of the piping laterals. The thermal movements of the air-cooled exchanger bundles must be considered. The bundles are usually anchored at the inlet header to control the direction of the tube axial expansion.

With stiff laterals, a single manifold has short, stiff connections to the air-cooled exchanger. The bundles are allowed to move laterally to accommodate the axial thermal expansion of the piping manifold header. The lateral nozzle connections must be as short as possible to move the air-cooled bundles without overstressing the nozzles or the manifold connections. The flexibility analysis of this approach is relatively complex since it must consider the restraining effect of friction in attempting to move the bundles laterally. It also must consider the stiffness effects of the exchanger tubes, which resist the free lateral movement of the bundles.

The stiff laterals approach will typically result in lower material costs. However, this approach requires special construction procedures to achieve proper fit and alignment between the header nozzles of all the exchanger bundles. This typically requires the field fabrication of the manifold and the laterals directly off the installed air-cooled exchangers. There also needs to be sufficient clearance between air-cooled headers and side frames to allow for the thermal expansion of the manifold.

Other Exchangers.   A pipe spool, elbow, or some such removable piece (other than the block valve) should be provided adjacent to the channel section of any exchanger which will be opened while the unit is in operation. Lines to condensers

• Bundles designed to slide in lateral direction to take up thermal expansion of the manifold.
• Make lateral connections, L, as short as possible so relatively stiff to avoid overstress in forcing header movement.
• Check for adequate clearances between the air fin header and side frames.
• Field fabrication of the manifold and laterals is usually required because of the short multiple nozzle connections off the air-cooled exchangers.

FIGURE C7.18   Alternative design layouts for air-cooled exchanger manifiolds.

should be sized to provide sufficient velocity to carry condensed liquids along with the vapors. Pockets must be avoided in these lines.

Heat exchanger lines which enter or leave the exchanger from a bottom nozzle need to be supported in such a way that the vertical expansion of the line between its first support and the exchanger does not overload the nozzle connections. The preferred layout design locates the first line support at about the same elevation as the midpoint of the heat exchanger saddle support. This balances the thermal expansion between the exchanger and the first pipe support.

Storage Tank Piping

The loads transmitted from piping to shell nozzles of large-diameter storage tanks are a major concern for tank designers. The loads which must be considered in the design of principal piping connections to tank nozzles include the following:

- Tank shell radial movements and nozzle rotations while filling and emptying a tank
- Design pressure of the pipe
- Thermal expansion of piping
- Differential settlement between the tank and the piping supports
- Weight of piping, valves, and contents

Stresses in the pipe caused by these load combinations should satisfy the ASME B31.3 Piping Code. Moment loads and resulting local stresses should also be checked in the tank nozzle and its connection to the tank, as covered by API Standard 650 for *Atmospheric Storage Tanks*.[45]

Figure C7.19 provides some examples of typical piping configurations that deal with the load conditions discussed in this section. For most systems, there is an advantage in locating the first horizontal bend of the line as close as possible to the tank nozzle. This provides for tank shell nozzle rotation through torsion in the leg of horizontal piping after this first bend. Depending on the level of predicted tank settlement, which can approach 12 in (305 mm) or greater over the life of the tank, spring hangers may be required for the supports nearest to the tank.

Process unit feed tanks should have separate filling and discharge piping systems to avoid sending slugs of water to the process units. Separate discharge and suction connections are specifically required if it is necessary to have facilities for recirculation or blending and there is no mixer in the tank. Block valves should be provided on all nozzle connections below the tank liquid level. Filling lines for tanks containing flammable fluids should discharge near the bottom of the tank without free fall because of the danger of static electricity being created.

Rack Piping

A *pipeway* is the space allocated for routing several parallel adjacent pipelines within process plants. A *pipe rack* (see Fig. C7.20) is the structure employed for carrying the pipelines and electrical and instrument trays. The pipe rack is usually constructed of steel or concrete frames called *bents*, on top of which the pipeline rests.

Pipe racks are necessary for arranging the process and service pipelines throughout the plant, and they are used in secondary ways; principally to provide a protected location for auxiliary equipment, pumps, utility stations, manifolds, and fire fighting and first-aid stations. Lighting and other fixtures can be fitted to the pipe rack columns. Air-cooled heat exchangers are often supported above pipe racks for economy of plot space.

Some other considerations when arranging piping on pipe racks are:

- Place utility and service piping on upper level of double-deck pipe racks.
- Do not run piping over columns as this will prevent adding another level.
- Locate large liquid-filled pipelines near columns to reduce bending stresses on pipe rack beams.
- Allow space for future piping systems; usually about 25 percent of final width.
- Electrical and instrument trays are best placed on outriggers or brackets to prevent interference with pipes leaving the pipe rack.
- Adjust elevation (up or down) of horizontal lines when making a change in direction. This will avoid blocking space for future lines.

FIGURE C7.19   Tank piping layout considerations.

- Piping can be supported on sleepers at grade if roads or walkways will not be required over the pipeway at a later date. Bottom of pipe elevations must allow for clearance under line drain valves.
- Minimum clearance under the pipe rack is a function of the available mobile lifting equipment requiring access and the minimum vertical clearance determined by the basic plant design parameters.
FIGURE C7.20 Typical pipe rack cross section.

An important aspect of rack piping design is the strategic location of line stops or anchors and guides to control the thermal expansion of the piping. Directional line stops also help to distribute expansion forces and support friction loads. Pipe expansion loops may be required for long lengths of rack piping, especially in elevated temperature service. The structural design of the rack bents must consider the combined loads imposed by the simultaneous operation of the piping it supports. Some percentage, usually 25 percent, of all the lines supported off a bent are assumed to simultaneously load the rack, since it is highly unlikely that all lines will be subjected to thermal expansion at the same moment in time.

Axial thrust loads in long horizontal runs, which are typical of rack piping and lines outside of process units, will be significant due to static friction resistance to thermal expansion at the support points. These thrust loads should not exceed the critical buckling load of the line involved. Lateral guides are usually necessary to give stability to the line.

Relief Valve and Flare Header Piping

Relief valve piping in a process plant should be in accordance with API RP 520, *Recommended Practice for the Design and Construction of Pressure Relieving Systems* and API RP 521, *Guide for Pressure Relief and Depressuring Systems.*[46,47] Piping for relief valves protecting pressure vessels should be in accordance with the applicable requirements of Section VIII of the ASME Boiler and Pressure Vessel Code.

The discharge of all pressure relief valves should be piped to a safe place for disposal. Liquid and readily condensable hydrocarbons are usually discharged to a closed system. Pressure relief valves discharging light hydrocarbons which are not likely to condense or accumulate at grade can frequently be safely vented to the atmosphere from the tops of tall towers. Discharging to the atmosphere reduces the size and cost of closed piping systems otherwise required and is the preferred method where it does not create a hazard and where recovery facilities are not necessary. The term *closed system* refers to the typical pressure relief valve collecting system at a process unit, wherein the discharge of pressure relief valves is collected in a piping system for disposal at a safe location. A *blowdown drum*, which may be integral with a vent stack, is usually provided for separating the vapors and collecting liquids. Vapors are typically vented to the atmosphere through a *flare stack* to safely ignite the combustible gas. Frequently this system is combined with any required facilities for emergency blowdown or depressurizing of equipment.

Pressure Relief Valve Piping Design

Block valves are usually provided upstream (and downstream if discharging into a closed system) of pressure relief valves where necessary to permit onstream isolation and maintenance of the PR devices without interrupting process unit operations. Where block valves are used, the installation should conform to the requirements of Section VIII of the ASME Boiler and Pressure Vessel Code when protecting an unfired pressure vessel. These valves are typically installed so that they are car-sealed open (CSO). Mechanical interlocks or key systems are usually required for spared PR valve installations to help ensure continuous safety protection of the system.

Generally, the most difficult and important feature associated with sizing relief valve discharge lines and headers is the determination of the maximum probable flow. The flow is based on the number of valves which may discharge simultaneously owing to a fire or to abnormal process conditions. To do this, the layout of the unit must be considered along with many possible abnormal operation conditions.

The permissible back pressure must also be determined. Generally, the back pressure should not exceed 10 percent of the set pressure for unbalanced safety valves. Balanced pressure-relief valves will operate satisfactorily at higher back pressures (approximately 30 percent of the set pressure), and consequently their use will sometimes result in a more economical relieving system.

Pressure relief valve discharge piping should be sized so that any back pressure that may exist or develop will not reduce the capacity of the pressure relief valve below that required to protect the equipment. Regardless, the discharge piping for each pressure relief valve should not be smaller than the nominal pipe size of the pressure relief valve outlet.

For gas, vapor, or flashing liquid service the inlet piping pressure drop at design flow should not exceed 3 percent of the safety relief valve set pressure. Nor should the inlet piping to a pressure valve be smaller than the valve inlet nominal pipe size. The inlet piping includes all piping between the protected equipment and the inlet flange of the valve. Excessive pressure drop in the inlet piping will cause *valve chatter* (extremely rapid opening and closing of the valve) which may lower the valve capacity and damage valve seating surfaces.

Pressure relief valves should be located so that the inlet piping is short and direct and self-draining with no pockets. However, on installations where pressure pulsations or turbulence are likely to effect the pressure relief valve (e.g., discharge
FIGURE C7.21   Snuffing steam to pressure-relief atmospheric vent.

side of reciprocating compressors and pumps), it may be desirable to locate the valve farther from the source in a more stable pressure region. The differential between operating and valve set pressures is also important when the operating pressure is not steady. A large differential will tend to reduce valve maintenance costs.

On certain vessels, pressure relief valve leakage and consequent premature shutting down of the process unit can be anticipated. These vessels should be provided with a sufficient number of pressure relief valves (and accompanying block valves) so that in the event of pressure relief valve leakage it will be possible to shut off any one defective valve and replace it while the vessel is in service and still retain full calculated relieving capacity.

Pressure Outlet Piping Discharge to Atmosphere

Outlet piping for pressure relief valves discharging flammable vapors directly to the atmosphere should normally be equipped with steam and drain connections controlled from grade, as shown by Fig. C7.21. Outlet piping from pressure relief valves should be equipped with drains or otherwise suitably piped to prevent accumulation of liquids at the valve outlet. Pressure relief valve outlet piping for water or other liquids should be self-draining.

Separate pressure relief valve lines should be provided for each valve discharging

directly to the atmosphere. On towers, the pressure-relief valve vent piping should be extended at least 10 ft (3 m) above the nearest working platform within a radius of 40 ft (12 m). Outlet piping should be arranged so that the pressure-relief valve discharge will not impinge on any equipment.

Closed Discharge Piping to Flare Header System

Pressure relief valve discharge piping connecting to a closed system should be self-draining to the blowdown drum, vent stack, or other means for liquid/vapor separation and disposal. The main headers are frequently sloped to assure drainage. A continuous purging connection should be considered for closed system piping to prevent flammable mixtures resulting from possible pressure relief valve leakage. Where necessary or desirable to detect leaking pressure relief valves, a NPS ¾ (DN 20) valved and plugged drain connection should be provided at the outlet of each valve.

The sudden initiation of relief valve outflow can cause severe stresses in attached equipment and structures. Consequently, such factors as the high- and low-temperature properties of material, thermal expansion, vibration, and fatigue must be considered in designing pressure relief valve discharge piping. Vibration is particularly a concern for liquid service relief valves, where flashing and valve chatter are possible, which can lead to loosening of flange and valve bolting, and subsequent leaks. The use of conical spring washers or other nut-locking devices should be considered in these relief valve services to minimize the possibility of inadvertent loosening of flange bolting.

Discharges into closed flare header systems also represent significant challenges to the piping designer. Flare headers often represent one of the more difficult piping systems to route along pipe racks from the process units to the offsite blowdown and flare stack facilities. The piping tends to be of relatively large diameter, and it normally must be designed for large variations in operating temperatures. This includes the possibility of severe longitudinal bowing of the line if liquid at either relatively high or low temperatures discharges into the flare header, resulting in mixed-phase flow, with a vapor layer above a liquid stream.

Vent and Drain Piping

Provisions for low-point drains and high-point vents are typically needed for pressure testing, start-up, chemical cleaning, and for decommissioning of process plant piping. Valved drain and vent connections are also provided for most types of process equipment. These drains and vents should be located on the equipment if practical, but they may be located in connected piping where there are no valves or blocks between the drain or vent connections and the equipment.

Piping from drain connections should be arranged to drain the equipment and the connected piping to the appropriate process drainage system. The alternate to complete drainage is a start-up procedure for water removal, such as (1) displacement by circulation, (2) gradual heating during start-up, (3) dry gas purging, or (4) high-velocity gas purging. Multistage pumps, furnace headers, control valves, and horizontal pipe that deflects between supports are typical locations where it is usually impractical to provide complete drainage.

Generally, drain connections to closed drainage systems may require double block valves and with a bleed connection between the block valves.

Drains, vents, and pump outs for piping and equipment in vacuum service should be blinded or plugged during operation of the unit to prevent the entrance of air. There are, however, drain and vent connections which need not be connected to a closed drainage system. Examples are connections which are not hazardous if left open, connections for checking water accumulations, and vessel vents which are not needed during operation. These drains and vents should be provided with a block valve and blind flange, plug, or cap. Valved vents may not be required for high-point vents used to bleed air for system pressure testing only. These connections should be plugged and seal welded after pressure testing.

In lines containing hazardous fluids, a drain should be provided between block and check valves where fluids could be trapped. Where check and block valves separate a hazardous fluid from process piping or other process equipment, the block valve should be located between the check valve and the process piping or equipment.

Water drainage from vessels in light-ends service can be complicated by the refrigeration effect of light hydrocarbons that vaporize at atmospheric pressure. An ice plug formed by this refrigeration effect can prevent proper valve closure, and hazardous vapors will be released when the ice melts. In most cases heat tracing or other means of heating drain lines and valves will prevent freezing.

Means should be available for removing the operating liquid contents from all vessels and heat exchanger units and the connected piping. Although process lines and pumps should be used for this purpose, an auxiliary pumping-out system may be needed. A permissible alternate is to use steam or inert gas to remove the contents of the equipment by pressure. On pressure vessels, pumpout connections should be provided for side drawoffs as well as at the bottom of the vessel.

The recommended minimum size for pipeline drains and vents is NPS ½ (DN 15). The recommended minimum size of drains and vents is NPS 1 (DN 25) for vessels and NPS ¾ (DN 20) for all other equipment. However, the size of vent and drain connections should be such that the water used for hydrostatic test or flushing may be drained off without pulling a vacuum. On some small pumps, compressors, and turbine and steam engine drives, NPS ¾ (DN 20) or larger drain and vent connections are not economical. In such cases, NPS ½ (DN 15) drains and vents are acceptable.

Instrument Piping/Sample Connections

The term *instrument systems*, as used here, includes piping associated with field instrument installations and associated systems to connect air or hydraulically operated instrument control apparatus. It does not include instruments or permanently sealed fluid-filled tubing systems furnished with sampling transport systems associated with process stream analyzers.

Instrument Piping.   Instrument piping must meet all the applicable requirements of the associated principal piping systems, and the following:

- The design pressure and temperature for instrument piping should be determined with consideration of short-time conditions. If it presents a more severe condition, the temperature of the piping during periodic operation of the blowdown valve should be considered a short-time condition.

- Consideration must be given to the mechanical strength, including the fatigue resistance, of small instrument connections or apparatus.

- Instrument piping containing fluids which are normally static and subject to freezing must be protected by heat tracing or other heating methods.
- When it is necessary to blow down or bleed instrument piping systems containing hazardous fluids, consideration must be given to the safe disposal of such fluids.

All instruments, including thermocouples, should be accessible for maintenance. Instrument process connections that require maintenance should also be accessible, including accessories such as rod-out connections, condensate pots, and seal connections. The overall piping design needs to consider the intended location of required instruments to locate appropriate take-off connections that allow good accessibility. During pipe layout, consideration should be given to routing process piping adjacent to platforms or to pipe and instrument grouping such that one platform will provide access to several instruments.

A block (usually gate) valve is typically installed in each instrument take-off connection. It should be located as close to the vessel or line as possible, consistent with the manual opening and closing of the valve. Take-off connections, including the first valve, should be in accordance with the line service classification. The use of elbows between the take-off point and the valve should also be avoided.

Sample Connections. On a process unit, sample connections are typically provided on feed and product streams and on such intermediate streams as are necessary for control and testing. Sample piping should be as short as possible and be adequately braced to enable it to resist unexpected external loads and to protect it from damage when valves are operated. If the piping is carefully supported and anchored, it is permissible to use an equipment drain for sample purposes.

As a general rule, sample connections should not be installed directly on pumps, compressors, or other equipment subject to vibration if other locations where samples might be taken are available. A likely location for sample connections is often combined with the installation of pressure gages. It is suggested that the minimum size of the first nipple attached to the piping or equipment from which the sample is taken be NPS ¾ (DN 20). A block valve of the same size as the nipple should be installed at the end of the nipple. A second valve should be installed in the sample line as close to the sampling point as practicable. A sample cooler will sometimes be necessary to assure safe handling of the stream being sampled.

Utility Piping

Air, steam, or water connections to process piping or process equipment should be temporary unless they serve as part of the process. Temporary connections should consist of a block valve, a check valve, and a blind flange. The block valve should be located between the check valve and the process piping or equipment. Both valves should conform to the specification of the more severe service.

When a permanent air, steam, or water connection to process piping or process equipment is needed, a check valve, a NPS ¾ (DN 20) bleed, and a blank should be provided in addition to the block valve. The block valve should be located between the check valve and the process piping or equipment, and the bleed should be located between the two valves. There must be a block valve in the utility line, upstream of the check valve to permit installation of the blank. A second bleed valve is recommended between these valves to test for back-flow through the check valve. All valves downstream of the blank should conform to the specification of the more severe service.

Utility and drain connections at the bottom of the equipment may be manifolded into a single header in order to simplify piping connections to the vessel, except that steam connections should not be in the same manifold as the drain and pump-out connections.

Service outlets for steam, water, and air hose connections are typically NPS 1 (DN 25) size. Outlets should be located so that working areas and process equipment can be reached with a single 50 ft (15 m) length of hose.

Water Service Piping.   Process plants have several water systems. These may include high pressure (for fire fighting), low pressure (for cooling and use in the process), potable water, and different types of process water systems. One of the most severe design problems for many locations is to protect water systems from freezing. One obvious way to do this is to place the piping underground and below the frost lines. However, in a process unit much of the water piping must be above grade. If the piping is out of doors and in intermittent or standby service, it should be heat traced and insulated. In cold climates, heat tracing and insulating should be considered for water lines with low continuous flow rates. An alternative to heat tracing and insulating is to provide a bypass to a drain so that flow in the water line is continuous and at a high enough rate to prevent freezing. On water mains, the high-point vent between block valves should be protected from mechanical damage as well as from freezing.

Drains should be provided on any water line located above the frost line so that it can be drained when it is shut down. Such drain connections and valves should generally be located underground, and drains should, where practicable, connect to a sewer. Drainage facilities should also be provided for the water side of heat exchangers.

Water injected into a process stream normally is taken from the low-pressure water system. However, where salt water is used for the cooling-water and fire-water systems, water for process purposes is usually taken from the potable water system.

Each cooling water exchanger that may be removed from service during operation of the unit should have a block valve in both the inlet and outlet piping. Multiple shells or exchanger in series, which cannot operate independently of each other, should be considered as a single exchanger.

The water supplied to shell and tube coolers and condensers should pass through a strainer. If a strainer is not provided at the water pump or in the supply main, individual strainers should be provided in the branch line. The necessity for installing an oil separator drum, a gas disengaging drum, or a bypass filter in the cooling-tower water return system should be considered.

Water from exchangers should generally be sent to a clear water sewer or cooling water return system. Sample connections should be provided for detection of process leaks. However, a separate connection need not be provided for this purpose if other connections (e.g., drains and vents) can be used. An NPS ¾ (DN 20) valved and plugged vent should be provided on top of the first horizontal section of the water line downstream of the exchanger. The vent should be plugged during operation of the unit.

For chemical cleaning of exchangers using cooling water, connections should be provided to the inlet and outer nozzles on the water side of each exchanger. The connections should be between any block valve and the exchanger. If there is no block valve, a pair of flanges must be provided nearby so that the piping can be blanked off during cleaning. It is suggested that the chemical cleaning connections be NPS 1½ (DN 40), and they should be equipped with a blind flange.

Sufficient connections to the water system should be provided so that water can

be supplied to the pressure vessels on the process unit for washing out or hydrostatic testing. These connections should be from the cooling-water system if the pressure in the system is adequate to supply water to the top of the tallest tower on the unit; otherwise the connections should be to the fire water system.

Normally vessels need not be permanently connected to a source of water. If a permanent connection is made, it should be at the bottom of the vessel and should be blanked off when the vessel is in operation.

Air Piping. Most process plants have a plant air system not only for use in the processes but to operate tools, equipment, and instruments.

Where necessary, the intakes of air compressors should be designed to minimize the noise level. Filters should be provided in the intake piping to reciprocating and rotary air compressors when they take suction from the atmosphere. Filters will sometimes be necessary for centrifugal air compressors. When a filter is not provided for a centrifugal air compressor taking suction from the atmosphere, the intake piping should be provided with a bird screen. Filters preferably should be of the dry, replaceable-cartridge type. Such filters should have an open area not less then three times the area of the intake pipe. The oil-bath-type filter should not be used with centrifugal air compressors.

Low points in the discharge line from an air compressor should be avoided because it is possible for lube oil to be trapped and subsequently ignited. If low points are unavoidable, they should be provided with drains.

When condensed moisture in air lines is undesirable from a process standpoint (which typically is the case for instrument air connections) or the possibility of moisture freezing exists, consideration should be given to providing an air drier drum in the supply line near the process unit. The drum should be located where it will not be exposed to heat from other equipment. Based on estimated future air requirements, the size of the drum should be such that (1) the velocity in the drum does not exceed 15 fpm (0.08 m/s) during shutdown periods when maintenance equipment is being used and (2) the capacity be equal to at least 6 percent of the free air requirements per minute during normal operation.

In climates where freezing is possible, the bottom 18 in (450 mm) of the dry drum should be insulated and heat traced. The drum drain (or blow-off) should also be traced or insulated. All blow-off connections should be installed pointing downward so that any rust or scale blown out will not endanger personnel.

Air piping should slope downward to dry drums or moisture traps, or be horizontal. Branch connections to air headers should be to the top of the pipe. Block valves should be provided in all branch lines.

When an air line is connected to process piping, two block valves, a check valve, and a bleeder should be provided. A second bleed valve should also be provided upstream of the check valve to test for backflow through the check. Consideration should be given to also providing a removable section of line or hose in order to guard against inadvertent operation.

Air for operating instruments is normally a separate system from the plant air system, and backup compression systems are often provided to increase in-service reliability. For process units, a steam-driven compressor should be furnished to supply instrument air in case of failure of the main supply. Where plant air is the primary source, and the possibility of a power failure is remote, electrically driven compressors may be used.

In extensive instrument air systems, the piping should be arranged with header and subheaders, such that groups of instruments may be isolated from the systems without affecting the air supply to all instruments. Block valves should be provided

at the instrument air headers in all branch lines to instruments. Leads to individual instruments should be NPS ½ (DN 15) minimum. As a rule of thumb, headers serving from 1 to 25 instruments should be NPS 1 (DN 25) pipe size, and headers serving from 26 to 75 instruments should be NPS 2 (DN 50) pipe size.

Steam and Condensate Piping.   Process plants usually have two or more steam systems and an exhaust steam condensate system. One of the steam systems generally operates in the range of 100 to 150 psig (690 to 1035 kPa) (low-pressure steam), and another operates at superheated conditions and significantly higher pressures (high-pressure steam). The exhaust steam system normally operates at a pressure of less than 50 psig (345 kPa). The design problems associated with these systems are not all similar to those encountered in a central power station; consequently a brief discussion on process plant steam piping requirements follows.

The principal concern is to supply clean, dry steam to the equipment using it. In accomplishing this, it is desirable to connect all branch lines (except condensate collection points) to the top of horizontal steam mains. However, if the line to a steam driver is at least one size smaller than the main and the steam has a considerable amount of superheat, it may be permissible to make a centerline connection to the side of the steam main. With other steam conditions it probably will be necessary to install a knockout pot or drum or a steam separator in addition to making the connection to the top of the main. Pockets should be avoided in the line to the turbine.

Connections to exhaust headers should preferably be made to the top of the header so that the condensate in the header does not run back into the driver.

In the steam line to a steam driver, a block valve(s) should be located at the driver and be easily accessible for operating purposes. A single gate valve is needed in the exhaust line from each steam driver that does not exhaust directly to atmosphere or directly into an individual condenser. However, valves need not be provided where two or more drivers, which will never be shut down separately, exhaust to the same condenser. This exhaust gate valve should be installed at the driver so that the position of the gate (i.e., open or closed) will be obvious to the operator whenever he is required to operate the inlet valve.

Wherever steam is exhausted to the atmosphere and could create such personnel hazards as burns, freezing of condensate on walkways, or the blanketing of working area with a heavy fog, the line should be fitted with an exhaust head and a drain to a sewer. The use of a silencer should be considered where noise nuisance is likely.

The flexibility of steam piping should be attained through the use of expansion bends and elbow fittings. The use of expansion joints is discouraged except where the size and arrangement of exhaust lines prevent the use of expansion bends, which may be the case of certain steam exhaust connections to steam condensers. Particular attention should be given to the anchorage and support of the connecting piping.

When required by the service, means should be available for purging process equipment with steam or inert gas. For example, each pressure vessel in hydrocarbon service should be provided with a steam-hose connection near the bottom if not permanently connected to the source of steam. However, where a permanent connection is made, it should be blinded during operation of the unit.

The steam supply for smothering, snuffing, service hoses, space heating, and auxiliary or protective heating should be connected to a source that will not be shut off during unit shutdowns or to a source that will not be shut off when the steam to a piece of equipment such as a turbine is shut off. For fire protection

purposes, smothering (or snuffing) steam usually is required for fired heaters and for relief valve discharge lines.

Condensate Removal and Steam Traps. Condensate should preferably be discharged into an oil free drain system, but under no circumstances should it be discharged into a sanitary sewer. Consideration should be given to a condensate collection system in installations which involve a large number of steam traps. When condensate is to be discharged to a cast iron or concrete sewer or a concrete sewer box, the hazard of vaporizing hydrocarbons which may exist in the sewer should be considered. Also, to avoid damage to the concrete, the connection should be below the water level. If there is insufficient quantity of water for quenching, the condensate should be first led to an atmosphere-pressure drain tank.

Steam traps should be provided for the removal of condensate from collection points in live and exhaust steam systems, in particular from condensate drip legs, drains on steam turbines, steam separators, connectors, unit heaters, and terminal ends of companion piping. All low points in steam lines, except steam companion lines and the ends of long headers, should be provided with drip legs. It may also be necessary to install drip legs at intermediate points on headers with long sections at one elevation (i.e., in addition to those low points at the end).

When a valve is installed in steam piping in such a manner that condensate can collect above the valve, a trapped drain should be provided above the valve seat.

Whenever possible, a steam trap should be installed below and close to the equipment pipeline being drained, but the trap should be easily accessible for periodic inspection. Each trap should serve only one collection point. Where large quantities of condensate are expected, either condensate pots or condensate drains should be provided.

Drains from turbine shaft packing glands and from governor valve stem packing glands should preferably be connected to an open drain system. The drain lines and headers should be of sufficient size to prevent a back-pressure buildup. Also, untrapped drains should be provided at the lowest point of the steam end of each reciprocating pump and compressor.

Drains not discharging into a closed drainage system should discharge downward and should be arranged so that rising steam does not create a hazard or condense on equipment, such as a turbine or pump. The condensation of rising steam on such equipment can create lube oil contamination. One thing that can be done to help eliminate this problem is to quench the condensate.

A principal cause of steam traps freezing is improperly designed discharge lines. Steam trap discharge lines should be sloped for drainage where possible. In cases where freezing is likely, no part of the trap discharge header should be at an elevation above that of the trap discharge. Pockets in the discharge lines should be avoided. Long trap-discharge lines, if not in heated enclosures, should be insulated. Trap-discharge lines in heated enclosures need to be insulated only if necessary for burn protection. To decrease further the possibility of freezing, steam trap bodies should not be insulated unless the following circumstances make doing so advisable:

- The trap is installed downstream of automatic steam controls that could shut the steam off for long periods of time.
- The trap is installed in a location where operators might be burned by the bare metal surfaces.
- The trap is part of a heat recovery system where retention of heat is important.

- The trap is installed to handle exhaust steam condensate that contains quantities of cylinder oil.

Inverted-bucket and thermodynamic steam traps, which are commonly used in process plants, are generally installed without strainers. Steam traps should be selected for a *continuous discharge rate*, which is the actual condensate rate multiplied by a safety factor. A safety factor of at least 3 should be used for inverted bucket type traps and thermodynamic traps. A larger safety factor is needed for traps draining jacketed equipment, and trap manufacturers should be consulted. In borderline cases offering a choice between two traps sizes, the smaller trap is usually preferred.

Steam Companion Piping for Auxiliary Heating.   The most commonly encountered situations requiring auxiliary heating are as follows:

1. Piping in which the fluid temperature could drop below the pour point or freezing point, and piping in which the fluid is subject to coagulation, excessive viscosity, or salting out
2. Hydrocarbon vapor and gas piping where condensate formation and icing will affect the safety and operation of the equipment, such as might be caused by the reduction in pressure that takes place through a control, throttle, or relief valve and
3. Lube and seal-oil systems for compressors and turbines

Auxiliary heating is normally not needed for freeze prevention and viscosity maintenance on equipment in intermittent service if the equipment is drained, flushed, blown, or steamed out when there is no flowing stream, or if the equipment is far enough underground to prevent freezing. When required, auxiliary heating is usually furnished by external steam companion piping (steam tracing). Other acceptable methods of heating piping and other equipment are internal steam tracing, steam jacketing, hot-water tracing and jacketing, and electric tracing. Details of various heat tracing techniques are covered in detail in Chap. B6 of this handbook.

It is desirable that each steam companion line be continuous from the header to a trap at the end of the line without any vents, drains, branches, or dead-end extensions at intermediate points. Each companion line should have a block valve at the upstream end and be arranged so that flow is generally downward, avoiding pockets as much as possible and leaving no section of the companion line at a greater elevation than the companion header. Live steam is preferred for steam companion piping in colder climates unless a lower temperature is required.

In the design of the companion piping system, provisions should be made for the differential expansion between the traced line and the tracer. When the piece of equipment which is to be kept hot is irregular in shape (such as traps, strainers, valves, and pumps), tubing must be used. The item should be spirally wrapped, starting at the top and working toward the bottom. Several lines to be traced may be grouped inside a single covering of insulation if they are to be maintained at the same temperature.

CASE HISTORIES: CHALLENGES/SOLUTIONS

Process plants offer the piping designer some unique challenges not found elsewhere. The combinations of demanding service requirements and mechanical needs will

necessitate innovative designs and solutions. Included herein are a few practical approaches to problem resolution:

Challenge

Installed Type 304L stainless steel piping and mating vessel nozzle NPS 8 (DN 200) Class 300 flanges were found to be inadequate for the specified 750°F (400°C) design temperature and 440 psig (2760 kPa) design pressure hydrofining reactor service. The reactor shell material and its other principal nozzles were constructed from low-alloy material weld overlayed with Type 304L stainless steel. The reactor flanges were all specified with Class 300 flanges, which is acceptable for the low-alloy flanges but not for the solid alloy Type 304L flanges. ASME B16.5 maximum working pressure for Type 304L SS Class 300 flanges is only 335 psig at 750°F (2310 kPa at 400°C) and clearly inadequate for the specified reactor design pressure.

Solution

ASME B16.5 downrates flanges in Type 304L material in elevated temperature service in comparison to the low-chrome reactor flanges and other non-low temperature grades of stainless steel. Attempts to rerate the installed Class 300 flange based on the provisions of B31.3 for 10 percent metal design temperature reductions for uninsulated flanges and the design procedures of ASME BP&V Code Sec. VIII, Division 1 proved to be unsuccessful. It was ultimately decided to replace the existing Type 304L flanges with Type 347 stainless steel Class 300 flanges, which permit a maximum working pressure of 490 psig (3380 kPa), and as such, clearly acceptable for the specified system design pressure.

Challenge

Two recent experiences with installed spiral-wound gaskets with flexible graphite filler have led to different but related instability problems with these gaskets, which raised questions about the standard ASME B16.20 covering these gaskets. The first experience involved Class 1500 and 2500 spiral-wound (SW) gaskets fitted with inner retaining rings that suffered severe inward buckling at initial boltup. The second experience pertains to the gross inward buckling of the inner spirals of Class 600 and lower rating gaskets supplied without inner rings. Events led to the ultimate removal of some 2000 gaskets supplied by 3 different manufacturers, which revealed that severe inward buckling had occurred on about 12 percent of installed gaskets across a wide range of sizes.

Solution

Gaskets supplied in both cases complied fully with ASME B16.20 requirements, which highlighted inadequacies in this standard for spiral wound gaskets. Efforts have been initiated to work with manufacturers in their assessment of fundamental design considerations and with appropriate code committees to address apparent deficiencies discovered with this type of gasket. The buckling in both experiences

had occurred during the initial compression of the gasket, before the flanges were put into service.

While the root cause of the problem has yet to be identified, the buckling phenomenon is clearly related to the incompressible properties of the flexible graphite and the tightness of the spiral windings. The experiences have also revealed that the inner ring widths specified by ASME B16.20 for many gasket sizes are inadequate to effectively resist buckling. Interim measures have been adopted by ASME B16.20, and it is recommended that users specify inner rings for all NPS 6 (DN 150) and larger SW gaskets with flexible graphite filler until more definitive measures are identified to resolve the root cause of the buckling phenomena. Reference 17 provides more information on this industrywide concern and overall considerations for gasket performance testing protocols.

Challenge

Severe acoustically induced piping vibrations generated by high-capacity pressure-letdown valves have led to fatigue failures at downstream piping branch connections within days of their initial operation. One such experience involved a safety letdown control valve within an LNG treat gas unit to a flare header system. The initial operation of this system led to cracks at an NPS 10 (DN 250) branch connection to an NPS 28 (DN 700) flare header. The failure occurred after about 5 to 10 hours of its initial startup and eventually led to the branch connection completely breaking away from the run header. The letdown valve was designed for a mass flow rate of about 383,000 lb/hr (175,000 kg/hr), with an upstream pressure of 620 psia (4278 kPa) letting down to 30 psia (207 kPa) flare header back-pressure.

This and other experiences in the gas production, petrochemical, and other industries have demonstrated that acoustic energy in high-capacity, gas pressure-reducing systems can cause severe piping vibrations that in extreme cases have led to piping fatigue failures within a few hours of commencing operation.

Solution

Based on a statistical approach, criteria were generated to reflect maximum levels of acoustic power generated by the pressure letdown valve before fatigue failure was experienced (see Ref. 5). The ultimate solution involved the replacement of the installed pressure letdown valves with low-noise producing valves with labyrinth multistaged pressure reducing trim to avoid choked sonic flow conditions generated by the valve.

Challenge

Severe vibrations were found with the initial start-up of an NPS 2 (DN 50) nitrogen utility line connected to an NPS 10 (DN 250) suction line of a reciprocating compressor in make-gas service. The nitrogen line was relatively flexible, and had long lengths of supported piping. Detailed acoustical analyses were conducted with the main suction and discharge piping of this reciprocating compressor, but this did not include the subject utility connection.

Solution

Additional pipe supports were installed to the nitrogen line, changing the natural frequency of the piping geometry and reducing the response to the compressor pressure pulsation excitations.

Challenge

An erosive slurry was causing material loss at changes of direction in a conventionally constructed piping system with elbows and tees. Space constraints did not allow for long-sweep turns.

Solution

Dead-end tees were installed where the solids filled the impact area of the tee. The abrasive solids then wore on themselves, thereby protecting the pressure boundary.

Challenge

A heater outlet line was expected to operate at about 1500°F (816°C). The attendant expansion and stress analysis difficulties were magnified, since the process piping material was well into the creep range. Premature failure was expected.

Solution

The hot metal heater line was transitioned into an internally refractory-lined system near the heater outlet. The lower shell temperature eliminated the probability of creep rupture failure, simplified the expansion and stress analysis problems, and reduced system maintenance.

The previous discussion only touches on the multitude of challenges/solutions encountered in the area of process piping. Reference literature has documented some of the many valuable experiences encountered in this regard.

CHAPTER C8
CRYOGENIC PIPING SYSTEMS

INTRODUCTION

Nicholas P. Theophilos, Ph.D., P.E.
Manager
Standards and Quality Assurance
Praxair, Inc.

Cryogenics (from the Greek "kryo-genikos," meaning cold generation) is the science and technology associated with very low temperatures. Depending on one's point of view, any temperature below $-20°F$ can be set to establish such a demarcation. Here the $-20°F$ point has been selected because it normally represents the onset of embrittlement for ordinary carbon steels in typical structural applications.

Cryogenics is not a separate branch of physics, since it obeys all laws of ordinary physics. In fact, cryogenics is low-temperature physics. The reasons for its special treatment, therefore, are not because of its uniqueness as a science but rather because of the very special problems it creates as a technology. These problems relate to embrittlement of materials, large displacements (expansion and contraction), rapid change of phase due to large heat fluxes (big delta T), and small latent heats of the fluids involved.

In order to obtain a better appreciation of the special considerations involved in cryogenic piping system applications, it was felt that it would be necessary to review the behavior of materials at cryogenic temperatures and the physical and thermodynamic properties of cryogenic fluids. These considerations are covered in the sections "Properties of Cryogenic Fluids" and "Materials Used in Cryogenic Piping Systems." Additionally, cryogenic piping system design is discussed in the sections "Piping Systems Design—Fluids" and "Piping Systems Design—Mechanical."

From the strictly heuristic point of view of fundamental applications of scientific principles there are hardly any differences between cold box piping and all other types. Nevertheless, we are making a special topic of cold box piping because of the confined spaces involved and the conceptual arrangements required to satisfy logistically workable and economically feasible process considerations. Such piping is discussed in the section "Cold Box Piping."

The coverage on cryogenic distribution systems, as provided under the sections "Liquid Storage and Conversion Systems" and "Mobile Equipment System," considers more than just piping; it covers the functional design philosophy of cryogenic fluid storage and distribution and provides quite an insight into the logistics of the entire operation.

With the advent of chip making, the need for ultra-high-purity inert gases has come into clear focus, and industry has responded to this need by developing suitable storage and distribution systems. These aspects of cryogenic piping systems are discussed in the last section.

Naturally, the drive behind most technologies is economic in nature, and in this

respect cryogenics is no exception. This is certainly much more so when it comes to liquid distribution because there is no other motive. Industrial gases can certainly be distributed in the compressed gaseous form, even in bulk quantities, if costs are not a consideration. Such economic aspects are discussed in the next section.

References for each section are at the end of each section.

ECONOMIC PARAMETERS OF CRYOGENIC FLUID DISTRIBUTION SYSTEMS

Norman H. White,

Engineering Associate
Praxair Inc.

Cryogenic processes are typically applied to commodity chemicals that exist as gases at normal ambients. Such gases are liquefied at reduced temperatures and are normally maintained at saturated conditions. The processing techniques generally involve both the liquid and gaseous phases and exploit the dramatic changes in physical and thermodynamic properties that occur with changes of state. Cryogenic temperatures are applied at each step in the process of bringing these gases to the final consumer, including production, distribution, and storage.

Typically, industrial gases are found in mixtures in which some of the components have commercial value. Two of the most important examples of such mixtures are gases from certain hydrocarbon wells and the Earth's atmosphere. The feed streams are separated by liquefaction and subsequent fractional distillation with the produced streams delivered in either the gaseous or liquid state. Cryogenic distillation allows a wide choice in the degree of separation, ranging from crude to extremely fine. It is a highly efficient process with power consumed chiefly in refrigeration lost to the environment and pressure lost in the product streams. Economic considerations in the liquefaction and distillation process involve trade-offs between operating efficiency and capital expenditure. No other method is as versatile or as effective as cryogenic separation of industrial gas mixtures for commodity usage.

The key to industrial gas distribution and storage operations is the use of a cost-effective method that increases the product density. The transport or storage vessel is reduced to manageable dimensions in this way. The historical solution to this problem is elevated pressures at ambient temperatures. Indeed, high-pressure cylinders and receivers made to a variety of U.S. Department of Transportation (USDOT) and ASME specifications are widely used today to store gases at pressures exceeding 2000 psig (138 bar). These vessels are typically of single-piece forged construction involving fabrication and inspection procedures that enable them to safely operate at ultimate to design stress ratios of 3:1. In spite of these measures to achieve an efficient package, the ratio of vessel weight to product weight is extremely high. Therefore, the cost of storing and transporting these gases in such vessels is very high relative to the value of the product they contain. Some of the characteristics of typical high-pressure receivers and cylinders are summarized in Table C8.1a and Table C8.1b.

   Liquefaction is another approach that has been widely used for efficient storage and transportation of industrial gases. Gases typically emerge from the liquefaction process saturated at approximately atmospheric pressure and from this point are transported and stored in cryogenic vessels. These are typically double-walled vessels with an inner container designed for the working pressure and temperature of the product and an outer casing designed for ambient temperatures and external pressure. In between the two vessels is a high-performance insulation system which is usually evacuated for the purpose of further enhancing thermal protection. Structural members to support the inner container and piping to provide access to it are also located in the insulation space. Heat is continuously entering the vessel through the insulation, supports, and internal piping. This heat will make the liquid contents boil, and the resultant gas must be removed from the tank if the pressure and temperature of the contents are to be held steady. For this reason, heat leak must be minimized. The thermal efficiency of the tank design is expressed in terms of the percentage of full capacity that will be lost per day when the tank is held at atmospheric pressure. This parameter is termed the *normal evaporation rate* (NER) and is product specific. Table C8.2 summarizes the specifications of typical tankage applied in various production and distribution functions.
   Gaseous state storage at high pressures and liquid state storage at cryogenic temperatures both have their place in industry today. Therefore, it is important to compare their relative economics. The primary costs to be compared are those for storage vessel construction, transportation, power to achieve the storage state, and product loss. The construction methods used in forged high-pressure receivers are very different from those used in high thermal efficiency cryogenic temperature vessels. However, the resultant costs per unit weight may be considered equal for

rough comparison. Therefore, storage vessel and transportation costs for alternative systems can be compared by the ratio of the vessel weight to product weight. Table C8.3 compares this ratio for several products stored in typical gas and liquid storage vessels. Generally the total cost (capital plus operating) to liquefy a product is lower than that required to compress it as a gas to receiver pressure. Indeed, receivers are most often charged with gas pumped to pressure in the liquid state and subsequently heated to ambient temperature rather than by gas state compression. Product losses to be expected in various liquid systems can be estimated from the NER specifications given in Table C8.2.

Considering these circumstances, cryogenic liquid phase storage is the most economical approach in most cases. Gas storage should be considered where the requirement involves small quantities or long periods of nonuse or difficulty in disposing of the gas boil-off expected in a cryogenic system.

The piping used in cryogenic systems obviously must meet the structural demands imposed by low temperatures. From an economic point of view, the thermal efficiency of the piping system must be carefully considered since the heat of addition to the system will ordinarily result in loss of product. There are two important factors of product loss involved in piping systems that must be considered: refrigeration required to bring the line to operating temperature (cool down) and steady state heat addition. Table C8.4 gives these parameters for uninsulated lines, lines insulated with closed-cell polyurethane foam, and lines insulated with radiation shields in high vacuum (vacuum insulation).

PROPERTIES OF CRYOGENIC FLUIDS

Theodore F. Fisher
Process Engineer
Praxair, Inc.

Physical and thermodynamic properties of cryogenic fluids constitute important data that are needed for the design of cryogenic piping systems. The following discussion, tables, figures, and references are furnished with this need in mind.

Transport property data are readily available for the more common pure cryogenic fluids. The bibliography at the end of this section lists sources of physical properties and thermodynamic tables and charts, which supply the detailed data required for the design of piping systems. Table C8.5M (Metric) summarizes some of the more important properties for a number of cryogenic fluids.

Thermodynamic charts show pressure-temperature-phase-density (or specific volume) and enthalpy (heat content, H) relationships for a specific fluid under a variety of formats. Entropy data are often included but are not generally required for the purposes under consideration in this chapter.

Fig. C8.1 is a pressure-enthalpy chart for nitrogen, which will be used to illustrate the behavior of fluids in transport systems, and various uses of pressure-temperature-volume-enthalpy (P-T-V-H) data. The most obvious use may be to determine the density (the reciprocal of specific volume) of a fluid which is being transported under constant pressure and temperature conditions. Referring to the chart, for example, the density of nitrogen at 101.5 psia (0.7 MPa) and 80°F (300°K) is found to be approximately 0.5 lb/ft^3 (8.0 kg/m^3). Other uses of the chart are illustrated in the examples which follow.

The dome-shaped curve at the bottom left of the chart encloses the two-phase (vapor-liquid) region. Nitrogen at pressure and temperature conditions to the left of the dome is a *saturated or subcooled liquid*. Conditions to the right of the dome correspond to *saturated or superheated vapor*. Vapor and liquid phases coexist within the dome at a unique pressure for a specific temperature. This pressure is designated as the *vapor pressure* of the fluid at that temperature. The length of the isobar (constant pressure) line between the sides of the dome is proportional to the heat input which is required to completely vaporize the fluid at the pressure and corresponding temperature. The fraction of the fluid which is vapor at a condition corresponding to a specific point along the isobar is equivalent to the fraction of its distance from the saturated liquid line, divided by the total length of the isobar within the dome.

The point at the very peak of the dome represents a unique condition of pressure and temperature which is designated as the *critical point* of the fluid. As nitrogen approaches 493 psia (3.40 MPa) and −232.5°F (126.2°K) from any direction, all distinctions between the characteristics of vapor and liquid phases disappear. Liquid being warmed at a pressure above the critical pressure behaves as a dense fluid, which gradually approaches the characteristics of a high-pressure gas at higher temperatures, without passing through any observable phase change.

The vertical lines on a pressure-enthalpy chart correspond to a constant heat

content condition. Movement along these lines designates an isenthalpic or adiabatic (no heat input or output) process. Flow through reasonably short or insulated runs of piping or fittings, or at a temperature close to that of the environment, approaches isenthalpic behavior.

When a fluid flowing within a pipe is throttled through a valve, the change in its pressure-temperature-phase and density relationships is essentially isenthalpic. If a fluid is initially a gas which is reduced in pressure, its decrease in pressure and density may be accompanied by a change in temperature (Joule-Thomson effect). In most cases this will be a decrease in temperature, as shown, for example, by nitrogen at 725 psia (5 MPa) and −153.7°F (170°K) following the 60.23 Btu/lb(m) (140kJ/kg) isenthalp to about −215°F (136°K) when throttled to atmospheric pressure. At conditions more remote from the critical point, the temperature change is less dramatic. A rise in temperature may occur when the fluid is well above its critical temperature. This is shown by nitrogen at 80°F (300°K) when throttled to 5800 psia (40 MPa) from a higher pressure, but it is more typically encountered with hydrogen or helium under normal processing conditions.

When a saturated liquid is throttled to lower pressure, an isenthalpic line is followed into the dome, indicating partial vaporization of the downstream fluid. For example, if liquid nitrogen which is initially saturated at 290 psia (2 MPa) and −251.6°F (115.58°K) is throttled to atmospheric pressure, the downstream condition will be about 45 percent vapor. This will be accompanied by a change in density from about 35.77 lb(m)/ft^3 to 0.637 lb(m)/ft^3 (573 to 10.2 kg/m^3), or a factor of 56 increase in volume. If nitrogen vapor is throttled from a point above the dome, it may partially liquefy (retrograde condensation) or, within a very narrow range of conditions, pass through the two-phase region before ending up as all vapor at a final low-pressure condition.

The large change in specific volume which may occur with throttling—and particularly vaporization—may necessitate a substantial increase in the diameter of downstream piping in order to maintain reasonable velocities of the fluid. If the process leads to a two-phase downstream condition, there may be some slippage between the phases (i.e., the relative fraction of the vapor and liquid inventoried in the piping may differ from that of the net throughput). Two-phase flow characteristics can be extremely complex, and determination of this behavior is beyond the scope of this discussion.

An important consideration in the design of a cryogenic piping system arises from recognition that a confined fluid cannot increase in specific volume, or change in density, when heated. Extreme overpressurization can result when a cryogenic liquid which is trapped between valves is warmed, for example by heat leak. Confined nitrogen which is initially liquid at 101.5 psia (0.7 MPa) will [following the 43.70 lb(m)/ft^3 (700 kg/m^3) constant density line] exceed 1160 psia (8 MPa) when warmed to −270.7°F (105°K) and approach 14,500 psia (100 MPa) at −100°F (200°K). This makes overpressure protection mandatory wherever entrapment of a cryogenic liquid or (initially) high-pressure cold gas is possible.

Pressure-enthalpy charts for other cryogenic fluids are similar to those for nitrogen. Charts for oxygen and argon are provided as Figs. C8.2 and C8.3, respectively. Sources of charts for additional fluids are given in the bibliography at the end of this section. The thermodynamic property interrelationships of these fluids are similar to those which have been illustrated for nitrogen.

Rapid exposure of a partially confined cryogenic liquid to heat may result in overpressurization even when some outlet is provided. The possibility of a cryogenic liquid spill into a warmer environment must be considered in designing any enclosure around a piping system.

Certain fluids require special consideration. Liquid carbon dioxide, for example, is not stable at atmospheric pressure. (This is indicated on Table C8.5M by a triple-point pressure above atmospheric). Loss of pressure on a liquid carbon dioxide system (or a high-pressure gas system at sufficiently low temperature) will result in dry ice formation.

Physical and thermodynamic property data on cryogenic mixtures are not readily available in easily applied chart or tabular format (as they are for pure fluids). Required design data are usually computer generated from complex correlations for specific cases. Knowledge of pure fluid behavior will, however, provide an awareness of many factors which require consideration in the design of a cryogenic piping system.

Among the specific differences between the behavior of pure fluids and that of mixtures is a potentially much broader range of temperature and pressure conditions within the two-phase region for the latter case, and differences in composition between the individual phases and that of the overall mixture. There is also a possibility of one of the components freezing under conditions wherein other components may exist as gas and/or liquid mixtures. Although a component which is below its normal freezing point may have considerable solubility in the liquid or gas mixture, the possibility of solid formation should be anticipated when any of the components is present in a mixture at a temperature below its triple point. This situation may result from the mixing of two streams, neither of which contains a frozen component.

The designer should have knowledge of the combustion and physiological properties of the fluids being handled. Air and other oxidants must be excluded from piping transporting flammable fluids and from any enclosure (such as a cold box) into which leakage may occur. Conditions which may concentrate flammable contaminants present a danger in air separation. A number of cryogenic fluids are toxic, and all can present an asphyxiation hazard, particularly within confined areas. Venting of these fluids must take into account the possibility that temperature differences from the ambient air may lead to unexpected localized concentration buildups which threaten the safety of personnel and equipment.

MATERIALS USED IN CRYOGENIC PIPING SYSTEMS

Robert Zawierucha
Manager, Materials Engineering Laboratory
Praxair, Inc.

Important considerations in the selection of materials for cryogenic piping systems include suitable mechanical and physical properties, compatibility with process fluids, fabricability, cost, and compliance with regulatory codes.

The subject of materials for cryogenic applications has been generously treated in the technical literature. For those interested in additional background information, a few selected works in this area appear in the references and bibliography at the end of this section. The prime focus of this section, however, is cryogenic piping for the chemical process industry and commercial cryogenic distribution applications. Consequently, this overview will be deliberately limited in its scope and coverage, and many materials (such as those used in aerospace applications) will not be covered. The materials that will be covered include ferrous alloys, nonferrous alloys, and nonmetallic materials.

FERROUS MATERIALS

Ferrous alloys most often encountered in cryogenic piping applications are usually classified as ferritic or austenitic types. The terms *austenitic* and *ferritic* refer to the predominant crystallographic phases ferrite or austenitic, which are body centered cubic (BCC) and face centered cubic (FCC), respectively.

Ferritic Alloys

Most of the steels in common use are ferritic. This classification also covers steels which are martensitic as a result of heat treatment. Low cost, ease of fabricability, and high strength via heat treatment are major reasons for their popularity. Ferritic alloys, however, can exhibit a ductile-to-brittle toughness transition. The Charpy Impact Test, by which measurements of energy absorption, lateral expansion, and ductile fracture appearance are made, is the *most* common method of measuring this transition.

However, the ductile-to-brittle transition temperature in ferritic steels can be influenced by a number of variables involved in the steel-making process which control the levels of residual elements, inclusion shape, and heat treatment techniques which in turn control grain size and crystallographic morphology. A comprehensive review of these approaches is beyond the scope of this document. However, alloying with nickel, reduction of sulphur levels, and reductions in grain size may be stated as the most popular approaches with ferritic alloys. Table C8.6 contains a listing of some of the most common ferritic alloy steels used in cryogenic piping. Minimum service temperatures are included as well as the applicable ASME specifications.

Table C8.7 and Table C8.7M (Metric) contain a listing of the same materials as

TABLE C8.6　Typical Ferrous Alloys Used in Cryogenic Piping

Table C8.6 with typical data, including some data not found in the ASME specifications. Included in Tables C8.7 and Table C8.7M are mechanical properties such as strength, impact, and elongation, as well as thermodynamic data such as thermal expansion and thermal conductivity at cryogenic temperatures (boiling point at 1 atmosphere).

Austenitic Alloy Steels

In addition to providing data on the ferritic alloy steels, Tables C8.6, Table C8.7, and Table C8.7M also contain a listing of austenitic stainless steels which are likely to be encountered in cryogenic piping. Most of the austenitic alloy steels used in cryogenic piping are chromium-nickel stainless steels of the AISI 300 type, such as 304, 304L, 316, and 316L. Other stainless steels classified as martensitic, duplex, and precipitation hardening also exist; however, the preceding alloys are most commonly used in cryogenic piping for chemical process and distribution applications.

A major consideration in the use of the 300 Series stainless steels is the improvement in toughness properties they provide and elimination of the sharp ductile-to-brittle transition found in ferritic steels. These alloys have been used to contain and distribute liquid hydrogen and helium. Consequently, while the austenitic stainless steels were originally developed for corrosion resistance, their toughness and excellent fracture properties are what led to their selection for cryogenic piping applications.

Of the 300 Series alloys, the AISI 304 composition is the most popular as measured by tonnage. It should be noted that there is a preference for AISI 316L in the electronics industry for the distribution of high-purity gases that are free of particulates. Furthermore, piping and tubing used in this application are frequently electro-polished, and the trend is for an increase in electro-polishing for ultra-high-purity applications.

Cast versions of the common austenitic stainless steels may be used if valve applications exist. CF3, CF3M, CF8, and CF8M are cast equivalents of 304L, 316L, 304, and 316, respectively. Note that the cast stainless steels have been optimized for castability, and increased delta ferrite levels may adversely affect toughness at cryogenic temperatures. Similar effects may be observed in austenitic weld filler metals, and both castings and weld fillers should be well characterized and qualified prior to use in cryogenic piping systems.

NONFERROUS ALLOYS

Nonferrous alloys encountered in cryogenic piping are usually of the aluminum, cuprous, or nickel families. None of the three alloy families exhibit ductile-to-brittle toughness transition due to the FCC crystal lattice. Common nonferrous alloys used in cryogenic piping appear in Table C8.8, Table C8.9, and Table C8.9M (Metric).

Aluminum Alloys

Common aluminum alloys used in cryogenic process piping do not represent the gamut of what is available in aluminum alloys. The high-strength aluminum alloys

TABLE C8.8 Typical Nonferrous Alloys Used in Cryogenic Piping

Alloy	Tempers	Minimum temperature	ASME[1] spec.
1100 Aluminum	O, H11	−254°C (−452°F)	SB 210
3003 Aluminum	O, H112	−254°C (−452°F)	SB 210

Source: Praxair Inc.

commonly used in aerospace applications are not used in the chemical process industry because of the lack of ASME Code coverage or other considerations such as corrosion.

Aluminum compositions of the 5083 and 6061 types constitute the highest-strength alloys used in cryogenic applications, and tempers of these alloys are suitable at temperatures as low as −452°F (−254°C). From the toughness standpoint, 5083 would be preferred. However, prolonged exposure to temperatures as high as 152°F (66°C) during thaws can result in both a reduction in corrosion resistance and toughness. For low-strength applications, the 3000 series are also used.

Copper and Cuprous Alloys

Most of the early work in the cryogenic industry was accomplished through the use of copper process vessels, piping, and tubing. Aluminum has extensively replaced copper and cuprous alloys in the fabrication or air separation plants. However, copper and cuprous piping are still extensively used in piping and tubing runs from cryogenic tankage for several reasons which include ease of fabrication (e.g., brazing, soldering), resistance to ignition, and combustion resistance in oxygen-enriched systems. It may be noted that orbital arc-welded stainless piping systems are increasingly replacing cuprous piping for the delivery of particulate and contaminant-free electronic grade gases.

Nickel Alloys

While nickel alloys could be used in cryogenic piping systems on the basis of their mechanical properties, their high cost generally precludes their use. One major exception is the use of Monel,® a nickel-copper alloy, which may be used in oxygen systems to minimize ignition tendencies where there is concern of impingement or the potential for high velocities.

NONMETALLIC MATERIALS

Although the bulk of the materials used in cryogenic pipelines are metals, nonmetallic materials have critical functions in cryogenic pipeline components such as valves and insulation. Numerous nonmetallic components have been used in cryogenic pipeline applications, and it would be beyond the scope of this section to cite them all. A brief listing of some of the more common nonmetallic materials used in pipeline components is found in Table C8.10, Table C8.11, and Table C8.11M (Metric).

TABLE C8.10   Typical Examples of Nonmetallic Materials Used in Cryogenic Piping

Application	Material
Gaskets	Durabla (bonded or compressed asbestos) Grafoil (flexible graphite)
Insulation (fiber)	Mineral wool Fiberglass
Insulation (foam)	Polyurethane Styrofoam Foamglass(R)
Insulation (powder)	Perlite Vermiculite
Insulation (sheet)	Mylar Aluminum opacified paper
Insulation (support brock)	Transite Micarta
Valve packing, seals, and lubricants	Viton KEL-F Glass-reinforced Teflon Fluorolube

Source: Praxair Inc.

TABLE C8.11 Typical Mechanical and Physical Properties of Nonmetallic Materials

Material	Tensile strength (ksi)	Modulus of elasticity (ksi)	Specific gravity	Thermal expansion (in/in/°F × 10⁻⁵)	Thermal conductivity [Btu/(h·ft·°F)]	Specific heat (Btu·lb·°F)
Durabla (asbestos gasket material)	4–11					
Grafoil (flexible graphite)	.75–1.00	200	1.1	0.02	432*	0.7

Again, compatibility and mechanical and physical properties must be considered in the selection of nonmetallic materials. With respect to compatibility, liquid oxygen is the commercial cryogen of greatest concern because of its large usage. Typical tests or experimental parameters covered in the selection of nonmetallic materials for oxygen service include *autoignition temperature, heat of combustion, impact test*, and *oxygen index*. Materials that are compatible with oxygen generally have high autoignition temperatures, low heats of combustion, high energy absorption in impact tests, and high oxygen index values. Reference 1 gives advice about the specific criteria levels required for different applications. It is recommended that nonmetallic materials be qualified for oxygen service on a batch-by-batch basis.

Liquid fluorine is of greater concern from the compatibility standpoint with respect to nonmetallic materials. However, the industrial usage of liquid fluorine is very low in comparison to the other industrial gases. Reference 2 should be consulted for information on liquid fluorine systems.

The mechanical and physical properties of significance in the use of nonmetallic materials relate to their application in the form of insulation, gaskets, seals, and lubricants. It may be noted that they are not currently used as structural materials. Development of composites is expected to significantly increase the use of nonmetallic materials as structural components in cryogenic piping.

JOINING

Welding is the most common joining technique used in cryogenic piping. Brazing and soldering may be encountered in cuprous piping. With the recent trends toward high purity, there is a greater tendency to use orbital arc-welded stainless steel piping in lieu of brazed copper alloy piping.

Joint selection, filler metals, process qualification, and welded qualification are covered in detail by the ASME Pressure Piping Code, Section B31.3, Process Piping Code. Generally, areas which have been welded, brazed, or soldered experience thermal effects which may exhibit reduced strength, ductility, or toughness if not properly controlled. Appropriate mechanical tests as specified by applicable codes must be performed to verify suitability.

Within components such as cold boxes there may be occasions when transitions must be made between metals such as stainless steel and aluminum, forming joints which are difficult to weld directly or are unweldable. Transition joints are commercially available which may be classified as mechanical, brazed, diffusion bonded, or explosion bonded. Such joints have been successfully used in cryogenic applications. However, caution is advised in order to avoid in-service problems such as leaks, embrittlement, or actual joint separation. Careful vendor evaluation, joint design evaluation, and attention to fabrication details are required when dissimilar metal joints are required.

ENVIRONMENTAL AND SAFETY CONCERNS

A number of metallic and nonmetallic materials may be toxic, carcinogenic, tetragenic, or have other properties which are considered environmentally undesirable (i.e., effects on the ozone layer). For example, the use of asbestos-containing materi-

als such as Durabla or certain vermiculite ores may be further restricted or phased out. Similar concerns exist with cadmium-bearing brazing alloys. The recent concern about ozone depletion caused by chlorofluorocarbons could affect polyurethane foam production. Consequently, many common materials currently used in cryogenic piping systems are likely to be phased out over time.

Recent legislation mandates that material safety data sheets (MSDS) be obtained for all industrial substances that are in industrial use. This obviously includes the metallic and nonmetallic materials used in cryogenic piping. Failure to comply with the requirements and implementation provisions of the original legislation can have serious consequences for fabricators.

Equipment used in oxygen services has additional requirements such as cleaning and velocity limitations which must be considered. Oxygen equipment must be cleaned to eliminate contaminants such as hydrocarbons and metal particulates, which could serve as ignition sources. Reference 3 provides a general discussion of this issue. In addition, velocity limitations may be placed on certain classes of material to preclude ignition by particle impingement. See Reference 4 for velocity limitations and design considerations pertinent to oxygen systems.

Other industrial gases that might be encountered in cryogenic pipelines have specific hazards associated with them (i.e., flammability, toxicity, etc.). These are summarized in MSDS forms available from industrial gas suppliers.

PIPING SYSTEM DESIGN — FLUIDS

M. J. Lockett
Corporate Fellow
Praxair, Inc.

PIPE SIZING CRITERIA

For all cryogenic fluids, except oxygen gas, pipe sizing is based on pressure drop considerations (for oxygen gas, see the section "Oxygen Gas Piping"). The pressure drop criteria presented in Chap. B8 are applicable to cryogenic fluids when the fluid is either in the liquid phase or gas phase flow regime.

Heat transfer into a saturated cryogenic liquid or a drop in pressure can cause a portion of the liquid to flash into a gas (see the section "Properties of Cryogenic Fluids"). A two-phase (gas-liquid) flow condition must then be considered when determining the required pipe size and pressure head requirements (see the next section). Two-phase flow will result in larger pressure drop losses or a larger pipe size requirement than will liquid phase flow. Therefore, whenever possible, the fluid should be maintained in a single-phase flow condition. The liquid can be subcooled to prevent flashoff due to pressure decreases such as across throttling valves. Use of pipe insulation can reduce the heat leak into the piping, thereby also reducing flashoff.

TWO-PHASE FLOW

For prediction of the pressure drop experienced by a two-phase cryogenic fluid flowing along a pipe, the usual practice is to divide the pipe into sections for calculation purposes (see Fig. C8.4). At the beginning of a given pipe section,
FIGURE C8.4 Pipe section.

conditions are assumed to be known. The pressure drop over the section is then calculated based on the conditions at the beginning of the section, and so the pressure at the end of the section can be determined. The heat leak into the section is estimated from heat transfer correlations. An enthalpy balance over the section then allows the enthalpy (h) at the end of the section to be calculated (potential and kinetic energy changes over the section can usually be neglected). Knowledge of the pressure and enthalpy at the end of the section allows new conditions to be calculated from the thermodynamic properties of the cryogenic fluid. Such conditions include the temperature, vapor fraction, and physical properties of each phase. The calculations are then repeated for the next section, and so on to the end of the pipe.

Two-Phase Pressure Drop

The total pressure drop for two-phase flow consists of three parts; the frictional, gravitational, and accelerational pressure drops, so that,

$$\left(\frac{dp}{dz}\right)_{TP} = \left(\frac{dp_F}{dz}\right) + \left(\frac{dp_G}{dz}\right) + \left(\frac{dp_A}{dz}\right) \tag{C8.1}$$

where p is the pressure, $p$dl ft^{-2} (Nm^{-2})and z is the distance along the pipe, ft (m).

Many correlations have been proposed to predict the frictional pressure drop (dp_F/dz) and they are discussed in Chap. B8. The earliest correlation, which is still widely used, is that of Lockhart and Martinelli.[1]

To use this correlation, the steps are:

1. Calculate the Reynolds number for each phase flowing alone in the pipe.

$$\text{Re}_L = \frac{M_L D}{A\mu_L} \tag{C8.2}$$

$$\text{Re}_G = \frac{M_G D}{A\mu_G} \tag{C8.3}$$

where M_L, M_G = liquid and vapor flow rates, lbs^{-1} (kg s^{-1})
      A, D = pipe cross sectional area, ft^2 (m^2), and diameter, ft (m)
    μ_L, μ_G = liquid and vapor viscosities, lb ft^{-1} s^{-1} (Nsm^{-2})

2. Calculate the frictional pressure drop for each phase flowing alone in the pipe.

$$\left(\frac{dp_F}{dz}\right)_L = \frac{2k_L(\text{Re}_L)^{-n}\rho_L}{D}\left(\frac{M_L}{A\rho_L}\right)^2 \tag{C8.4}$$

$$\left(\frac{dp_F}{dz}\right)_G = \frac{2k_G(\text{Re}_G)^{-m}\rho_G}{D}\left(\frac{M_G}{A\rho_G}\right)^2 \tag{C8.5}$$

Where ρ_L, ρ_G = liquid and vapor densities, lb ft^{-3} (kg m^{-3}).

The following table can be used to determine k_L, k_G, n, and m:

Liquid	Vapor	Re_L	Re_G	k_L	k_G	n	m
t	t	>2,000	>2,000	0.046	0.046	0.2	0.2
v	t	<1,000	>2,000	16	0.046	1.0	0.2
t	v	>2,000	<1,000	0.046	16	0.2	1.0
v	v	<1,000	<1,000	16	16	1.0	1.0

The value of 0.046 is based on smooth pipes, and t and v denote turbulent or laminar flow respectively.

3. Calculate X from

$$X = \left[\left(\frac{dp_F}{dz}\right)_L \Big/ \left(\frac{dp_F}{dz}\right)_G\right]^{0.5} \tag{C8.6}$$

4. Use Fig. C8.5 to determine ϕ_L or ϕ_G.
5. Calculate the frictional pressure drop for two-phase flow from either,

$$\left(\frac{dp_F}{dz}\right) = \phi_L^2\left(\frac{dp_F}{dz}\right)_L \quad \text{or} \quad \left(\frac{dp_F}{dz}\right) = \phi_G^2\left(\frac{dp_F}{dz}\right)_G \tag{C8.7}$$

This correlation typically allows prediction of the frictional pressure drop to about ±30%, but the discrepancy can be greater under some circumstances.

Where the flow is other than horizontal, the gravitational pressure drop becomes significant, and in vertical flow it is the dominant term. It may be calculated from

$$\left(\frac{dp_G}{dz}\right) = g\sin\theta[\alpha\rho_G + (1-\alpha)\rho_L] \tag{C8.8}$$

where g = acceleration due to gravity, ft s^{-2} (ms^{-2})
α = void fraction
θ = angle to horizontal, deg.

Numerous correlations are available for the void fraction, and that of Lockhart and Martinelli is shown in Fig. C8.5. As it was derived originally for horizontal flow, it can be rather inaccurate for vertical flow. Other void fraction correlations are mentioned in Chap. B.8.

The accelerational pressure drop is often negligible for two-phase flow of cryogenic fluids. It can be estimated from,

$$\left(\frac{dp_A}{dz}\right) = \frac{1}{A^2}\frac{d}{dz}\left[\frac{M_G^2}{\rho_G\alpha} + \frac{M_L^2}{\rho_L(1-\alpha)}\right] \tag{C8.9}$$

where the expression on the right-hand side is evaluated over the pipe section.
The total pressure drop calculated by this method should be increased by at
FIGURE C8.5   Lockhart-Martinelli correlation.

least 30% for design safety. A final check should also be made for critical, or choked, flow at the downstream end of the pipe. An equation proposed by Schweppe and Foust[2] for the maximum possible flow rate is

$$M_c = -\left[\frac{A^2}{\left(\dfrac{\partial v}{\partial p}\right)_s}\right]^{0.5} \tag{C8.10}$$

where M_c = maximum flow rate of the mixture, lbs^{-1} (kg s^{-1}).
   v = specific volume of the mixture based on homogenous flow, ft^3 lb^{-1} (m^3 kg^{-1}).

so that

$$v = \frac{M_G / \rho_G + M_L / \rho_L}{M_L + M_G} \tag{C8.11}$$

and the partial derivative is evaluated under isentropic conditions. It can be calculated for conditions at the downstream end of the pipe from the thermodynamic properties of the cryogenic fluid.

An alternative version, involving the enthalpy, h, which is sometimes more convenient, is

$$M_c = -\left[\frac{A^2}{\left(\dfrac{\partial v}{\partial p}\right)_h + v\left(\dfrac{\partial v}{\partial h}\right)_p} \right]^{0.5} \tag{C8.12}$$

where the two partial derivatives are evaluated at constant enthalpy and constant pressure respectively.

If M_c is less than the assumed total flow rate, the pressure drop calculation should be repeated with a reduced total flow rate or an increased pipe diameter.

OXYGEN GAS PIPING

For oxygen gas, the fluid velocity must also be considered when determining the pipe size. The allowable velocity is a function of the oxygen gas pressure and temperature and the material of the piping and its components. For systems with pressures up to 1000 psi (69 bar) and a maximum temperature of 200°F (366 K), carbon steel and stainless steel piping are acceptable provided that the maximum allowable gas velocity as shown in Fig. C8.6 is not exceeded.
FIGURE C8.6   Maximum velocity versus internal pressure for steel pipelines. (Ref. 3.)

When the velocity is exceeded, copper or a copper-base material such as brass or monel is required. The velocity criteria should also be considered at valves. For example, sonic velocity can occur at throttling and safety valves. Copper-base materials are required for the parts of the valves where high velocity can occur.

When oxygen gas impinges directly on ferrous piping, such as from a side back feed line, the allowable velocity must be reduced to one-half the values given in Fig. C8.6, or the impingement surface must be a copper-base alloy. When the velocity returns to acceptable levels, the copper base alloy is extended for 8 diameters in pipe length before returning to ferrous piping. For a more thorough discussion of material requirements for oxygen service, see Ref. 3 at the end of this section.

PIPING ARRANGEMENT

Consideration of the cryogenic fluid properties has an effect on the piping arrangement. Because the cryogenic fluid is colder than ambient air, the continuous heat leak from ambient air to the piping system is a design consideration.

Whenever cryogenic liquid can be trapped between two valves, a line block safety valve must be provided to prevent overpressurization caused by heat transfer from the ambient air to the cryogenic fluid. As noted earlier in the discussion of cryogenic fluids, containment of the pressure increase caused by vaporization of the trapped cryogenic liquid is not practical and use of a line block safety valve is mandatory. When cryogenic gas can be trapped between two valves, the pressure rise should be calculated to ensure that the piping system design pressure is not exceeded when the trapped gas warms up to ambient temperature. When the design pressure can be exceeded, a line block safety valve should be used.

Traps are normally designed into liquid piping systems to prevent undesirable heat leak from a branch of the piping system when it is not in use. To form a trap at the branch and main run connection, a vertical rise equal to a minimum of 2 pipe diameters is provided in the branch. Heat transfer into the nonflowing branch will cause the liquid to vaporize and a gas-liquid interface will form in the trap. The gas-liquid interface in the vertical rise will prevent flow from the main run into the nonflowing branch. Undesirable heat transfer and liquid loss is therefore reduced. When liquid flow is required through the branch, the liquid will flow through the trap.

When a cryogenic liquid line is initially put in service, the warm piping will cause *liquid flashoff,* which could restrict the flow during the two-phase flow transient period. When it is possible to precool the lines, the piping can be sized for liquid phase flow, which will result in smaller piping. If rapid cooldown is required, the piping must be sized for two-phase flow.

As a good approximation, the amount of liquid required to cool down a line is

$$W = \frac{M_m C_{pm} \Delta T_m}{(H_v - H_1)} \tag{C8.13}$$

where W = liquid, lb (kg)

M_m = line to be cooled, lb (kg)

C_{pm} = mean specific heat of line, Btu/(lb · °F), (kJ kg^{-1}K^{-1})

ΔT_m = temperature change through which line is cooled, °F(K)

H_v = enthalpy of fluid as a vapor at ambient conditions, Btu/lb (kJ kg^{-1})

H_1 = initial enthalpy of liquid when entering line, Btu/lb (kJ kg^{-1})

PIPING SYSTEM DESIGN—MECHANICAL

A. R. Belair
Engineering Manager
Praxair, Inc.

APPLICABLE CODES AND MATERIALS

The applicable code for the design of cryogenic piping systems is the ASME B31.3 Process Piping Code.[1] B31.3 presents a design procedure to determine the stresses in the pipe due to fluid pressure, pipe and fluid weight, and thermal expansion and contraction of the pipe. The code also lists piping materials by ASTM specification number. The allowable stress as a function of design temperature is listed for each material. The listed minimum design temperature is used to determine which materials are suitable for cryogenic service.

Some of the materials can be used in lower-temperature service, provided the specified impact test is performed to ensure adequate ductility at the lower temperature. The B31.3 Code also lists pipe fittings and bolting by ASTM number so that materials compatible with the pipe can be selected. For more discussion of materials, see the section ''Materials Used in Cryogenic Piping Systems.''

Other piping design considerations such as corrosion resistance, chemical compatibility, and material melting point can affect the material selection. Some examples of these conditions include:

1. Copper-base materials are not recommended for ammonia or acetylene service because copper alloys react with the fluid.

2. Stainless steel piping is recommended for flammable fluids such as hydrogen rather than lower-melting-point materials such as copper or aluminum unless the piping is protected to prevent exposure to heat in the event of a fire.

3. Copper-base materials (such as monel) are recommended for high-velocity oxygen service.

See Chap. B2 for discussion of formulas which can be used to calculate the pipe wall thickness as required to contain the fluid pressure.

ECONOMIC PIPE SIZING

When a piping system is being designed, an initial pipe size must be selected before the piping configuration is developed. This subsection provides recommendations for selecting the initial pipe size. However, after the piping system is developed, the pipe size selection is finalized by calculating the pressure drop based on the actual piping configuration and comparing it to the pressure head available.

For cryogenic liquid lines, the initial pipe size should be selected so that the liquid velocity is in the range of 5 ft/s (1.5 m/s).

For cryogenic liquid lines, the initial pipe size should be selected based on the available pressure head (see section "Piping System Design—Fluids," subsection "Pipe Sizing Criteria"). When estimating pipe length and number of fittings to calculate the initial pipe size, add 50 percent to the total resistance coefficient, K, to allow for pipe loops and extra fittings as may be required for thermal flexibility. To ensure good process control, one-third of the total system pressure drop should be allotted to the control valves.

Except for oxygen gas, as discussed in the section "Piping System Design—Fluids," subsection "Oxygen Gas Piping," there are no specific gas velocity limitations. However, the gas velocity is normally less than 400 ft/s (130 m/s) to avoid noise problems and excessive pressure drop. For systems with pressures up to 400 psi (2750 KPa), gas velocities in the range of 50 to 200 ft/s (15 to 65 m/s) are common.

When the pipe size of the gas line affects the plant power consumption, the initial pipe size can be selected by using the following equation. The equation calculates the pipe diameter that provides the minimum total cost; that is, pipe capital cost plus operating power cost.

Economical pipe sizing (Imperial units)

$$D = (0.0275)\left(\frac{MTUCY}{EA}\right)^{0.16}\frac{Q^{0.48}}{P^{0.32}} \quad \text{(C8.14)}$$

PIPING COMPONENTS

The types of valves used in cryogenic service are similar to those used for conventional fluids, except that the valves may require unique design features due to the

cryogenic fluids. Metallic and nonmetallic materials must be suitable for the low-temperature service. See the discussions on materials in the section "Materials Used in Cryogenic Service." Valve types used include gate, globe, butterfly, ball, check, and safety.

The stems of gate, globe, butterfly, and ball valves are extended so that the valve packing and operator remain at ambient temperature when cryogenic fluid is in the valve body. The valves are oriented so that the packing is at a higher elevation than the valve body, so that a gas pocket can form inside the valve's extension tube, thereby making the extension tube more effective at insulating the packing from the cold temperatures. Figure C8.7 shows an extended stem gate valve.

LEGEND

4	STEM	9	YOKE BUSHING
5	EXTENSION TUBE		
FIGURE C8.7 Extended stem gate valve. *(Courtesy Praxair, Inc.)*

Valves must be designed so that liquid cannot be trapped in a portion of it when the valves are cycled from open to closed. When a conventional gate valve is closed, it is possible for liquid to be trapped in the bonnet area. If liquid is trapped, heat input from the atmosphere will cause the liquid to vaporize and overpressurize the valve body. When a gate valve is used in cryogenic service, the bonnet area is vented to one side of the valve so that any vaporized gas cannot be trapped in the bonnet area. Figure C8.8 shows one method that is used to vent the bonnet area of a gate valve.

With a conventional ball valve, liquid can be trapped between the ball and the
FIGURE C8.8 Gate valve—vented bonnet. *(Courtesy Praxair, Inc.)*

seat. Similarly, for ball valves in cryogenic service, the ball area is vented to one side of the valve.

During the cool-down or thaw of a cryogenic piping system, different parts of the valves may cool down or warm up at different rates, resulting in varying rates of contraction and expansion. The valve design must consider that the valves are required to be operational during these conditions.

FLEXIBILITY ANALYSIS AND SUPPORTS FOR CYROGENIC PIPING SYSTEMS

Piping flexibility analysis is an important design consideration because the large difference between ambient and cryogenic temperatures will result in significant thermal contraction. The analysis methods used are similar to those required for conventional piping systems as discussed in Chap. B4. The one difference is that piping in cryogenic service contracts rather than expands as is the case with high-temperature service. However, since the commercially available flexibility analysis computer programs have the temperature range as an input value, and the program calculates the resulting thermal contraction, the analysis methods become identical to those used for conventional piping systems.

When possible, cryogenic piping is routed so that the piping configuration provides adequate flexibility. Generally, piping is routed in a manner that includes Z, L, and U bend configurations to take up the pipe movement while keeping the stresses within the allowable range. When additional flexibility is required, the flexibility can be increased by the addition of expansion loops (U bends) or the addition of flexible metal hose. Flexible hose can accommodate larger pipe movements and can result in a more compact design. However, the use of flexible hoses

may result in requiring more pipe supports to guide the piping so that the pipe movement is taken up by the hose.

The flexible hose is located so that pipe movement is lateral to it. The braided cover on the flexible hose prevents any significant pipe movement axial to the flexible hose. A flexible hose acts similarly to an expansion joint designed for lateral movements. The recommended upper pressure limit for flexible hose and expansion joints is 1000 psi (6900 kPa).

Hanging-style pipe supports can be used to accommodate significant pipe movement in both the lateral and axial directions. Roller-style pipe supports can be used to accommodate large axial pipe movement. When the amount of pipe movement exceeds the capability of a hanger or roller pipe support system, a fixed support located in the center of the pipe span can be effective in reducing the amount of movement.

When an uninsulated cryogenic line is supported, a portion of the pipe support will be at cryogenic temperature. The lower temperature should be considered when selecting the materials for the pipe support and its hardware.

INSTALLATION OF PIPING COMPONENTS

To minimize potential leaks, welding and brazing are the most common assembly methods for cryogenic piping systems. In accordance with the B31.3 Code, solder joints are not acceptable for cryogenic service. However, to allow removal of valves and other piping components for maintenance, other assembly methods are used at piping components.

Piping components with threaded fittings are used in small sizes, usually NPS 1½ pipe size and smaller. Flange joints are used for large sizes, with flanges provided in accordance with ASME B16.5. For raised-face and flat-face flanges, gaskets are usually compressed asbestos sheets, spiral-wound stainless steel with asbestos or Teflon filler, or flexible graphite such as Grafoil.

INSULATION SYSTEMS

Most piping in liquid cryogenic service is insulated. The only reasons a line would not be insulated are that (1) its use is very infrequent and brief; (2) it is a temporary installation; or (3) the refrigeration losses are inconsequential. The following table shows the heat leak from a frosted, uninsulated line containing liquid nitrogen and subjected to an 8 mi/h (3.6 m/sec) wind:

Pipe size (in)	Heat leak per foot of pipe (BTU/hr)	Pipe size (mm)	Heat leak per meter of pipe (Watt)
1	280	25	270
2	530	50	510
4	1000	100	960

The type of insulation used for cryogenic piping includes (1) expanded foams such as polyurethane and foamglass, (2) powder insulations such as perlite, and (3)

vacuum-insulated pipe. For an insulation system to remain effective, the vapor barrier system must keep atmospheric moisture from entering the insulation space and freezing against the cryogenic line. When this occurs, the ice that is formed will degrade or destroy the insulation system.

When the cryogenic liquid is colder than the boiling point of oxygen ($-297°F$ or $-183°C$), oxygen can condense out of the air and collect in the insulation space. For this situation, the insulation system should be noncombustible in the presence of oxygen.

TABLE C8.12 Thermal Conductivity of Pipe Insulation Materials at an Insulation Mean Temperature of $-100°F$

Insulation	Thermal conductivity [Btu/(h·ft·²°F)]	Thermal conductivity W/(m·°K)
Urethane foam	0.012	.021
Foamglass	0.024	.042
Perlite (at atmospheric pressure)	0.018	.031
Perlite (vacuum at 1 μm)	7.9×10^{-4}	1.37×10^{-3}
Laminar radiation shielding (vacuum at 0.1 μm)	2.1×10^{-5}	3.63×10^{-5}

The typical values for thermal conductivity are shown in Table C8.12. The expanded foam insulations use a plastic covering, such as PVC or neoprene sheeting, to provide the vapor barrier protection. The initial capital cost is usually lower than the other systems, but more frequent maintenance is required to maintain a tight vapor barrier.

Powder insulation is generally used when several piping segments and pieces of equipment can be grouped in one area. A metal jacket or casing is used to contain the perlite around the piping and equipment. When the insulation space is maintained at atmospheric pressure, it must be purged with a dry gas, such as nitrogen, to keep atmospheric moisture out of the casing. For improved heat transfer performance, the casing can be made vacuum-tight and the insulation space evacuated to a high vacuum. For powder insulation, high vacuum is a pressure level less than 1 μm of mercury when the line is at the normal cryogenic temperature operation condition (1 μm of mercury is equal to 10^{-3} torr). See Table C8.12 for typical thermal conductivity values. When considering this insulation option, the difficulty in maintaining a vacuum-tight casing must be weighed against the difficulty of maintaining a dry gas purge, considering the difference in heat transfer performance.

Vacuum-insulated piping (VIP) is constructed of a stainless steel inner pipe that contains the cryogenic fluid, a stainless steel outer jacket to form the vacuum space, and insulation in the vacuum space. The insulation is normally laminar radiation shielding that consists of alternate layers of a reflective material, such as aluminum foil, and an insulation material, such as glass paper. For vacuum-insulated pipe, the required vacuum is a pressure level less than 0.1 μm, when the line is at the normal cryogenic operating condition. Heat leak by conduction and radiation is reduced by the laminar radiation shielding. The heat leak by convection is reduced by the vacuum.

Nonmetallic spacers are required in the vacuum space to support and maintain alignment of the inner pipe within the outer pipe jacket. Bellows are required in one pipe to account for the differential expansion between the inner and outer

† For the inner pipe.

pipe. Due to the labor-intensive nature of fabricating VIP, it is normally shop-fabricated. To accommodate field installation, a mechanical joint is required between pipe segments. A bayonet assembly is one type of joint that has an extended heat leak path between the inner pipe and the flange connection of the outer pipe. Figure C8.9 illustrates the bayonet assembly.

Table C8.12 shows typical values of insulation thermal performance for laminar radiation shielding. For a vacuum-insulated piping system, the thermal performance of the straight pipe is affected by the number and type of spacers. The thermal performance of fittings and other components depend on fabrication techniques. Tables C8.13 and Table C8.13M (Metric) show typical heat leak performance values for commercially available vacuum insulated pipe.

The total cost, including the piping system and the cost of refrigeration losses due to heat leak, should be considered when selecting an insulation system. For many permanent piping systems, vacuum-insulated pipe provides the most cost-effective insulation system.

CLEANING

All materials used in oxygen piping systems or connected with oxygen systems should be cleaned before the system is put into service. The cleaning must remove mill scale, rust, dirt, weld slag, oil, grease, and other organic materials. The purpose of the cleaning is to remove hazardous hydrocarbons and particulate contaminants which could ignite and cause a fire in an oxygen atmosphere. To obtain additional information on cleaning requirements, see Ref. 2. For a discussion of the factors affecting ignition in an oxygen system, see Ref. 3.

All materials used in nonoxygen cryogenic systems are also cleaned before the system is put in service. The purpose of the cleaning is to reduce contaminants to the point where they will not migrate, seize up moving parts at low temperatures, or prevent the attainment of high product purity or vacuum levels.

VENTS

When a cryogenic fluid is vented, such as from safety valves, safe disposal of the fluid must be considered. The fluid should be directed so that it will not contact personnel, because the low temperature can cause burns.

When cold, most cryogenic fluids are heavier than air. A heavier-than-air gas can displace the air and create a potential for asphyxiation. Some cryogenic fluids, such as hydrogen, are flammable. An oxygen-enriched atmosphere can promote flammability of other materials. Therefore, all vents should be located outdoors and directed so that high concentrations will not collect in confined areas.

COLD BOX PIPING

J. K. Howell
Cold Box Engineer
Praxair, Inc.

A *cold box* is a mechanical system that insulates an entire low-temperature process mechanical embodiment in a single assembly instead of insulating each pipe and vessel individually. The cold equipment and piping are installed in an airtight steel insulation casing. The void space inside the casing is filled with insulation powder or fibers.

The design of cold box piping requires knowledge of some basic engineering disciplines, such as strength of materials, fluid mechanics, and heat transfer. Also required are some piping design skills such as flexibility analysis, pressure drop calculations, and material selection. These skills are discussed in Chap. B4 of this handbook.

For safe design, cold box piping is usually designed to meet the engineering requirements of ASME B31.3[1], Process Piping Code. Further, the designer should be aware of the design considerations for safe operation and maintenance of cold boxes discussed in Sec. 8 of Ref. 2 of this article.

What follows is a description of problems unique to the design of cold box piping, and, where appropriate, suggested methods of solution.

DESIGN REQUIREMENTS FOR COLD BOX PIPING

General System Architecture

Cold boxes tend to be tall, vertical structures. They often contain tall distillation columns and brazed aluminum heat exchangers which are oriented for vertical flow (see Fig. C8.10). A minimum of 12 in (30 cm) of space is usually provided between the casing and the piping and equipment inside. This space provides adequate insulation for the cold equipment and access to the piping for fabrication, testing,
FIGURE C8.10   Schematic cold box diagram. *(Courtesy Praxair, Inc.)*

and maintenance. Valves and controls above grade level are located so as to be easily accessible from operating platforms. The piping arrangement within the cold box is very compact to minimize the amount of insulation and to fit shop-fabricated cold boxes within the maximum outline which can be shipped by rail or by truck. Heat exchangers operating in parallel are located at the same elevation to avoid flow unbalance due to density differences between the warm and cold streams.

Insulation System

Before start-up, the insulation is purged with a dry inert gas, usually nitrogen. A small flow of purge gas is continued during operation to maintain a slight positive pressure in the casing and to prevent inflow of oxygen and moisture. Pipe and valve stem penetrations through the casing must be airtight.

Equipment and pipes operating at different temperatures must be separated to minimize unwanted heat flows. The piping and pipe supports must withstand loads from the insulation material. These loads occur when fibrous insulation is being packed into the casing and when powder insulation is being loaded or removed.

Reliability

Piping inside the cold box is not readily accessible for maintenance. Repair of a simple leak requires that the cold box be out of service for several days. Erosion caused by insulation and powder propelled by the leaking fluid can enlarge a small leak or cause another leak in nearby equipment. For these reasons, leak-tight integrity of cold box piping is extremely important. The number of flanged joints inside a cold box is kept to a minimum. Welded or brazed pipe joints are used wherever possible. Transition joints are often used to join stainless valves to aluminum pipe. Weld-end, top-entry, extended-stem globe valves afford maximum reliability. These valves do not have any flanges inside the casing, and the plug and seat can be replaced from outside the cold box. When flanges are used inside the casing, proper torquing of flange bolts must be assured. Threaded joints and tubing compression fittings are usually not used inside the casing. Flanges are sometimes installed in a separate, small, insulated compartment where access can be achieved without removing the insulation from the entire cold box. A careful leak test in done on all piping inside the casing before the insulation is installed.

Thermal Expansion and Contraction

Typically, cold box piping is heated to 212°F (100°C) before start-up to remove any moisture, and then cooled to operating temperature—as low as −320°F (−195°C), as is the case in an air separation plant. In that example, the total temperature range is 532°F (295°C). The total thermal expansion and contraction of aluminum pipe in this range is 6 in/100 ft (0.5 cm/m). The flexibility analysis of the piping must consider the full temperature range as well as any more severe differential temperature conditions which may occur during upset, thaw, or cool-down. Clearance must be allowed for the pipes to move through their full expansion and contraction range. This clearance is especially critical for pipes connected near the top of tall vessels. Pipe penetrations through the casing will restrict the movement of the pipe unless the casing is made flexible by use of a metal bellows or a rubber boot.

Piping Installation Details

Pipes running from liquid pipes or vessels to the casing must have thermal traps (upward rise of at least 2 pipe diameters) to gas-bind the connection and keep the cold liquid away from the warm casing. Thermal traps are also used in gas pipes to prevent unwanted convection currents.

Extended stem valves used in cold pipes are installed with the body located at least 12 in (30 cm) inside the casing and with the packing gland and the operator or handwheel located outside. Liquid valve stems are tilted upward at least 15° to gas-bind the stem extension tube and keep the liquid away from the packing.

Supports for cold pipes are commonly made from austinitic stainless steel because

it is strong, ductile at cryogenic temperature, and has a relatively low thermal conductivity. Blocks of insulation material can be included in the supports to reduce heat leak from the casing.

Low-point drains are provided where necessary to remove process liquids for shutdown and to remove liquid water formed during thaw of the cold box.

Cleaning

Cold box piping is cleaned to remove contaminants (see the earlier discussion of cleaning in this chapter). The cleaning is usually done before the pipe is installed. Pipe ends and other openings are covered after completion of fabrication to maintain cleanliness.

DESIGN REQUIREMENTS FOR SPECIAL SITUATIONS

Reversing Exchangers

Reversing heat exchangers and regenerators are often used in air separation cold boxes. The piping in the reversing streams is subjected to cyclic pressure variations. Fatigue analysis should be performed on this piping. Paragraph K304.8 of Ref. 1 can be used as a guide for the fatigue analysis. Liquid water may be present in the warm-end piping from these heat exchangers. Possible corrosion and freeze-up problems should be considered in the design of this piping.

Liquid Oxygen Evaporation

Most liquid oxygen contains some traces of hydrocarbon contaminants. If this liquid vaporizes in a dead-ended pipe or crevice, the hydrocarbons will concentrate. Explosive mixtures can result. Crevices should be avoided in liquid oxygen piping where a source of heat is present. Drains and other dead-ended pipes connected to a liquid oxygen source should be trapped as close as possible to the liquid source. Liquid oxygen piping should be well-insulated from the casing and from warmer process equipment.

Vacuum-Insulated Cold Boxes

In some cold boxes, a vacuum is pumped on the insulation casing to reduce the heat leak. In such cases, the piping and vessels are tested with helium to find and repair tiny leaks which would greatly reduce the effectiveness of the vacuum insulation. The design pressure for such piping is based on the absolute rather than the gauge pressure.

Instrument Lines

Instrument pipes in the cold box must be designed with care. These pipes have a small diameter and are easily damaged. The design of instrument lines should

provide adequate flexibility, support, and protection from insulation and/or inadvertent loads due to using these lines to support the weight of a worker during fabrication. Equation (16), paragraph 319.4.1 (c), Ref.1 can be used for assuring adequate flexibility of instrument lines.

Flammable Fluid

Some cold boxes process flammable fluids such as hydrogen, hydrocarbons, carbon monoxide, and so forth. Any aluminum or other low-melting-temperature piping outside the casing should be protected by fireproof insulation. The insulation should not contain any chemicals which would corrode or otherwise degrade the piping material. Discharges from the drains, vents, and relief valves must be piped to a flare stack or other safe means of disposal. Connections are provided on dead-ended pipes for purging air from the lines before admitting the flammable process fluids.

LIQUID STORAGE AND CONVERSION SYSTEMS

N. H. White
Engineering Associate
Praxair, Inc.

Bulk liquid storage systems are often used at or near the point of final consumption. They typically supply product in three basic forms: as a gas at less than the storage tank working pressure, as a gas at high pressure, and as a liquid. The equipment and piping required may vary, depending on which of these delivery forms is used. However, several general considerations apply to the piping design in all cases.

The working pressure of all lines in the system should be at least 10 percent higher than that of the tank. Relief valves required to protect the piping should be set at this pressure. This configuration of relief valve set points will ensure that if the tank is overpressured, it will be relieved in the gas phase from its safety valve and not in the liquid phase through one of the pipeline relief valves.

Vaporizers are commonly used in storage and conversion systems to gasify liquid product and bring it to ambient temperatures. The piping downstream of these units should be designed for liquid product temperature. This should continue up to the point where a safety device is installed to automatically shut off flow in the event that low temperature is sensed. The response time of this device must be

compatible with the failure modes of the vaporization system used. The set point chosen must consider the design temperature of all components downstream.

Relief valves should be installed between any set of valves that can trap liquid or low-temperature gas if they are simultaneously closed. These *blocked-line relief valves* are required to relieve pressure buildup due to heat absorption. They should be set at the line working pressure and sized to relieve gas at conditions of maximum heat absorption. Particular attention should be paid to situations where the source of heat is natural convection associated with bare lines and ambient vaporizers. They are of special concern because even moderate winds can greatly increase the rate of heating and subsequent pressure buildup.

Bulk liquid units are typically employed in intermittent flow situations. For this reason, liquid lines will frequently have to be cooled down to liquid temperatures when product is demanded. Therefore, such lines should be sized to pass the required flow in the gaseous state to avoid excessive pressure drop at the start of demand. Design for cryogenic temperature requires that particular attention be paid to line flexibility. Although large displacements are involved due to the extreme temperature changes, they can be accommodated by conventional techniques, including flexible hose sections and expansion loops. In addition, most piping materials experience reduced impact strength at cryogenic temperatures. The materials section in this chapter deals in depth with this topic.

Thermal trapping is a piping technique that can be used in any liquid line, whether it is insulated or not, to minimize heat input to an idle piping section or branch. Where the branch is oriented vertically a gas-to-liquid interface will be established near the connection, and the majority of this section will be filled with gas approaching ambient temperature. This configuration greatly reduces heat input to the branch when it is idle.

LOW-PRESSURE BULK CONVERSION SYSTEMS

The most common bulk liquid units deliver gas at a pressure less than the storage tank working pressure. The working pressure of such systems is typically less than 250 psig (17.2 bar). However, systems with as high as 600 psig (41.4 bar) working pressure tankage have been used commercially. The delivery pressure must be limited to approximately 80 percent of the tank working pressure to allow for tolerance on the safety relief valve setting, and for buildup in product pressure during periods of nonuse. Figure C8.11 illustrates a typical piping configuration, and item numbers in the following discussion refer to this figure.

The lines connecting the vessel the to pressure relief safety devices (No. 301 and No. 302) are sized to meet the requirements of ASME Boiler and Pressure Vessel Code, Sec. VIII, Div. 1. Guidelines for the required calculations are given in the pamphlet CGA S-1.3 ''Pressure Relief Device Standards—Part 3—Stationary Storage Containers for Compressed Gases,'' published by the Compressed Gas Association. Normally both a relief valve and a burst disk are included. The relief valve is sized to handle the vapor generated due to the heat load resulting from the loss of insulation (loss of vacuum). The bursting disc is designed to handle the simultaneous loss of vacuum and fire conditions. Where it is critical that the system not be taken out of service for periodic inspection of the relief devices, it is common to use a dual set of safety devices with a diverter valve.

The fill system is arranged so that the tank can be filled from either the top or the bottom. Tank pressure is controlled during the fill operation by adjusting the
FIGURE C8.11 Low-pressure bulk conversion system *(Courtesy of Praxair, Inc.)*

portion of refill liquid entering from the top relative to that entering from the bottom with valves No. 402 and No. 404. Filling from the top reduces tank pressure by condensing the vapor in the gas space of the storage tank. Filling from the bottom increases tank pressure because the liquid acts as a piston, compressing the gas space. Special piping considerations for the fill lines involve the line size, which should be adequate to permit refill to occur in a reasonable time period and yet not be oversized to limit heat input. Insulation is not typically used on these lines because of their short length, intermittent use, and high transfer rate. Helium and hydrogen fill operations are an exception to this practice because of their extremely low temperature and low heat of vaporization. Other products may justify the use of insulation based on their value.

Bulk tanks are normally filled from transports, which are discussed in the mobile equipment section of this chapter. The transfer is driven either by a centrifugal pump or by pressurizing the supply vessel. The centrifugal pumps are typically one- or two-stage designs matched for the discharge rate and pressure by adjusting the speed and impeller cut as in conventional service. The system—including the transport piping, the off-loading pump or pressurization circuit, the tank fill piping, and the tank pressure relief circuit—must be analyzed to ensure that the tank cannot be overpressurized in the refill process. Compressed Gas Association position paper PS-8, ''Protection of Storage Tanks From Over-pressure during Operator Attended Refill,'' addresses this topic.

The tank instrument piping includes a gas phase line called the *full trycock* that extends into the gas space to the full liquid level. This line is used by the operator during manual-fill operations to determine when the tank is full. The operator opens valve No. 200 when the fill is nearly complete and observes when liquid is discharged, which indicates the full level has been reached. Also included in the instrument piping is a liquid- and gas-phase line used to measure contents and pressure.

Control of pressure between refills is accomplished by the combined actions of the pressure building, economizer, and pressure-relief systems. The pressure-building circuit consists of components Nos. 500 through 503 and is driven by the difference in densities of the liquid and gas phases. It functions when product flows from the liquid-phase line, is vaporized in the pressure-building vaporizer No. 503, and returns to the gas space. This system is required when the demand for product at the use point is sufficient to cause the tank pressure to fall. Attention must be paid to the very low driving pressure in this circuit.

Product is normally delivered to the use point from the tank in liquid phase. In the case of low or intermittent demand, the product vapor pressure can increase above the delivery pressure. At this point pressure-building is no longer necessary, and it is desirable to withdraw product from the tank in gas phase. Product delivered in the gas phase will remove approximately five times the heat from the tank as the same mass withdrawn in liquid phase. A scheme to automatically switch to gas phase supply at high tank pressure is called an *economizer*. A siphon cycle economizer is illustrated in items Nos. 550 through 552, together with the siphon line inside the tank. When tank pressure is high, regulator No. 502 is closed and back-pressure valve No. 550 is open. The siphon is broken in this way, and gaseous product is withdrawn through valve No. 600. The siphon is reestablished at reduced tank pressure when the positions of valves Nos. 502 and 550 are reversed. There are alternative economizer designs, and care must be taken in selecting one because most are limited to low instantaneous flows.

The product is next vaporized and superheated in the vaporizer No. 601. Vaporizers are classified as *ambient* where the required heat is derived from the atmosphere,

or as *powered* where the heat is supplied from another source such as steam, electricity, or hot water. Relief valve No. 602 provides protection in the event of a blocked line condition, and special attention should be paid to the vaporizer power source in selecting this valve.

A low-temperature pipeline protection device is normally included downstream of the vaporizer to automatically shut down flow in the event of vaporizer failure. This shutdown device is the transition point between cryogenic and noncryogenic pipe design. In addition, a pipeline regulator is usually used to provide constant pressure in the pipeline. The low-temperature protection and pressure regulation module given as components Nos. 700 through 755 has emerged as the preferred way of providing these functions. Regulator No. 703 is pressure-loaded so that discharge pressure is approximately equal to the loading pressure as read on gauge No. 753. Temperature pilot No. 750 opens and reduces the loading pressure when gas temperature falls into the set control range, until No. 703 is completely closed.

HIGH-PRESSURE BULK CONVERSION SYSTEMS

In some applications, gas is required at greater than the working pressure of the tank. In such cases, it is pumped in the liquid state, vaporized, superheated to ambient temperature, and regulated to the required pipeline pressure. A bank of high-pressure receivers is usually included to match the demand to the pump discharge rate. The pump is typically a reciprocating single-acting design ranging in configuration from simplex to triplex. Figure C8.12 gives a typical flow diagram of a high-pressure conversion system employing a standard cryogenic storage tank. Item numbers referred to in the following discussion are given in this figure. Piping practice for much of the system remains unchanged from the low-pressure gas system just discussed. However, special considerations must be made for the piping both upstream and downstream of the pump to ensure proper system operation.

The fluid at the suction flange must be subcooled in order to meet the net positive suction head (NPSH) requirements. The degree of subcooling required ranges from 2 to 10 psi, depending on pump design, condition, and discharge requirements. The liquid at the bottom of the storage tank is normally subcooled by approximately the static head of the liquid phase above it. The suction piping must minimize both heat input and pressure drop to preserve the available subcooling. Pressure losses are primarily due to the fluid acceleration required by the reciprocating pump and may be calculated using classical analysis. Heat input generally increases with pipe diameter, but may be essentially eliminated by the use of high-performance insulation. Insulation should always be used where the tank working pressure is low, the demand is intermittent, or the pump discharge rate is low. It is used almost universally in hydrogen pumping systems.

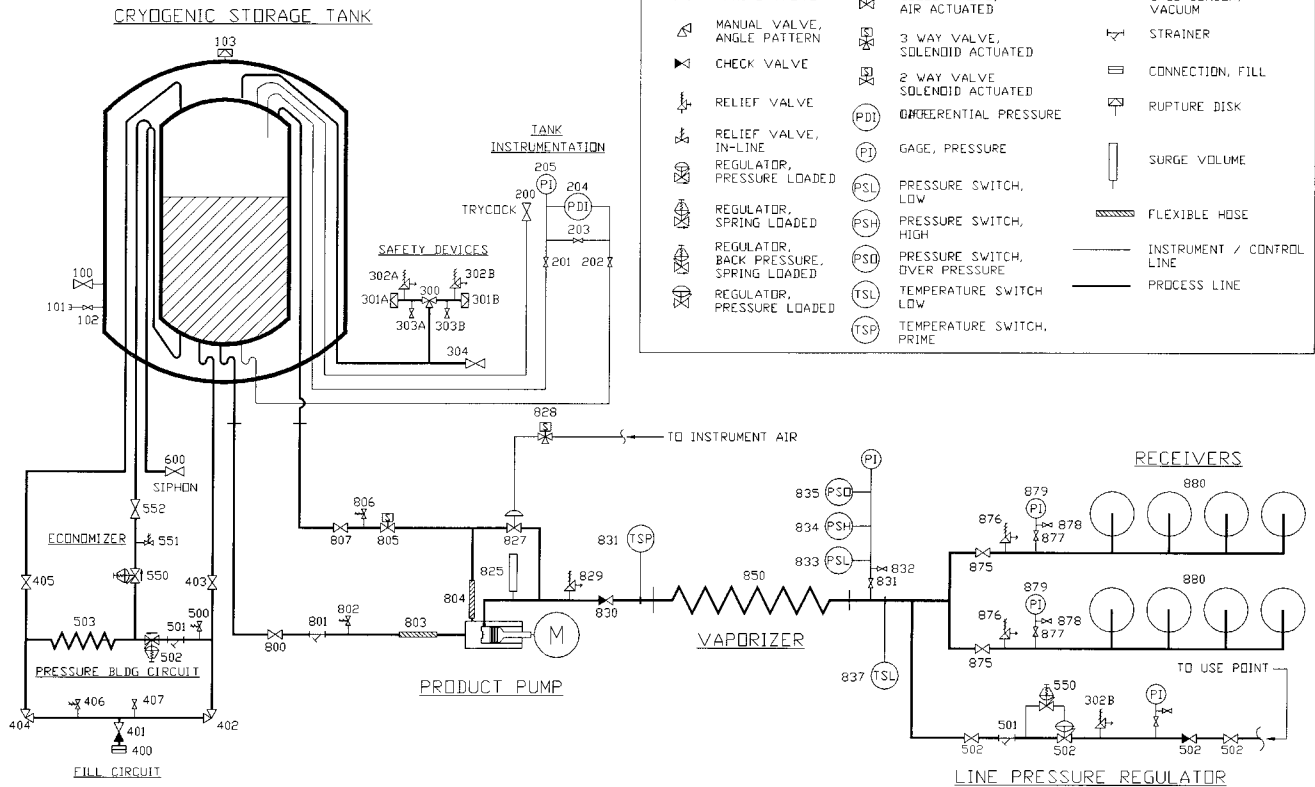
The pump is usually contained in a small vacuum-insulated sump, which is connected to the storage tank gas and liquid phases. As the first step in priming the pump, components Nos. 800 through 807 are used to fill the sump with liquid. The product vaporized in cooling these components is returned to the tank gas phase, increasing system pressure and thereby available subcooling. The second step is to run the pump with valve No. 827 open, which circulates liquid through the pump and discharges it to the tank gas phase, cooling the pump compression chamber. Finally, valve No. 827 is closed, forcing the pump to discharge against receiver pressure which is being held by check valves No. 830. Temperature sensor No. 831 is used to check for pump prime.


FIGURE C8.12 High-pressure bulk conversion system. *(Courtesy of Praxair, Inc.)*
FIGURE C8.13 Thermosiphon prime system for cryogenic pumps. *(Courtesy of Praxair, Inc.)*

C.442

The piping downstream of the pump must be designed for cryogenic temperatures and high pressures as well as the pulsations and vibration generated by the reciprocating pump. Temperature switch No. 837 is used to shut the pump off in the event of low pipeline temperature. Although noncryogenic materials may be used downstream of this sensor, it is common practice to use cryogenic materials for all high-pressure piping in the bulk delivery system.

Priming with this conventional piping arrangement works well while the liquid level in the tank is high. In this case a circulation flow develops, with fluid gaining heat in the path through the suction line, the pump sump, and the return line, which reduces its density. The lightened liquid flows up the return line and dumps into the tank. This circulation is driven by the difference between the static head due to the tank gas and liquid phase contents and that due to the less dense liquid in the return line. When the depth of the liquid contents is nearly equal to the height of the tank, this circulation flow quickly cools the pump and presents subcooled liquid at the suction valve to enable a good pump prime. However, circulation flow is reduced at lower tank levels because the static head of the tank contents is less, and priming becomes impossible. Figure C8.13 gives an improved arrangement in which both the suction and return lines are connected to the tank liquid phase through an extension of the vacuum jacket. The two penetrations are separated by a short baffle to promote convection within the tank liquid phase. The difference in height between the traps within the extension provides the head needed to start the circulation flow. The heat picked up in traveling to and from the pump sump reduces the density of the returned liquid, which maintains the circulation once started. This configuration allows priming to occur regardless of the tank level.

BULK LIQUID DELIVERY SYSTEMS

Where liquid-phase product is required at the use point, refrigeration rather than the fluid itself is usually of interest. Therefore, minimizing heat addition through the tank and piping is the primary design consideration in these systems. Some degree of pipe insulation can almost always be justified. The tank insulation performance is also critical to satisfactory system operation.

Ideally, the tank should be elevated so that the entire pressure requirement can be provided by the static head of the tank contents. This eliminates the need for pressure building in the storage tank, which can easily represent several times the heat load from all other sources. A horizontal tank is preferred to a vertical tank, in this case, both because the elevated foundation is less expensive and because the variation in static head, as the contents are withdrawn, is reduced. Where pressure building is required and the tank will not be elevated, a vertical tank is preferred to minimize heat transfer through the gas to liquid interface area of the vessel.

In spite of the efforts, the fluid normally arrives at the use point with at least a small gas component. Normally, conditioning by a subcooler, phase separator, or similar equipment is required to achieve satisfactory process control. This hardware is located at the application and at a minimum delivers saturated liquid by venting the gas that is generated in the piping system.

Figure C8.14 illustrates a self-contained system that delivers subcooled fluid. It consists a of heat exchanger formed by a tube within a tube, called an *in-line subcooler* because it replaces a section of the supply line. It is arranged so that the
FIGURE C8.14 Inline cryogenic subcooler. Courtesy of Praxair Inc. (*Covered by U.S. Patent No. 5477691.*)

main product stream flows through the inner tube, and control valve No. 200, located at the discharge end, emits a small portion into the annular space. This control valve is actuated by the difference between the vapor pressure of bulb No. 256, located in the vent, and the reference pressure set by regulator No. 251. When the vapor pressure of the vent fluid rises above the reference pressure, the control valve opens. The reference pressure is selected to ensure that cold gas—but not liquid—is emerging from the vent. The temperature of the liquid in the annular space is reduced, since the pressure is maintained at a near-atmospheric level. Liquid flowing through the inner tube is cooled by the annular stream.

MOBILE EQUIPMENT SYSTEM

R. C. Cipolla
Consultant
Trucking Operations
Praxair, Inc.

Bulk atmospheric gases, oxygen, nitrogen, and argon are transported as liquids in various styles of double-walled tank trucks. This section presents the most common semitrailer-style transport vehicles used for the distribution of atmospheric gases.

A doubled-walled cylindrical tank truck has a product tank, or inner pressure vessel, enclosed in an outer casing or jacket. The inner pressure vessel is designed, manufactured and tested to meet requirements of Sec. VIII of the ASME Boiler and Pressure Vessel Code. The casing or jacket is designed to the requirements of CGA-341, Standard for Insulated Cargo Tank Specification for Cryogenic Liquid, Compressed Gas Association. The annular space between the inner pressure vessel and casing is insulated and evacuated in order to minimize the amount of heat leak from the casing shell to the cryogenic liquid. Heat transferred to the product will result in a pressure rise, with the eventual release of product. The inner pressure vessel is normally supported or attached to the casing at or near the inner pressure vessel heads. The upper coupler king pin, landing gear support legs, and tandem axle assembly for the cryogenic semitrailer are standard automotive components available to the trucking industry.

Atmospheric gases are typically transported in low-pressure semitrailers equipped with an on-board pumping system used for off-loading the product to a customer storage tank. This pumper-style semitrailer allows for a maximum payload at a gross combination weight limit of 80,000 lbs (36,300 kg)—the road limit for a five-axle tractor-trailer combination. Inner pressure vessels are rated for a maximum allowable working pressure of from 40 to 60 psia (276 to 414 kPa) and constructed from AISI type 304 stainless steel or AA-5083 aluminum alloy (ASTM B-209). Casings are constructed from either carbon steel or aluminum alloys. Carbon steel casings are used along with stainless inner pressure vessels, and aluminum casings are matched to aluminum inner pressure vessels. A lightweight casing design can be achieved by providing closely spaced circumferential ring stiffeners. These ribs reinforce the cylindrical casing section against the external pressure load which results from the evacuation of the insulation or annular space.

Atmospheric gases have different product densities, which will in turn result in different-sized product-optimized semitrailers. When optimized for an 80,000 lb [36,300 kg] road limit, a nitrogen-sized semitrailer has a volume of about 8000 gal (30.3 m³); an oxygen semitrailer about 6000 gal (22.7 m³); and an argon semitrailer about 4500 gal (17.1 m³).

Liquid oxygen, nitrogen, and argon are exempt from the U.S. Department of Transportation (DOT) hazardous material regulations for design requirements of the semitrailer or package when the product pressure is maintained at less than 40 psia [276 kPa] during transportation. However, DOT markings and shipping preparation, along with regulations pertaining to the trucking components such as braking and lighting systems, are all considerations when designing a cryogenic transport. Basic requirements for vessels, structural supports, structural protection, and external piping are covered by CGA-341 specifications.

Piping systems for cryogenic transports can be separated into two categories: *internal piping,* which includes piping internal to the inner pressure vessel as well as annular space piping; and *external piping,* which includes all piping exterior to the casing envelope. Both internal and external piping systems are normally fabricated with butt-welded joints.

INTERNAL PIPING

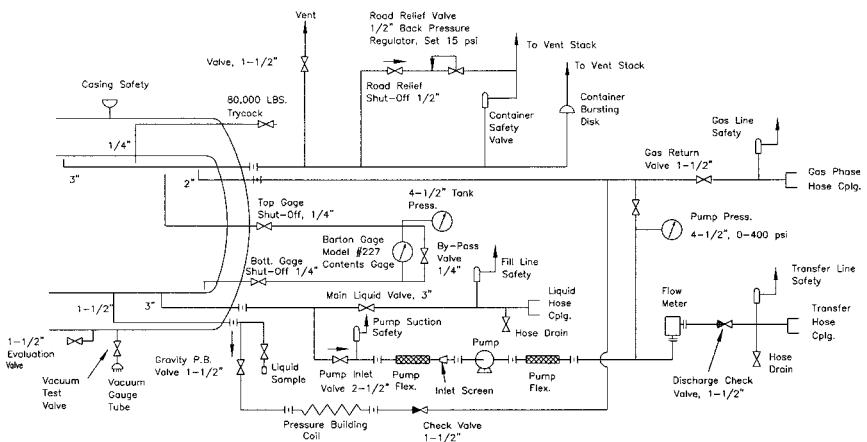
An internal piping system is constructed from stainless steel for stainless inner pressure vessels and of aluminum for aluminum inner pressure vessels. A typical internal piping arrangement has the piping penetrating the vessel walls through the rear casing head, as compared to a location on the cylindrical portion of the vessel. (See Fig. C8.15 for a typical piping schematic.) Piping sections inside the inner pressure vessel are not subject to an internal pressure loading. Design


FIGURE C8.15   Schematic of typical internal piping arrangement.

considerations for piping supports and attachments include loadings imposed by road vibration and thermal contraction due to temperature as low as $-320.4°F$ ($-195.8°C$).

Annular space piping configurations must have consideration given to heat leakage, flexibility, and trapping of liquid or gas. Since heat leakage to the cryogenic liquid is primarily by conduction down the pipe wall, the length of the piping run is of importance. Stresses induced by thermal contraction of the line or movement of the inner pressure vessel relative to the casing are typically accommodated by providing adequate piping flexibility in the form of loops and bends. Stress levels due to flexibility are generally kept to within the allowable limits imposed by ASME B31.3, Process Piping. Piping bellows to accommodate thermal displacements are not generally considered an acceptable way of providing flexibility to annular space piping. Road vibrations have proven to be detrimental to bellows-style fittings.

Testing of internal piping systems includes pressure, leak, and other examinations when required by codes. Pressure-testing procedures follow ASME B31.3 requirements. Nozzle penetrations at the inner pressure vessel wall may require examination of the welded joint using dye-penetrant techniques. Annular space piping is thoroughly leak tested, since any leaks would deteriorate the vacuum condition within the insulation space. A helium mass spectrometer technique is the most common method used for vessel and piping leak testing.

EXTERNAL PIPING

The external piping system is commonly located inside an operating compartment at the rear of the semitrailer; however, the pressure-building coil is located under the semitrailer forward of the tandem axle assembly. The rear grouping has accident protection features provided by the tandem axle subframe, rear bumper, and the piping compartment.

Stainless steel external piping systems are used on all transports regardless of inner vessel construction, with the exception of the pressure-building coil. The coil is normally constructed of aluminum extruded-fin tubing, which is flanged to stainless steel inlet and outlet piping. The function of the coil will be discussed later. Valves, gauges, and other instruments and controls are not necessarily constructed from stainless steel materials. Bronzes, copper alloys, and aluminum alloys are used for various component parts. Internal and external piping runs are joined at the casing penetrations with piping flanges. For aluminum vessel designs these flanges provide a simple way of connecting aluminum internal lines to stainless steel external lines.

As Fig. C8.15 schematically illustrates, cryogenic semitrailers typically have two liquid phase lines. The first piping run is used to fill the trailer at the production plant and to unload the trailer using the off-loading pump. The second liquid line is used for the pressure-building system. Pressure in the inner pressure vessel can be increased by vaporizing a small amount of liquid. The coil with a large heat transfer surface can readily vaporize liquid and return the warmed gas to the ullage space of the trailer. This pressure buildup is performed prior to and during the off-loading process in order to maintain adequate suction pressure for the centrifugal transfer pump.

Gas-phase piping includes a pressure-relief device line which directly communicates with the vapor or gas space near the midpoint of the top centerline. A spring-

loaded pressure relief valve and a rupture disk device are normally provided on the cryogenic semitrailer. These relief devices are designed to maintain pressure at a safe level under emergency conditions, including exposure of the vessel to a fire. Pressure-relief devices are designed to the requirements of Section VIII of the ASME Boiler & Pressure Code as well as CGA pamphlet S1.2, ''Pressure Relief Device Standards—Cargo and Portable Tanks for Compressed Gases.'' The same piping run is also used to provide for a manual vent system and a *road relief* circuit. The road relief valve, typically set at about 30 psia (207 kPa), controls the inner vessel pressure during transportation. Venting of product when the pressure reaches the road relief valve setting can occur. A shutoff valve upstream of the road relief allows isolation during off-loading and, therefore, permits the buildup of pressure to an operating level near the working pressure of the inner pressure vessel.

A second gas-phase circuit has multiple uses as a gas-phase outlet, pressure-building coil return, and a transfer pump recirculation line.

An optional sparger, or gas-phase fill header, has various uses. A typical design has a pipe running along the top of the inner vessel with a series of holes which act as spray nozzles for the liquid. With this line teed from the main fill line, transfer of liquid to the trailer can occur in an all-liquid phase, all-gas phase, or any combination. Gas-phase filling of an empty trailer through the sparger will cause a partial collapse of the gas pressure. This pressure reduction by collapse eliminates product losses that would occur by manually venting the pressure from the vessel. A sparger also provides a means of uniformly cooling down or shrinking a warm inner pressure vessel. Uneven shrinking of a inner vessel from near ambient to liquid temperatures can cause serious structural damage to the vessel, supports, or piping.

Inner vessel pressure, transfer pump discharge pressure, and liquid contents are monitored with trailer-mounted gauges. A differential pressure indicator is the most common device used for contents measurement. Liquid and gas taps are provided for this gauge.

Sampling of product in the inner pressure vessel is necessary in order to determine the level of product purity. A liquid tap typically teed externally to a liquid line can be used for sampling.

The liquid fill level can be detected by a small-diameter fixed-length dip tube. Flow of liquid through the line indicates the liquid level in the tank. If the semitrailer is used to transport various cryogenic liquids, dip tubes positioned at different levels would be provided.

As previously stated, the annular space is evacuated. Pressure levels below 0.04 in (1×10^{-4} meter) of mercury are achieved by pumping down the space through a line equipped with a shutoff valve. A filter on this pipe eliminates problems with the insulation material being carried to the valve or pump. The vacuum level can be monitored using the trailer-equipped thermocouple gauge tube. Vacuum level is determined by a portable vacuum meter.

Cryogenic piping must be protected from overpressurization in any piping section which can be isolated. After liquid or gas has been transferred, the cold product warms up and builds pressure which can exceed the bursting pressure of the pipe or fittings. For this reason, *block line safety devices* are a mandatory feature in cryogenic piping circuits.

Thermal contraction of external pipes can cause high forces when constrained. Typically, centrifugal transfer pumps and meter systems are protected from these forces by expansion bellows in the inlet and discharge piping. Piping bellows are made from corrugated stainless steel hose.

ULTRA-HIGH-PURITY PIPING

Raymond Dale Woodward
Manager
Praxair Semiconductor Materials
Praxair, Inc.

Ultra-high-purity (UHP) piping systems are found in gas and liquid supply systems used in the fabrication of electronic semiconductor chips and other related devices. The requirements for purity in UHP systems typically involve contamination levels of less than 1 part per billion (ppb) of foreign materials.

Semiconductor fabrication involves forming alternate layers of very fine lines of semiconducting material on the surface of nonconducting material such as silicon. The lines form miniature ultra-large-scale-integrated (ULSI) electronic circuits on a small silicon chip. Many small chips are simultaneously fabricated on a single silicon wafer. The line or feature size of ULSI chips approaches 5 μin (0.13 μm) or less. Any particle one-tenth of the line size can cause a defect in the circuit, resulting in chip destruction. To keep the percentage output yield of defect-free chips high, the gases and liquids used in the fabrication of ULSI circuits must be very pure and free of particulate contamination.

The present requirements for gas purity are that trace gas contamination must be held to the parts-per-trillion (ppt) level. For particulates, contamination with particles greater than about one-tenth the semiconductor feature size must be held to less than 5 particles/ft^3 (190 particles/m^3) of gas.

GENERAL GAS SUPPLY SYSTEM DESCRIPTION

Semiconductor manufacturers require UHP gases at the point of use inside their facilities (fabs). In most industries, a gas supplier is only required to supply gas to some interface point near the customer's plant boundary. However, for ultraclean systems, the gas supplier is typically required to provide UHP gas to the final point of use. This means that the gas supplier is responsible for the UHP piping system within the customer's fab, in addition to the gas storage and conditioning system at the fab boundary. This ensures that the gas meets the customer's requirements at the point of use.

Gas supply systems can range from single small cylinders to large air separation plants. The specialty gas requirements can usually be met with high-pressure gas cylinders, although bulk specialty gas supply systems are becoming increasingly more common. Bulk gas supply requirements are usually met by a combination of on-site production facilities and liquid storage pad packages. However, regardless of the gas supply system size or complexity, it must be able to reliably supply gases in UHP condition to the customer.

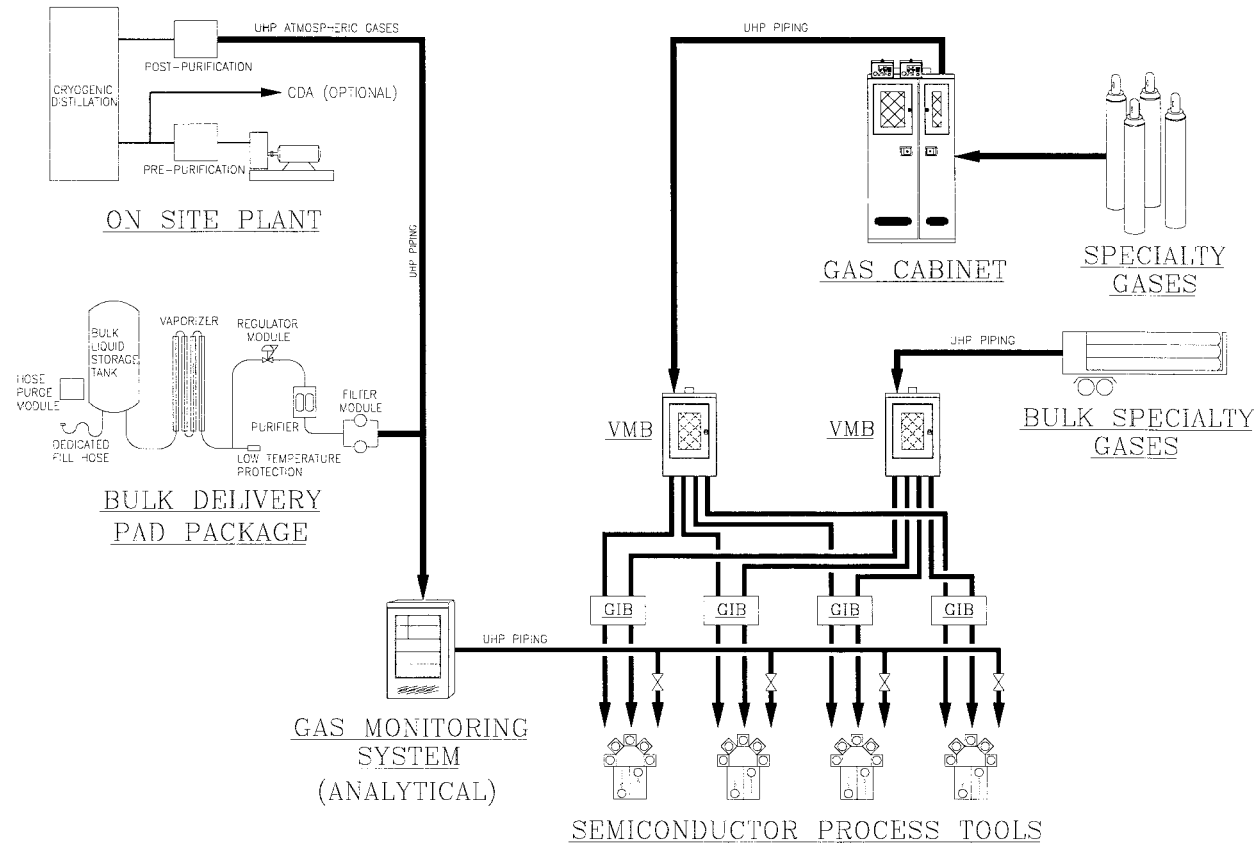
Typical facilities require most, if not all, of the supply systems described above. High-volume consumption gases such as nitrogen and clean dry air (CDA) are usually supplied from an on-site plant. A typical on-site system may consist of air


FIGURE C8.16 Ultra-high-purity gas supply system. *(Courtesy of Praxair, Inc.)*

compressors, a cryogenic distillation column, purification equipment to remove selected impurities from the air or product streams, control systems to regulate flow and pressure of products delivered to the customer, filtration systems to remove particulate contamination, and a piping system to deliver the gas to the customer's point of use.

Other bulk gases and backup supplies for nitrogen are supplied from bulk liquid storage pad packages. These systems typically consist of a bulk liquid storage tank, a vaporizer to convert the liquid to gas, control systems to regulate the flow and pressure delivered to the customer, gas purifiers to remove any residual trace gas impurities, filtration systems to remove particulate contamination, and a piping system to conduct the gas to the customer's point of use.

In some cases, liquid supply is needed also. Usually the liquid is transported to the point of use in a small storage vessel or dewar. For some supplies, the liquid may be piped directly to the point of use using UHP liquid vacuum-insulated piping (VIP). In these instances, the inner carrier pipe of the VIP must meet the same requirements as the UHP gas piping.

Most specialty gas supply systems are from special high-pressure, high-purity cylinders, or from bulk specialty gas supply systems if their usages are high. Bulk specialty gas supply systems replace the high-pressure cylinders typically used with larger volume containers such as high-pressure modules or tube trailers or special bulk containers for liquefied specialty gases. Specialty gas supply systems typically consist of the gas source (cylinder or bulk) with the appropriate gas cabinet or gas panels with controls to regulate the flow and pressure to the customer; valve manifold boxes (VMBs) or panels to distribute to multiple use points where appropriate; gas isolation boxes (GIBs) to isolate sources of gas at a point of use; and interconnecting piping. Piping may be single-wall or double-contained, depending on gas characteristics and local codes and regulations. These installations may include purifiers where appropriate.

A schematic representation of a typical supply system to a fab is shown in Fig. C8.16.

SYSTEM DESIGN AND FABRICATION REQUIREMENTS

UHP gas supply systems must meet extremely stringent design, fabrication, installation, checkout, and commissioning requirements. A brief description of typical requirements is presented in this subsection.

Design Requirements

Designers of UHP gas systems need to consider many items often thought to be unrelated to the piping design. Obviously, the designer must consider the basic system requirements such as flow and pressure. Basic material compatibility within the system and especially with the gas itself must also be considered, since many of the gases are toxic and/or corrosive and/or flammable. But the designer must also look at the entire facility design philosophy and be familiar with the basic safety considerations, codes, and regulations. What quantities of gases will be permitted on-site for use and for storage? How will hazardous gas monitoring and toxic gas

detection be handled? Answers to these questions may alter gas systems design, determine which systems are to be double-contained, and how the containment system is to be installed and monitored.

Once these considerations are resolved, then the system designer can proceed and address such things as purity and contamination issues. Traditional industrial gas systems are considered clean when contamination levels meet parts-per-million (ppm) requirements. In the semiconductor industry, however, contamination levels must meet purity requirements on the order of less than 1 ppb. For instance, particulate cleanliness may require the following specifications:

< 10 particles/ft$^3 \geq .01 \mu$m in size $(< 380$ particles/m$^3 \geq 0.4 \mu$in in size)

< 1 particle/ft$^3 > 0.1 \mu$m in size $(< 38$ particles/m$^3 > 4 \mu$in in size)

Trace gas impurities are typically trapped within parts of the system during component manufacture and system assembly, and later released into the process stream. Joining materials, laps within joints, screw threads, and other cavities can trap moisture, welding gases, and other contaminants and can become long-term outgassing sources, often referred to as virtual leaks. For this reason, such geometric discontinuities must be eliminated from the system by design and through proper fabrication and installation practices.

Particulate contamination is found in many of the same places as the trace gas contaminants (i.e., crevices, joints between mating pieces, dead-end legs off the process stream). In addition, particulates become trapped within indentations and small voids that exist within the natural roughness of most materials. For this reason, all pipe and component surfaces exposed to process gas streams are polished as smoothly as possible to eliminate contamination from this source. Industry standards typically require surface finishes to be electropolished to a value of less than 7 μin Ra (0.28 μm Ra) roughness. Electropolishing also leaves an enriched chromium oxide layer on the surface. Alternative surface treatments such as special passivation techniques are sometimes used in selected system designs, especially for corrosives.

Particles can also be generated by erosion of the process stream over surfaces of system components in the flow path. Also, contact between moving parts scrapes off metal particulates from contacting surfaces. Therefore, sharp edges, rough surfaces, and sliding or contacting surfaces must be eliminated from the design.

Many process conditions promote the generation of particulates or promote the release of particulates from component surfaces. High process gas velocities erode particulates from component surfaces. Vibration or mechanical shocks shake loose particulates resting on process flow surfaces. These actions can either be caused by external conditions such as adjacent rotating or reciprocating machinery that is not properly dampened or isolated from the system, or from valve or regulator operation within the system. Valve or regulator operation may also generate particles resulting from contact and erosion of moving surfaces.

Finally, transient process conditions can also generate contamination. Variations in system temperatures may enhance release of trace-gas impurities or cause thermal expansion and contraction that could cause particulate release. Outgassing and particulate shedding upon system start-up can also release contamination into the process stream.

The basic design concept in UHP gas systems design is to *design clean, build clean, and operate clean*. The UHP gas systems should be designed to be leak-free, outgas-free, deadspace-free, and particle-free. Component selection should include a thorough evaluation of all the components in static, dynamic, and impacted conditions.

Materials of Construction

The obvious starting point in meeting requirements of this type is to use the right materials. All materials must be compatible with the process gas itself in order to avoid such problems as corrosion. In addition, all materials in the system must be compatible with each other to avoid chemical or electrical reactions between different materials and again to prevent corrosion problems.

The only material generally acceptable for fabrication of bulk gas piping and system components is 316L (low carbon) stainless steel. In addition, the steel must have low sulfur content in order to obtain better weld qualities. Where 0.035 percent sulfur content is acceptable for normal applications, the sulfur content for UHP systems should be in the 0.003 to 0.017 percent range.

As the semiconductor industry continues to reduce feature size and line widths, component and tubing manufacturers have to evaluate and address ever-increasing concerns over not just the sulfur content, which impacts both weldability of the system and machinability of the component, but also such concerns as nonmetallic inclusions in the base steel. This has led to the increasing use of vacuum arc remelt (VAR) or VIM/VAR and other specially produced 316L stainless steels.

Additionally, gas-absorbing materials (especially nonmetallics) must be avoided. Contaminant gases dissolve into many materials of construction. This occurs primarily in nonmetallic components such as valve seats and filter cartridges, but it can also occur in the metallic parts. Since so much steel exists in the system components, dissolved gases within these components could present a serious contamination problem. Special manufacturing procedures, as well as final cleaning and conditioning procedures, must be considered to reduce dissolved gases within steels and other metals used in ultraclean systems.

Many nonmetallic materials, particularly those used in the filter cartridges, tend to dissolve gases, primarily water vapor. This is one of the most serious contaminants in semiconductor fabrication. Special materials or special procedures to remove the contaminants are necessary to prevent these contaminants from entering the system.

Any material not used in the particular semiconductor fabrication step could cause unacceptable contamination. Heavy-metal ions cause severe problems when they enter the semiconductor fabrication process. Metals such as sodium used in the fabrication or cleaning process of other metallic parts could leave undesirable metal ions on or within the parts. These ions must also be eliminated as much as possible.

Ideally, all pipe and components for one piping run should be of a single heat. This ensures that chemical properties of the two pieces at a weld joint are similar. In practice, this is often impossible. Most important is to ensure that all tubing and components have similar chemistries to guarantee weldability. If it is necessary to use a component with a dissimilar chemistry, care must be exercised to ensure weldability and integrity.

Standard elastomeric seal materials such as Teflon®, Kel-F™, etc., are acceptable for seals. However, if metallic seals can be designed into the system, greater leaktight systems are possible. For this reason, valves with diaphragm or bellows seals on the stems should be used to totally isolate the product stream from external contamination.

Purity and cleanliness are important. Outgassing of dissolved or adsorbed gases must be reduced to very low levels. This is sometimes accomplished by special material processing such as passivating steels in acid mixtures or by subjecting steels to a double-melt process. It may be necessary to "bake out" some of the

components or the entire system, if the contamination is serious, to drive off the adsorbed gases.

Welding

Conventional welding practices such as lap and socket welding are unacceptable for UHP application since they do not permit full penetration and leave overlaps and crevices that are very difficult to clean, creating virtual leaks. Hand welding, which leaves rough surfaces on the interior, is also unacceptable. Rough surfaces, as well as discoloration from the heat-affected zone, are sources of particulate generation. Rough surfaces also retain more moisture.

All process line tube joining is done by autogenous orbital butt welding performed by special automatic process welding machines. The joint to be welded is purged both internally and externally with high-purity inert argon to avoid oxidation of the hot weld surface. A good orbital weld must be free of stain on the product surface, can have no undercut or concavity of the weld area, and must have a generally smooth process surface finish. Weld buildup and metal puddling are not acceptable.

Weld samples (or coupons) must be made at the beginning and end of each shift or whenever the weld machine variables or parameters such as line size or heat number are changed. These weld coupons must be marked with the welder's name, and a log of all sample welds must be maintained.

Weld requirements for field welds are the same as for shop welds. That is, all welds must be autogenous orbital welds wherever possible. All welding and weld preparation takes place in either a clean room or a controlled work area to maintain system cleanliness. Field welders must pass the same certification requirements as shop welders.

Fabrication and Installation

Fabrication and installation procedures for UHP systems are not dramatically different from normal industrial practice, except for cleanliness. Because of such similarity, cleanliness becomes analogous to quality or safety in that it involves a culture rather than a procedure. Procedures are easy to establish; cultures are not. A culture requires a completely new approach to the fabrication and installation process.

Fabrication of UHP gas supply systems must be conducted in as clean a manner as possible. The work should be done in an enclosed shop where clean conditions can be controlled more easily. Generally, it is less expensive to build as much as possible in the shop. To provide the cleanest conditions possible, all component fabrication must be conducted in a clean room, preferably at least Class 100 quality, as determined by federal standards.

The UHP gas systems must be fabricated as a system. Each step in the fabrication and installation process involves UHP argon purges. Once the fabrication process begins, the entire system should be kept under a UHP argon purge until the system is ready for introduction of the process gas at start-up.

Since cleanliness is a prime requirement, the cleaning process is one of the most critical steps in all stages of fabrication and assembly. As stated earlier, in addition to general cleaning, cleanliness involves polishing (i.e., mechanical, chemical, or electropolishing). All parts must be cleaned at critical steps in the manufacturing process and must be kept clean between fabrication steps and during shipping.

The best method of cleaning is to electropolish the component. This procedure actually removes some of the surface metal, along with any contaminants on the surface.

All gas supply system components such as valves and regulators should be fabricated in a shop where cleanliness can be controlled. Also, some subassemblies and piping "spools" should be fabricated in a cleanliness-controlled shop area. However, fabrication of the gas distribution piping to interconnect the various components is usually done in the field at the job site. This exposes the components and piping pieces to contamination from the atmosphere. Therefore, the division of work between the shop and the field must be carefully considered.

Components must be packaged to ensure the cleanliness level is maintained. Double-wrapping in plastic bags is a minimum requirement. Piping must have the ends capped. The tubes must be pressurized with pure nitrogen or argon, or sealed in a pressurized container. Consideration must be given to both the final destination and the route of transit. Changes in altitude, and hence pressure, could damage packaging.

Once the clean components arrive at the plant site, they must be stored so that the cleanliness of the components is maintained. While waiting for installation, all components must be stored in their protective wraps, and only opened when ready to be finally installed.

Special care and procedures must be used to install the component without introducing unnecessary contamination. It may be necessary to provide a portable clean room at the installation site to perform some of the required on-site fabrication in as clean an environment as possible. The clean room should be at least Class 100 quality. As much of the subcomponent assembly as possible should be done in this portable clean room. After subcomponent fabrication, all open ends of "spool pieces" must be covered with an anti-static polyethylene or anti-static mylar wrap and kept sealed until just prior to welding into the final assembly.

It may also be necessary to construct a clean environment around some system parts to ensure that minimum contamination is introduced as final component installation is performed.

To reduce the possibility of atmospheric contamination entering the partially fabricated piping system, the portion of the system that has been completed must be continually purged with a pure, inert gas filtered to submicrometer levels. Since inert gases are used for purging and for maintaining clean conditions, safety provisions must be made to protect personnel against asphyxiation.

In addition, all tools that might come in contact with process gas surfaces must be maintained in as clean a condition as possible. These tools must be specially cleaned; used only on the clean system; and stored in the clean room or a clean environment.

QUALITY ASSURANCE

An independent quality assurance representative should be used to review and approve all installation procedures for the construction of a gas supply system, and to conduct certain tests and inspections as agreed to by the owner. These procedures and tests should include the following activities:

1. Inspect the precleaned, UHP components prior to shipment.

2. Review and approve written procedures for the fabrication and field installation of the UHP piping system.

3. Qualify personnel to work on the UHP piping system, including welder qualifications.

4. Approve weld coupons prior to actual production welding each day.

5. Observe and inspect actual construction work to ensure that agreed-upon procedures are being followed.

6. Witness leak tests on the UHP piping system.

7. Conduct or witness analytical construction verification testing of the gas system for moisture, oxygen, hydrocarbons, and particulates during construction.

To ensure that minimal contamination migrates into the UHP gas supply system during operation, the gas supply piping system must be as leak-tight as possible. Extensive helium leak testing using either a helium-argon test mixture under pressure on the inside of the piping (outboard test) or pure helium on the outside with a vacuum on the inside of the piping (inboard test) must be conducted in which each component, piping system weld, and mechanical joint is separately tested. Specification of leak rates of less than 1.27×10^{-6} ft^3/hr (10^{-9}/sec) at one atmosphere of helium are typically required. Use of either the inboard or outboard test method may be acceptable; each has specific benefits and problems. The designer must take into account which method is to be used.

Construction verification testing of the system may be required at several points in the project installation schedule in addition to certification at completion. The quality assurance representative should also oversee the final analysis of the UHP system to verify that it meets all product purity specifications.

CHECKOUT AND START-UP

The same care that was taken in the design and installation of the UHP gas system must be extended to system start-up. If proper precautions are not taken, all the benefits of a UHP installation can be nullified with the introduction of gross contamination into the system. Typically, the gas supplier oversees the start-up of the gas supply and distribution systems in coordination with the customer. Great care must be exercised so as not to contaminate the system.

The entire system must be systematically purged of the weld argon and test gases and replaced with product gas. For example, if an outboard helium leak test was conducted, it must be recognized that the helium has permeated into the elastomeric materials such as valve seats, and that trapped gases may be downstream of isolation valves that were shut off to isolate segments of the system during testing.

Finally, since the output yield of semiconductor fabs is so dependent upon the purity and cleanliness level of the gas supplies, knowledge of system operation and cleanliness level is necessary at all times to warn of poor operation, back-contamination, or impending performance degradation. Continuous, automatic, computer-controlled, analytical monitors have been developed to very rapidly survey all critical operating parameters, gas purities, and particulate cleanliness. These monitors analyze system maladies and either send out alarms with suggested corrections or correct system adjustments automatically.

CHAPTER C9
REFRIGERATION SYSTEMS PIPING

William V. Richards
Refrigerant Consultant
Lincolnshire, Illinois

The broad term *refrigeration* refers to a general science concerned with the use of producing temperatures below normal for commercial or other useful purposes. Refrigeration piping is used in conjunction with refrigeration equipment. Refrigerants are fluids which absorb heat by evaporating at a lower temperature and pressure and transfer heat out when they condense at a higher pressure and temperature. The increase in pressure necessary to elevate the temperature level is produced by a compressor of the reciprocating, rotary, or centrifugal type. In the case of an absorption system, the transfer of heat, thereby boiling the more volatile refrigerant out of a solution.

Fluids which do not change state are sometimes used to transfer heat in an indirect system. Such fluids are called *secondary coolants*. To be classified as a secondary coolant, the fluid must be used for the transfer of heat without a change in its state. Brine, a solution of salt and water, is a secondary coolant.

Many fluids have been used as volatile refrigerants in the evaporation, compression, condensing, and expansion cycle. This chapter will deal with application and structural design of piping for the more commonly used volatile refrigerants such as ammonia and some of the halogenated hydrocarbons. It will also cover general methods for other refrigerants where specific tables are not presented. Since volatile refrigerants are used in the liquid, vapor, and mixture phases, each of these will be treated separately.

Many fluids have been used for brines. Originally, the term *brines* applied to salt solutions such as calcium chloride or sodium chloride. The use of such salt brines permitted the transfer of heat at lower temperature levels without introducing refrigerant of the volatile type into refrigerated spaces. These brines were commonly used for cold storage plants, ice plants, or commercial and process refrigeration.

Solutions of glycols are also used as secondary coolants. Ethylene glycol and propylene glycol are most commonly used for this purpose. Several other compounds or mixtures have been developed specifically for the purpose of heat-transfer media. These compounds are specifically designed to have high thermal capacities, low viscosities, and other desirable properties for high heat transfer and low pressure losses.

Two major codes relate to refrigeration piping. One of these is the American Standard Safety Code for Mechanical Refrigeration. This code is reviewed and revised periodically. The most recent edition at the time of this writing was issued in 1994. This code is sponsored by the American Society of Heating, Refrigerating, and Air Conditioning Engineers and has been adopted by many states and munici-palities to be the existing law in these localities. This Code will be referred to frequently in this section and will be designated as ANSI/ASHRAE 15.[1]

Another important Code on piping is the American Standard B31 Code for Pressure Piping.[2] Section B31.5 covers refrigeration piping and relates to structural design rules, fabrication, construction, and testing. The code in this section will be referred to as the ASME B31.5 Code.

This section recognizes and uses the definitions included in Sec. 3 of ASHRAE 15. The definitions included in Sec. 500.2 of the ASME B31.5 Code are also used. In general, the definitions in these two Codes coincide with definitions in the ASME Boiler Code, Sec. VIII, usually called the Pressure Vessel Code.[3] In addition, the ASME B31.5 Code recognizes and refers to the basic definitions of the American Welding Society.

Other basic definitions accepted by the refrigeration and air-conditioning indus-try are given in ASHRAE *Terminology of Heating, Ventilation, Air-Conditioning and Refrigeration*, published by the American Society of Heating, Refrigerating, and Air Conditioning Engineers.[4]

REFRIGERATION CYCLES

Compression System

Figure C9.1*a* shows a typical single-stage refrigeration cycle plotted on a pressure-enthalpy chart. Figure C9.1*b* is a typical diagram of a single-stage compression system and shows a compressor, a condenser, an optional receiver, an expansion device, and an evaporator. The state points on the line diagram of Fig. C9.1*b* are numbered to correspond to the same points on the pressure-enthalpy chart of Fig. C9.1*a*.

In a typical system, P_1 represents the pressure in the evaporator corresponding to the temperature at which the refrigerant is evaporating. From point 1 to point 2, the refrigerant vapor is carried to the compressor in a suction line. The pressure-enthalpy chart indicates a small pressure drop in this line. From point 2 to point 3, the refrigerant vapor is compressed. The connection between points 3 and 4 represents the discharge, or hot-gas, line, and the pressure-enthalpy chart also indicates the pressure drop due to friction in this line. Desuperheating and condensa-tion of the refrigerant at constant pressure in the condenser occur between points 4 and 5. The liquid line is represented by the section between point 5 and point 6. From point 6 to point 7, there is a representation of the pressure reduction or ''expansion'' through the expansion device. From point 5 to point 8, the refrigerant is a mixture of liquid and vapor because of the expansion at constant enthalpy. At point 8, the liquid and vapor mixture enters the evaporator; heat transferred from the evaporator results in evaporation of the liquid in the liquid-vapor mixture and, as indicated, a slight superheating of the resultant vapor. At point 1, the cycle is completed.

In this chapter, the line between points 1 and 2 will be referred to as the *suction line*. The pipe or tubing between points 3 and 4 will be designated as the *hot-gas*

(a)

(b)
FIGURE C9.1 Compression refrigeration cycle. *(Courtesy Carrier Air Conditioning Co.)*

line. The piping between points 5 and 6 will be termed the *liquid line before expansion,* and that between points 7 and 8 will be called the *liquid line after expansion.*

Absorption System

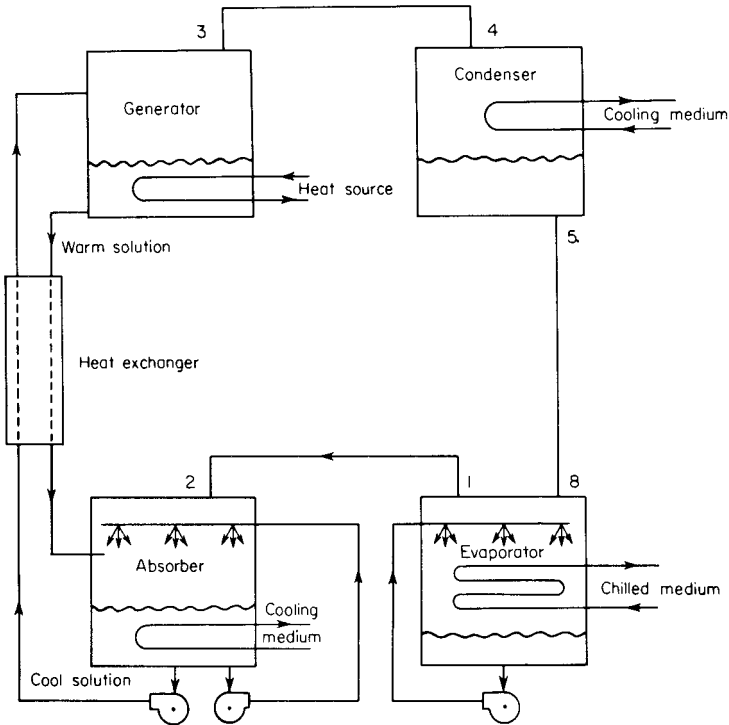
Figure C9.2 shows a typical piping arrangement for an absorption-refrigeration cycle in which a lithium salt solution is used with water as the refrigerant. In such


FIGURE C9.2   Absorption refrigeration cycle, lithium bromide type. *(Courtesy Carrier Air Conditioning Co.)*

a system, the absorber and generator serve the same purpose as the compressor in a compression system. The refrigerant is absorbed in solution at low pressure in the absorber and is pumped to the generator, where the refrigerant is boiled out of the solution at high pressure. The state points are numbered in Fig. C9.2 to correspond to the similar points of the compression system cycle in Fig. C9.1a.

For other types of absorption systems (such as ammonia and water), a rectifier or a fractionating-column type of purifier would be installed between the generator and condenser. Also, the evaporator might be remote or of some other type, such as a flooded cooler or a direct expansion type in which the refrigerant passes through coils.

In a consideration of the piping of an absorption system, the piping between points 3 and 4, 5 and 8, and 1 and 2 may be handled in a manner similar to those of a compression system when the different fluids and flow rates which might be encountered are taken into account. The solution lines between the absorber and generator and through the heat exchanger would be treated as brine lines in the case of lithium bromide or lithium chloride systems. For ammonia-water systems, properties of aqueous solutions of ammonia are available, and these lines would be desinged in the same manner as would be brine or water lines.

Present-day absorption-refrigeration systems are integrally designed as complete units, and in many instances the enitre assembly including the piping is made at the factory. For these reasons it is seldom necessary to consider piping for an absorption system as a separate design problem. However, the principles involved in this chapter could be applied to the corresponding sections of an absorption system.

Flow Rates

Refrigeration is usually measured in tons (kW) of refrigeration or in Btus per hour. The relationship between these is

$$1 \text{ ton of refrigeration} = 200 \text{ Btu/min or } 12,000 \text{ Btu/h} = 3.517 \text{ kW}$$

$$(1 \text{ kW} = 1 \text{ KJ/s} = 0.2843 \text{ Tons})$$

For selection of piping, it is necessary to relate refrigeration rate to flow rate of the refrigerant. Since the refrigerant changes state in the process, it is customary to calculate refrigerant flow in pounds per hour or per minute (kg/s). This weight flow rate for a constant rate of refrigeration will be constant throughout the system (for a single-stage system). The volume of refrigerant handled at the various points of the cycle can be determined if the density at these various points is known. Since the volume handled in a suction line is important not only for the piping selection but also for the compressor selection, charts are frequently made showing the cubic feet per minute per ton ($M^3/s \cdot kW$) of refrigerant gas or vapor at this point.

To calculate the flow rate of refrigerant for a given rate of refrigeration the following procedure is used:

$$\frac{\text{lb}}{(\text{min ton})} = \frac{200}{(h_g - h_f)} \tag{C9.1}$$

$$\left(\frac{\text{Kg}}{\text{s} \cdot \text{kW}} = \frac{\text{Kg}}{\text{KJ}} = \frac{1}{hg - hf} \right) \tag{C9.1M}$$

where h_g is the enthalpy of dry saturated vapor at the evaporator outlet pressure or temperature and h_f is the enthalpy of the liquid refrigerant at the expansion device inlet.

To calculate the flow rate it is necessary to have thermodynamic properties of the refrigerant available. After the mass-flow rate has been determined as shown in the equation, it is possible to determine the volume flowing at various points in the system.

If the specific volume of the refrigerant is known at the state point leaving the evaporator corresponding to point 1 in Fig. C9.1a, the volume at that point can be determined as follows:

$$\frac{\text{cfm}}{\text{ton}} = \frac{200\,V}{(h_g - h_f)} \tag{C9.2}$$

$$\left[\frac{\text{M}^3}{\text{s} \cdot \text{kW}} = \frac{V}{(h_g - h_f)} \right] \tag{C9.2M}$$

where V is the specific volume of the vapor at the evaporator suction temperature. For purposes of design, this value may be taken as the specific volume of dry, saturated vapor.

In the previous equations, h_g corresponds to the enthalpy of the refrigerant vapor at point 1 leaving the evaporator. In the flooded type of cooler, this state point is close to saturation, but for a direct-expansion coil-type evaporator, the vapor may be slightly superheated. For low amounts of superheat, it is permissible to ignore the superheat for purposes of selecting the piping, although this should not be done for compressor selection or for very accurate determination of the velocity.

The value h_f corresponds to the enthalpy of the liquid entering the expansion device. Some subcooling of liquid may exist at this point, in which case point 6′ would result in a more accurate figure. However, for selection of piping, it is customary to use the enthalpy of the saturated liquid at the condensing temperature (point 5) for determining the flow rate. Later considerations will show when the actual state of the liquid may have an effect on the liquid line size. A later example will illustrate methods of calculation for flow rate by weight and by volume in the suction line for a typical refrigerant.

Table C9.1 shows flow rates in pounds per minute per ton and cubic feet per minute per ton at the suction condition for three common refrigerants: ammonia, refrigerant R134a (tetrafluoroethane) and refrigerant 22 (monochlorodifluoromethane). This table is based on enthalpies read at saturated conditions of refrigerant vapor and liquid as previously mentioned.

The cubic feet per minute per ton (dm³ per second per kW) in the discharge line cannot be calculated readily because the actual temperature at the end of the compression is a function of the compressor design and efficiency and these will vary among various manufacturers. The discharge cubic feet per minute per ton (dm³ per second per kW) for single-stage systems can be approximated by the following formula:

$$\text{Discharge cfm/ton} = \text{suction cfm/ton} \times \frac{P_1}{P_2} \times 1.2 \tag{C9.3}$$

$$\left(\text{Discharge dm}^3/\text{s} \cdot \text{kW} = \text{suction dm}^3/\text{s} \cdot \text{kW} \times \frac{P_1}{P_2} \times 1.2 \right) \tag{C9.3M}$$

where P_1 = absolute pressure at suction
P_2 = absolute pressure at discharge

This formula is not exact, but it will serve as an approximation when it is necessary to determine approximate velocities in discharge lines.

ALTERNATIVE REFRIGERANTS

Because of the depletion of stratospheric ozone, which is partly attributed to chlorine released to the atmosphere from chloro-fluoro-carbon (CFC) chemicals, many alternative refrigerants made from fluorinated hydrocarbon gases are being evaluated within the refrigeration industry. The common CFC refrigerants R-12 and R-502 are no longer produced. The hydro-chloro-fluoro-carbon (HCFC) refrigerants, such as R-22, are to be phased out of production in the United States by the year 2015, and earlier phaseouts are scheduled in Europe.

The natural refrigerants ammonia (R-717), propane (R-290), and carbon dioxide (R-744) are being promoted in new applications because when released they do not contribute to ozone depletion or to global warming. In addition to the customary use of ammonia in industrial food processing and storage, ammonia is now being widely used in district cooling plants for cooling of commercial buildings. Some food processing plants, now using R-12, R-22, or R-502, are converting or planning to eventually convert to ammonia. Some new processing plants are being designed to use R-22 currently and to convert to ammonia in the future. Propane is now being used in domestic refrigerators in Europe and Asia. Carbon dioxide is now being used as a low-stage refrigerant in supermarkets.

In the United States, the Environmental Protection Agency evaluates and regulates substitutes for the CFC ozone-depleting chemicals. The Significant New Alternatives Policy (SNAP) rule lists substitutes for R-11, R-12, and R-502 in both retrofit and new equipment.

- For new centrifugal chillers which previously used R-11, R-12, R-113, R-114, or R-500, the substitute refrigerants are R-123, R-124, R-22, R-134a, R-227ea, R-717, and absorption systems.
- For new reciprocating chillers, which previously used R-12, the substitutes are R-22, R-134a, and R-227ea.
- For direct air-conditioning applications, previously using R-12, the popular substitute is R-134a.
- For cold storage and retail food refrigeration formerly using R-12 and R-502, the substitutes are R-22, R-134a, R-227ea, R-402A, R-402B, R-404A, R-507, and R-717 vapor compression.

For gauge pressure in psig, subtract 14.696: For gauge pressure in kPa, subtract 101.33. For temperature in °C = 5/9(°F-32)

The marketplace is determining the popular substitutes for the CFCs. The HCFCs such as R-22, R-402A, and R-402B will be eventually phased out. The present choices being made in the United States, as reported in the commercial news, are:

- R-134a and R-22 to replace R-12 in refrigeration systems
- R-134a, R-407C, and R-410A to replace R-22 in air-conditioning equipment
- R-404A, R-407A, R-507, and R-717 to replace R-22 and R-502 in refrigeration systems

Tables C9.2a and C9.2b show the temperature-pressure relation for the main candidates. The pressures shown may be expected in refrigerant lines when both liquid and vapor are present. Propane (R-290) is included; however flammable options are not used in equipment exposed to the public in the United States because of liability laws. Table C9.2b shows the pressure-temperature relation for blends of two or more components. These mixtures have temperature changes, called *temperature glides,* during vaporizing and condensing. Note that R-404A and R-410A have very little temperature glide, so that they may be treated similarly to azeotropes (mixtures with a constant boiling temperature, such as R-507). These and similar mixtures with very small glides are informally referred to as *near-aseotropic refrigerant mixtures* (NARMs). R-407A, R-407C, and many other blends have significant temperature glide. With careful design of evaporators and condensers, the glide can be used to improve efficiency. However, blends with significant temperature glide must be charged into the system in the liquid phase in order to maintain the percentage of the components. Also, blends with glide are not suitable for use in flooded evaporators.

PRESSURE DROP IN REFRIGERATION PIPING

There are two separate tasks when designing a refrigeration piping system. The first task is to select the size of a pipe for a given flow. The second task, determining pressure drop, is accomplished after the pipe size is selected. Both tasks use the same equation, which describes the pressure drop in fluid flow within piping.

However, the tasks must be addressed separately. Customary piping tables, such as C9.4 through C9.9, list capacities at specified temperature or pressure drops per unit length of piping. These tables are an aid to determining the pressure drop after the equivalent length is known. But the equivalent length depends upon the diameter selected. Thus it is clear that the listed capacities are only correct for the unit length basis used in developing the table and are not to be used as recommended capacities.

Darcy-Weisbach Equation

The pressure drop of most fluids in piping is described by the Darcy-Weisbach equation:

$$\Delta p = f\left(\frac{L}{D}\right)\left(\rho\frac{V^2}{2g}\right) \tag{C9.4}$$

$$\left(\Delta p = f\left(\frac{L}{D}\right)\left(\rho\frac{V^2}{2}\right)\right) \tag{C9.4M}$$

where Δp = pressure, psf (pa)
$\quad\quad f$ = Moody friction factor, dimensionless
$\quad\quad L$ = length of pipe, ft (m)
$\quad\quad D$ = inside diameter of pipe, ft (m)
$\quad\quad \rho$ = density, lb/ft^3 (kg/m^3)

V = velocity, ft/s (m/s)
g = gravity acceleration, 32.174 ft/s^2 (9.807 m/s^2)

Optimum Sizing

In order to select a pipe size, some previous experience or criteria is needed, other than the customary capacity tables. Figure C9.3 illustrates the economics of selecting

A. Present value of fluid friction cost.
B. Cost of installed pipe.
C. Total cost.
FIGURE C9.3   Cost of fluid friction and installed pipe.

a pipe size. Initially, it may seem that for a given flow and refrigerant condition, the optimum diameter of a long pipe will be greater than that of a short one. Richards[7] shows, however, that the optimum diameter is independent of length. The method sets the present installed cost of pipe minus the present worth of the lifetime pumping costs equal to zero, and then differentiates with respect to diameter to determine the optimum diameter. The length cancels in this analysis, which

proves that the optimum diameter is independent of length. The effect of longer lengths is to increase the power cost for operation and may, for extreme lengths, require a slightly larger pump or compressor. The first cost of the next-larger pipe size will always exceed the savings represented by the present worth of future power costs. The total owning costs of a smaller pipe size will always be greater than for an optimum choice, because the present worth of the future cost of operation will always exceed the first cost savings.

Studies[8],[9] recently made for R-717 and R-22 give some guidance for recommended piping capacities. Conservative conditions are assumed in ammonia industrial applications. Assume typical equipment efficiencies, running 40 percent of the time at full load for 15 years, with power cost of \$0.05 per kW, the cost of money 5 percent higher than inflation, and with installed insulated pipe costs of \$13.00 per in of dia per ft of length (\$1.68 per mm of dia per m of length). The results of such studies can be expressed in recommended velocity pressures per velocity head, $\Delta p/k = \rho V^2/2g$ ($\Delta p/k = \rho V^2/2$). A more convenient form is to state the recommended equivalent temperature drop in a globe valve.

Recommended Temperature Drop Gradients for Vapor Flow in Industrial Applications

- For R-717 vapor, the result of such studies suggests that the temperature drop in a globe valve at low temperatures should be about 0.25°F (0.14°C), that is at −40°F (−40°C), and at high temperatures about 0.125°F (0.07°C), i.e. ≥ at 41°F (≥5°C).

- For R-22 vapor, the suggested temperature drop in a globe valve at low temperatures should be about 0.5°F (0.28°C), and at high temperatures about 0.25°F (0.14°C).

Practical temperature drop gradients can be much greater with higher installation and operating costs, with less running time, and with shorter capital recovery life. For each doubling of any combination of increased costs or reduced running time or life expentancy, the optimum capacity increases by 28 percent, the pressure gradient increases by 58 percent in copper tube and by 62 percent in steel pipe. The natural refrigerants R-290 and R-744 use similar pressure gradients as R-717. All halocarbon refrigerants use similar pressure gradients to R-22.

Comparing Pipe Flow Capacities

To compare pipe flow capacities we can rewrite the Darcy equation in terms of mass flow. Since mass flow equals area times velocity times density, we can insert the mass flow divided by area and density in place of velocity.

$$\Delta p = f\left(\frac{L}{D}\right)\left(\frac{w^2}{2 * A^2 * \rho * g}\right) \tag{C9.5}$$

$$\left(\Delta p = f\left(\frac{L}{D}\right)\left(\frac{w^2}{2 * A^2 * \rho}\right)\right) \tag{C9.5M}$$

where w = flow, lbm/s (kg/s)
$\quad A$ = inside flow area of pipe, ft^2 (m^2)

Rearranging the equation to show the mass flow capacity:

$$w = A \left(\frac{2 * g * \Delta p * \rho * D}{f * L} \right)^{0.5} \tag{C9.6}$$

$$(w = A \left(\frac{2 * \Delta p * \rho * D}{f * L} \right)^{0.5} \tag{C9.6M}$$

Now, since it can be shown that all pipe sizes have similar L/D ratios and since the pressure drop and density are relatively constant for a given application, we can show that the mass flow is proportional to the area divided by the square root of the friction factor.

$$w \approx \frac{A}{\sqrt{f}} \tag{C9.7}$$

The relative values of friction factors for fully turbulent flow extend reasonably well in the area of the Moody chart between laminar and fully turbulent flow where most applications occur. Table C9.3 compares optimum pipe flow capacities for R-717 suction lines compared to capacities listed in Table C9.7. The friction factors used are those for fully turbulent flow.

The obvious point to be made in the previous comparison is that the listed capacities in Tables C9.4 through C9.9 are not recommended capacities. These tables merely provide a convenient starting point for adjusting the capacity and temperature drop to other lengths and to other capacities. After a pipe size is

selected, the equivalent lengths including the valves and fittings are totaled from Tables C9.10a, b, and c. The pressure drop or temperature drop can be found by using the formulas in Notes 2 and 3 under Tables C9.7, C9.8, and C9.9. There are factors other than economics, that affect line sizes. These factors are discussed in the following paragraphs.

Suction Lines

In Fig. C9.1a, the evaporator pressure between points 8 and 1 is established by the heat load in the evaporator. The compressor pumps the refrigerant from point 2 to point 3. A pressure loss in the suction line between point 1 and 2 causes the compressor to operate at a lower suction pressure. Since the vapor expands at a lower pressure and since the compressor is essentially a fixed-volume device, a reduction in suction pressure causes a decrease in mass flow. The increased pressure differential due to pressure loss also results in more power per ton (per kW) of refrigeration.

Pressure drop and costs are not the only considerations in the selection of suction lines for refrigeration systems. The chlorinated hydrocarbons (CFCs and HCFCs) are miscible to some degree with mineral oil. The newer fluorinated hydrocarbons (HFCs) require synthetic lubricants in most cases to provide for mutual solubility that will keep the oil in circulation to enable the return of oil to the compressor. The sizing of oil return lines for vertical suction risers is discussed later in connection with Table C9.13.

It is customary to size suction lines so that the total loss in pressure doesn't exceed the equivalent of about 4°F (2.2°C) in saturated temperatures for halocarbon refrigerants and about 2°F (1.1°C) for ammonia. Greater equivalent pressure drops are tolerated in very long piping systems. Tables C9.2a and C9.2b reveal the relation between pressure change and temperature change for common refrigerants. Keep in mind that the system capacity loss, or the increased cost of refrigeration due to suction line pressure loss is about 2.2 percent per°F (4 percent per°C). Tables C9.4, C9.5, and C9.6 show suction line capacities in tons for two temperature loss rates per 100 feet (kW per K/m). The capacities are shown for single-stage systems with condensing temperatures at 86°F (30°C) for R-717 and 104°F (40°C) for R-134a and R-22.

When the liquid feed is precooled in economized or two-stage systems, the system capacities increase in proportion to the enthalpy increase between liquid and suction. Tables of the thermal properties of the refrigerant are required to assist in such an analysis. Table C9.7 for ammonia lists suction line capacities. Tables C9.8 for R-134a and C9.9 for R-22 list suction line capacities. The formulas in the table notes provide the means of adjusting the line capacity or temperature drop from the table values to actual values. The factors in Note 4 provide for the effect of different condensing temperatures.

The application of two-phase flow or the simultaneous liquid and vapor flow in return lines from evaporators to accumulators is not treated in this discussion. Suffice it to say that the pressure drop in horizontal two-phase flow increases the pressure drop approximately in proportion to the increase in the mass flow. This means that the velocity in the suction line for liquid overfeed applications should be reduced approximately by the reciprocal of the square root of the circulating number. The circulating number is the reciprocal of the refrigerant quality at the evaporator exit. For example, the velocity in return piping, for a circulating number of 4 (vapor quality at the exit of the evaporator is 0.25 or 3 parts liquid and 1 part

Note: Capacities are in tons of refrigeration resulting in a line friction loss (Δp in psi per 100 ft equivalent pipe length), with corresponding change (Δt in °F per 100 ft) in saturation temperature.

vapor) should be reduced to 50 percent of the velocity allowed for the vapor flow alone. Vertical risers in two-phase flow require higher velocities or multiple risers to carry the liquid upward with reduced pressure losses. Pressure losses in two-phase flow are reduced when accumulators are located below and close to evaporators. When accumulators are located above evaporators, arrangements for separating and pumping the liquid return improve efficiency.

Notes:
1. Table capacities are in tons of refrigeration.
   Δp = pressure drop due to line friction, psi per 100 ft of equivalent line length
   Δt = corresponding change in saturation temperature, °F per 100 ft
2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.51}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.96}$$

4. Values in the table are based on 90°F condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Condensing temperature, °F	Suction lines	Discharge lines
70	1.05	0.78
80	1.02	0.89
90	1.00	1.00
100	0.98	1.11

5. Discharge and liquid line capacities are based on 20°F suction. Evaporator temperature is 0°F. The capacity is affected less than 3% when applied from −40 to +40°F extremes.

TABLE C9.7M (SI) Suction, Discharge, and Liquid Line Capacities for Ammonia (Single- or High-Stage Applications)

Notes:
1. Table capacities are in kilowatts of refrigeration resulting in a line friction loss per unit equivalent pipe length, with corresponding change in saturation temperature, where

$$\Delta p = \text{pressure drop due to line friction, Pa/m}$$

$$\Delta t = \text{change in saturation temperature, K/m}$$

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.51}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \frac{\text{Actual } L_e}{\text{Table } L_e} \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.96}$$

4. Values in the table are based on 30°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures:

Condensing temperature, °C	Suction lines	Discharge lines
20	1.04	0.86
30	1.00	1.00
40	0.96	1.24
50	0.91	1.43

5. Discharge and liquid line capacities are based on -5°C suction.

Notes:

1. Table capacities are in tons of refrigeration.

   Δp = pressure drop due to line friction, psi per 100 ft of equivalent line length
   Δt = corresponding change in saturation temperature, °F per 100 ft

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

   $$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.541} \text{(0.51 for steel)}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

   $$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.85} \text{(1.96 for steel)}$$

4. Values in the table are based on 105°F condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Condensing temperature, °F	Suction line	Discharge line
80	1.158	0.804
90	1.095	0.882
100	1.032	0.961
110	0.968	1.026
120	0.902	1.078
130	0.834	1.156

[a] The sizing shown is recommended where any gas generated in the receiver must return up the condensate line to the condenser without restricting condensate flow. Water-cooled condensers, where the receiver ambient temperature may be higher than the refrigerant condensing temperature, fall into this category.

[b] The line pressure drop Δp is conservative; if subcooling is substantial or the line is short, a smaller size line may be used. Applications with very little subcooling or very long lines may require a larger line.

Notes:
1. Table capacities are in kilowatts of refrigeration.

Δp = pressure drop per equivalent length of line, Pa/m
Δt = corresponding change in saturation temperature, K/m

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.541} \text{(0.51 for steel)}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.85} \text{(1.96 for steel)}$$

4. Values in the table are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Condensing temperature, °C	Suction line	Discharge line
20	1.239	0.682
30	1.120	0.856
40	1.0	1.0
50	0.888	1.110

[a] The sizing shown is recommended where any gas generated in the receiver must return up the condensate line to the condenser without restricting condensate flow. Water-cooled condensers, where the receiver ambient temperature may be higher than the refrigerant condensing temperature, fall in this category.

[b] The line pressure drop Δp is conservative; if subcooling is substantial or the line is short, a smaller size line may be used. Applications with very little subcooling or very long lines may require a larger line.

Notes:

1. Table capacities are in kilowatts of refrigeration.

Δp = pressure drop per unit equivalent length of line, Pa/m
Δt = corresponding change in saturation temperature, K/m

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.541} \text{(0.51 for steel)}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.85} \text{(1.96 for steel)}$$

4. Values in the table are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Condensing temp., °C	Suction line	Discharge line
20	1.18	0.80
30	1.10	0.88
40	1.00	1.00
50	0.91	1.11

[a] The sizing shown is recommended where any gas generated in the receiver must return up the condensate line to the condenser without restricting condensate flow. Water-cooled condensers, where the receiver ambient temperature may be higher than the refrigerant condensing temperature, fall in this category.

[b] The line pressure drop Δp is conservative; if subcooling is substantial or the line is short, a smaller size line may be used. Applications with very little subcooling or very long lines may require a larger line.

Discharge Lines

In Figure C9.1*a*, the condenser pressure between points 4 and 5 is established by the temperature of the cooling medium. A pressure loss in the discharge line, shown between points 3 and 4, increases the pressure ratio in the compressor, shown between points 2 and 3. With higher discharge pressures, the compressor must pump against a higher pressure differential. This increases the power required, reduces the volumetric efficiency, and reduces the capacity of the system. Similarly as with suction lines, the sizing of oil return lines for vertical risers with halocarbon refrigerants is discussed later in connection with Table C9.14 for discharge (hot gas) risers.

It is desirable to not exceed 2.0°F (1.1°C) equivalent loss in the discharge line. Greater equivalent pressure drops are tolerated in large systems. The discharge lines are listed for capacities at 1°F per 100 feet (0.02 K/m) in Tables C9.7, C9.8, and C9.9*a*. The information in the notes is useful in adjusting the line capacities and pressure drops to other conditions.

Liquid Lines

When a system is equipped with a refrigerant receiver, the liquid line entering the receiver is usually sized generously to assure free flow from the condenser. An allowable velocity of 100 ft/min (0.5 m/s) is typical. However, Table C9.15 provides a rational sizing of condenser drain lines when the line also provides equalization between the receiver and condenser. Velocities of 150 percent of Table C9.15 are used when a separate equalizing line, from the top of the receiver to the condenser inlet, allows the condenser drain line to run full of liquid.

Piping for condensers is a complex subject, requiring consideration of pressure drop, trapping of individual circuits, subcooling of liquid, provision for purging of air, and accommodation of temperature differences between the receiver and the condensers, among other issues. A single condenser coil can be connected to the receiver without an equalizer, and with no liquid head *H*, provided the drain line is sized in accord with Table C9.15 capacities so as to allow vapor flow from the receiver back to the condenser.

Multiple condensers can be connected in series, but are usually connected as shown in Fig. C9.4. This parallel arrangement requires that the condenser coils be of equal size, that the units operate together, and that the receiver be located in an ambient temperature that is equal to or lower than the inlet air temperature to the condenser. Some liquid subcooling occurs, as the liquid tends to hang up in the lower tubes. The amount of liquid head *H* under these restraints is only that which will induce flow. If the coil sizes are unequal or do not always operate together, or if the receiver is not located such that it is below the ambient temperature of the inlet air to the condenser, additional height *H* is needed to make up for differences in coil pressure drops at full load, or to overcome the pressure equivalent of the temperature difference between the receiver and the condenser.

Two methods of piping parallel evaporative condensers are illustrated in Figs. C9.5 and C9.6. Both methods require equalizer lines from the receiver to the condenser inlet piping. When adequate equalizer lines are used, the drain lines can be sized for 150 percent of the flow suggested in Table C9.15. One advantage of the surge-type hookup in Fig. C9.5 is that subcooling of liquid accomplished in the condenser is delivered directly to the liquid line feeding the evaporators. This can be a measurable increase in efficiency, since the heating of liquid in a warm receiver
FIGURE C9.4   Multiple air-cooled condensers.

is bypassed. Another feature of the surge-type arrangement is that the individual drop legs are isolated from each other by the liquid trapped at the liquid level in the receiver. Also, as the liquid rises in the drain leg to accomodate increased load and reduced pressure at the coil outlet, the receiver can usually provide plenty of liquid to fill the individual drop legs. When coils are not of equal size or when some condensers may be shut off, the static pressure of the liquid height in the drains of the working coils equalizes the pressure drop across all of the coils and provides individual pumping force to drain each condenser coil. With through-type receivers, shown in Fig. C9.6, the horizontal portion of the drain line should be limited to the flow in Table C9.15, as the liquid volume in the horizontal line should provide for filling the individual drop legs of the working coils. The liquid head h in either case needs to be equal to the differences in pressure drops in the parallel coils under all conditions of load. Typical height h with ammonia is 4 to 6 ft (1200 to 1800 mm). Typical height h with halocarbons is 8 ft (2400 mm).

The design constraint on liquid line sizes between points 5 and 6 in Fig. C9.1a, when the liquid is near to saturation or at the bubble point, is that too much pressure drop will result in liquid flashing to vapor. The object is to deliver liquid to the expansion valve. Excessive pressure drop in high-pressure liquid lines causes formation of vapor bubbles or *flash gas*. This flash gas can severely erode the valve seat or needle in an expansion valve. Also, since vapor occupies a much greater volume than liquid, the remaining liquid will be forced along the pipe at a much higher velocity. The increased velocity causes a greater pressure drop, which also restricts the mass flow. A rise in elevation of the line, or the pressure drop due to pipe friction, may lower the pressure below the *bubble point*. In some cases, a means of cooling the liquid may be necessary to avoid forming flash gas. The liquid cooling can be obtained in an extra circuit in the condenser, or may be provided with
FIGURE C9.5   Piping for parallel condensers with surge-type receiver.

suction/liquid heat exchangers or separately refrigerated liquid subcooling heat exchangers. In condenser arrangements similar to Fig. C9.4, there is some liquid subcooling accomplished in the bottom of the condensers. However, in equalized condenser arrangements as shown in Fig. C9.5, there is little or no liquid subcooling. For receivers located above evaporators, there is little concern about liquid flashing because the liquid gains in static pressure as it flows downward, which provides effective subcooling. For evaporators located above and remote from liquid receivers, the pressure loss in the liquid line must be kept to a very low amount. Alternatively, the liquid may be delivered with pumps as is common in many large piping systems. In Tables C9.7, C9.8, and C9.9, the listed capacities of large liquid lines suffers some overstatement compared to recommended capacities, while the listed
FIGURE C9.6   Piping for parallel condensers with top inlet receiver.

capacities of smaller lines are understated. As a guide for selecting the size of high-pressure liquid lines, the velocity pressure in one velocity head for the natural refrigerants, R-717, R-290, and R-744 should be about 0.055 psi (375 pa). The velocity pressure in one velocity head for high-pressure liquid halocarbon refrigerants should be about 0.11 psi (750 pa). See the definition of velocity pressure per velocity head in the second paragraph under "Optimum Sizing."

Pressure Loss in Valves and Fittings

Two methods are used for determining the pressure losses in valves and fittings. The most convenient one to use is the equivalent-length method, which expresses the flow resistance of valves and fittings in terms of length of the same size of pipe. Tables C9.10a, b, and c show equivalent lengths for valves and fittings. The total of the actual run of pipe plus the equivalent lengths for the valves and fittings gives the length used in the calculation of pressure loss.

The flow resistance of pipe and fittings can also be expressed in velocity heads k, where one velocity head is $k = f(L/D)$. This method is more complex, but it may be more accurate. In order to use this method, the length of pipe that has a resistance of one velocity head is determined so that the actual run of pipe can be expressed as a number of velocity heads (k). In order to accurately calculate the number of velocity heads in a length of pipe, the friction factor must either be calculated or determined from a Moody chart. To accurately estimate the number

TABLE C9.10a (IP)   Valve Losses in Equivalent Feet of Pipe

Note: Losses are for valves in fully open position and with screwed, welded, flanged, or flared connections.

[a] These losses do not apply to valves with needlepoint seats.

[b] Regular and short pattern plug cock valves, when fully open, have same loss as gate valve. For valve losses of short pattern plug cocks above 150 mm, check with manufacturer.

[c] Losses also apply to the in-line, ball-type check valve.

[d] For Y pattern globe lift check valve with seat approximately equal to the nominal pipe diameter, use values of 60° wye valve for loss.

of velocity heads in a length of piping, the Reynolds number and the pipe or tube roughness must be determined. Tables C9.11a and b show representative velocity heads or k factors for valves and fittings.

It should be noted that sizes of copper tubes are referred to by nominal inside diameter in Tables C9.10 and C9.11. In all other capacity tables, the nominal outside diameter is used. This practice is probably carried over from the industry usage of referring to ASTM-280 or AC&R tubing by nominal outside diameters, and referring to other copper tubing used in plumbing by nominal inside diameters.

Example C9.1

Example of Pipe-Sizing Process.   The following example details methods for determining flow rates, volume of flow, line sizing, and pressure-drop for R-22.

Given:

A refrigeration system uses refrigerant R-22 with a capacity of 100 tons (352 kW) at an evaporating temperature of 23°F (−5°C) and a water-cooled condensing temperature of 104° (40°C). The suction line is 82 ft (25 m) long, with two angle valves, one swing check valve, and three elbows. The discharge line is 98 ft (30 m) long, with one globe valve, one lift check valve, and three elbows. The liquid line is 180 ft (55 m) long, with two angle valves and three elbows.

From Table C9.1, the refrigerant flow rate is 2.96 lb/min per ton (6.36 × 10⁻³ kg/s per kW)

Flow for 100 tons 100 × 2.96 = 296 lbm/min (352 × 6.36 × 10⁻³ = 2.24 kg/s)

Suction specific volume at 23°F (−5°C) from table of thermophysical properties: $V_g = 0.8856$ lbs/ft³ (14.19 kg/m³).

Actual suction volume: 296/0.8856 = 334 cfm (2.24/14.19 = 0.158 m³/s)

Approximate discharge volume from Eq. C9.3:

Absolute pressure of R-22 @ +104°F from Table C9.2a (IP) = 222.5 psia

Absolute pressure of R-22 @ 23°F from Table C9.2a (IP) = 61.21 psia

Approximate discharge volume = suction volume × P_1/P_2 × 1.2

262 × (61.21/222.5) × 1.2 = 86.5 cfm

(Absolute pressure of R-22 @ +40°C from Table C9.2a SI = 1534 kPa)

(Absolute pressure of R-22 @ −5°C from Table C9.2a SI = 422 kPa)

(Approximate discharge volume m³/kW = suction volume × P_1/P_2 × 1.2)

(0.124 × 422/1545 × 1.2 = 0.0406 m³/s)

Liquid density at 104°F (+40°C) from table of thermophysical properties is: 70.44 lb/ft³ (1.128 kg/m³)

Actual liquid flow volume = mass flow/liquid density

296/70.44 = 4.2 cfm (2.24/1,128 = 1.98 dm³/s)

Suction Line. For the suction line, try the nominal NPS 4 steel pipe: (See Tables C9.10a and b; note that the IP and SI valve and fitting losses are not exactly equivalent because of rounding.)

Length of run	=	82 ft	(25 m)
Two angle valves	=	94 ft	(28 m)
One swing check	=	40 ft	(12 m)
Three elbows	=	20.1 ft	(6 m)
Total equivalent length	=	236.1 ft	(71 m)

Suction line temperature and pressure drop using Note 2 under Table C9.9

Interpolate tons capacity at +23°F ...... ∼ 123 tons   (−5°C at 433 kW)

$$\Delta t = 2 \times 236.1/100 \times (100/123)^{1.96}$$

$$= 3.15°F \quad (1.74°C)$$

Interpolate pressure drop at +23°F ...... ∼ 2.32 psi   (16 kPa)

$$\Delta p = 2.32 \times 236.1/100 \times (100/123)$$

$$= 4.33 \text{ psi} \quad (30.68 \text{ kPa})$$

The NPS 4 steel pipe is satisfactory for the pressure drop. The rated pressures from Table C9.20 for ERW pipe is 732 × 0.85 = 622 psig (4277 kPa), while the

suggested test pressure for R22 in Table C9.19 for the low side is 182 psig (1255 kPa). Either seamless or ERW NPS 4 steel pipe is satisfactory for the required capacity and pressure.

Discharge Line. For the discharge line, try the 3 IPS steel pipe. (See Tables C9.10a and b, note that the IP and SI equivalent lengths are not exactly equal because of rounding.)

Length of line	= 98 ft	(30 m)
One globe valve	= 69 ft	(21 m)
One lift check	= 69 ft	(21 m)
Three long radius elbows =	15 ft	(4.6 m)
Total equivalent length	= 251 ft	(76.6 m)

Using Table C9.9: The capacity of a NPS 3 pipe is 116.4 tons @ 1°F temperature drop.

$$\Delta t = 1.0(251/100)(100/116.4)^{1.96}$$

$$= 1.86°F \qquad (1.03°C)$$

$$\Delta p = 3.05 \times (244.1/100)(100/116.4)^{1.96}$$

$$= 5.6 \text{ psig} \qquad (39.2 \text{ kPa})$$

The 3 IPS steel pipe is satisfactory for pressure drop. For strength, Table C9.20 shows the pressure rating as 664 psig (4564 kPa) for ERW schedule 40 pipe. Table C9.19 shows a suggested minimum field test pressure of 235 psig, (1628 kPa) while Table C9.18 shows the ANSI minimum design pressure as 208 psig (1433 kPa). Actual U.S. industry practice is to use 250 psig (1724 kPa) design pressure for water-cooled R-22 systems, and 300 psig (2068 kPa) or higher for air-cooled R-22 systems.

Liquid Lines. For the condenser drain, use 100 fpm (0.5 m/s) for sizing, when vapor from the receiver may flow in opposition with the free-draining liquid. Table C9.9 indicates the NPS 3 (DN 80) has a capacity of 118.5 tons at 100 fpm (412.7 kPa @ 0.5 m/s). When an equalizer line is used to vent the receiver to the top of the condenser, a velocity of 150 fpm (0.75 m/s) may be used for full liquid flow in the drain. A NPS 2½ (DN 65) has a capacity of 115 tons at 150 fpm (401 kPa at 0.75 m/s).

For the liquid line to the evaporator, try a NPS 2 steel pipe. From Tables C9.10a IP and C9.10b IP:

Line length	= 180 ft	(55 m)
Two angle valves	= 48 ft	(14.6 m)
Three elbows	= 9.9 ft	(3.0 m)
Total equivalent length	= 237.9 ft	(72.6 m)

From the receiver to the evaporator, check the equivalent temperature drop in a NPS 2 steel liquid line. Table C9.9 indicates a 1°F temperature drop per 100 feet of NPS 2 line (0.02°K/m in DN50.)

Temperature and pressure drop in NPS 2 liquid line for 100 tons (352 kPa in DN50):

$$\Delta t = 1.0 \times 237.9/100 \times (100/192)^{1.96}$$

$$= 0.662°F \qquad (0.368°C)$$

$$\Delta p = 3.05 \times 237.9/100 \times (100/192)^{1.96}$$

$$= 2.02 \text{ psi} \qquad (13.93 \text{ kPa})$$

For the illustrated calculations, the selected line sizes are as follows:

Suction line	NPS 4 (DN 100)
Discharge line	NPS 3 (DN 80)
Liquid line to receiver	NPS 3 (DN 80)
Liquid line to expansion valve	NPS 2 (DN 50)

The compressor selection must be adjusted for the suction and discharge line losses, so the compressor should be selected for the following gauge pressures:

Suction pressure	= 46.54 − 4.45	= 42.09 psig	(290 kPa)
Discharge pressure	= 222.56 + 5.68	= 228.2 psig	(1575 kPa)

Secondary Coolants

Piping for secondary coolant service may be designed by the methods used for water.

Consideration must be given to an economical choice of pressure loss and pump power. In evaluation of pressure drop, the density and viscosity have a direct effect. An additional consideration is the compatibility of materials with the fluid.

In the selection of the concentration of water-based secondary coolants, it is desirable to select a mixture which has a freezing point at least 18 to 20°F (10 to 11°C) below the operating temperature expected in the system. Use of lower freezing point mixtures provides a larger margin to prevent freezing. However, this is costly because of reduced heat transfer and increased pumping costs. The methods in Chap. B8 may be applied for sizing of secondary coolant piping. For four common water-based secondary coolants, Table C9.12 in IP shows the specific gravity, freezing point, and viscosity at various concentrations. Table C9.12 in SI shows percent by mass, density, specific heat, and viscosity at a temperature 18°F (10°C) above the freezing point. This information enables determination of the friction factor and the subsequent pressure loss.

Oil Return

The CFC and HCFC and hydrocarbon refrigerants are miscible with mineral oil. These refrigerants carry some oil in the liquid phase without separation, whereas the newer HFC refrigerants require synthetic oil to provide mutual solubility. Some practitioners suggest the use of small additions of R-290 or other hydrocarbons to improve the oil circulation when using conventional mineral oils with HFC

refrigerants. Some oil is carried with the discharge gas from most conventional vapor compressors. In halocarbon direct-expansion systems without oil separators, the oil will pass through the system, returning with the suction vapor. In fact, mineral oil in small amounts improves vaporizing heat transfer by reducing the surface tension of the boiling liquid. Oil in greater quantities drastically reduces the vaporizing heat transfer in an evaporator. Reducing the proportion of oil circulating in the system is accomplished by use of synthetic oil, by lower temperatures in the discharge gas to reduce the amount of vaporized oil, and by the use of high-efficiency separating elements.

Oil discharged from the compressor is carried through the discharge line to the condenser and through the liquid line to the receiver. It then proceeds through the liquid line from the receiver to the evaporator, where it will collect in flooded evaporators as it does not vaporize. Various methods are used to bleed a mixture of oil and liquid refrigerant from flooded evaporators into the suction line. Heat exchange between the return suction line and the warm liquid feed line is a common method used to "dry" the returning refrigerant. The cooling of the liquid feed by the evaporation of the returning refrigerant conserves the refrigeration effect. Other methods of oil return involve heating the return mixture in a separate line through heat exchange with the discharge gas. Still other successful methods involve automated refrigerant gas pumping devices such as ejectors or electrically heated oil stills that are intermittantly pressurized or are equipped with pumps to transfer distilled oil back into the suction of the compressor.

After oil is introduced into the suction line by a direct expansion system or by one of the just-noted methods from flooded evaporators, the gas velocity in vertical return risers must be maintained so that the oil will be carried up the riser. The necessary velocities expressed in tons (kW) capacity have been experimentally

determined. Table C9.13 lists the minimum capacities in copper tubes that will carry oil up suction risers. Table C9.14 lists the minimum capacities in copper tubes that will carry oil up discharge or hot gas risers. Multipliers shown at the bottom of Table C9.14 can be used for sizing oil return risers at various temperatures.

When a system operates over a range of capacities, the riser sized for the full load condition may not be functional for oil return at part loads. Is such cases, a double riser will increase the range of loads that will provide oil return. See Fig. C9.7 for details of a double riser. Lines A and B are sized so the two together will handle the full load with proper oil return in accordance with Tables C9.13 or C9.14, or with equivalent velocities of other refrigerants. Line A should be sized for the minimum capacity.

Since mineral oil has a very limited solubility with liquid ammonia, and is not mutually soluble with vaporized ammonia, it does not travel back to the compressor in dry vapor suction lines. Control of oil in ammonia plants is usually accomplished with efficient oil separators, and manually operated oil drain pots, stills, and pump-out systems. Some degree of automation is successfully used to return oil from evaporators to ammonia accumulators, such as is used in hot-gas defrosting methods. However, the separation of oil in the low side means that the principal method of oil control in ammonia systems is provided by oil stills or oil pots at the accumulators in flooded or circulated system evaporators. Additional automation of oil return is

Notes:

1. Refrigeration capacity in tons is based on 90°F liquid temperature and superheat as indicated by the listed temperature. For other liquid line temperatures, use correction factors in the table to the right.
2. This table has been computed using an ISO 32 mineral oil for R-22 and R-502. R-134a has been computed using an ISO 32 ester-based oil.

Refrig-erant	Liquid temperature, °F

Notes:

1. Refrigeration capacity in kilowatts is based on saturated evaporator as shown in table and condensing temperature of 40°C. For other liquid line temperatures, use correction factors in the table below.
2. The tables have been computed using an ISO 32 mineral oil for R-22 and R-502. R-134a has been computed using an ISO 32 ester-based oil.

Refrigerant	Liquid temperature, °C		
	20	30	50
134a	1.20	1.10	0.89
22	1.17	1.08	0.91
502	1.26	1.12	0.86

Notes:

1. Refrigeration capacity in tons is based on a saturated suction temperature of 20°F with 15°F superheat at the indicated saturated condensing temperature with 15°F subcooling. For other saturated suction temperatures with 15°F superheat, use the correction factors in the table to the right.
2. This table has been computed using an ISO 32 mineral oil for R-22 and R-502. R-134a has been computed using an ISO 32 ester-based oil.

	Saturated suction temperature, °F			
Refrigerant	−40	−20	0	+40
22	0.92	0.95	0.97	1.02
134a	—	—	0.96	1.04
502	0.85	0.91	0.95	1.04

practiced by equipping accumulators with oil stills and pumps that operate on demand from oil level controls to transfer oil to individual compressor packages.

Suction Line Design for Oil Return.   Suction lines should be designed so that oil from an active evaporator does not drain into an idle one. Various multiple coil arrangements are shown in Figs. C9.8*a, b, c,* and *d.*

Figure C9.8*a* shows multiple evaporators on different floor levels, with the suction line above. Each suction line is brought upward and looped into the top of the common suction line to prevent oil from draining into inactive coils. Figure C9.8*b* shows multiple stacked coils on the same level, with the suction line above, using an alternative double riser method.

Figure C9.8*c* shows multiple coils on the same level, with the suction line below. Figure C9.8*d* shows multiple coils on the same level, with the suction line above.

In all cases that use thermostatic expansion valves, the control bulbs are located upstream of the liquid traps or the elbows which turn down, as illustrated in Fig. C9.9. This prevents erratic operation that may be caused by liquid holdup during compressor-off cycles.

Condenser Drains.   In the section on selection of line sizes, liquid lines were sized on the basis of about 100 fpm (0.5 m/s). When liquid lines run vertically downward from the bottom of a horizontal shell-and-tube or shell-and-coil condenser to a receiver and where full equalization of the condenser and receiver is required through the condensate drain line, it may be necessary to maintain velocities less than 100 fpm (0.5 m/s). Table C9.15 shows the maximum velocity based on full pipe area which should be allowed in vertical outlets from condensers to assure full equalization and to prevent gas binding. This table is equally applicable to pipe or copper tubing, and is applicable to any refrigerant compatible with the materials, since it is based on the hydraulic effect of liquid flowing into vertical outlets. If the velocities exceed those shown in this table, separate vapor-equalizing lines should be used.

Marine Condensers.   Refrigerant condensers for use on land usually have a single liquid outlet. Condensers intended for use on shipboard are usually mounted fore

and aft to take advantage of the lower pitch angle. Outlets are provided at each end of the condenser. These are piped into a common header having a single outlet in the center. Each condenser outlet should be capable of handling the entire full capacity of the condenser.

Insulation.   Since refrigerating systems are designed basically to produce temperatures below normal, many of the pipelines in a refrigeration system will be at temperatures below the dew point of the surrounding air. In addition to a heat gain from the surroundings, condensation, commonly called *sweating,* will form on

TABLE C9.15   Maximum Velocity in Condenser Vertical Drains to Assure Equalization

Inside diameter			
in	mm	Max. velocity, fpm	(m/s)
1	25	45.5	0.231

12	305	153.8	0.781

Table shows maximum velocity permitted in round vertical drains, based on full pipe area, to assure full equalization with receiver.

Based on the formula: Velocity (fpm) $= 44.4\sqrt{d}$ where d is in inches ($0.04475\sqrt{d}$ where d is in mm).

these pipes. The condensation may be objectionable and even harmful. It is customary to insulate all refrigerant lines where there is a possibility of condensation on the refrigerant line.

The amount and type of insulation depend upon the operating-temperature level. Chapter B7 covers insulation in detail with recommendations for economical thicknesses, types, and application.

An important consideration in the application of any insulation to refrigerant piping is to assure that there is a vapor seal on the outside of the insulation. If the insulation type is such that moisture can enter it, the natural difference in vapor pressure between the surrounding atmosphere and the surface of the pipe will result in moisture migration into the insulation and eventually to the surface of the pipe. Vapor seals at all joints and on the outside of the insulation are essential to assure efficient performance and the avoidance of future trouble.

It is also necessary to avoid thermal bridges between the cold piping and the outside ambient air or atmosphere. Pipe hangers for supports should not contact the cold piping and should be arranged so that the supports bear against saddles of adequate area which are outside the insulation. Any metal in contact with the cold pipe wall, because of the higher conductivity of the metal hanger or rod, will cause condensation on the hangers.

MECHANICAL PIPING DESIGN

Code Requirements

The Safety Code for Mechanical Refrigeration, ANSI/ASHRAE 15[1], was written to assure the safe design, construction, installation, operation, and inspection of every refrigerating system using a volatile refrigerant. ANSI/ASHRAE 15 Standard covers refrigerant piping, valves, fittings, and related parts.

The ASME Code for Pressure Piping, Section B31.5,[2] is a standard covering the minimum requirements for materials, design, fabrication, assembly, examination, inspection, and testing of refrigeration piping, including limitations.

The ANSI/ASHRAE 15 and ASME B31.5 Codes recognize that refrigeration equipment of the self-contained or unit type which has been designed in accordance with good practice and which has been submitted to an approved, nationally recognized testing laboratory which provides uniform testing and examination procedures and which has a follow-up inspection service of current production of such units will be construed as meeting the requirements of either of these codes.

The ASME B31.5 Code also excludes water piping from consideration but does include secondary coolant piping.

Materials. Since volatile refrigerants have different chemical compositions, some materials are incompatible with certain refrigerants. Table C9.16 shows that several common materials are not compatible with certain of the refrigerants; it also indicates certain other limitations from a code standpoint. It will be noted that cast-iron pipe is not permitted by the Pressure Piping Code for any volatile refrigerant; case-iron valves and fittings of approved types are permitted.

Copper and brass are not compatible with ammonia. Aluminum, zinc, and magnesium are not suitable for use with methyl chloride. Zinc and magnesium are not suitable for use with any of the halogenated hydrocarbon refrigerants or ammonia.

In addition to the limitations and qualifications shown in Table C9.16, each of

TABLE C9.16   Material Compatibility

Material	Refrigerant number

* NP, not permitted by ASME B31.5 Code; NS, not satisfactory; Q, qualified—moist refrigerant may corrode—consult supplier; S, satisfactory.

the eight listed refrigerants is classified according to the Underwriters' Laboratories classification and according to a group classification system covered in the ANSI/ASHRAE 15 Safety Code.

The ANSI/ASHRAE 15 classification of Groups A1 and B1 include refrigerants which are not considered flammable toxic or in the ordinary sense (remember that many refrigerants can smother if present in heavy concentrations).

Groups A2 and B2 in the ASHRAE classification cover flammable or toxic refrigerants, and GROUPS A3 and B2 cover highly flammable or explosive refrigerants.

Limitations.   Table C9.17 shows the limitations of various types of materials and group classifications with respect to the service with refrigerants. It will be noted that steel pipe must be Sch 40 or heavier for use with volatile refrigerants, with certain limitations with respect to size.

ASME B31.5 no longer permits the use of butt-welded carbon steel with refrigerants. However, it does permit the use of listed electric-resistance welded pipe and tube.

Cast-iron pipe is not allowed for any volatile, flammable, or toxic refrigerant but may be used for water or nonvolatile brines. Cast-iron is not allowed for temperatures below −150°F (−65°C).

Copper or brass tubing may be used with any refrigerant with which it is compatible and in any size or pressure when selected by the design rules. If copper tubing is erected on the premises, it must be Type *K*, *L*, or ACR.

The ANSI/ASHRAE 15 Safety Code has certain requirements for institutional, public assembly, residential, and commercial occupancies. These rules prohibit the carrying of refrigerant piping through floors except that it may be carried from the basement to the first floor or from the top floor to a machinery penthouse to the roof.

Refrigerant piping may be connected to a condenser on the roof if it is carried through an approved rigid and tight, continuous, fire-resistant pipe duct or shaft having no openings on intermediate floors, or it may be carried on the outer wall of the building provided it is not located in an air shaft, closed court, or any other similar opening enclosed within the outer walls of the building.

For Group A1 refrigerants, the refrigerant piping may be carried through floors intermediate between the first floor and the top floor provided it is enclosed in an

TABLE C9.17 Piping Limitations

Type or material	ASHRAE 15 group number	Line size NPS	Service	Limitation
Carbon steel or wrought iron	A2, B2, A3, B3	1½ or smaller	Refrigerant liquid	Sch 80 or heavier
	A1, B1	6 or smaller	Refrigerant liquid	Sch 40 or heavier
	A2, B2, A3, B3	2 through 6	Refrigerant liquid	Sch 40 or heavier
	All groups	6 or smaller	Refrigerant vapor	Sch 40 or heavier
Butt-welded carbon steel or wrought iron	Any	Any	Refrigerant liquid	Not permitted by code
Cast-iron pipe	Any	Any	Refrigerant	Not permitted for refrigerants
Cast-iron pipe	—	—	Brine	Permitted above −150°F (−65°C)
Cast-iron pipe	—	—	Any	Not permitted below −150°F (−65°C)
Copper or brass	Any (except ammonia)	Any	Any (except ammonia)	Type K or L if erected on premises; soft annealed may not exceed 1⅜ in OD (DN 32)
			Ammonia	Not compatible
Aluminum, zinc, magnesium	—	—	Methyl chloride	Not compatible
Magnesium	—	—	Halogenated hydrocarbons	Not compatible
Threaded joints	A3, B3	1 and smaller	Any	Seal welded or braze
		See limitation	Group A3 or B3 fluids	Not allowed over 1 in (DN 25)
			Salt brines	Not allowed over 6 in (DN 150)
			Any	Not lighter than Sch 40 up through 6 in (DN 150); not lighter than Sch 30 on 8, 10, or 12 in (DN 200, 250, 300)

approved, rigid and tight, continuous fire-resisting pipe or shaft where it passes through intermediate spaces not served by the system. The piping of direct systems need not be enclosed where it passes through space served by that system. The pipe duct or shaft must be vented to the outside or to a space served by the system.

The ANSI/ASHRAE 15 Code further requires rigid or flexible metal enclosures for soft, annealed copper tubing used for refrigerant piping which contains other than Group A1 refrigerants.

Schedule 40 wrought-steel or wrought-iron pipe may be used for design working pressure not exceeding 300 psig (2100 KPa) provided electric-resistance-welded, or seamless pipe is used.

For limitations on copper tubing, refer to ANSI/ASHRAE 15.

Joints on copper tubing containing Groups A2, A3, B1, B2 and B3 refrigerants as classified by the ANSI/ASHRAE 15 Code must be brazed. Solder joints are prohibited in such systems.

A brazed joint is obtained by the joining of metal parts with alloys which melt at temperatures higher than 800°F (425°C) but less than the melting temperatures of the joined parts.

A soldered joint is obtained by the joining of metal parts with metallic mixtures or alloys which melt at temperatures below 800 (below 425 and above 200°C) and above 400°F.

Systems containing 100 lb (45 kg) of refrigerant with positive-displacement compressors should have stop valves on each inlet of each liquid receiver and on each branch liquid and suction line except on receivers which are in a condensing unit or which are an integral part of the condenser.

Refrigerant piping crossing an open space which affords a passage way in any building must be not less than 7½ ft (2.3 m) above the floor unless against a ceiling of such space.

Free passageway must not be obstructed by refrigerant piping. Refrigerant piping must not be placed in any elevator, dumb-waiter, or other shaft containing a moving object or any shaft which has openings to living quarters or to main exit hallways. Refrigerant piping is not to be placed in public hallways, lobbies, or stairways except that such refrigerant piping may pass along a public hallway if there are no joints in the section in the public hallway and provided that nonferrous tubing of 1⅛ in OD and smaller is contained in a rigid metal pipe.

Limitations on Threaded Joints. Threaded joints should be seal welded or brazed for refrigerants. Threaded joints larger than NPS 1 (DN 25) in size should not be used for Group A3 and B3 fluids and must be no larger than NPS 6 (DN 150) in size for salt brine. Threaded joints must not be used on lighter than Sch 40 pipe up through NPS 6 (DN 150) in diameter or on lighter than Sch 30 pipe for NPS 8-, 10-, or 12 pipe (DN 200, 250, 300).

Design Pressures

Minimum design pressures for refrigerants are defined in the ANSI/ASHRAE-15 Safety Code as not less than pressure arising under maximum operating, standby, or shipping conditions, but not less than the saturated gauge pressure corresponding to certain specified temperatures. See Table C9.18 for minimum design gauge pressures of 9 refrigerants. Design pressures in other codes, as typified by the Safety Requirements in ISO-5149[6], specify higher temperatures than are used in the ANSI standards. The notes under the table explain the temperature basis for the minimum

Notes:
1. ANSI/ASHRAE-15 defines ''Design Pressures'' as not less than pressure arising under maximum operating, standby, or shipping conditions, but not less than the saturated gauge pressure corresponding to the following temperatures: For low sides, not less than 80°F (26.7°C); For water-cooled high sides, not less than 30°F (16.7°C) higher than the summer 1 percent wet-bulb, or 15°F (8.3°C) higher than the highest design leaving condensing water temperature for which the equipment is designed, or 104°F (40°C), whichever is greatest. For air cooled high sides, 30°F (16.7°C) higher than the highest summer 1 percent design dry-bulb for the location but not lower than 122°F (50°C).
2. ISO-5149 defines the pressures for systems only protected by pressure limiting devices, as the pressure of the refrigerant having at least the following temperatures: For ambient temperatures up to 32°C (89.6°F): 32°C (89.6°F) low side, 43°C (109.4°F) water-cooled high side, 55°C (131°F) air cooled high side.
3. ISO-5149 defines the pressures for ambient temperatures up to 43°C (109.4°F): 43°C (109.4°F) low side, 43°C (109.4°F) water cooled high side, 63°C (145.4°F) air cooled high side.
4. The gauge pressures shown in psig are minimums. To convert to kPa gauge, multiply by 6.89474.

TABLE C9.19 Suggested Minimum Field Test Pressure for Refrigerant Piping, psig

Refrigerant	Group	Name	Formula	Low side	High side water-cooled	High side air-cooled
R-22	A1	Chlorodifluoromethane	CHCLF2	185	250	325
R-134a	A1	Tetrafluoroethane	CH_2FCF_3	115	160	225
R-290	A3	Propane	C_3H_8	165	220	290
R-404A	A1/A1	R-125/143a/134a	(44/52/4)	240	300	400
R-407A	A1/A1	R-32/125/134a	(20/40/40)	230	285	380
R-407C	A1/A1	R-32/125/134a	(23/25/52)	230	285	380
R-410A	A1/A1	R-32/125	(50/50)	300	400	535
R-507A	A1	R-125/143a	(50/50)	230	325	405
R-717	B2	Ammonia	NH_3	200	275	385

Notes:
1. The suggested field test pressures are approximately 110 percent of the ISO minimum design pressures in Table C9.18 for all refrigerants, except approximately 120 percent of the ISO minimum design pressure for ammonia.
2. Most safety and jurisdictional mechanical codes no longer speficy field test pressures. The field test pressure should follow the manufacturer or designer's specification, or be guided by performance codes such as IIAR-2 for ammonia systems, or be adjusted to not more than 130 percent of the nameplate pressure rating of any components in the parts of the system being tested.
3. When not otherwise specified, the minimum suggested field test pressure is 110 percent of the design or maximum working pressure, so as to test the system at the rated operating pressure of the safety relief valve.
4. The gauge pressures are shown in psig. To convert to kPa gauge, multiply by 6.89474.

low-side and high-side pressures. The refrigeration industry in the United States usually designs to higher pressures than specified in ANSI codes. The principal reason for this practice is to provide safety relief valve set points at design pressures that are 25 percent higher than the maximum expected pressure. This practice enhances adequate closing pressure in conventional spring-loaded safety relief valves. System internal pressures within 90 percent of the set point can cause weeping or leaking of refrigerants from conventional relief valves.

The new International Mechanical Code which is replacing juridictional codes, references ANSI/ASHRAE-15 for safety requirements and references ANSI/IIAR-2 for equipment and design of ammonia refrigerating systems. There are no specified field test pressures in the International Mechanical Code. Table C9.19 lists suggested minimum field test pressure for refrigerating piping.

REQUIRED THICKNESS OF PIPE OR TUBE

The *required thickness* of pipe or tubing is determined from the following equations and nomenclature:

$$t_m = t + c \tag{C9.8}$$

$$t = \frac{PD_o}{2(S + Py)} = \frac{Pd}{2(S + Py - P)} \tag{C9.9}$$

$$P = \frac{2St}{(D_o - 2yt)} \tag{C9.10}$$

where t_m = minimum required thickness (in) (mm)
  c = allowance for grooves, threads, tolerances, corrosion, erosion (in) (mm)
  P = internal design pressure (psig)(kPa gauge)
  D_o = outside diameter of pipe (in) (mm)
  d = inside diameter of pipe (in) (mm)
  S = allowable stress (psi) (kPa)
  t = calculated thickness in (mm)

y is a material coefficient for which

Ductile nonferrous materials = 0.4

Ferritic steels = 0.4

Austenitic steels = 0.4

The design of piping for external pressure involves the use of charts to determine factors which are used to calculate the thickness or allowable working pressure. The method and charts referred to in paragraphs UG 28 and UG 31 of Section VIII of the ASME Boiler and Pressure Vessel Code[3] are acceptable for design of pipes and tubes subject to external pressure.

The Pressure Piping Code recognizes and permits the use of the design rules of the ASME Unfired Pressure Vessel Code for closures, flanges, and blind flanges. For blanks, the following equation should be used:

$$t = d_g \sqrt{3P/16S}$$

where t = required thickness (in) (mm)
  d_g = inside diameter of gasket for raised or flat-face flanges or the pitch diameter of retained gasket flanges (in) (mm)
  P = internal or external design pressure (psig) (kPa)
  S = allowable stress (psi) (kPa)

Since the Pressure Piping Code[2] and the Safety Code for Mechanical Refrigeration both limit the minimum thickness of steel pipe and the minimum thickness for copper tubing for erection on the premises, it is possible to calculate the maximum working pressure for these commonly used weights of pipe or tubing.

Table C9.20 shows the maximum allowable internal working pressure for seamless steel pipe in the permitted schedule numbers. The maximum allowable external pressure has also been calculated for a length-over-diameter ratio in excess of 15 which will be common in most piping systems. It will be evident that the allowable working pressure for the permitted thicknesses of pipe is usually far in excess of that required by the design working pressure requirements for the various refrigerants. In most cases except in unusual circumstances, in cases where shock may be anticipated, or in the larger sizes, no further checking of allowable working pressure will be necessary.

Table C9.21 shows rated internal working pressures for type ACR copper tubing normally used for air conditioning and refrigeration service in the field. Ratings are given for annealed tubing.

The ASME B31.5 Pressure Piping Code establishes certain allowable working stresses for many grades of pipe and tubing in various materials. These allowable stresses are to be used in conjunction with the design equations listed above for special calculations.

TABLE C9.20   Allowable Working Pressures for Carbon Steel Refrigerant Piping

Nominal pipe size, NPS	(DN)	Schedule no.	Allowable internal working pressure, psig	Allowable external working pressure, psig

10	(250)	40	496	340
12	(300)	STD.	436	260

For internal pressure:
    Based on minimum wall thickness; no corrosion or erosion allowance: thread allowance factor from ANSI/ASME B.1.201.
    Allowable stress = 12,000 psi.
    y (material coefficient) = 0.4.
    $P = 2St/(D_0 - 2yt)$.
For external pressure:
    Based on minimum wall thickness: no corrosion, erosion, threading, or grooving allowance.
    Yield: 24,000 psi to 30,000 psi.
    $L/D_o = 15$ or greater where D_o = outside pipe diameter in inches; L = maximum straight length of run between flanges, elbows, caps or stiffening rings (in).
    To convert psig to kPa gauge, multiply by 6.89474.

Low-Temperature Design Criteria.   It is recognized that certain materials tend to become brittle at low temperatures and may be subject to failure which would not occur normally at usual temperatures or at elevated temperatures. The transition temperature at which certain materials become brittle is not well defined. Some ferrous materials may pass through the transition range at normal temperatures, while others may not become brittle until quite low temperatures are attained. The ASME Unfired Pressure Vessel Code[3] arbitrarily establishes a temperature of −20°F as a point below which all vessels constructed of carbon or low-alloy steels should be impact tested, with certain exemptions.

    Refrigeration piping is frequently subject to temperatures below normal atmospheric temperatures to the degree that embrittlement may occur, and the ASME

TABLE C9.21 Rated Internal Working Pressures (psig) for Copper Tube Type ACR*

Size and wall thickness (in)	Rated internal working pressure (psig)						
	100°F (38°C)		200°F (93°C)		300°F (149°C)		400°F (204°C)
	Annealed	Drawn	Annealed	Drawn	Annealed	Drawn	Annealed or drawn
⅛ (.030)	3130	—	3090	—	2620	—	1310

To convert inches to mm, multiply by 25.4.
To convert psig to kPa, multiply by 6.89474.

B31.5 Piping Code also requires impact tests on certain materias subject to temperature below −20°F. There are certain materials and certain conditions under which impact tests are not required. The exemptions are as follows:[2]

1. No impact tests are required for aluminum, austenitic stainless steel in grades 304, CF8, 304L, CF3, 316, CF8M, or 321, or copper, red brass, copper-nickel alloys, or nickel-copper alloys.

2. No impact tests are required for bolting material conforming with A193, Grade B7 for use at temperatures above −50°F.

3. No impact tests are required for bolting materials conforming with A320, Grades L7, L10, and L43 at temperatures above −150°F or above −225°F for A320, Grade L9.

4. No impact test is required for material used in fabricating a piping system for metal temperatures between −20 and −150°F when the most severe condition of pressure (internal if above atmospheric and external if below atmospheric) does not produce a stress exceeding 40% of the allowable material stress.

For low-temperature application, the use of nonferrous materials or the stainless steel mentioned will normally be satisfactory. The use of nickel-steel pipe in conjunction with the use of nickel-steel pressure vessels has long been an acceptable material for low-temperature when these materials are subjected to and pass the impact-testing requirements.

Impact tests, when conducted, shall follow the requirements of ASME B31.5, Paragraph 523.2.2.

The standard 10- by 10-mm specimen is used if the thickness of the material being tested is ⁷⁄₁₆ in or greater. For material that is not of sufficient thickness to permit preparation of full-size specimens, tests may be made on the largest possible of the subsize specimens listed in the following table.

The impact properties for each size specimen are as follows:

Size of specimen (mm)	Minimum impact value required (ft · lb)	(J)
10 × 10	15	20.3
10 × 7.5	12.5	16.9
10 × 5	10	13.6
10 × 2.5	5	6.8

In welded fabrication, the weld also is required to meet the impact-test requirement.

Expansion and Contraction.   Since refrigeration piping systems are subject to changes in temperature, some precautions must be taken to assure that these changes in temperature during operation or during shutdown are considered in the design of the piping and in the design of supports and flexibility.

Piping systems must be designed to have sufficient flexibility to prevent thermal expansion from causing

1. Failure of piping or anchors from overstress or overstrain

2. Leakage at joints

3. Detrimental distortion of connected equipment resulting from excessive thrusts or moments

Expansion strains are usually taken up by bending or torsion or by compression and tension. The concentration of stresses will be different in each case.

Bending or torsional flexibility may be provided by the use of bends, loops, or offsets. While swivel joints, ball joints, and corrugated expansion joints are recognized by the Pressure Piping Code, some of these are not considered desirable for volatile refrigerant piping. Bends, loops, and offsets are generally used to provide flexibility. Loops and cold springing also may be used in the design of piping. Chapter B4 covers in detail the general design considerations involved in expansion and flexibility of piping. These same principles must be applied to refrigeration piping, and the maximum temperature cycle involved in the installation should be taken into account in determining the nature and direction of the stresses which may be caused by temperature effects. As previously mentioned under "Insulation," pipe hangers or supports for low-temperature piping normally will not be in direct contact with the metal portion of the piping. Consideration must be given to the

insulation in types of support which are peculiar to refrigeration piping when the problems of expansion and flexibility are considered.

Miter Joints. The ASME B31.5 Pressure Piping Code gives details for design of branch connections where the angle between the axes of the branch and of the run is between 45 and 90°. Branch connections less than 45° impose special design and fabrication problems. The Code permits connections to be made by the use of tees and welding outlet fittings such as cast or forged nozzles or couplings, or by attaching a branch pipe directly to the run pipe by welding.

Normally the use of standard forged fittings of the butt-welding or socket types will provide sufficient strength in the case of a branch connection to permit application of these fittings without additional reinforcement. However, when a branch connection is welded into a hole cut into the main-run pipe, it is recognized that certain reinforcement may be required. The analysis of the extent of reinforcement, if required, is similar to that used on unfired pressure vessels for nozzle connections. The complete detailed analysis for such determinations and the means of determining the amount of reinforcement required are shown in the ASME B31.5 Pressure Piping Code or in the ASME Unfired Pressure Vessel Code. The general method is to calculate the amount of metal cut out of the pipe and to calculate the amount of metal which is added by extra thickness of the pipe wall over that required for strength, the extra metal in the nozzle or branch connection, and the extra metal which would be added within certain limiting geometric zones by welding. If the added metal provides the equivalent of the amount of metal which had been cut out, no additional reinforcement is necessary. Reinforcement metal usually is provided in the form of a ring or a saddle which is welded to the run pipe. This reinforcement material must be added within certain limiting dimensions as defined by the code. The use of ribs, gussets, or clamps is permissible to stiffen the branch connection, but their areas cannot be counted as contributing to the reinforcement area.

Welding, Brazing, and Soldering. Joints in piping which is to convey volatile refrigerants are usually made by welding, brazing, or soldering. This does not exclude the use of flanged connections, which are commonly used to connect valves or control devices in refrigeration piping. Flanged connections are commonly used to connect to pressure vessels and to compressors. Couplings of the friction type with seal rings may be used for refrigerants when the materials are compatible with the refrigerant and when the pressures permit. Use of such fittings is normally confined to low-pressure refrigerants. Limitations on threaded connections have already been listed, and frequently threaded connections, where used and where permissible, will be seal welded.

Welded joints may be used in any materials for which it is possible to qualify the welding procedures, the welders, and the welding operators.

Butt welds are permitted. Usually, backing rings are used in butt-welded joints, but where it is necessary to have a smooth interior surface or where the backing ring may result in severe corrosion or erosion, the joint may be welded without backing rings provided the piping is suitably cleaned. Socket welds are permitted under the Pressure Piping Code. The Pressure Piping Code defines in detail the required weld sizes and joint arrangements which are recommended for use in welded-part construction.

The ASME Boiler and Pressure Vessel Code, Section IX, defines in detail the qualification of welding procedures and welders' performance requirements for unfired pressure vessel construction. These rules have been adopted by the Pressure

Piping Code ASME B31.5 and form part of the requirements of that Code. The welders and the procedures should be qualified to assure that their quality is in conformance with these codes.

The ANSI/ASHRAE 15 Safety Code for Mechanical Refrigeration requires brazing of certain joints. Also certain joints in restricted areas may require high-melting-point filler material. The ASME B31.5 Pressure Piping Code defines the filler metal used in brazing to be nonferrous metal or alloy having a melting point above 800°F (425°C) but below that of the metal being joined. Good practice in cleanliness of joints and the use of proper fluxes is required for brazed joints.

Brazing procedures and operators, except for socket-type capillary joints, should be qualified in accordance with the requirements of Section IX of the ASME Boiler and Pressure Vessel Code.

For soldered joints, the ASME B31.5 Code defines the solder metal to be a nonferrous metal or alloy having a melting point below 800°F (425°C) and below that of the metal being joined. Good soldering technique requires proper cleanliness and preparation of the joints, proper joint clearances, and proper heating. Procedures to be used on soldering or brazing socket type joints are outlined in ASTM B828-92.[5]

Miscellaneous Considerations

Corrosion.   The ASME B31.5 Pressure Piping Code recognizes that corrosion or erosion may be factors to be considered in piping design. When corrosion or erosion is expected, an increase in wall thickness of the components above that dictated by other design requirements is to be provided consistent with the expected life of the particular piping involved. In the basic equation for calculating the pressure ratings of pipe or in determining the required wall thickness of pipe, the Pressure Piping Code requires the addition of a factor to the calculated wall thickness to result in the actual thickness required. The factor includes allowance for threading, groove depth, and manufacturers' minus tolerance plus corrosion and erosion allowances.

Corrosion allowance on the inside of piping for volatile refrigerants is not mandatory. The refrigerant is recirculating and is usually charged into the system in a commercially pure state after thorough cleaning and evacuation of the entire system. When installed in accordance with good practice, a leaktight refrigerating system will not tend to corrode and it is not customary to add corrosion allowances. It is possible, with certain of the halogenated hydrocarbon refrigerants when contaminated with noncondensible gases or with water which may leak into a system under vacuum, to have corrosive products form. On some occasions, in hermetically sealed refrigeration systems, compressor motor burnouts have resulted in formation of contaminants which also may be damaging to the inside of the system. However, these considerations are not properly part of the piping design and are usually the result of carelessness or misapplication. It is ordinarily not necessary to add corrosion allowance to volatile-refrigerant piping.

For secondary coolant piping, especially with salt brines, the consideration of possible corrosion should be kept in mind in the design of the piping system. Ordinarily standard-weight pipe for either volatile-refrigerant use or for brine piping inherently has sufficient strength so that the normal wall thickness of pipes which are used are much heavier than are required for the actual pressure service, and therefore it may not be necessary to add additional allowances for corrosion.

Fittings. The Pressure Piping Code permits the use of standard fittings, provided they are compatible with the refrigerant or fluid. The standard ratings of forged steel flanges, fittings, and similar parts may be used for refrigerant service

Bell-and-spigot fittings may be used only for water and drainage service.

Couplings made of cast, malleable, or wrought iron may not be used on pipe containing flammable or toxic fluids. Wrought-iron couplings are subject to the same limitations in temperature, stress, and service which apply to cast-iron screwed fittings.

Valves. Cast-iron gate valves and plug cocks must not be used in liquid-refrigerant lines unless consideration is given to the expansion of liquid trapped in a space when the valve is closed.

Several manufacturers make standard lines of refrigeration fittings which do not fall into the classification of ANSI Standards for forged-steel valves. These valves and fittings over long years of usage have gained acceptability and are widely used and acceptable for refrigeration service to the degree recommended by the manufacturer.

Other Factors. The Pressure Piping Code lists the following dynamic effects which should be taken into account in the design of refrigerant piping.

1. Impact forces (including hydraulic shock) caused by either external or internal conditions.

2. The effect of wind loading on exposed piping.

3. Piping systems located in regions where earthquakes are a factor are to be designated for a horizontal force in conformity with the good engineering practice using governmental data as a guide in determining the earthquake force. However, this force is not to be considered as acting concurrently with lateral wind force.

4. Piping shall be arranged and supported with consideration for vibration.

The Pressure Piping Code also calls attention to the following weight effects which should be taken into account in the design of piping:

1. Live loads such as the weight of the fluid transported and snow and ice loads if the latter will be encountered. If low-temperature piping is not insulated, there can be a buildup of ice on the pipe even in high ambient temperatures.

2. Dead loads, consisting of the weight of the piping components and insulation and other superimposed loads.

3. Test loads which consist of the weight of the test fluid in the pipe.

CHAPTER C10
HAZARDOUS PIPING SYSTEMS

Ronald W. Haupt, P.E.*

Senior Consultant
Pressure Piping Engineering Associates, Inc.
Foster City, California

INTRODUCTION

Recent serious accidents[1] involving unwanted release of hazardous materials in the process industries worldwide have focused attention on the need to provide a process by which such accident occurrences can be prevented. This chapter discusses one aspect of that process—the design, construction, operation, maintenance, and modification of hazardous piping systems. The organization generally follows the sequence of piping design, construction, and operation discussed in greater depth in other chapters of this book. However, this chapter focuses on those elements of the design, construction, and operation of hazardous piping systems that are of particular importance to the owner, designer, and operator. Some of the elements discussed herein have been safely neglected in the design of more benign piping, but are mentioned here because it is felt they should be considered for hazardous piping. This chapter does not discuss in any depth the requirements or methods to perform process safety management, except to note elements of piping systems which may be susceptible to piping failures and need to be considered in any system designed to prevent fluid handling system failures. Lastly, this chapter does not discuss piping systems intended to handle nuclear power or nuclear power waste materials. These piping systems are highly regulated, and prescribed requirements are published elsewhere.

The American Society of Mechanical Engineers, Code for Pressure Piping, B31.3 *Process Piping*[2] defines a hazardous fluid service as:

> ''a fluid service in which the *potential* for personnel exposure is *judged* to be *significant* and in which a single exposure to a *very small quantity* of a toxic fluid, caused by leakage, can produce *serious* irreversible harm to persons on breathing or bodily contact, even when *prompt* restorative measures are taken [*emphases added*].''

The emphasized words in the definition are all qualitative, and what may constitute a hazard in one condition (steam in a confined space, for example) may not constitute a hazard under other circumstances (i.e., steam in an open field). A fluid that may be a hazard to the uninformed general public, if exposed to it, may not be considered a hazard if knowledgeable service personnel are handling it. The responsibility of what constitutes a hazard ultimately resides with the owner, and the designer of a hazardous fluid handling system in concert with the owner. The responsibility for a hazardous fluid handling system does not end with its design and construction. Responsibility extends beyond system start-up to the owner to operate and maintain the system safely and provide for the emergency conditions of hazardous fluid releases.

Piping typically will only be part, perhaps even a small part, of a fluid handling system. Pressure vessels, pumps, heat exchangers, turbines, compressors, and other primary fluid handling equipment items may represent greater capital investments and contain greater quantities of hazardous fluids, but all parts of the fluid handling system, including the piping, must be designed, operated, and maintained so as to limit the release of the hazardous contents to nonhazardous levels.

It must be emphasized that during the service life of a plant (as high as 40 years or more), only diligent stewardship will ensure safe, reliable operation of hazardous piping systems. This stewardship begins at the early design phase, and continues through detail design into the construction, erection, and test phase and operation. However, this is only the beginning—a comprehensive monitoring and preventative maintenance program must be developed and implemented to ensure a hazard-free system. And finally, any modifications or repairs need to be performed with the same care and considerations required for the original design and construction, amplified by the recognition that hazardous residues may be present and reactive at and adjacent to the interface between the existing construction and any new or additional fabrications.

Table C10.2 at the end of this chapter summarizes many of the design and operation recommendations developed herein.

TERMS USED IN THIS CHAPTER

Definitions

Some of the terms used in reference to hazardous systems are defined below. Other common piping-related terms are defined in Chap. A1 of this book;

however, the following definitions of owner and designer are specific to this chapter.

Designer. The person responsible for the design decisions to be made regarding the hazardous piping design. It is important that the designer have considerable piping design experience and have access to relevant expertise in the hazardous materials being handled and regarding possible interaction between the hazardous materials and the materials of construction. Professional engineering registration would seem to be a necessity, complemented by an understanding of the intentions of the various codes and standards which may be used in the design, construction, operation, and maintenance of hazardous piping systems.

Explosive. Extremely rapid combustion of a material such that a high-pressure wave is formed and propagated away from the source, often causing extreme damage to nearby objects.

Flammability. The degree of susceptibility to ignition or combustion of a material under specific environmental conditions.

Owner. The organization which will operate the constructed hazardous piping system. The owner is typically viewed by legal systems as having the overall responsibility for the safe design, construction, and operation of owned facilities and, as such, has the primary responsibility for the identification of hazards. While the designer may have some shared responsibility and provide the owner with expertise with which to evaluate hazards, it is nonetheless usually held that the final responsibility for the identification of hazards lies with the owner. Further, it does not seem plausible that hazardous piping would ever be constructed in a speculative environment, and if an engineering construction is purchased by an organization not involved in its design, the new owner should closely evaluate piping systems which handle hazardous and potentially hazardous materials.

Process hazard analysis. A comprehensive review designed to identify potential hazards and to produce specific recommendations that will reduce the probability of a hazard occurring.

Process safety management. The systematic process of design, operation, maintenance, emergency planning, and training by which the unwanted release of hazardous materials is sought to be prevented or mitigated.

Reactivity. The susceptibility of materials to release energy either by themselves or in combination with other materials.

Risk-based inspection. A process by which the evaluation of the risks of failure are prioritized for the purpose of developing a system inspection program to limit system failures and the adverse consequences of those failures.

Safeguarding. The provision of protective and preventative measures that reduce the probability of hazardous conditions occurring.

Toxicity. The ability of a chemical molecule or compound to produce injury once it reaches a susceptible site in or on the body.

CODES, STANDARDS, AND REGULATIONS

The latest edition and addendum of an applicable code or standard should be used for the design and construction of hazardous piping. It may be assumed that the latest edition and addendum of most codes is the clearest interpretation of the requirements of that code. The codes and standards mentioned in this chapter are U.S. codes and standards, but could be reasonably replaced by comparable foreign codes and standards.

New-construction piping codes and standards set forth engineering requirements, normally considered minimum, to assure the safe design and construction of piping systems. Codes and standards use simplified approaches to gain the widest possible usage. Codes and standards typically caution the owner and designer that these documents are not handbooks; that not all service conditions and environmental effects can be known; and, further, that requirements cannot be written to evaluate all such conditions and effects. The owner and designer are asked to use their experience and engineering judgment to meet the safety

factors inherent or explicit in the codes and standards. This necessity is compounded when the possibility of a hazard exists with a breach of the fluid-containing boundary.

At present there are few codes or standards which address the area of operations and maintenance of fluid handling systems, much less hazardous piping systems. There is a growing awareness of the problem as evidenced by recent U.S. PSM regulations[3] and efforts by industry to develop approaches to operation and maintenance, such as new and proposed codes and standards by the AIChE, API, ASME, and NBBPVI. However, specific guidance for component evaluation in these new and proposed codes and standards is limited; rather these documents tend to outline procedural requirements and often rely on new-construction rules to guide the operation and maintenance of fluid-handling systems.

The jurisdiction and the obligations of the various parties with regard to codes and standards are discussed at length in Chap. A4.

Piping codes and standards do not list hazardous substances; therefore the owner and designer must identify such materials. However, codes and standards may assist in the identification process. The following is a listing of codes and standards, or documents which may loosely be described as a code or standard, that may assist the owner and designer to identify hazardous materials, to properly design and construct hazardous piping systems, and to evaluate the performance of existing piping systems.

API 570, ''Piping Inspection Code: Inspection, Repair, Alteration, and Rerating of In-service Piping Systems''

API RP 574, ''Inspection of Piping, Tubing, Valves, and Fittings''

API RP 750, ''Management of Process Hazards''

ASME B31 ''Code for Pressure Piping.'' The ASME B31 Code for Pressure Piping consists of several sections: B31.1 *Power Piping,* B31.3 *Process Piping,* etc. (see Chap. A4). All the sections, published as separate books, may have useful information relevant to the design and construction of hazardous piping systems for their particular application. B31.3, however, is the only section that includes a chapter on hazardous piping systems.

ASME B31G, ''Remaining Strength of Corroded Pipe''

ASME Boiler and Pressure Vessel Code, Section VIII, Divisions 1 and 2, ''Rules for Construction of Pressure Vessels''

NBBPVI, ''National Board Inspection Code''

NIOSH, ''Registry of Toxic Effects of Chemical Substances''

NFPA 30, ''Flammable and Combustible Liquids Code''

NFPA 49, ''Hazardous Chemical Data''

NFPA 325M, ''Fire Hazard Properties of Flammable Liquids, Gases, and Volatile Solids''

NFPA 491M, ''Manual of Hazardous Chemical Reactions''

The references also include several miscellaneous noncode or standard publications which may assist the owner and designer in their efforts toward the identification of hazardous fluids and meeting PSM requirements.[4,5]

In addition, U.S. regulations have been published (1992) which require establishing procedures to ensure the integrity of systems handling hazardous materials.

TABLE C10.1 Materials Having High Toxicity or Reactivity

Acetaldehyde
Acrolein (2-Propenal)
Acrytyl chloride
Allyl chloride
Allytamine
Alkylaluminums
Ammonia, Anhydrous
Ammonia solutions
Ammonium perchlorate
Ammonium permanganate
Arsenic hydride (also called Arsine)
Arsine (also called Arsenic hydride)
Bis(chloromethyl) ether
Boron trichloride
Boron trifluoride
Bromine
Bromine chloride
Bromine pentafluoride
Bromine trifluoride
3-Bromopropyne (also called Propargyl bromide)
Butyl hydroperoxide (tertiary)
Butyl perbenzoate (tertiary)
Carbonyl chloride (also called Phosgene)
Carbonyl nitrate
Chlorine

Diisopropyl peroxydicarbonate
Dilaluroyl peroxide
Dimethyldiclorosilane
Dimethylhydrazine, 1,1-
Dimethylamine, anhydrous
2, 4-Dinitroaniline
Ethyl methyl ketone peroxide (also called Methyl ethyl ketone peroxide)
Ethyl nitrite
Ethylamine
Ethylene fluorohydrin
Ethylene oxide
Ethyleneimine
Fluorine
Formaldehyde (Formalin)
Fuming sulfuric acid (also called Oleum)
Furan
Hexafluoroacetone
Hydrochloric acid, anhydrous
Hydrofluoric acid, anhydrous
Hydrogen bromide
Hydrogen chloride
Hydrogen cyanide, anhydrous
Hydrogen fluoride
Hydrogen peroxide
Hydrogen selenide

Nitric acid
Nitric oxide
Nitroaniline
Nitromethane
Nitrogen dioxide
Nitrogen oxides (NO; NO_2; N_2O_4; N_2O_3)
Nitrogen peroxide (also called Nitrogen tetroxide)
Nitrogen tetroxide (also called Nitrogen peroxide)
Nitrogen trifluoride
Nitrogen trioxide
Oleum (also called Fuming sulfuric acid)
Osmium tetroxide
Oxygen difluoride (Fluorine monoxide)
Ozone
Pentaborane
Peracetic acid (also called Peroxyacetic acid)
Perchloric acid
Perchloromethyl mercaptan
Perchloryl fluoride
Peroxyacetic acid (also called Peracetic acid)
Phophoryl chloride (also called Phosphorus oxychloride)
Phosgene (also called Carbonyl chloride)
Phosphine (Hydrogen phosphide)

Chlorine dioxide
Chlorine pentrafluoride
Chlorine trifluoride
Chlorodiethylaluminum (also called Diethylaluminum chloride)
1-chloro-2, 4-dinitrobenzene
Chloromethyl methyl ether
Chloropicrin
Chloropicrin and Methyl bromide mixture
Chloropicrin and Methyl chloride mixture
Cumene hydroperoxide
Cyanogen
Cyanogen chloride
Cyanuric fluoride
Diacetyl peroxide
Diazomethane
Dibenzoyl peroxide
Diborane
Dibutyl peroxide (tertiary)
Dicloro acetylene
Diclorosilane
Diethylaluminum chloride (also called Chlorodiethylaluminum)
Diethylzinc

Hydrogen sulfide
Hydroxylamine
Iron, pentacarbonyl
Isopropylamine
Ketene
Methacrylaldehyde
Methacryloyl chloride
Methacryloyloxyethel isocyanate
Methyl acrylonitrile
Methylamine, anhydrous
Methyl bromide
Methyl chloride
Methyl chloroformate
Methyl ethyl ketone peroxide (also called Ethyl methyl ketone peroxide)
Methyl fluoroacetate
Methyl fluorosulfate
Methyl hydrazine
Methyl iodide
Methyl isocyanate
Methyl mercaptan
Methyl vinyl ketone
Methyltrichlorosilane
Nickel carbonyl (Nickel tetracarbonyl)

Phosphorus oxychloride (also called Phosphoryl chloride)
Phosphorus trichloride
Propargyl bromide (also called 3-Bromopropyne)
Propyl nitrate
Sarin
Selenium hexafluoride
Stibine (Antimony hydride)
Sulfur dioxide (liquid)
Sulfur pentafluoride
Sulfur tetrafluoride
Sulfur trioxide (also called Sulfuric anhydride)
Sulfuric anhydride (also called Sulfur trioxide)
Tellurium hexafluoride

Tetrafluorohydrazine
Tetramethyl lead
Thionyl chloride
Trichloro (Chloromethyl) silane
Trichloro (Dichlorophenyl) silane
Trichlorosilane
Trifluorochloroethylene
Trimethyloxysilane

International efforts follow similar paths. In the United States, 29CFR1910, App. 2 lists 140 chemicals with high toxicity and reactivity which OSHA considers highly hazardous above the concentrations and threshold the quantities listed there. The chemicals only are listed in Table C10.1. For concentrations, threshold quantities, and revisions to the list of chemicals in Table C10.1, the latest CFR document should be consulted. Note that not all of the materials listed are in a liquid form capable of being piped.

IDENTIFICATION OF HAZARDOUS PIPING

The identification of the hazards associated with the materials to be handled by a system is the first and most important step in the piping design process. Complicating the process are human error and inadequate management of mechanical systems, which have been said to be the largest causes of hazardous accidents. Various methods may be used to identify these hazards. The ''Emergency Planning and Community Right-to-Know Act'' passed by the U.S. Congress in 1986 established a framework for community emergency planning programs to deal with chemical releases. Additional federal actions eventually led to the publication of 29CFR1910 and identification of the hazardous materials listed in Table C10.1. It would not be typical for the piping designer to be as involved in community emergency planning as the owner. However, the piping designer may be more involved in the facility's mandatory PHA, if covered by 29CFR1910, or more informal hazards assessment, if not covered by 29CFR1910. From the designer's involvement in these tasks, it may be a simple matter to establish whether a piping system needs to be designed as hazardous. If the designer is not involved in any hazard analysis, it is incumbent upon the owner to ensure that all relevant knowledge developed from these analyses is communicated to the designer. It is the responsibility of both the designer and the owner to be sure that all of the relevant information has been received and appropriately applied. Further, the designer is responsible to clearly communicate the design intent to the fabricator and erector and to provide the operator with clear guidance as to the proper operation of the constructed piping system.[6] A composite system diagram (see Fig. C10.1) may be useful in organizing piping system design features and in communicating them to the operator.

Various methods are used to perform PHA or less formal assessments such as HAZOPs (Hazard and Operability Studies), ''what if'' checklists, FMEAs (Failure Mode and Effect Analyses), and ''Fault-Tree Analyses.'' These methods often can be used jointly, complementing each other, to produce a higher quality product. While it is beyond the scope of this chapter to describe the different hazard assessment techniques, they all have some basic objectives:

Identify hazardous contents or functions relating to safe handling of such contents

Evaluate the operational and environmental effects and their potential to cause a failure which would result in a hazard

Evaluate the consequences of a postulated failure

Develop specific recommendations to contain, control, or limit the identified hazard.
FIGURE C10.1   Composite system diagram.

With regard to piping systems, the *hazard assessment* task should at least consider the following:

- What is the amount and hazard level of the contents in the materials handling system?
- How much of the materials handling system contents could be released if the piping pressure boundary is breached?
- What is the effect on the materials handling system if the piping system fails to operate?
- What is the size of the piping (small piping can be more robust relative to large piping, but small piping can also be more easily abused by activities around the piping system)?
- Where is the piping located (who will be exposed, and in what form will the exposure take place, should a release of the hazardous material occur, and how knowledgeable are those who might be exposed)?
- Are the piping materials of construction compatible with the hazardous contents?
- What are the normal and abnormal service conditions (are the service conditions, so extreme, above and below ambient conditions, or even the ambient conditions themselves, that extra care appears prudent)?
- What is the potential for the piping system to experience a lot of service cycling or be subject to hammering or slugging or flow or mechanically induced

vibrations (high flow rates and two-phase flow can accelerate erosion and corrosion effects, excite piping system modes of vibration, or impose significant hydraulic loads)?

- What are the environmental conditions (is the plant location, or the piping configuration or elevation such that extreme environmental loads can be expected)?
- What is the expected piping system service life (is the time during which the piping system is to be operated of such duration that the probability of failure, such as, creep, fatigue, or erosion/corrosion damage, is significantly increased)?
- What protective measures are appropriate, (for example, guarded piping, structural separation, leak sensing, measures to mitigate the effects of leaks)?

Hazard assessments can be conducted at various stages of a project:

- A preliminary hazard assessment can be conducted early in the project to highlight major potential hazards and define those areas where further study is needed.
- A design hazard assessment can be performed after the process design has been completed to ensure that the process hazards have been identified and necessary corrective recommendations have been implemented.
- A design verification assessment can be performed after the piping system has been designed, to ensure that all items relating to previous hazard assessments have been satisfactorily resolved.
- An operational readiness assessment can be conducted prior to plant start-up to ensure that the design measures established as a result of the various hazards assessments have been incorporated into the construction and planned operation of the piping system.
- Operating assessments can be performed on a routine basis during operating and outage periods to ensure that proper operation, maintenance, and repair procedures are being adhered to.

Note that even if a piping system does not handle a hazardous substance, if the piping system is critical to the operation of a hazardous substance handling system it may need to be designed, constructed, and operated with the object of maintaining its operability under all conceivable operating and environmental conditions. Where there is any question regarding the toxicity or reactivity of a chemical, experienced technical personnel knowledgeable about that chemical should be consulted. The exclusion of a chemical from Table C10.1 should not imply that piping is not hazardous if the contents are released under unfavorable conditions, in an unfavorable location, and in a sufficient amount. When in doubt, a conservative approach would be to adopt appropriate provisions of this chapter. In B31.3 services it is not uncommon to adopt the provisions for hazardous fluid service without referring to the service as such.

QUALITY ASSURANCE AND QUALITY CONTROL

Quality Assurance (QA) and Quality Control (QC) programs are normally associated with the design and construction activities, respectively. To some extent the

hazards assessment process can be used to implement and complement both activities. However, the design process for hazardous piping systems, even if a formal QA program is not used, should incorporate document controls covering all relevant calculations, specifications, and drawings; a system whereby all relevant calculations, specifications, and drawings are checked by an independent knowledgeable person; and the calculation, specification, and drawing originator(s) and checker(s) acknowledging their activities by signature and dates; and a documented periodic review of the design activities by supervisory, technically knowledgeable personnel.

It would be expected to find formal QC programs implemented by quality manufacturing, fabrication, and construction organizations. In the construction of hazardous piping systems it is probably not a good idea to use any product from or service by an organization that does not have a functioning QC program. A functioning QC program is one which appears to have been used and revised periodically to meet new operating conditions, organizational changes, or improve the conformance to the way the organization works. A lack of revisions might indicate a lack of commitment to the QC program. A QC program will be able to document work performed; provide proof of materials, workmanship, and conformance to the construction documents; and maintain a segregation of parts and materials throughout the manufacturing, fabrication, and construction process.

DESIGN CONSIDERATIONS

The hazardous piping system should be designed for the entire range of possible design conditions. More information about the operating, possible abnormal, and environmental conditions should be understood than typically may be necessary for a more benign piping system. The designer should have access to a greater variety and level of expertise (e.g., in materials, welding, erosion/corrosion, thermal hydraulics, structural dynamics, chemical interactions, and systems operation) than would be typically necessary for more benign systems. The designer should be skeptical of untried methods and product forms without sound test data to back up analytic presentations. Common sense and reasonable conservatism are necessary to design a hazardous piping system.

Piping Failure Modes

The piping failure modes of greatest concern are *rupture, mechanical joint disengagement*, or *excessive deformations* and *collapse*. These represent the "worst case" failure scenarios. A rupture has the potential to release a large amount of the piping system contents. Disengagement of a mechanical joint has a like potential. Excessive deformations or collapse may cause active equipment (e.g., valves, pumps, turbines, and compressors) to bind and not function and other piping components to pinch or otherwise impede fluid flow.

Other piping failure modes of lesser but still significant concern are the effects of cyclic behavior or the excessive deformations of mechanical joints. Cyclic effects can lead to a fatigue failure, either resulting in a leak or possibly a rupture. Excessive deformation of a flange can also result in a leak but probably not a rupture.

Design Conditions

The design pressures and temperatures should represent the highest (or lowest if the piping system is to operate below ambient conditions) coincident pressures and temperatures the piping is expected to experience during any normal or abnormal operating condition, including any possible environmental effects. Possible variations in normal and abnormal operating conditions should not be allowed to exceed the design pressures and temperatures. The design pressures and temperatures and the maximum coincident external (hydraulic, mechanical, and environmental) loadings should be used to establish the design wall thicknesses and classes for all fittings. Note that considering the effect of external loads may necessitate higher classes of fittings than would be necessary for pressure-temperature conditions alone. Based on variations in external loads, the classes of fittings may vary within the piping system.

Material Selection

Highly ductile materials should be used for hazardous piping. The use of low-ductility materials, such as cast-iron or glass, should be avoided. Materials with demonstrated brittle behavior or sensitivity to thermal and mechanical shock loadings limit their serviceability and range of use. Low-ductility materials are susceptible to brittle failure in hazard mitigation situations, for example from thermal shock when exposed to fire or fire-fighting measures.[8] Impact testing should be used to verify material ductility.

Proprietary materials may be used if the designer is confident of the suitability of the materials for the range of normal and abnormal conditions the material will be exposed to. Materials without sufficient service experience should be avoided.

Material selection should take into account the suitability of the piping to resist deterioration in service. Information should be sought to determine material performance in corrosion or erosion environments.[9,14] Information may be provided; either qualitatively (e.g., acceptable or not acceptable) or quantitatively (e.g., expressed as a uniform corrosion rate). Quantitative information is used to establish corrosion or erosion allowances; qualitative information to select a material that will minimize erosion/corrosion damage. Obviously, the qualitative approach is preferable.

The designer should be aware that in actual service corrosion and erosion will typically be localized and not occur uniformly throughout the piping system. Corrosion is a function of many parameters, such as trace elements in the material, temperature, flow geometry, and flow rate. Corrosion is usually accelerated at crevices, under backing rings, in threaded joints, in socket-welded joints, at weld metal areas and heat-affected zones, or in other stagnant, low-flow areas of the piping system. Erosion is typically accelerated where high flow velocities exist, for example, in undersized pipe, at elbows, branches, reducers, or other locations where there are flow disturbances.

In addition to evaluating the piping base materials, the method of pipe or piping component manufacture should be considered. Joints, material postforming treatment, and manufacturing processes can render piping less resistant to erosion/corrosion than the base materials.

Metallic Piping. Metallic material identification for hazardous piping systems is out of the scope of this chapter. Numerous sources can provide meaningful data for use in the materials selection process.[9,14] But the final choice of material should

at least be reviewed by an expert in the chemical and erosion and/or corrosion performance of the candidate material.

Metallic and weld material selection should consider the potential adverse effects of any dissimilar materials that may be in contact, as galvanic action at dissimilar joints can promote accelerated corrosion where it would not otherwise be expected to occur. Material test reports should be sought for all pipe and components so they are available during maintenance activities to determine more realistic factors of safety against failure.

Time-dependent material properties must also be addressed during the material selection process. At high temperatures, typically over 700 to 800° F (370 to 430° C), and over a period of time ferrous materials lose ductility, decrease in strength, and flow (creep). Other metallic materials (e.g., copper, aluminum) experience this phenomenon at lower temperatures and are typically not used where creep would affect performance. It may be wise to select a conservative design temperature when the hazardous piping system must operate in the creep regime. Additional supports and the judicious use of rigid supports can reduce pipe sag and pipe migration during service.

Nonmetallic Piping. Nonmetallic piping typically creeps at room temperature and can suffer degradation due to temperature effects or exposure to sunlight. Consideration should be given to additional supports and protection from sunlight. Using a nonmetallic lining in pipe or a metallic frame around the nonmetallic material may offer protection or additional support. Providing protection for nonmetallics during operation by isolation, double containment, or other means may also be appropriate.

Nonmetallics are attractive because of their corrosion-resistant properties and low cost, but typically they are not erosion resistant. Also, nonmetallics are susceptible to undetectable damage due to impact during transport, storage, and installation. Pipe-joining procedures require care that must be observed, but because nonmetallics are perceived as ''low tech,'' such procedures are often abridged.

Nonmetallics typically exhibit highly anisotropic behavior. Seeking the actual material properties (e.g., yield and tensile strengths, elastic modulus) in the transverse and longitudinal directions may be warranted to assist in maintenance activities for the same reason they are sought for when using metallic materials.

Because of nonmetallic piping's low elastic modulus, internal pressure can cause significant expansion of the pipe that is similar to thermal expansion in metallic pipe. The performance of nonmetallics under cyclic loadings is not well understood because of the wide range of nonmetallic materials, many being proprietary, the lack of material standards, and their typically nonisotropic behavior. If loads are expected to cycle more than a couple of hundred times, including pressure cycles, fatigue testing of the material may be warranted.

The designer should also be aware that nonmetallics can often be combustible and may require fire protection.

At this time (1999) there are no proven volumetric NDE methods available. Visual and dye penetrant methods are used, but these methods are limited to the pipe surfaces, and usually to the outside surfaces. Ultrasonic methods have been suggested as offering a potential volumetric examination, but these are thus far unproven. Refer to Chapter B13 and Part D of this handbook.

Design Criteria

Hazardous piping should be designed to a recognized piping code or standard. B31.3 has a chapter dedicated to the design of hazardous piping, but other codes

and standards could be used with proper consideration of the hazards and mitigating design attributes. Safety codes and standards, however, do not address levels of hazard. The designer should consider specifying greater safety attributes for hazardous piping to the degree he feels they may be necessary. A review of the B31.3 nonmandatory App. F, Precautionary Considerations, and G, Safeguarding[2] may provide the designer with ideas for enhancing the safety of the hazardous piping system.

If the designer plans to use nonstandard or unlisted materials and components or to use more rigorous analysis or alternative examination methods, the justification for the use of such materials and components under all the possible operating and environmental conditions and the reasons for justifying the use of such analysis and examination methods should be fully documented for the owner's approval before the release of specifications and drawings for construction.

PRESSURE DESIGN

The most significant safety attribute of piping is *pressure containment*. Hazardous piping should be designed for the most severe condition of coincident pressure, temperature, and loading. B31.3 does not permit, nor should any hazardous piping be allowed, to exceed design values, even for short periods of time. It may, in fact, be wise to overdesign the pipe for pressure (i.e., specify a thicker wall than is required by the piping code used). Other loadings may be increased by thicker pipe walls, but these other loadings, such as thermal expansion, may be compensated for by adding to the length and location of pipe in the anchor-to-anchor piping runs.

Straight Pipe

The design of straight pipe should be in accordance with the specified piping code. Flow velocities should be limited to a maximum of about 10 ft/s (3 m/s) for liquids and about 140 ft/s (43 m/s) for gases, especially where the potential for erosion and corrosion exists. Higher velocities may be justified by thorough investigation of the erosion/corrosion potential, but higher velocities may result in undesirable flow-induced vibrations and noise.

The additional wall thickness provided to allow for erosion and corrosion should be based not only on the expected rate of wall loss and the anticipated life of the system, but also on the expected examination interval of the in-service inspection program.

Since hazardous piping is often small piping, protection of the piping from damage after installation is also advisable. An additional wall thickness could be provided, or the piping may be isolated or located in channels, cable trays, or double containments.

Standard Components

Standard piping components are discussed at length in this and other books (see Chap. A2). The designer, however, should be confident that components supplied as standard actually meet the standards specified; for example, the manufacturer

should be able to provide evidence that the B16.9 fitting furnished or a comparable fitting has met the burst test provisions of B16.9.

The designer should be careful to ensure that components are specified to match the pipe to which they are connected. Further, the designer should request to be advised if the fabricator or erector deviates from matching components to the pipe or uses a nonstandard fitting in place of a standard fitting (e.g., using a Schedule 160 fitting rather than Schedule 80 fitting, or replacing a standard welding tee with a fabricated branch connection). Such deviations can result in stresses not considered in the design.

The designer should also be aware that velocities will increase locally in non-straight pipe components over the mass (bulk) velocity in straight pipe and thus can increase the local potential for erosion and corrosion.

Valves

A valve is usually defined by the piping codes as a standard piping component. As is the case with other standard components, the designer should be aware that fluid velocities, particularly in the vicinity of the valve seat, will be higher than in matching pipe and can result in erosion and corrosion problems.

The selection of valve type, style, and valve body and trim materials should be based on hazardous fluid properties, required operating characteristics, and ease of maintenance. When locating valves, the designer should consider required operability and service access. Selection of valve materials and location should also include consideration of potential accidents (e.g., fire). The valve construction (i.e., bolted bonnet versus pressure seal or welded) should include consideration for pressure boundary integrity required to prevent leakage of hazardous material (see Fig. C10.2). It is recommended that the valve meet recognized piping code requirements for design, materials, and manufacture.

Isolation and Control Valves. The number and locations of isolation valves should be based on system requirements and include consideration for potential release of hazardous materials in the event of pipe rupture or inadvertent improper operation.

Metal-seated gate valves should be of the flexible disc, split wedge, or double disc design which provide tighter shut-off than solid wedge designs, and prevent jamming of the gate, if the valve cools down in the closed position. The wedge and/or body seat should be hard-faced to prevent galling.

Remote-controlled valves (with motor operators, air operators, etc.) versus manual valves should be considered for more rapid valve operation and operation in a contaminated area. Similarly, remote manual operating devices, such as extension rods and chain-wheel operators, should be considered for ease of and safe valve manipulation. For large valves where motor operators cannot be justified, but where a valve may be required for isolation in an emergency, consider using portable air drives to assist in rapid valve closure. Also, for large manual valves consider ''impact'' handwheels to assist in the seating or unseating of the disc.

Valve and operator type should be such that valve position is easily visually determined (for example, see Fig. C10.2). For valves essential to plant safety, consider the use of remote position indication. To preclude the possibility of inadvertent, improper valve operation, consideration should be given to using valve position-locking devices.

Permissible valve leakage (i.e., leakage across the seat[s] when closed) should be based on the properties of the fluid media and hazard presented by leakage.

Rising stem

leak areas

Back seat

Possible
leak areas

Valve stem
FIGURE C10.2   Conventional gate valve.

Valve backseat capability should be considered for gland repacking while the system is energized. The design of valve gland injection or leakoff collection devices should also be based on the properties of the fluid media and hazard presented by leakage. Valve body drains should be considered for removal of fluid media from the lower cavities for ease of maintenance activities.

Control valve redundancy (i.e., parallel installations) should be considered based on required system operation. The designer should be aware that cavitation can occur in the piping downstream of control valves and can result in severe erosion/corrosion problems. Control valve positioner linkage materials need to be compatible with the external environment and contained fluids.

Although service failures in valves have resulted from shrinkage cavities in cast

valve walls,[7] through-wall cracking of valves is rare. On the other hand, leakage through the stem/bonnet is relatively common.[11] Recent design enhancements have produced valves with sophisticated devices to eliminate valve stem leakage. Most of these designs employ a proprietary bellows-like device to effect a hermetic seal. These devices, along with conventional backup seals, may provide a solution to the problem of fugitive emissions emanating from valve stem areas.

Relief and Safety Valves. Relief and safety valves should conform to a recognized pressure component code which requires overpressure protection of the pressure boundary. B31.3 requires that the design pressure shall not be exceeded by more than 10 percent during a pressure-relieving event. Note that this is in conflict with the B31.3 requirement that piping shall be designed for the most severe condition of coincident pressure, temperature, and loading. It is recommended that the design pressure and temperature include values expected during the pressure-relieving event. However, should the 10 percent requirement of B31.3 be applied, the designer should consider including a temperature correction, if the design temperature is also exceeded during the pressure-relieving event.

Unless the pressure-relieving system is designed to regularly recycle or eliminate the hazardous contents, the set pressures of relief and safety valves should be set sufficiently above the normal and recoverable abnormal operating conditions such that the pressure-relieving system is not activated except in an emergency.

Since small safety/relief valves (sentinel valves) have a tendency not to reseat once they lift, they should have the spring cap drilled and tapped for a gag which should be attached to the valve to facilitate closure.

Rupture disc and breaking pin devices are normally unsuitable for relieving pressure in hazardous piping.

Nonstandard Components

Special fabrications, forgings, castings, and other specialties may complicate the design and cause difficulties later, if replacements are required. However, if used they should be qualified for pressure design in accordance with a recognized piping code or standard proof test, such as found in B16.9. The proof test procedure and the results should be reviewed and approved by the designer. The proof test should prove the nonstandard component's capability to function at 110 percent of the piping system's design pressure, adjusted for the design temperature, with the factor of safety inherent in the piping code used for design.

Expansion Joints and Flexible Hose

Expansion joints and flexible hose should be avoided unless absolutely necessary to accommodate thermal movements where expansion loops are not feasible or to decouple the piping from potential sources of mechanical vibration, (e.g., rotating equipment). If used, it should be realized that portions of the joint or hose are typically highly stressed and can degrade rapidly in an adverse environment or if manufactured with materials unsuitable for the service. If tie rods are not used, the pipe supports must be designed for the very large loads resulting from pressure thrust. The designer should follow the recommendations of the manufacturer and the Expansion Joint Manufacturers Association.[16]

JOINT DESIGN

Piping joints, whether welded or mechanical, must be suitable for the anticipated pressure, temperature, and external loading conditions. The designer should also be aware that joints may be sensitive to the type of loading or be subject to selective attack by the erosive or corrosive nature of the fluid handled. Barriers and shields should be considered for mechanical joints to protect personnel from leakage.

Welding

Welding is the preferred method of making a joint in hazardous piping. Welding should be performed in accordance with the ASME Boiler and Pressure Vessel Code, Sec. IX, *Welding and Brazing Qualifications*. While welds between pipe supports or other attachments and the pressure-retaining boundary should also be in accordance with Sec. IX, welds between pipe support items may not need to be Sec. IX welds if they conform to an acknowledged structural welding code.

Meeting the requirements of Sec. IX should assure the quality of welding. Section IX requires the preparation of a written welding procedure specification (WPS). The procedure is qualified in a procedure qualification record (PQR) which documents physical testing proving that welds made in accordance with the WPS provide the required mechanical properties, essentially equivalent to the base material properties. Just as important is the qualification of the welder, which is done to prove the ability of the welder to make sound welds in accordance with the WPS. This is also proven by testing sample weldments done by the welder. For hazardous service, the designer may wish to require more stringent testing of either or both the procedure and welder and in-process checks to ensure the desired weld quality.

To minimize any adverse effects from welding, the designer should review and approve the welding procedures and qualifications of the manufacturer, fabricator, and erector. The welding processes chosen should be based on the materials being welded, the quality level desired, and the availability of personnel capable of depositing sound weld metal. The filler material should be selected to essentially match the chemical composition and material properties of the base materials. Corrosive environments, low temperatures (requiring toughness considerations), and high temperatures (requiring creep considerations) may necessitate special attention to welding processes.

Longitudinal welds used to manufacture pipe are typically made in accordance with Sec. IX, but also typically these welds are penalized, using a joint efficiency factor to reduce the allowable base material stress resulting in a thicker weld. Some care should be exercised if welded pipe is to be used for hazardous piping. B31 joint efficiency factors have been subjectively developed and do not take into account possible operating degradation (e.g., due to creep). If the joint efficiency factors are less than 1.0, using B31 specified NDE can improve the joint efficiency factors to a value of 1.0, but this should not necessarily be construed as removing the metallurgical or geometric discontinuity that the weld joint represents. Consideration should be given to using seamless pipe in hazardous piping. On the other hand, high-resolution NDE in conjunction with a mill hydrotest has been shown to produce a high-quality weld seam in welded pipe. Because anisotropic properties are a typical result of the pipe manufacturing process (with more disparity expected in seamless pipe), the designer may consider testing for both transverse and longitudinal, yield and tensile properties as it is not unusual to have the maximum properties given in material test reports.

Butt welding is also the preferred method of joining two pieces of pipe because it typically produces a relatively small local stress riser in the form of surface imperfections,[15] compared to other types of welded joints, and a butt weld joint can be readily examined by most conventional nondestructive techniques.

Typically, with hazardous materials, a smooth internal root condition is desired. In order to achieve this, the gas tungsten arc-welding (GTAW) process is often chosen, sometimes with the additional application of automatic welding. This is true because the GTAW process characteristics allow for close control of heat input. Other processes may be used to fill the weld joint after the initial layers are deposited.

Socket welds can be used if the designer evaluates and accepts its deficiencies. Several problems could be anticipated with the use of socket welds. Socket welds are susceptible to failures due to pressure cycling. The gaps required for fit-up and crevices in the socket are also potential debris collectors and places where corrosive elements can accumulate. Recent improvements in automatic welding in the field renders such a reasonably viable alternative to socket welding. Backing rings used for butt welds may also be subject to problems similar to the crevices in socket welds and it may be wise to avoid their use.

Branch connections are often made using proprietary products (so-called ''integrally reinforced'' weld-on fittings). It is important to obtain the manufacturer's recommendations for welding, in particular the attachment weld profiles, prior to their specification in the design. It is also important to specify a cover weld for the attachment weld to the header similar to the requirements of the various B31 codes. If the branch connection is large, cover welds larger than those required by code would be prudent. Details of the required weld should be specified in the engineering design.

If fatigue is a problem, consideration should be given to grooming the surface of the finished circumferential and branch welds. For cleanliness, and if the inside of the pipe is accessible, grooming the inside surface of the weld might also be considered.

Dissimilar metal welds should not be used unless the thermal expansion effects of the two materials are evaluated. If the dissimilar metal weld is necessary, it should be a butt weld, not a socket weld or a branch connection weld.

Brazing and Soldering

Brazing and soldering should not be used in hazardous piping.

Bonding

It is obvious that the bonding of nonmetallic piping is critical to the construction of a safe hazardous piping system. However, the designer should recognize the fact that many bonds are carelessly made because the use of plastic pipe is not typically treated with the same regard as metallic piping.

The bonding of nonmetallic piping components should be done in accordance with a written bonding procedure specification (BPS). The BPS should be qualified by testing the mechanical properties of an assembly made in accordance with the BPS. All bonders should be qualified by preparing an assembly in accordance with the BPS that is tested to prove the bonder can make acceptable bonds. Refer to Chaps. D1 and D2 of this handbook.

Flanges

It bears repeating that flanges should be designed for the maximum coincident pressure, temperature, and loading. This is a fact that is often missed because typically flange standards list pressure and temperature ratings only. If piping loads are significant and if the flange is not properly sized, then the flange will inevitably leak. Increasing the flange class (e.g., using a Class 300 flange where the pressure and temperature would indicate the use of a Class 150 flange) will result in a joint less likely to leak and in flange bolts that are less likely to be overstressed. The equivalent pressure method described in *Design of Piping Systems*[8] is suitable for sizing flanges with external loads and has been incorporated into a number of piping codes.

Flanges conforming to B16.5 are recommended. Flanges manufactured to other recognized consensus standards may need to be used for large-diameter piping and would be acceptable with due consideration given to external loads and fit-up.

Standard flanges include flat face, raised face, tongue and groove, ring joint, and lap joint flanges. Gasket materials include rubber, cork, elastomeric composition, spiral wound and laminated metallic-elastomer mixes, and solid metal rings. The effects of the hazardous contents on the gasket material should be considered.

These flanges offer the advantages of ease of joint assembly, standardized dimensions, and general availability. A disadvantage is that assembly requires high bolt loading during initial seating to retain sufficient gasket pressure in service. This should be a consideration if the joint is subject to high cyclic loads or operates in the creep regime of the flange materials.

Proprietary flanges are nonstandard components and should meet the requirements described for nonstandard components. The designer or the manufacturer should also understand how the flange will perform when subject to external loadings. These joints typically have fine surface finishes and tight tolerances. They usually require great care in assembly, and the tight gaps may create the potential for crevice corrosion.

Published flange ratings (pressure-temperature-material class) presume the proper selection of gasketing and bolting materials. The flange joint is an assembly of flange, gasket, and bolting. In most cases the gasket seating surface is critical to proper joint sealing. Should the designer be inattentive to the interdependency of the flange assembly components, the flanged joint may not withstand the operating and environmental loadings.

The designer should endeavor to locate flanged joints where external loads are low. The loading on a flanged joint includes internal pressure, bolt loads, and the piping operating and environmental loads.

Weld-neck flanges are recommended for hazardous piping systems. Other flanges may be used if due consideration is given to their deficiencies. Other flanges, excepting lap joint flanges, are typically joined to the pipe with a fillet weld, which is less desirable than a butt weld. The attachment (strength) fillet weld is typically more highly stressed and subject to a stress amplification due to its geometry. Slip-on flanges, if used, should be double-welded with the seal (or back) weld at a minimum distance from the face of the flange. Care must be taken to avoid having the seal weld interfere with the proper function of the flange. Threaded flanges should be avoided due to their susceptibility to crevice corrosion and because threads represent significant stress risers. Socket welding flanges should only be used for NPS 2 (DN 50) and smaller. When using socket welding flanges care must be used regarding fit-up to ensure a minimum gap between the pipe and the bottom of the socket. Plate flanges (flanges without hubs) should be avoided unless double-

welded and the flange thickness is increased to offset the high attachment weld stresses. Lap joint flanges are susceptible to crevice corrosion and potential sealing problems. Crevices in any of the flanges may collect contaminates, and the collected contaminates could present a problem when servicing flanged piping and equipment.

Flanged joints in hazardous fluid service can be safeguarded with flange shields to confine any escaping fluid.

Threaded Connections

Threaded connections should be avoided, if possible. Their vulnerability to fatigue damage is significant, especially where exposed threads are subject to corrosion. Note that materials susceptible to corrosion will corrode if exposed to unconditioned air. If used then, external piping loads should also be kept as low as possible. Seal welds covering the exposed threads may reduce external damage, but exposed threads within piping may also pose erosion, corrosion, and fatigue problems. Construction documents should specify seal welds where appropriate.

Other Mechanical Joints

There are a number of proprietary mechanical joints which may be acceptable if consideration is given to their deficiencies. Generally these mechanical joints have crevices which can trap fluids and would be susceptible to crevice corrosion. These proprietary joints should be treated as nonstandard components and meet the requirements previously set forth. In addition, the mechanical joint's ability to withstand the operating and environmental loads to which it will be subjected must be verified. Proprietary joints meeting industry standards may not necessarily be suitable for hazardous service. There are instances where industry standards do not comply with the factors of safety inherent in recognized piping codes.

Requirements for Leak Testing

B31.3 requires a sensitive leak test in addition to other required leak testing. It is recommended that a sensitive leak test be performed regardless of the piping design code used and such should be specified in the engineering design. If the design is in accordance with a piping code other than B31.3 or if the designer concludes a greater sensitivity is required than that required by B31.3, the required sensitivity should also be specified.

EXTERNAL LOADS DESIGN

There are two components to piping system design. The first is component design as previously discussed. The second is analyzing the designed pressure components as a postulated anchor-to-anchor structural system, subjecting the system to the possible external (operating and environmental) loads, judiciously adding supports to limit stresses due to weight and other loads, but not unduly restraining the piping.

Piping System Considerations

The design should provide for possible isolation means and/or devices to monitor and contain or recover inadvertent discharges of hazardous contents.[10] Open air process units lessen the potential for concentrating hazardous vapors, but increase the potential exposure to personnel near hazardous piping.

Double containment systems offer the opportunity to protect the hazardous piping plus an additional barrier to the release of the hazardous contents of the "carrier" pipe (see Chap. B13). The annulus between the carrier and outer pipe can provide insulation, but more important, a location for a leak monitoring system to detect failures of the carrier pipe.[13] The design of double containment systems may present difficulties in accommodating thermal expansion effects and problems in ease of construction.

Hazardous fluids, if released, should be collected in a dedicated system for safe removal and to eliminate any cross-contamination with other services. If the release of hazardous liquids is to the open air, a diked area should be used to contain the spill, and a system for safe removal of the fluid and fumes would be required. If the release is a hazardous gas, a ventilation system may be used to remove hazardous vapors, mists, and dust and supply fresh air to the vicinity of the failed pipe. Such a ventilation system should be equipped with a scrubber to strip the vented air of hazardous materials prior to its release to atmosphere.

Piping Layout

Every effort should be used to "hard-pipe" systems using seamless, matching standard pipe and components. Layouts should be routed near possible support points; the support hardware should preferably attach to straight pipe, rather than piping components. The developed (total) length of pipe should be minimized. Expansion loops, unequal Z-bends, and unequal offsets should be used to accommodate thermal expansion effects; while the use of mechanical devices to accommodate thermal expansion or contraction should be avoided. Layouts should facilitate operation and maintenance and protect piping from activities not related to the piping system function or maintenance. Drains and vents should be provided and piping sloped to facilitate liquid drainage and gas venting.

Early identification of hazardous systems will allow layout considerations to be incorporated into the plant housing the system. A structural "flexibility" analysis, typically evaluating the startup-shutdown cycle, should be performed to determine if the piping system layout is not unduly restrained. The allowable flexibility stress-range will need to be reduced if the startup-shutdown cycle occurs once a day or more.

System Controls and Safety Systems

Process controls need to be provided to monitor system conditions to protect the system from excessive excursions of pressure, temperature, and fluid flow. The controls should limit the quantity of hazardous fluid that can escape in the event of a pipe rupture.

A systematic monitoring and leak detection program designed to identify small leaks and potential problems as early as possible should be implemented.

It would be unusual for a hazardous piping pressure relief or safety relief system

to directly discharge hazardous material into the atmosphere. Most often hazardous systems will be relieved into a closed system of piping and holding or treatment vessels. In this case, the relieving systems must be designed to accommodate the full volume of the maximum possible release. Obviously, the piping portion of the pressure relieving system must also be identified as a hazardous piping. The relieving event will typically introduce significant momentum change forces and possibly dynamic amplification of the discharge forces.

Where hazardous piping is connected to a vessel requiring entry, two stop valves with a "free blow" drain, in between, should be provided as close to the vessel as possible.

External Loads Analyses

The evaluation of sustained stresses due to weight is normally less of a concern than limiting the displacements (sag) between supports. Limiting the sag between supports to about ⅛ in (3 mm) will limit weight stresses and, in vapor systems, the pooling of condensibles. Long vertical risers or downcomers may require vertical supports to limit weight stresses not typically calculated using piping code compliance computer programs.

Short-term sustained load stresses, such as single-phase flow pressure transients, two-phase flow transients, wind, and earthquake, should be evaluated. In general, limiting the displacements due to these short-term loadings will limit their potential to cause a piping collapse or rupture and likewise limit the fatigue damage, if these loadings are frequent. Two-phase flow transient forces may also be reduced by reducing flow velocities. Piping displacements can be limited by active supports, such as hydraulic and mechanical snubbers and sway braces, or passive supports, such as gapped framing around the pipe. Passive supports are preferred over active supports because active supports typically require periodic maintenance. Gapped supports and the piping may each suffer impact loads during these short-term loadings. Passive protection for the piping can be provided by special coverings, sleeves surrounding the insulation, devices or materials designed to take impact, heavier pipe walls, or pads in the vicinity of the gapped support.

The startup-shutdown thermal stress-range (usually based on normal operating conditions, rather than design conditions) is typically analyzed to assure adequate piping flexibility. But all temperature ranges, whether due to normal or abnormal excursions, should be considered and evaluated along with the startup-shutdown range, if significant. Further, all other load ranges, such as due to pressure and short-term hydraulic and mechanical excursions, result in some cyclic (fatigue) damage. However, if an excursion does not often occur and the stress-range of the excursion is less than half the allowable startup-shutdown stress-range, it will probably not result in significant fatigue damage. Remember that because of a low elastic modulus, nonmetallics will experience significant pressure expansion effects similar to thermal expansion, often requiring consideration of their startup-shutdown stress-range. Pressure expansion will occur in metallic piping too, but it is usually only a small fraction of coincident thermal expansion.

The designer should be aware that significant fatigue damage can result from relative anchor motions from any cause and need to be considered in the cyclic (fatigue) analysis. The greatest number of piping failures due to earthquake motions have been caused by excessive relative anchor motions. The number of times that any significant cyclic stress-range occurs must be estimated to properly evaluate a piping system for fatigue.

Creep damage from external loads should only occur from long-term sustained loadings. Using the design temperature to determine the allowable stress for sustained loads should limit external load creep damage.

Evaluation of local stresses may be necessary as the result of rapid fluid temperature changes at geometric discontinuities and at a material discontinuity due to any temperature change.

The magnitudes of flow and mechanically induced vibrations are hard to predict, although they should be expected if flow rates are high or in the vicinity of reciprocating and rotating machinery. If expected, a conservative estimate of their magnitudes may be necessary for analysis or the design should incorporate features to mitigate their effects. Vibration may only be realized after system operation begins and may need to be evaluated then.

Pipe Support Design and Analysis

Pipe supports are part of a piping system and should be of concern in hazardous piping because improper support design and their attachment to the pipe wall have caused failures in piping systems.[7] For example, a support lug welded directly to the wall of a high-temperature pipe under the insulation, with the other end of the lug exposed to the atmosphere can "pull" a crack in the pressure boundary because of the lack of lug flexibility near the pipe wall.

Attachment welds to and a portion of the attachment nearest the pipe wall should be considered as part of the pressure boundary and evaluated and constructed accordingly. A distance no less than $2t$ from the pressure boundary, where t is the thickness of the pressure boundary, should be considered the "portion of the attachment nearest the pipe wall." This means that within $2t$ materials should be pressure boundary materials and welds should conform to Section IX. Beyond that distance, support materials should be suitable for the service. Note that B31.1 requires support materials for metallic piping to be listed, but that this could be interpreted as the attachment material should be listed for the purpose of considering the interaction between the attachment and the pressure boundary.

The design locations of supports and the method of attachment to the pipe should be reviewed with the piping designer, and to the building with the building designer, for large piping, to assure that those locations and the method of attachment are acceptable.

Generally, supports need not be integrated with the analysis of the piping system (i.e., the support stiffness need not be incorporated in the analysis of the piping system). Incorporating support stiffnesses in the piping analysis will typically reduce loads on the supports. This should only be necessary if the piping loads are very high. However, supports should be stiffer than the pipe at the support point or they may not support the pipe. This should be able to be assessed merely by observation by an experienced support designer.

Pipe supports should support the pipe in the operating condition. For this reason, pipe supports should typically be adjustable and the piping system reviewed during normal operation and pipe supports adjusted as necessary. Pipe supports should also be designed to facilitate sloping the pipe for drainage or venting.

Mechanical expansion anchors in concrete should be avoided; cast in place or epoxy grouted or equivalent anchors are preferable.

Threaded hangers should be designed so that the threads are not subject to bending.

OPERATING MANUAL PREPARATION

After completing the design, the designer should prepare an operating manual which describes the normal and abnormal operating and environmental conditions assumed in the design of the hazardous piping. Recommended operating and maintenance instructions for active components should be included. Manufacturers of active components, such as valves, pumps, instrumentation, and snubbers, will typically provide operating and maintenance instructions. All design drawings, including component manufacturer's design drawings, should also be included. The operating manual should include any other information the designer concludes is necessary to guide the operator in operating and maintaining the hazardous piping system safely. Recall, as was previously stated, that a composite system diagram (see Fig. C10.1) may be useful to communicate the piping system's design features to the operator.

FABRICATION AND ERECTION

Fabrication and erection of hazardous piping should be performed in as clean conditions as possible to avoid any contamination that would compromise the process that is to occur with the finished system.

Forming

It would be wise to verify that piping code required heat treatment is performed on identified materials after cold or hot forming of components.

Welding and Bonding

The welding and bonding procedures established by the fabricator's and erector's QC programs should be followed. The fabricator and erector may augment the required examination by additional spot checking of the welding or bonding being performed.

Butt Welds. A butt weld is expected to fill the weld groove between two pieces of pipe from the inside surface to the outside surface of the pipe. Any deviations from this practice, such as between two heavier than nominal pipe fittings, should be reviewed with the designer.

The piping layout and shop fabrications should consider how to facilitate field welding; for example, a field weld should not be located too near a wall such that the welder must use a mirror or other device to finish the weld.

Butt weld joints should be made without the use of backing rings and inserts, unless otherwise permitted by the engineering design.

Branch Connection Welds. Shop welding of branch connections is preferred to field fabrication. Non-90° branches are more difficult to fabricate than 90° branches. The engineering design may detail required branch connections. If not, it is recom-

Cover weld creates an effective

mended that the fabricator or erector consider the following good practices to
provide quality branch connections (see Fig. C10.3):

The sharp inside corner of large high-pressure branch connections should be ground
off, creating an effective inside radius. The outside welds to the header should not
have abrupt corners; cover welds, such as those specified in B31 codes, should be
used to provide an effective radius between the branch attachment weld and the
header. The cover weld should effectively make a constant smoothed transition
around the circumference between the attachment weld and the header. For large
branch connections, the cover weld should probably be larger than the minimum
typically required by the B31 codes.

Socket Welds.   Unless otherwise specified in the engineering design, a socket weld
is expected to be a 45° fillet filling the joint created by inserting the pipe into a

matching socket welding fitting (see Fig. C10.4). The weld is expected to fill the joint to the edge of the machined boss on the face of the fitting. This means the leg length (size) of the fillet weld is approximately 1¼ times the nominal matching pipe thickness. Weld buildup on the unmachined surface of the socket welding fitting is not expected. Piping codes may mention a preference for a concave (smoothed) weld, but such a weld should not reduce the throat of the weld below that of the 45° fillet expected. The concave smoothing should only be done at the toe of the weld.

Bonding.   The fabricator and erector should take care that nonmetallic compo-nents and bonding materials are protected from damage or deterioration prior to assembly.

The fabricator and erector should be careful during fit-up that joints to be bonded are well supported and that the bond is allowed to cure for the time required by the BPS before construction supports are moved.

Mechanical Joints

Mechanical joints should be assembled in accordance with the requirements of the fabricator or erector's QC program.

Flanges.   Large flanges and their gaskets need to be carefully aligned prior to bolting. The torquing of the bolts needs to follow a sequence to achieve the required bolt efficiency (i.e., bolt tightness) without overloading the flange or overstressing the bolts. The gasketing, if not specified in the engineering design, needs to be reviewed with the designer.

Small flanges may not need to comply with the alignment requirements of the piping codes. The flexibility of the attached small piping may be sufficient to not overstress the flange elements; however, this should be reviewed with the designer.

Threaded Connections.   Where the erector uses threaded connections not specified, but not prohibited, in the construction documents, the erector should verify the acceptability of such. Where the erector finds threaded connections specified in the construction documents but seal welds are not, the erector should consult the designer regarding his intentions.

Other Mechanical Joints.   Fabricators and erectors should make sure that all mechanical joints are properly assembled by following the manufacturer's recommendations, which typically describe a method to verify proper assembly. Documentation of the verification may be warranted.

Erection.   The piping should be erected in accordance with the engineering design and the piping code used in the design. Deviations from the design required for constructability should be reviewed with the designer.

Bending or forming required for fit-up or alignment may require postforming heat treatment in accordance with the piping design code.

Temporary supports for erection should not damage the piping or allow excessive deformations of the piping or equipment to which the piping is attached.

After completing the installation of the piping the original design drawings should be revised to show all changes made; that is, the piping system drawings should be ''as-built'' and made part of the turn-over documentation.

EXAMINATION, INSPECTION, AND TESTING

Most piping codes distinguish between *examination* and *inspection*, examination being the responsibility of the manufacturer, fabricator, or erector, and inspection being the responsibility of the owner. There is a tendency to limit examination and inspection to the welds, but more than the welds should be looked at prior to piping system startup, especially for hazardous piping.

The manufacturer and erector can use various NDE methods to minimize substandard workmanship, and the owner can employ the same or different methods to verify the manufacturer's or erector's work. However, most piping codes specify the examination (NDE) methods with little opportunity for variations. Along with the prescribed methods, these same piping codes specify acceptance criteria appropriate to the type and extent of required examination. Code inspection is normally limited to the owner reviewing the manufacturer, fabricator, or erector's work to the extent that the inspector is confident that the manufacturer, fabricator, or erector has performed the proper examinations and has made repairs where appropriate. However, the owner's inspection should include an overall review to assure that the construction meets the engineering design.[2]

Because the piping is considered hazardous, the owner or designer may wish to impose more rigorous examination requirements (i.e., either NDE methods or acceptance criteria) than is required by the piping code being used. For example, the designer may want to limit the porosity in a butt weld to less than that permitted in a highly corrosive, high cyclic service. But more rigorous or multiple NDE methods may not be required by the code being used and the acceptance criteria of the codes is only appropriate for the required examination. This is true for all ASME pressure component codes and is illustrated by paraphrasing a 1985 B31.1 Interpretation.[17]

Paraphrased Question: When an NDE method is not required by B31.1, but is used, must the acceptance criteria meet the requirements of B31.1?

Paraphrased Reply: The acceptance criteria are not within the scope of B31.

In addition, piping codes typically specify NDE methods that have been proven over long periods of use. Thus, if more rigorous, alternate, or newer NDE methods are imposed by the owner or designer, then acceptance criteria appropriate for the NDE method and extent of examination must also be developed and provided in the engineering design. It should be noted that the code examination methods and their acceptance criteria do not correlate well to specific failure modes. Defects detected by NDE methods are typically repaired because they are perceived rather than relating the defect to a specific failure mechanism. The detection of defects having little or no bearing on piping component performance may result in unnecessary, and sometimes counterproductive repairs.[7] Fracture mechanics holds the promise of one day being able to correlate defects with failure modes, but that is not necessarily a given in 1999.

Adapting the B31.3 in-process examination for nonmetallic piping may be prudent.

The owner's inspection should include a detailed review of the erected system prior to startup to ensure that the pipe components and sizes, support types and orientation, valve types and orientation, and specialty items are in accordance with the engineering design. The materials of construction could be verified by spot checks or more rigorous forms of examination, if this was not already performed during construction. During startup the owner's inspection should also include verification that piping moves as is intended (e.g., spring hanger indicators move to the hot location) and that no undue vibrations or movements are observed.

Examination of a branch connection and socket weld joints is normally limited to visual and surface examinations. However, with careful interpretation, radiography can provide relevant information about these fabrications and, further, it might be expected that the welding done could be of better quality if the manufacturer's, fabricator's, or erector's welders knew that some of their fabrications were going to be evaluated by radiography. Recall from the previous discussion that this examination may be beyond the requirements of the design piping code, and acceptance criteria would need to be based on a prior agreement between the owner and the contractor.

Leak testing of the erected piping system is a normal requirement of piping codes and should be performed as required by the piping code used in the design. The required leak testing should be performed before the hazardous piping system is painted or the insulation is applied so that the system welds and other joints may be viewed as completed or assembled. Where a hydrotest is impractical, a pneumatic

test or more rigorous examination may often be substituted. A sensitive leak test[2] should be used to augment whatever other leak testing methods are used. If testing requirements are not specified in the engineering design, the erector should review with the designer the expected leak-testing requirements.

A recent and very practical B31.3 code change permits exempting ''closure'' welds from hydrotesting, if in-process and either radiography or ultrasonic examinations are substituted. This exemption is also useful for dealing with additions of small piping (e.g., instrumentation taps) to piping already tested.

OPERATION AND MAINTENANCE

The operator should operate the piping system within the design parameters of the system. The operator should be trained to understand the design parameters, other possible events that could cause a failure, and operating conditions that can degrade the system over time. The operator should be familiar with the hazardous material handling system in sufficient detail to be able to identify signs of system distress should they appear. One possible source of this information is the plant hazards analysis study and the results of any continuing hazards analyses.

If design pressures or temperatures exceed the design limits by more than 10 percent, consideration should be given to having an engineering evaluation of the excursion performed. The same consideration should be given if the piping system experiences an abnormal operation not considered in the original design or is exposed to a severe environmental event (e.g., hurricane or major earthquake).

It would be wise to maintain an operating log (time versus operating pressures and temperatures, including outage time) to be able to evaluate fatigue and creep damage. This need not be a minute by minute log, but could log average values over a given period between identified maximums and minimums, with excursions beyond the maximums and minimums documented. Based on an understanding of the materials of construction, the original designer could be consulted or an engineering study be used to devise such a log.

Maintenance of the hazardous piping system should include establishing an in-service inspection program to detect system deterioration before such deterioration can cause a failure. The in-service inspection could be based on emerging (in 1999) risk-based technology, tailored to the piping system. Risk-based technology seeks to rank the piping system components as to the probability of failure and the consequences of failure and implement inspection based on the ranking. The ranking is based on the component and the fluid contents: component materials, geometry, and the history of like components; and fluid content's chemistry, conditioning, flow, and temperature. Through-insulation radiography has been successfully used in such a program to screen sections of a piping system for local thinning, followed by ultrasonic testing to refine thickness measurements. Other existing and developing NDE methods can be used for in-service monitoring, should they prove to be appropriate. Acoustic emission is possibly one such appropriate developing method; the acoustic emission methods endeavor to identify locations of high stress by ''listening'' for material grain-structure fracturing.

As of 1999, several efforts are under way to develop standards for flow evaluation and inspection planning. These include:

- B31.1 is revising its nonmandatory appendix ''Recommended Practice for Operation, Maintenance, and Modification of Power Piping Systems'' and considering making it mandatory.
- B31.8 and the API are developing ''fitness for service'' rules.
- ASME and the API are developing RBI guidelines for the power and petrochemical industries.
- ASME Post-Construction Committee is developing new standards for post-construction conditions.

These activities should be monitored for the completion and publication of their efforts.

The operator should maintain maintenance records of the system and its critical components.[12] These records should be of sufficient detail to provide information of any significant change to the physical structure of the pipe or piping components. Any changes in operating parameters should also be documented, since changes in temperature, pressure, flow, or the amount of cycling, or the chemical composition of contents, can result in increased corrosion, erosion, decreased serviceability of components, or a decrease in the life expectancy of materials.

Piping which operates in the creep range or is subjected to high thermal expansion stresses will self-spring (or shake down). Caution must be exercised when unbolting flanges or cutting loose piping that has self-sprung. Large movements of the flanges or pipe ends may result. If no problems existed with the previous operation of near equipment, reassembly of the piping should be done by pulling the flanges or pipe ends together and rebolting or rewelding.

The pipe supports may offer considerable information about system performance. Lift off or adjustments to maintain piping in its design location may be an indication of piping system drift or the results of system loads not considered in the original design. Spring supports should be monitored to see if operating between the operating and ambient conditions moves the load indicator between the operating and ambient marks on the spring hanger assembly; nonmovement would obviously indicate the spring is not functioning; variations from the expected movements may indicate piping system drift or loads at variance with the predicted design loads.

MODIFICATIONS AND REPAIRS

Hazardous piping system modifications should be made in accordance with the latest piping codes. The interaction between the new piping and the existing piping should be evaluated. Piping system drawings should be revised to show the modifications.

Repairs should also be made in accordance with the latest piping codes. The effect that the repair will have on the piping system should be considered. The repair should be fully documented as to the cause necessitating the repair and whatever repairs are made. Any revisions to the piping drawings necessary to reflect the repair should be made (e.g., due to erosion/corrosion damage a segment of pipe might be repaired by a replacement segment of a more corrosion-resistant material).

TABLE C10.2 Design and Operation Recommendations for Hazardous Piping

"DO"	"DON'T"
Identify and give hazardous piping systems special consideration.	View hazardous piping systems as conventional systems.
Evaluate consequence of piping failure (for example, quantities released, personnel exposure, harm to the environment).	Assume piping system cannot fail.
Understand operating modes of the system, including variations in normal and abnormal operating conditions.	Expect operating conditions to be without variation.
Consider dynamic effects, such as fluid hammering, vibrations, earthquake.	Overlook potential dynamic effects.
Perform stress analysis incorporating all the loadings expected.	Disregard short-term loadings combined with sustained loads or the fatigue effects of short-term loadings.
Select materials that will not deteriorate in service.	Choose materials sensitive to corrosion or erosion.
Use ductile materials.	Use low-ductility materials, such as cast-iron or glass.
Eliminate or minimize the use of mechanical joints.	Use mechanical joints without considering means to safeguard them.
Provide smooth transitions at welded joints.	Have abrupt changes in joint geometry.
Choose valves to be consistent with hazardous service.	Use stem packing designs that can leak.
Provide designs to minimize fugitive emissions.	Forget to perform a sensitive leak test with an appropriate sensitivity.
Use appropriate NDE methods to assure quality fabrication and erection.	Limit NDE methods to those in codes and standards if newer methods will give reliable results.
Try to provide advice to plant designers regarding piping layout needs.	Believe that plant designers will understand hazardous piping layout needs.
Use piping geometry to compensate for thermal expansion and contraction.	Use expansion joints.
Provide a collection and disposal system for pressure relief of hazardous systems.	Vent directly to atmosphere without proper treatment.
Segregate hazardous piping systems during fabrication, erection, and testing to facilitate all requirements being met.	Treat hazardous piping like other systems.
Design and maintain supports as part of the piping system.	Treat piping supports as independent components.
Provide design details of critical elements to construction.	Leave critical fabrication and assembly details to be provided by field.
Provide mechanism for positive identification of piping materials of construction.	Rely on specifying materials with no follow-up.
Provide an in-service monitoring program for early detection of problems.	Wait for a catastrophic event.
Maintain service records throughout life of system.	Repair piping without documenting it.
Periodically examine critical elements.	Install system and forget about it.

CHAPTER C11
SLURRY AND SLUDGE PIPING

Ramesh L. Gandhi
Principal Engineer
Bechtel Corporation
San Francisco, CA

DEFINITION AND BACKGROUND

Slurry is a mixture of solids and liquid. A sludge denotes a mud or a concentrated slurry having a considerable amount of fine material that imparts high viscosity. Typical examples of slurries are the solid-liquid mixtures encountered in mineral processing plants and dredged material from waterways and dams. Most of the slurries are made up with water. However, industrial paints, rocket fuel, coal-oil mixture, and coal-methanol slurries are made up with liquids other than water.

River sediment in the form of slurry appears to have been handled since ancient times.[1] All ancient civilizations arose on river banks. Maintenance of waterways requires periodic dredging which results in a sand and silt water slurry. Today dredging represents the largest volume of solids handled in slurry form. Slurry transport is also used for dam construction.

Blatch[2] reported the first hydraulic test results for a sand-water slurry flowing through NPS 1 (DN 25) pipe. Gregory,[3] O'Brien and Folsom,[4] and Howard[5] reported results of tests of clay, sand, and gravel slurries. The flow of muds and sludges through pipes was first examined by Caldwell and Babbit.[6] The first large-scale experimental program on the flow of slurries through pipes was reported by Durand.[7] The correlations proposed by Durand and his coworkers serve as a basis for the present-day design methods.

Design of a slurry piping system involves

- Selection of pipe diameter
- Estimate of friction loss and pumping requirements
- Selection of pipe material, valves, and fittings
- Selection of pumps
- Selection of instruments and control system for safe and reliable operation

Pipelines transporting liquids such as oil and water can be operated at any velocity up to their design limits. In most slurry applications, a certain minimum velocity needs to be maintained, to keep solids from settling out in horizontal

sections of the pipe. The velocity below which particles tend to settle out and form a deposit in the pipe is called the *deposition velocity.* The pipe diameter should be selected such that the velocity in the pipeline is maintained above the deposition velocity over the operating range of flow rates.

The operating flow rate range is determined by the expected range of solids throughput and slurry concentration. *Solids throughput* is defined as the weight of solids to be transported per unit time. It is normally expressed in tons per hour (tons/h). The slurry concentration is expressed as the weight of solids per unit weight of slurry, or volume of solids per unit volume of slurry.

The slurry concentration may be established by the requirements of the upstream or downstream processing facilities. This is normally the case with in-plant piping. In the case of long-distance pipelines, it becomes advantageous to adjust the slurry characteristics and concentration to reduce the cost of the pipeline system. An economic study is performed to select parameters acceptable to upstream and downstream plants while offering economies in pipeline construction and operation.

The deposition velocity and friction loss in a given size pipe at a given concentration depend upon the slurry flow behavior. The selection of pipe material, valves, fittings, and pumps depends upon the velocity of flow, abrasivity of the slurry, and pumping pressures which are in turn governed by the slurry flow behavior.

SLURRY FLOW BEHAVIOR

Flow of slurry in pipes depends upon the interaction between the solids and liquid as well as between the slurry and the pipe.

Depending upon the velocity of flow, pipe diameter, solids size distribution, fluid properties, and solids characteristics, four different flow conditions can be encountered in a horizontal or nearly horizontal pipeline.[8] These are homogeneous flow, heterogeneous flow, intermediate regime, and saltation regime.

Homogeneous Flow

Homogeneous flow implies that the solid particles are uniformly distributed across the pipeline cross section. Homogeneous flow, or a close approximation to it, is encountered in slurries of high concentrations and fine particle sizes. Slurries exhibiting homogeneous flow properties do not tend to settle and form a deposit under flowing conditions. Typical examples of homogeneous slurries are sewage sludge, coal-water fuel, clays, drilling mud, paper pulp, titania, fine limestone (cement kiln feed slurry), thorium oxide, and many other finely ground materials.

Heterogeneous Flow

In heterogeneous flow conditions, there is a pronounced concentration gradient across the pipeline cross section. Slurries at low concentration with rapidly settling (coarse particles) solids generally exhibit heterogeneous flow. Typical examples are sand and gravel slurries, coarse coal slurries, and coarse tailings slurries.

Intermediate Regime

This type of flow occurs when some of the particles are homogeneously distributed while others are heterogeneously distributed. Most industrial applications involve a wide range of particle sizes. Intermediate regime of flow is expected with transportation of tailings slurry from mineral processing plants and transportation of coal-water slurries.

Saltation Regime

The fluid turbulence may not be sufficient to keep fast settling particles in suspension. The particles travel by discontinuous jumps or roll along a sliding or stationary bed on the pipe bottom. This type of flow will occur with coarse sand and gravel slurries.

IN-PLANT SYSTEMS

In-plant systems generally involve horizontal, vertical, and inclined sections of pipe. The pipe lengths are generally short. A large number of bends, valves, and fittings may be present in such systems. The pressure losses due to bends, valves, and fittings may be a significant part of the total friction loss. Static head due to change in pipe elevation may be a significant part of the total pumping head requirements for in-plant systems. Typical examples of in-plant system are slurry preparation plants, mineral beneficiation plants, and municipal and industrial waste treatment plants.

In a mineral beneficiation plant, different types of slurries may be handled in the same plant. The slurry concentration as well as the particle size distribution of the slurry may change as the mineral passes through various grinding, separation, and settling stages. Large variations in slurry characteristics and flow rate may be encountered in the same section of pipe owing to changes in ore characteristics or plant operations. The pipes should be sized for these anticipated variations.

LONG-DISTANCE PIPELINES

A number of slurry pipelines have been built to transport solid particles. The materials transported include coal, limestone, kaolin clay, China clay, iron concentrate, copper and nickel concentrates, phosphate concentrates, gold ore, fly ash, sludges, and mineral tailings. Because of the relatively long length of these pipelines, pressure losses through bends and fittings are not a significant part of the total friction loss. Pumping requirements should include changes in pipeline elevation which could be substantial in long-distance pipelines traversing rugged terrain.

Because of the relatively large investment required for a long-distance pipeline, it is generally advantageous to adjust the characteristics of the slurry to suit the pipeline requirements. The slurry concentration, particle size distribution, and throughput are generally controlled within relatively narrow operating limits. The

material is generally finely ground to obtain a pseudohomogeneous flow condition in the pipeline.

Slurry pipeline systems range from single-station low-pressure centrifugal pump installations to multistation high-pressure reciprocating pump systems. In all cases, the basic requirement for successful slurry pumping is to maintain pipeline flow above a minimum operating velocity. The minimum operating velocity is set at a desired margin of safety above the critical velocity. The critical velocity in turn is determined by the solids screen analysis, solids density, and concentration as well as the specific system characteristics—pipe diameter, slurry temperature, etc.

In a positive displacement system, the flow is controlled by varying the pump speed. This can be accomplished by the use of a fluid coupling, eddy current coupling, ac or dc variable-speed drive, or a hydraulic clutch system. Diesel-driven pumps have also been used in remote areas where electric power was not available. For optimum system efficiency, most pumps should be operated at their maximum design speed.

A short list representative of the long-distance slurry pipelines in use throughout the world is presented in Table C11.1.

TABLE C11.1 List of Selected Long-Distance Slurry Pipelines

Material	System, location	Throughput, mmtpy	Length, mi	Start of operation
Coal	Consolidation Coal, Ohio	1.2	105	1957
	Russia	4.0	7	1966

SLURRY CHARACTERISTICS

Slurries may be classified as settling suspensions and nonsettling suspensions. Settling suspensions require turbulence to maintain individual particles in motion or in suspension. With finely divided solids, homogeneous flow could also be achieved for settling suspensions in turbulent flow. Nonsettling suspensions, as the name implies, do not settle, even under the no-flow condition.

Mineral concentrates, tailings, and coal slurries require turbulence to maintain particles in suspension. Digested sludge and coal-water fuel slurries do not settle under static conditions.

The flow characteristics of a settling suspension are largely governed by the settling velocity of solids in it. The flow characteristics of a nonsettling suspension are governed by its rheological characteristics and densities. Most commercial slurries contain appreciable amounts of finely divided solids that change the rheological properties of the suspending fluid. For these slurries, both the settling characteristics of solids and rheological properties and the density of the slurry become important.

Slurry Density

The *density* of a slurry is given by

$$\rho_m = \frac{100}{C_w/\rho_s + (100 - C_w)/\rho_l} \tag{C11.1}$$

where ρ_l = density of suspending liquid, lb/ft^3 (kg/m^3).
ρ_m = density of mixture, lb/ft^3 (kg/m^3)
ρ_s = density of the solids, lb/ft^3 (kg/m^3)
C_w = solids concentration by weight in slurry, %

Measurements of slurry concentration, solids density, and liquid density are straightforward. The slurry concentration is obtained by evaporating a liquid component from a known weight of slurry and measuring the weight of dried solids.

The density of slurry in a pipe may be measured by using a nuclear density meter or by measuring head loss per unit length along each vertical leg of a test section arranged as an inverted U. The slurry density may also be measured by collecting a sample in a suitably designed specific-gravity bottle or by a Marcy balance. Note that these devices measure the specific gravity of slurry. The density of slurry is computed by multiplying its specific gravity by the density of water.

Example C11.1. Slurry concentration is determined by drying to constant weight a sample of slurry in an oven maintained at 220°F (104°C). Determine the slurry concentration based on the following data:

Weight of empty dry container	0.1 lb (0.0454 kg)
Weight of container plus slurry	0.32 lb (0.1454 kg)
Weight of container plus dry solids	0.21 lb (0.0954 kg)

Solution

$$\text{Weight of dry solids} = 0.21 - 0.1$$

$$= 0.11 \, \text{lb} \, (0.05 \, \text{kg})$$

$$\text{Weight of slurry} = 0.32 - 01$$

$$= 0.22 \, \text{lb} \, (0.01 \, \text{kg})$$

$$\text{Weight percent solids } C_w = \text{weight of solids} \times \frac{100}{\text{weight of slurry}}$$

$$= 50\%$$

Example C11.2.   Determine the density of the slurry considered in Example C11.1 if the solids and liquid specific gravities are 3.0 and 1.0, respectively.

    Solution

$$\text{Density of solids } \rho_s = 3.0 \times 62.4 \, \text{lb/ft}^3 (3000 \, \text{kg/m}^3)$$

$$\text{Density of liquid } \rho_l = 1.0 \times 62.4 \, \text{lb/ft}^3 (1000 \, \text{kg/m}^3)$$

$$\text{Solids concentration } C_w = 50\%$$

Substituting into Eq. (C11.1), we get

$$\text{Density of slurry } \rho_m = 93.6 \, \text{lb/ft}^3 (1500 \, \text{kg/m}^3)$$

Example C11.3.   A nuclear density meter gives a slurry specific gravity of 1.167 for a coal-water slurry. If the specific gravity of coal is 1.4, find the weight percent coal in slurry.

    Solution

$$\text{Density of coal slurry } \rho_m = 1.167 \times 62.4 \, \text{lb/ft}^3$$

$$= 72.82 \, \text{lb/ft}^3 (1167 \, \text{kg/m}^3)$$

$$\text{Density of water } \rho_l = 62.4 \, \text{lb/ft}^3 (1000 \, \text{kg/m}^3)$$

$$\text{Density of coal } \rho_s = 1.4 \times 62.4 \, \text{lb/ft}^3$$

$$= 87.36 \, \text{lb/ft}^3 (1400 \, \text{kg/m}^3)$$

Rearranging Eq. (C11.1), we get

$$C_w = 100 \frac{\rho_s (\rho_m - \rho_l)}{\rho_m (\rho_s - \rho_l)}$$

$$= 50\%$$

Slurry Rheology

In the presence of subsieve particles (those smaller than 35 μm) and at relatively high concentrations, the slurry flow properties are governed by its rheology. Slurries

that do not contain particles smaller than 35 μm or that are at low concentrations exhibit heterogeneous flow behavior. Heterogeneous flow properties are not governed by slurry rheology.

Rheology is the relationship between the shear stress and the corresponding rate of shear in a slurry under laminar-flow conditions. The friction loss in a pipeline depends upon the rheology of the slurry in homogeneous and intermediate flow regimes. In the case of pure liquids, the shear stress is directly proportional to the rate of shear in laminar flow. The proportionality constant is called the *viscosity* of the liquid. This type of flow behavior is called *newtonian*. Liquids containing long-chain polymers and finely ground solids exhibit a nonlinear relationship between shear stress and the rate of shear under laminar-flow conditions. Such slurries are said to exhibit *nonnewtonian* flow properties. Depending upon the size distribution of solids, slurry concentration, and interaction between solids and liquid, the slurry may have newtonian or nonnewtonian flow properties.

Slurries containing nonflocculated particles generally exhibit newtonian flow behavior. Nonnewtonian flow behavior is generally encountered with flocculated suspensions.

Some slurries require a certain minimum stress before flow starts. For example, fresh concrete does not flow over a chute until a certain slope is exceeded. The slurry is said to possess a yield stress which must be exceeded to initiate flow.

The rheology of a newtonian fluid is expressed by its viscosity, which is the ratio of shear stress to the corresponding rate of shear. Two or more parameters are needed to describe the rheological properties of a nonnewtonian liquid. Bingham plastic, pseudoplastic, and yield pseudoplastic models are generally used to describe the flow behavior of slurries. The relationships between the shear stress and shear rate for these rheological models are as follows:

Newtonian:

$$\tau = \mu\gamma \tag{C11.2}$$

Bingham plastic:

$$\tau = \tau_y + \eta\gamma \tag{C11.3}$$

pseudoplastic:

$$\tau = K\gamma^n \tag{C11.4}$$

yield pseudoplastic:

$$\tau = \tau_y + K\gamma^n \tag{C11.5}$$

where τ = shear stress, lbf/ft^2 (Pa)
τ_y = yield stress, lbf/ft^2 (Pa)
γ = rate of shear (velocity gradient), 1/s
μ = newtonian viscosity, lbf·s/ft^2 (Pa·s)
n = flow behavior index
K = consistency index, lbf·s^n/ft^2 (Pa·s^n)

Example C11.4. The following rheology test results were obtained for a sample of a mineral tailings slurry containing 50 percent solids by weight.

Rate of shear, 1/s	Shear stress τ, lbf/ft^2 (Pa)	$\tau - \tau_y$, lbf/ft^2 (Pa)
0	0.1250 (6.000)	0.0000 (0.000)
0.1	0.1256 (6.029)	0.0006 (0.029)
1.0	0.1280 (6.144)	0.0030 (0.144)
5.0	0.1343 (6.445)	0.0093 (0.445)
10	0.1400 (6.718)	0.0150 (0.718)
20	0.1494 (7.168)	0.0244 (1.168)
40	0.1647 (7.900)	0.0397 (1.900)
80	0.1895 (9.088)	0.0645 (3.088)
100	0.2004 (9.610)	0.0754 (3.610)
150	0.2250 (10.79)	0.1000 (4.79)
200	0.2474 (11.86)	0.1224 (5.86)
300	0.2876 (13.79)	0.1626 (7.79)
400	0.3240 (15.53)	0.1990 (9.53)
500	0.3575 (17.13)	0.2325 (11.13)
600	0.3890 (18.64)	0.2640 (12.64)
700	0.4190 (20.08)	0.2940 (14.08)
800	0.4480 (21.47)	0.3230 (15.47)

Solution. The shear stress at zero shear rate is 0.125 lbf/ft^2. The slurry yield stress is therefore 0.125 lbf/ft^2 (6 Pa). Find the difference between the observed shear stress τ and the yield stress τ_y at each shear rate shown in the third column of the above table.

A plot of $\tau - \tau_y$ versus shear rate on an arithmetic scale (Fig. C11.1) shows a nonlinear relationship. A similar plot on log-log scale (Fig. C11.2) shows a linear relationship (note that the data for zero shear rate is excluded). The value of τ at a shear rate of 1 gives the value of K in lbf·s^n/ft^2. (Pa·s^n). The slope of the line gives the value of the flow behavior index n. The results from the graph are

$$K = 0.003\,\text{lbf} \cdot \text{s}^n/\text{ft}^2(0.144\,\text{Pa} \cdot \text{s}^n)$$

$$n = 0.7$$

Estimate of Slurry Rheology

Correlations between slurry concentration and rheology of the slurry for newtonian and Bingham plastic slurries have been proposed by various investigators. These relationships may be used for preliminary estimates when rheology test results are not available.

The viscosity of a slurry depends upon the volume fraction of solids in slurry. The volume fraction of solids is determined by using

$$C_v = C_w \frac{\rho_m}{100\rho_s} \tag{C11.6}$$
FIGURE C11.1 Plot of $\tau - \tau_y$ versus shear rate on an arithmetic scale.
FIGURE C11.2   Plot of $\tau - \tau_y$ versus shear rate on a logarithmic scale.

where C_v is the volume fraction of solids in slurry. The viscosity of slurries exhibiting newtonian behavior can be estimated by the correlation proposed by Thomas[9]

$$\frac{\eta_m}{\eta\gamma} = 1 + 2.5C_v + 10.05C_v^2 + 0.00273e^{16.6C_v} \qquad (C11.7)$$

where η_m = slurry viscosity
     η_o = suspending fluid viscosity

Chong et al.[10] have proposed the following equation for concentrated suspensions of spherical particles:

$$\frac{\eta_m}{\eta_o} = 1 + 0.75 \frac{C_v/C_{voo}}{1 - C_v/C_{voo}} \tag{C11.8}$$

where C_{voo} is the maximum packing concentration of the solids in slurry. Equation (C11.8) should be used for values of C_v greater than 0.4.

Gay et al.[11] have proposed the following correlations for estimating the Bingham plastic viscosity and yield stress, based on their experimental data:

$$\eta_m = \mu \exp \left\{ \left[2.5 + \left(\frac{C_v}{C_{voo} - C_v} \right)^{0.48} \right] \frac{C_v}{C_{voo}} \right\} \tag{C11.9}$$

$$\tau_y = 200 \left(\frac{d}{C_{voo} - C_v} \right) \left(\frac{C_{voo}}{1 - C_{voo}} \right)^2 \frac{1}{\zeta^{1.5} \sigma_g^2} \tag{C11.10}$$

where μ = viscosity of suspending medium, lbf·s/ft^2 (Pa·s)
η_m = Bingham plastic viscosity of slurry, lbf·s/ft^2 (Pa·s)
τ_y = yield stress of slurry, lbf/ft^2 (Pa)
d = geometric mean particle diameter, ft (m)
ξ = particle shape factor, defined as ratio of surface area of sphere of equivalent volume to surface area of particle
σ_g = geometric standard deviation of particle diameter

SLURRY HYDRAULICS

Homogeneous Flow

The friction loss for a homogeneous slurry depends upon the rheological characteristics of the slurry. The flow through a pipeline can be laminar or turbulent depending upon the velocity of flow. For a nonsettling suspension such as sewage sludge or a highly concentrated coal-water fuel slurry, laminar flow may be encountered. Turbulent flow should be maintained when the suspension exhibits a settling tendency. It is, therefore, necessary to estimate the velocity at which transition from laminar to turbulent flow occurs.

Transition Velocity

The *transition velocity* is defined as the velocity below which laminar flow is encountered. For a newtonian slurry, the transition velocity corresponds to a Reynolds number of 2000. The Reynolds number should be based on the viscosity of the slurry.

For slurries exhibiting Bingham plastic rheology, the transition velocity is governed by the Reynolds number as well as the Hedstrom number. The Reynolds number should be defined using the plastic viscosity. The critical Reynolds number corresponding to the transition velocity can be estimated from a knowledge of the
FIGURE C11.3 Laminar-turbulent transition Reynolds number $Re_c = 8\rho D^n V^{2-n}[n/(2 + 6n)]^n(Kg_c)$ as a function of Hedstrom number $He = [D^2\rho\tau_y(t_y/K)^{2/n-2}]/(K^2g_c)$ for Bingham plastic slurries, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft³), K = consistency (lbf · sⁿ/ft²), τ_y = yield stress (lbf · /ft²), g_c = 32.2 lb · s/(lbf · ft²).

physical properties of the slurry and the pipe system from Fig. C11.3, proposed by Hanks and Pratt.[12] In this figure the Reynolds number Re and the Hedstrom number He are defined as follows:

$$Re = \frac{vd\rho}{\eta} \tag{C11.11}$$

$$He = \frac{D^2\rho\tau_y}{\eta^2 g_c} \tag{C11.12}$$

where D = pipe inside diameter, ft (m)
V = average flow velocity, ft/s (m/s)
g_c = dimension conversion factor = 32.2 lbm·ft/(lbf·s²) (1 for SI units)
η = Bingham plastic viscosity, lbf·s/ft² (Pa·s)
ρ = fluid density, lb/ft³ (kg/m³)
τ_y = yield stress, lbf/ft² (Pa)

For slurries exhibiting pseudoplastic rheology, the transition velocity is governed by the flow behavior index of the slurry. Figure C11.4 shows the variation of the transition critical Reynolds number with the flow behavior index n. Note that the Reynolds number for a pseudoplastic slurry is given by

$$Re_p = 8\rho D^n V^{2-n}\left(\frac{n}{2 + 6n}\right)^n\left(\frac{1}{Kg_c}\right) \tag{C11.13}$$
FIGURE C11.4 Laminar-turbulent transition Reynolds number (Re_c) as a function of flow behavior index, n for pseudoplastic slurries, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft^3), K = consistency (lbf·s^{n}ft^2), g_c = 32.2 lb·s/(lbf·ft^2).

where K = consistency index, lbf·s^n/ft^2 (Pa·s^n)
　　Re_p = Reynolds number for pseudoplastic slurry
　　n = flow behavior index

For a yield pseudoplastic slurry, the generalized Reynolds number corresponding to the transition critical velocity can be estimated by using the following equations, proposed by Hanks and Ricks.[13]

$$Re_{cp} = \frac{6464n}{(1+3n)^n}(2+n)^{(2+n)/(1+n)}\frac{\left[\dfrac{(1-x)^2}{1+3n}+\dfrac{2x(1-x)}{1+2n}+\dfrac{x^2}{1+n}\right]^{2-n}}{(1-x)^n}$$

$$(C11.14)$$

The value of x, which is the ratio of yield stress to wall shear stress, at the critical Reynolds number is obtained from the following equation:

$$He_{yp} = \frac{3232}{n}(2+n)^{(2+n)/(1+n)}\left[\frac{x}{(1-x)^{1+n}}\right]^{(2-n)/n}\left(\frac{1}{1-x}\right)^n \quad (C11.15)$$

The Reynolds number Re_{cp} in Eq. (C11.14) is the same as that for a pseudoplastic in Eq. (C11.13). The Hedstrom number He_{yp} is defined as follows:

$$He_{yp} = \frac{D^2\rho\tau_y}{K^2 g_c}\left(\frac{\tau_y}{K}\right)^{2/n-2} \quad (C11.16)$$

For given slurry characteristics and pipe diameter, the Hedstrom number is computed by using Eq. (C11.16). This value of the Hedstrom number is used in Eq. (C11.15) to compute the value of x. This value is then used in Eq. (C11.14) to compute the critical Reynolds number. The corresponding transition velocity is calculated by using Eq. (C11.13).

Figure C11.3 also shows the variation in critical Reynolds number with Hedstrom number for the yield pseudoplastic slurries.

Example C11.5.   Estimate the laminar-turbulent transition critical velocity for the slurry considered in Example C11.4 if the pipe inside diameter is 12 in and the solids specific gravity is 3.0.
    Solution.   Given data:

$$\text{Pipe ID, } D = 12\,\text{in}(0.3048\,\text{m})$$

$$= 1\,\text{ft}$$

$$\text{Yield stress of slurry} = 0.125\,\text{lb/ft}^2\,(6\,\text{Pa})$$

$$\text{Slurry consistency } k = 0.003\,\text{lbf}\cdot\text{s}^n/\text{ft}^2\,(0.144\,\text{Pa}\cdot\text{s}^n)$$

$$\text{Solids specific gravity} = 3.0$$

$$\text{Solids concentration } C_w = 50$$

Computed results:

$$\text{Solids density } \rho_o = 3 \times 62.4\,\text{lbm/ft}^2\,(3000\,\text{kg/m}^3)$$

$$\text{Liquid density } \rho_1 = 62.4\,\text{lbm/ft}^3(1000\,\text{kg/m}^3)$$

Substituting in Eq. (C11.1), we get

$$\text{Slurry density } \rho_m = 93.6\,\text{lbm/ft}^3\,(1500\,\text{kg/m}^2)$$

Compute the Hedstrom number He_{yp}, using Eq. (C11.16):

$$\text{He}_{yp} = 9.9 \times 10^5$$

From Fig. C11.3 find the critical Reynolds number corresponding to $n = 0.7$ and the computed value of the Hedstrom number.

$$\text{Re}_{yp} = 8850$$

Next compute the laminar-turbulent transition velocity, using Eq. (C11.13):

$$v = 3.58\,\text{ft/s}(1.09\,\text{m/s})$$

Friction Loss in Laminar Flow.   For a homogeneous flow condition, the friction loss in a pipeline is estimated by using the following equation:

$$h = 4f \left(\frac{L}{D}\right) \frac{V^2}{2_g} \tag{C11.17}$$

where D = pipe inside diameter, ft (m)
L = pipe length, ft (m)
V = velocity of flow, ft/s (m/s)
f = friction factor
h = friction loss, ft (m) of slurry head
g = acceleration due to gravity, ft/s^2 (m/s^2)

The friction factor for a newtonian slurry is given by the following:

$$f = \frac{16}{\text{Re}} \tag{C11.18}$$

$$\text{Re} = \frac{VD\rho}{\eta_m g_c} \tag{C11.19}$$

where ρ = slurry density, lbm/ft^3 (kg/m^3)
η_m = slurry viscosity lbf·s/ft^2 (Pa·s)
g_c = 32.2 lbm·ft/(lbf·s^2 (1 for SI units)

The laminar-flow friction factor for Bingham plastic slurries is given by

$$\frac{f}{16} = \frac{1}{\text{Re}} + \frac{\text{He}}{6\text{Re}^2} - \frac{\text{He}^4}{3f^3\text{Re}^8} \tag{C11.20}$$

The Reynolds number Re and the Hedstrom number He are given by Eqs. (C11.11) and (C11.12), respectively.

The laminar-flow friction factor for a pseudoplastic slurry is given by Dodge and Metzner[14] as

$$f = \frac{16}{\text{Re}_p} \tag{C11.21}$$

where Re_p is the generalized Reynolds number given by Eq. (C11.13). The laminar-flow friction factor for a slurry exhibiting yield pseudoplastic flow behavior is given by

$$f = \frac{16}{\text{Re}_p \Psi} \tag{C11.22}$$

where the Reynolds number Re_p is given by Eq. (C11.13).

$$\Psi = (1 + 3n)^n (1 - x)^{1+n} \left[\frac{(1 - x)^2}{1 + 3n} + \frac{2x(1 - x)}{1 + 2n} + \frac{x^2}{1 + n} \right]^n \tag{C11.23}$$

The value of the ratio x of the yield stress to wall shear stress is obtained from

$$\text{Re}_p = 2\,\text{He}_{yp} \left(\frac{n}{1 + 3n} \right)^2 \left(\frac{\Psi}{x} \right)^{(2-n)/n} \tag{C11.24}$$
FIGURE C11.5 Laminar flow function Y as a function of Hedstrom number He $= [D^2 \, \rho\tau_y(t_y/K)^{2/n-2}]/(K^2 g_c)$, for yield pseudoplastic slurries, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft^3), K = consistency (lbf·s^n/ft^2), τ_y = yield stress (lbf/ft^2), g_c = 32.2 lb·s/(lbf·ft^2).

Figure C11.5 shows a plot of ψ as a function of the Hedstrom number for various values of the flow behavior index n.

Stainsby and Chilton[15] have proposed a hybrid model incorporating yield pseudoplastic behavior at low shear rates and Bingham plastic behavior at high shear rates. They claim that their model gives better correlations with pipeline friction loss data than those of other models.

Example C11.6.   Estimate the friction loss in a 12-in-ID (304.8-mm-ID) pipe at a velocity of 3 ft/s (0.914 m/s) for the slurry considered in Example C11.5.
    Given data:

$$\text{Pipe ID } D = 1 \text{ ft } (0.3048 \text{ m})$$

$$\text{Slurry density} = 93.6 \text{ lbm/ft}^3 \ (1500 \text{ kg/m})^3$$

$$\text{Velocity } v = 3 \text{ ft/s } (0.914 \text{ m/s})$$

$$K \text{ (from Example C11.5)} = 0.003 \text{ lbf} \cdot \text{s}^n/\text{ft}^2 \ (0.144 \text{ Pa} \cdot \text{s}^n)$$

$$\tau_y \text{ (from Example C11.5)} = 0.125 \text{ lbf/ft}^2 \ (6 \text{ Pa})$$

$$n \text{ (from Example C11.5)} = 0.7$$

$$g = 32.2 \text{ ft/s}^2 \ (9.8 \text{ m/s})^2$$

$$\text{He}_{yp} \text{ (from Example C11.5)} = 9.9 \times 10^5$$

Using Eq. (C11.13), find $\mathrm{Re}_p = 7023$. The Reynolds number is less than the critical Reynolds number. The flow is laminar.

From Fig. C11.5, the value of ψ is found to be 0.184. The friction factor

$$f = \frac{16}{\Psi}\,\mathrm{Re}_{yp}$$

$$= 0.0124$$

$$\text{Friction loss per unit length} = \frac{4fv^2}{2gD}$$

$$= 6.92 \times 10^{-3}\ \text{ft/ft (m/m)}$$

Friction Loss in Turbulent Flow. The friction factor for newtonian liquids in a turbulent-flow regime is given by the Colebrook equation:

$$\frac{1}{\sqrt{f}} = 4\log\frac{D}{2\varepsilon} + 3.48 - 4\log\left(1 + \frac{9.35D}{2\varepsilon\mathrm{Re}\sqrt{f}}\right) \qquad \text{(C11.25)}$$

where ε = the roughness of the pipe, ft (m). Figure C11.6 shows the friction factor as a function of Reynolds number with the relative roughness ε/D as a parameter.

Hanks and Dadia[16] have developed a friction factor–Reynolds number relationship for Bingham plastic liquids. This relationship was later modified by Hanks[17]
FIGURE C11.6 Friction factor f as a function of Reynolds number for newtonian slurries, where D = pipe ID (ft), V = velocity (ft/s), r = density (lb/ft^3), μ = viscosity (lbf·s/ft^2), g_c = 32.2 lb·s/(lbf·ft^2).
FIGURE C11.7 Friction factor f as a function of Reynolds number for Bingham plastic slurries, $\mathrm{Re} = \rho D V/(\eta g_{cy})$, $\mathrm{He} = D^2 \rho \tau_y/(\eta g_c)$, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft^3), η = viscosity (lbf·s/ft^2), τ_y = yield stress (lbf/ft^2), g_c = 32.2 lb·s/(lbf·ft^2).

based on further analysis of their data. Figure C11.7 shows the friction factor–Reynolds number relationship for Bingham plastics. Note that for Hedstrom numbers greater than 500,000, there is a long transition region between the laminar-turbulant transition critical Reynolds number and the Reynolds number at which the friction factor curve for Bingham plastics intersects the newtonian curve. The friction factor for Bingham plastic in this transition region is significantly greater than the newtonian friction factor.

Dodge and Metzner[18] carried out a semitheoretical analysis of the turbulent flow of pseudoplastic liquids in smooth pipe. They proposed the following equation for the friction factor in turbulent flow:

$$\frac{1}{\sqrt{f}} = \frac{4}{n^{0.75}} \log \left(\mathrm{Re}_p \, f^{1-n/2} \right) - \frac{0.4}{n^{1.2}} \tag{C11.26}$$

Figure C11.8 shows a plot of friction factor as a function of Reynolds number for various values of n based on Eq. (C11.26).

Hanks and Ricks[19] have used the concept of mixing length in developing a semitheoretical relationship between friction factor and Reynolds number for turbulent flow of pseudoplastics. This method was extended by Hanks[20] for estimating turbulent-flow friction factors for yield pseudoplastic fluids. Interested readers should refer to the referenced article for further details.

Figure C11.9 presents the friction factor–Reynolds number relationship with Hedstrom number as a parameter for selected values of flow behavior index n.

The following friction factor–Reynolds number relationship, developed by Tor-
FIGURE C11.8 Friction factor f as a function of Reynolds number for pseudoplastic slurries. $Re_p = 8\rho D^n V^{2-n}(n/(2 + 6n)^n/(Kg_c)$ where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft³), K = consistency (lbf·s^n/ft²), g_c = 32.2 (lb·s/(lbf·ft²).

rance,[21] is applicable to turbulent flow of newtonian, pseudoplastic, and Bingham plastic as well as yield pseudoplastic fluids in smooth pipes.

$$\frac{1}{\sqrt{f}} = \frac{2.69}{n} - 2.95 + \frac{4.53}{n} \log\left(1 - x\right) - \frac{4.53}{n} \log\left(Re_r \sqrt{f^{2-n}}\right) + \frac{0.68}{n}$$

(C11.27)

where

$$Re_T = \frac{8\rho D^n V^{2-n}}{K(8^n)}$$

(C11.28)

Torrance has also extended his analysis to rough wall fully turbulent friction factor for nonnewtonian fluids and obtained the following relationship:

$$\frac{1}{\sqrt{f}} = 4.07 \log \frac{D}{2\varepsilon} + 6.0 - \frac{2.65}{n}$$

(C11.29)

Wilson and Thomas[22] and Thomas and Wilson[23] have used a mixing-length approach for the yield pseudoplastic fluids. Their model includes corrections to change
FIGURE C11.9a   Friction factor f as a function of Reynolds number for yield pseudoplastic slurries for $n = 0.7$, $He = [D^2 \rho \tau_y (t_y/K)^{2/n-2}]/(K^2 g_c)$, $Re = 8\rho D^n V^{2-n}[n/(2 + 6n)]^n/(Kg_c)$, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft^3), K = consistency (lbf · s^n/ft^2), τ_y = yield stress (lbf/ft^2), gc = 32.2 lb · s/(lbf · ft^2).

the thickness of the viscous sublayer according to the rheology and a term to account for the central unsheared core. Their method has been shown to give fairly good agreement with experimental data.

Stainsby and Chilton[24] have given a turbulent-flow friction factor correlation based on their model.

Example C11.7.   Estimate the friction loss in a 12-in-ID (0.3048-m-ID) pipe at a velocity of 5 ft/s (1.52 m/s) for the slurry considered in Example C11.5. Since the velocity of flow is greater than the transition velocity (see Example C11.5), the flow will be turbulent. Find the Reynolds number corresponding to the given velocity, using the slurry rheological data given in Example C11.5.

$$Re_p = 13,644$$

The Hedstrom number from Example C11.5 is 9.9×10^5. Using Fig. C11.9c, find the friction factor $f = 0.008$. Substituting the values of $D, V, f,$ and g in Eq. (C11.17), find the head loss per unit length of pipe:

$$\text{Head loss} = 0.0124 \text{ ft (m) slurry/ft (m) pipe}$$

Heterogeneous Flow

Fluid turbulence is needed to maintain particles in suspension or motion in a horizontal pipe carrying setting suspension. At low velocities, particles settle and form a stationary bed on the bottom of a horizontal pipe.
FIGURE C11.9b Friction factor f as a function of Reynolds number for yield pseudoplastic slurries for $n = 0.5$, He $= [D^2\rho\tau_y(t_y/K^{2/n-2}]/(K^2g_c)$, Re $= 8\rho D^n V^{2-n}[n/(2 + 6n)]^n/(Kg_c)$, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft³), K = consistency (lbf · s^n/ft²), τ_y = yield stress (lbf/ft²), $g_c = 32.2$ (lb · s/(lbf · ft²).

Deposition Velocity.   The velocity below which bed deposits form is called the deposition velocity. Operating the pipeline at or below the deposition velocity for prolonged time could result in a pipeline blockage. The minimum operating velocity in a slurry pipeline should be kept greater than the deposition velocity, to prevent pipeline blockages.

A number of empirical correlations have been proposed for estimating the deposition velocity. For uniform-size particles, the Durand[25] correlation, given as follows, is widely used:

$$V_D = F_L \sqrt{2gD(s-1)} \qquad (C11.30)$$

The value of F_L in Durand's correlation can be obtained from Fig. C11.10. In Eq. (C11. 30).

$$D = \text{pipe ID, ft } (m)$$

$$V_D = \text{deposition velocity, ft/s (m/s)}$$

$$g = \text{acceleration due to gravity, ft/s}^2 \text{ (m/s}^2)$$

$$s = \text{solids specific gravity}$$

Zandi and Govatos,[26] Wasp et al.[27] and Graf et al.[28] have proposed minor modifications of Durand's correlation based on additional data.
FIGURE C11.9c   Friction factor f as a function of Reynolds number for yield pseudoplastic slurries for $n = 0.3$, He $= [D^2\rho\tau_y(t_y/K)^{2/n-2}]/(K^2 g_c)$, Re $= 8\rho D^n V^{2-n}[n/(2 + 6n)]^n/(Kg_c)$, where D = pipe ID (ft), V = velocity (ft/s), ρ = density (lb/ft³), K = consistency (lbf·s^n/ft²), τ_y = yield stress (lbf/ft²), $g_c = 32.2$ (lb·s/(lbf·ft²).

Most industrial applications involve nonuniform-size particles. Pilot plant test results or prior experience with similar material is generally used for estimating deposition velocity for nonuniform-size particles.

Oroskar and Turian[29] have developed a semiempirical correlation which can be used for nonuniform-size particles. Their correlation is as follows:

$$V_D = \left\{ 5C_V(1 - C_V)^{2m-1} \left(\frac{D}{d}\right) \left[\frac{D\sqrt{gd(s-1)}}{g_c}\right]^{1/8} \left(\frac{1}{Z}\right) \right\}^{8/15} \sqrt{gd(s-1)}$$

(C11.31)

where V_D = deposition velocity, ft/s (m/s)
z = function of V/V_D, as shown in Fig. C11.11
d = mean diameter of particles, ft (m)
w = settling velocity of solid particle in slurry, ft/s (m/s)
m = hindered settling velocity exponent as a function of particle Reynolds number, shown in Fig. C11.12
w_o = settling velocity of solid particle in clear water of infinite extent, ft/s (m/s)
μ = viscosity of water, lbf·s/ft² (Pa·s)
FIGURE C11.10 Durand coefficient F_L as a function of particle size where $V_D = F_L \sqrt{2gD(s-1)}$, where V_D = deposition velocity (ft/s), D = pipe ID (ft), g = 32.2 ft/s², s = solids specific gravity.

The settling velocity w_o of a single particle in a fluid is given as

$$w_o^2 = \frac{4gd(\rho_s - \rho_l)}{3C_D\rho_l} \tag{C11.32}$$

where C_D = drag coefficient
d = particle diameter, ft (m)
g = acceleration due to gravity, 32.2 ft/s² (9.81 m/s²)
ρ_s = density of solid particle, lbm/ft³ (kg/m³)
ρ_l = density of liquid, lbm/ft³ (kg/m³)
w_o = settling velocity, ft/s (m/s)
FIGURE C11.11   Function z as a function of w/w_o for use in Eq. (C11.31), where w = hindered settling velocity of solid particle in slurry (ft/s), and w_o = settling velocity of single particle in suspending liquid (ft/s).

The drag coefficient of spherical particles depends upon the particle Reynolds number Re_w.

For $Re_w < 0.1$, the drag coefficient, C_D is given by

$$C_D = 24/Re_w \qquad \text{(C11.33)}$$

where

$$Re_W = \frac{d\rho_l w_o}{\mu g_c} \qquad \text{(C11.34)}$$

and μ = viscosity of liquid, lbf·s/ft^2 (Pa·s). The value of C_D equals 0.4 for a particle Reynolds number greater than 1000. Figure C11.13 shows variation in the drag coefficient with particle Reynolds number for spherical particles.

Use of $C_D\,Re_w^2$ instead of C_D enables determination of the particle Reynolds number from a plot of $C_D\,Re_w^2$ versus Re_w, shown in Fig. C11.13.

$$C_D Re_W^2 = \frac{4gd^3(\rho_s - \rho_l)}{3\mu^2 g_c^2} \qquad \text{(C11.35)}$$
FIGURE C11.12 Hindered settling velocity exponent m as a function of particle Reynolds number $Re_w = d\rho_l w_o/(\mu g_c)$, where d = particle diameter (ft), w_o = particle settling velocity (ft/s), ρ_l = liquid density (lb/ft³), μ = viscosity of fluid (lb·s/ft), g_c = 32.2 lb·s/(lbf·ft).

The drag coefficient is larger for a nonspherical particle than for a spherical particle of the same diameter. Experimental data on settling velocity as a function of particle diameter may be used to establish the relationship between C_D and Re_w.

The settling velocity of a solid particle in slurry (hindered settling velocity) is given by

$$w = w_o(1 - C_v)^m \qquad (C11.36)$$

where the exponent m varies with the particle Reynolds number, as shown in Fig. C11.12.

Wilson[30,31] has developed a semitheoretical analysis for heterogeneous slurries. He has presented nomographs for estimating the deposition velocity for particles larger than 0.15 mm in diameter.

Example C11.8. Estimate the deposition velocity for a sand-water slurry in a 12-in (0.3048-m) ID pipeline. The sand particle diameter is 0.2 mm, and its specific gravity is 2.65. The slurry concentration is 31.9 percent solids.

Solution. Using Eq. (C11.1), we find the slurry density, ρ_m = 77.9 1b/ft³ (1248 kg/m³). Using Eq. (C11.6), we find the volume fraction of solids C_v = 0.15. From
FIGURE C11.13 Drag coefficient C_D of spherical particles settling in liquid. $C_D = 4gd(\rho_s - \rho_l)/[3W_o^2\rho_l]$, where d = particle diameter (ft), w_o = settling velocity (ft/s), g = acceleration due to gravity (32.2 ft/s^2), ρ_s = particle density (lb/ft^3), ρ_l = liquid density (lb/ft^3).

Fig. C11.10, we find the value of F_L equal to 1.3 based on a particle diameter equal to 0.2 mm and C_v equal to 0.15. In Eq. (C11.30) we substitute the following values to compute the deposition velocity V_D:

$$F_L = 1.3 \qquad D = 1\,\text{ft}\,(0.3048\,\text{m}) \qquad g = 32.2\,\text{ft/s}^2\,(9.8\,\text{m/s}^2) \qquad S = 2.65$$

$$V_D = 13.4\,\text{ft/s}\,(4.08\,\text{m/s})$$

Example C11.9. Estimate the deposition velocity for a coal-water slurry having a mean particle diameter equal to 0.01 in (0.0254 mm) in a 12-in (0.3038-m) pipe. The volume fraction of coal in the slurry is 0.4, and the specific gravity of coal is 1.4. The viscosity of water is 2.1×10^{-5} lbf·s/ft^2 (1.0 m·Pa·s).
We are given

$$d = 0.01\,\text{in}\,(0.254\,\text{mm})$$

$$= 8.33 \times 10^{-4}\,\text{ft}\,(2.54 \times 10^{-4}\,\text{m})$$

$$\rho = 62.4\,\text{lb/ft}^3\,(1000\,\text{kg/m}^3)$$

$$\rho_s = 87.36\,\text{lb/ft}^3\,(1400\,\text{kg/m}^3)$$

$$\mu = 2.1 \times 10^{-5}\,\text{lbf}\cdot\text{s/ft}^2\,(0.001\,\text{Pa})$$

$$g_c = 32.2\,\text{lbm}\cdot\text{ft/(lbf}\cdot\text{s}^2)\,(1\,\text{in SI units})$$

Thus

$$C_D \text{Re}_w^2 = 84.5$$

From Fig. C11.13, $\text{Re}_w = 2.7$. Using Eq. (C11.32), we find w_o equal to 0.035 ft/s (0.0107 m/s). Next we find the hindered settling velocity exponent m from Fig. C11.12: $m = 2.8$.

Now we compute the hindered settling velocity, using Eq. (C11.36):

$$w = 0.0084 \text{ ft/s } (0.0026 \text{ m/s})$$

The ratio $w/w_o = 0.24$. From Fig. C11.11, we find z equal to 0.98. Next we compute the deposition velocity, using Eq. (C11.31).

$$V_D = 3.5 \text{ ft/s } (1.07 \text{ m/s})$$

Friction Loss for Heterogeneous Flow-Horizontal Pipes. The formula proposed by Durand,[32] Eq. (C11.37), is widely used for graded solids. The formula is based on sand-and-gravel slurries with particle sizes ranging from 0.2 to 25 mm, pipe diameters from 38 to 580 mm, and solids concentrations up to 60 percent by volume.

$$\frac{i - i_w}{C_v i_w} = 81 \left[\frac{V^2 \sqrt{C_D}}{(s-1)gD} \right]^{-1.5} \qquad \text{(C11.37)}$$

where i = friction loss for slurry, ft (m) water per ft (m)
  i_w = friction loss for water, ft (m) water per ft (m) at same velocity
  C_D = drag coefficient of suspended solid particle settling in fluid of infinite extent
  S = specific gravity of solid particles

Zandi and Govatos[33] concluded from an examination of 2549 data points that Durand's formula predicted the observed head losses fairly well once the saltation data were separated from the heterogeneous flow data. Turian and Yuan[34] have divided the available data into heterogeneous flow, saltation flow, and flow with stationary bed and have developed correlations applicable to each individual type of flow. Their correlations fit the available data better than Durand's correlation.

In Eq. (C11.37), the difference $i - i_w$ represents an increase in pressure drop due to the presence of solids in the slurry. The effect of particle size on slurry pressure drop is accounted for by the inclusion of the drag coefficient C_D.

In most industrial applications, the particle size is not uniform. A mean value of C_D is developed in Eq. (C11.37) to account for actual size variations. Equation (C11.37) can be written as follows:

$$\frac{i - i_w}{i_w} = 81 \left[\frac{V^2}{(s-1)gD} \right]^{-1.5} C_v C_D^{-0.75} \qquad \text{(C11.38)}$$

$$\frac{i - i_w}{i_w} = 81 \left[\frac{V^2}{(s-1)gD} \right]^{-1.5} \sum_{i=1}^{N} C_{vi} C_{Di}^{-0.75} \qquad \text{(C11.39)}$$

where C_{vi} = volume fraction of solids having size d_i
  d_I = particle size of ith fraction
  C_{Di} = drag coefficient of particle having size d_i
  N = total number of size fractions into which given particle size distribution is divided

TABLE C11.2 Tyler Screen Sizes

Note that the particle size distribution is determined by screen analysis. Tyler mesh screens are widely used. The diameter of openings for Tyler screens is given in Table C11.2.

Example C11.10. Estimate the friction loss for a coal-water slurry in a 12-in-ID (0.3048-m-ID) pipe at a velocity of 8 ft/s (2.44 m/s) based on the following data:

Coal specific gravity	1.4
Volume fraction of coal in slurry	0.2
Pipe roughness	0.002 in (0.05 mm)
Viscosity of water	2.1×10^{-5} lbf·s/ft^2 (1 m·Pa·s)

The particle size distribution is as follows:

Diameter, in (mm)	Weight %
0.24 (6.1)	10
0.12 (3.05)	40
0.06 (1.52)	40
0.03 (0.76)	10

Solution. Find the drag coefficient of particles of individual size fraction.

Particle diameter d_i, ft (m)		$C_D \operatorname{Re}_{w^2} i$	Re i	C_{Di}
0.02	(0.0061)	1.17×10^6	1710	0.4
0.01	(0.00305)	1.46×10^5	520	0.54
0.005	(0.00152)	1.83×10^4	145	0.87
0.0025	(0.00076)	2.29×10^3	36	1.76

Now,

$$\Sigma C_{vi} C_{Di}^{-0.75} = 0.269$$

Next we find the friction loss i_w for water. The Reynolds number for water is 2.38×10^7. And relative roughness of pipe $= 0.0002/12 = 0.000167$. From Fig. C11.6, $f = 0.00325$. Next we find

$$i_w = 4f \frac{V'^2}{2gD}$$

$$= 0.0129 \text{ ft/ft}$$

Using Eq. (C11.39), we get

$$\frac{i - i_w}{i_w} = 1.97$$

Thus,

Friction loss for slurry $i = (1 + 1.97)i_w$

$$= 0.0383 \text{ ft water/ft}$$

Friction Loss for Saltation Flow-Horizontal Pipes. At low velocities or with particles having large settling velocities, flow with a moving bed or saltating particles may arise.

The saltation flow regime is encountered when N_I is less than 40.

$$N_I = \frac{V^2 \sqrt{C_D}}{C_v g D(s - 1)} \tag{C11.40}$$

Newitt et al.[35] have developed the following formula based on their experiments:

$$\frac{i - i_w}{i_w C_v} = 66(s - 1)\frac{gD}{V^2} \tag{C11.41}$$

Babcock[36] has proposed the following formula based on his tests:

$$\frac{i - i_w}{i_w C_v} = 60.6(s - 1)\frac{gD}{V^2} \tag{C11.42}$$

Friction Loss for Intermediate Regime. Most of the formulas for heterogeneous flow and saltation regime are applicable to uniform particles. For a mixture of two or more size fractions, it is necessary to determine an average particle diameter for use in various formulas. Use of a weighted-average diameter or drag coefficient was illustrated in the previous section.

For slurries containing finely ground particles, a better approach is to divide solid particles into a fraction that is carried in homogeneous flow and a fraction that is carried in heterogeneous or saltation regimes. The friction losses for each fraction are computed separately, using appropriate formulas, and then added to obtain the total slurry friction loss. This approach also allows the use of nonnewton-

ian flow properties of the slurry in computing homogeneous friction loss. Wasp et al.[37] have successfully used this approach for correlating coal slurry data.

The method of Wasp et al.[38] is an iterative procedure which works as follows:

1. Divide the total size fraction into a heterogeneous part and a homogeneous part, using the following formula:

$$\log\frac{C}{C_A} = -1.8\left(\frac{w}{\beta\kappa u^*}\right) \tag{C11.43}$$

where C = volume fraction of solids at $0.98D$ from bottom
C_A = volume fraction of solids at pipe axis
$u^* = \sqrt{\tau_w g_c/\rho}$ = friction velocity, ft/s (m/s)
w = settling velocity of particles, ft/s (m/s)
β = ratio of mass-transfer coefficient to momentum-transfer coefficient (about 1)
κ = Von Karman constant = 0.4

It is assumed that for each size fraction, the fraction C/C_A is homogeneously distributed and that the remainder is heterogeneously distributed. At the start of the iteration, the slurry may be assumed to be homogeneous to compute the initial value of the wall shear stress.

2. Compute the friction losses for the homogeneous part, using the rheological properties of the slurry. Compute the friction loss for the heterogeneous part, using Durand's formula [Eq. (C11.38)]. The sum of the two parts gives an initial estimate of the slurry friction losses.

3. Determine the C/C_A values of each size fraction based on the value of friction loss estimated in step 2.

4. Based on these new values of C/C_A, determine the fraction of solids in the homogeneous phase and in the heterogeneous phase.

5. Recompute the friction loss for slurry as in step 2. This provides a new estimate of slurry friction losses. The iteration is continued until the new estimate closely agrees with the previous estimate. The computational procedure is suitable for analysis using a digital computer.

Lazarus[39] has described a method of estimating friction loss as well as determining whether a sliding or stationary bed of solids exists for slurries containing a mixture of coarse and fine particles.

Wilson and coworkers[40] have developed a mechanistic approach for estimating deposition velocity and friction losses for mixtures of fine and coarse slurries. Gillis et al.[41] have described a method of estimating friction losses for such slurries based on Wilson's mechanistic approach.

Friction Loss in Vertical Pipes. In vertical pipe flow, there is an absence of a concentration gradient. The slurry flow may be treated as homogeneous flow. For coarse particles, the friction loss for slurry has been found to be the same as that for water at the same velocity. With fine particles, the viscosity of the slurry should be considered in computing the friction losses. The friction factor for slurry is estimated using the equations presented earlier.

Friction Losses in Inclined Pipes. Worster and Denny[42] have proposed the following equation relating the friction loss for inclined pipes with that for horizontal pipe for heterogeneous slurries:

$$i_\theta = i_w + (i - i_w)\cos\theta \qquad (C11.44)$$

where i_θ = friction loss in inclined pipe
θ = angle of inclination of pipe from horizontal

This equation suggests that the friction losses in an inclined pipe are the same with both up- and downflow and that they are smaller than those in a horizontal pipe.

Experimental evidence presented by Kao and Hwang[43] shows that the friction losses in an inclined pipe with upflow first increase and then decrease after the angle reaches a certain magnitude. In the case of downflow, the friction losses are less than those for horizontal pipe flow.

Friction Losses in Pipe Fittings. Turian et al.[44] have shown that the friction loss in fittings can be approximated by using the relations for single-phase newtonian fluid provided that the density of the liquid is set equal to that of the slurry.

DESIGN FEATURES

System Components

Figure C11.14 shows a sketch of a slurry pipeline system. It includes a slurry preparation plant, pipeline, pump stations, and slurry receiving terminal.
FIGURE C11.14   Sketch of a slurry pipeline system.
FIGURE C11.15   Sketch of pumping system for Example C11.10.

Slurry handling operations in a preparation plant may involve pipelining of slurry from one processing unit to another. Example C11.11 illustrates the design of such a piping system.

Example C11.11.   Determine the pipe size and pumping requirements for the slurry piping system schematically shown in Fig. C11.15. The design basis for the system is as follows:

Maximum flow rate	2000 gpm (455 m³/h)
Minimum flow rate	1000 gpm (227.5 m³/h)
Slurry concentration, wt%	50
Specific gravity of solids	3.0
Slurry specific gravity	1.5

Estimated deposition velocity in 12-in (0.3048-m) pipe is 4.0 ft/s (1.22 m/s). The average value of C_D for use in Eq. (C11.37) is 50. Viscosity of water = 1 m·Pa·s (2×10^{-5} lbf·s/ft²). Use steel pipe with a roughness of 4.57×10^{-5} m (0.00015 ft).

   Solution.   Assuming that the deposition velocity varies as the square root of the pipe inside diameter [refer to Eq. (C11.30)], estimate the pipe diameter that will give a velocity greater than the deposition velocity at the minimum flow rate of 1000 gpm (227.5 m³/h).

$$\text{Minimum flow} = 1000 \text{ gpm } (227.5 \text{ m}^3/\text{h})$$
$$= 2.23 \text{ ft}^3/\text{s } (0.063 \text{ m}^3/\text{s})$$

Let D = pipe ID, ft (m)

$$\text{Deposition velocity} = 4D^{1/2} \text{ ft/s}$$

Let the velocity at the minimum flow rate be 1 ft/s (0.3 m/s) above the estimated deposition velocity.

Thus,

$$\frac{2.23}{(\pi/4)D^2} = 4\sqrt{D} + 1$$

$$D = 0.79 \, \text{ft} \, (0.241 \, \text{m})$$

Try 10.75-in (273-mm) outside-diameter pipe with 0.25-in (6.4-mm) wall thickness and 0.375-in (9.5-mm) thick rubber lining.

$$\text{Pipe ID} = 10.75 - 2(0.25 + 0.375)$$

$$= 9.5 \, \text{in}$$

$$= 0.79 \, \text{ft} \, (0.241 \, \text{m})$$

The computations of friction loss and pumping head requirement are summarized in Table C11.3.

Pipe Wall Thickness

The pipe wall thickness must be sufficient to withstand the expected maximum pressure in the pipe and expected corrosion-erosion effects on the pipe wall during the intended operating lifetime. Most pipelines are designed to have a service life of at least 10 years. An example based on the ASME B31.11 Code, with enhancements based on typical service conditions, follows:

The pipe wall thickness is computed by using the following equation:

$$t = \frac{pD}{2S} + c \tag{C11.45}$$

where t = pipe wall thickness, in (mm)
p = maximum design pressure in pipe, psi (Pa)
S = maximum allowable design stress, psi (Pa)
c = allowance for corrosion-erosion, inch (mm)

The maximum allowable pipe stress is given as follows, per ASME B31.11:

$$S = 0.8E \times \text{specified minimum yield strength of pipe}$$

where E = weld joint factor, as summarized in Table C11.4.

Example C11.12. Determine the wall thickness required at point A in the pipeline shown in Fig. C11.16. A 12-in (324-mm) steel pipe is used. The pipe is manufactured in accordance with API 5LX. The minimum yield strength of the pipe is 52,000 psi (358.5 MPa). The design hydraulic gradient is shown in Fig. C11.16. The design head at point A is 800 ft (244 m). The slurry specific gravity is 1.5. The metal loss due to corrosion-erosion is estimated to be 4 mils/yr (0.1 mm/yr), and the design life of the pipeline is 25 yr.

Solution. Maximum design pressure at A

Maximum design pressure at $A = 800\,\text{ft slurry}$

$$= \frac{800 \times 1.5}{2.31\,\text{psi}}$$

$$= 520\,\text{psi}\,(3589\,\text{kPa})$$

Maximum allowable stress $= 0.8 \times \text{minimum yield strength of pipe steel}$

$$= 0.8 \times 52{,}000\,\text{psi}$$

$$= 4160\,\text{psi}\,(286.8\,\text{MPa})$$

Corrosion allowance $C = 0.004 \times 25\,\text{in}$

$$= 0.1\,\text{in}\,(2.5\,\text{mm})$$

Wall thickness $t = \dfrac{pD}{2S} + c$

$$= \frac{4160(2.75)}{2(4160)} + 0.1$$

$$= 0.18\,\text{in}\,(4.53\,\text{mm})$$

The next-higher commercially available pipe wall thickness is 0.188 in (4.78 mm).

Corrosion-Erosion Control

In a slurry pipeline, metal loss is expected to be a result of corrosion with possible erosion of the corrosion products taking place simultaneously. Under some conditions, mechanical abrasion will play a part in producing the metal loss.

Erosive wear (abrasive) is governed by the size, shape, and angularity of the solids, slurry concentration, and velocity of flow. In a slurry pipeline, these parameters are interdependent to some extent. For example, use of large solids requires an increase in minimum transportation velocity. It has been found that above some critical velocity, the abrasive wear increases as the cube of slurry velocity. Wear also increases as the size of the solid particles increases. Thus, by reducing the size of the solids, the abrasive wear can be substantially reduced due to the combination of lower required velocity and reduction in wear due to smaller particle size. The effect of slurry concentration on the abrasive wear is more complicated.

From experience, it has been found that the metal loss due to abrasion is insignificant if the velocity of flow is less than about 10 ft/s (3 m/s). For long-distance slurry pipelines, velocities in the range of 4 to 6 ft/s (1.2 to 1.8 m/s) result in an optimum design from the standpoint of economics. Thus, when possible, a particle size should be selected so that the slurry is nearly homogeneously suspended at velocities of 4 to 6 ft/s (1.2 to 1.8 m/s).

Corrosion can be controlled by passivating either the anodic or the cathodic reaction at the pipe wall. Elimination of dissolved oxygen and the adjustment of slurry pH can reduce the corrosion rate substantially.[45] In most long-distance slurry

TABLE C11.3 Summary of Hydraulic Computations

Item	Min. flow Metric	Max. flow Metric	Min. flow U.S. Units	Max. flow U.S. Units	Remarks
1. Flow rate, ft³/s (m³/s)	0.095	0.126	3.34	4.45	Given
2. Velocity, ft/s (m/s)	2.1	2.8	6.8	9.1	Flow/area

  * Definitions for the various pipe types (weld joints) are given in paragraph 1100.2 of ASME B31.11 Code.
  † A weld joint factor of 1.0 may be used for electric resistance-welded or electric flash-welded pipe manufactured prior to 1959 where
   1. Pipe furnished under this classification has been subjected to supplemental tests and/or heat treatment as agreed to by the purchaser, and such supplemental tests and/or heat treatment demonstrates the strength characteristics of the weld to be equal to the minimum tensile strength specified for the pipe; *or*
   2. Pipe has been tested as required for a new pipeline in accordance with paragraph 1137.4.1 of the ASME B31.11 Code.
  ‡ For classes and grades that have been hydrostatically and nondestructively tested to specification requirements.
  § Manufacture was discontinued and process deleted from API 5L in 1962.

pipelines carrying mineral concentrate, the slurry pH is adjusted to 9.0 or higher, using lime to reduce the corrosion rate.

Slack Flow and Its Control

Slack flow occurs when the available static head between the discharge point of the pipeline and a given point in the pipeline exceeds the friction loss between
FIGURE C11.16 Pipeline profile and hydraulic gradient showing design gradient, batch gradient, and slack flow area.

those points at a given flow rate. It usually occurs just downstream of peaks where the hydraulic gradient intersects the ground profile. For example, Fig. C11.16 shows slack flow area.

In slack flow areas, the velocity of flow is governed by the pipe slope. The velocity in the slack flow area is higher than that in the fully packed pipe section. The section of pipe which flows full and is under pressure is called *fully packed.* In slack flow sections the pipe flows partly full, and pressure generally drops below atmospheric. Erosion takes place in the slack flow area owing to higher flow velocity as well as possible cavitation at the point where the pipeline changes from slack flow to a packed flow condition.

Because of the higher density of slurry compared to water, slack flow can occur when water is displaced by slurry. For example, Derammelaere and Chapman[46] have described the development of slack flow in the Samarco iron concentrate pipeline during operation of the pipeline in batch mode. This is illustrated in Fig.

C11.16, where the hydraulic gradients for pipe full of slurry as well as for batch operation are shown.

Slack flow can be avoided by using a smaller-diameter pipe section or orifice chokes. The velocity of flow in the smaller-diameter pipe should not exceed about 10 ft/s (3 m/s); otherwise, erosion may occur. Either orifice chokes or a combination of orifice chokes and smaller-diameter pipe may be used to achieve flexibility and economy.

Storage

It is very seldom that the flow of solids in a slurry pipeline matches its rate of production at the mine site or its rate of utilization at the terminal facility. To provide means by which the pipeline can operate efficiently by transporting solids in a nearly continuous fashion, storage facilities are required at both ends of the line. The type and amount of storage are determined by the specific system operating parameters as well as the characteristics of the material being transported.

Tanks

For live slurry storage at the head and tail ends of a long-distance pipeline system, agitated tanks are typically utilized. The number and size to be used are determined by comparing the plant and pipeline availabilities in addition to normal engineering criteria such as allowable soil loadings and an economic analysis of available sizes. If the pipeline is to be operated in batch mode, for the first few years of operation, because of low throughput requirements, the size of the tanks may be determined by the minimum batch length chosen for the system. This in turn is a function of pipeline length.

Agitated storage may also be required at intermediate pump stations. The purpose would be to facilitate pipeline section reconnection during restart operations as well as hold slurry which has been flushed from station piping during pump change-out.

Ponds

Ponds are utilized for the storage of high volumes of solids over intermediate to long periods. Ponds are generally used when the storage requirement exceeds 24 h of pipeline flow. Their prime advantage is that no energy is required to maintain continuous suspension of the solids.

Slurry storage ponds can be classified into two basic types: semiactive and dead storage. Semiactive ponds are equipped for recovery and reslurrying on short notice. Depending on the design, it may be necessary to remove all the stored material before refilling the pond.

The major consideration in pond design is recovery of a uniform solids particle size distribution. Segregation of the solids can occur during the filling or recovery operation. The resulting coarse and fine slurry slugs can be very difficult to handle in the downstream processes. Three major recovery methods have been utilized: mechanical, dredge, and the Marconaflo technique.

Mechanical recovery uses conventional earthmoving equipment to remove the settled solids. Prior to the start of recovery operations, the bulk of the free water

must be removed from the pond by evaporation, natural drainage, sand points, or an underdrain system.

Dredge recovery requires the maintenance of a water layer over the settled solids to float the dredge. The recovery dredge may be maintained on site or moved in for the recovery operation, depending on whether semiactive or dead storage is required.

The Marconaflo technique[47] was originally developed to remove settled slurries from the hold of ore ships. A high-pressure water jet on a rotating head undercuts and reslurries the solids, and the material flows into an underdrain system for pumping away.

Slurry Pumps

Centrifugal as well as positive displacement pumps are available for pumping slurry. The maximum pressure capability and maximum particle size limits for different types of pumps are shown in Fig. C11.17.[48]

The positive displacement pumps can be divided into piston, diaphragm, and plunger pumps. Piston pumps can be used for relatively less abrasive materials while the diaphragm and plunger pumps are used for handling abrasive slurries at high pressures. The initial capital costs and maintenance costs of positive displacement pumps are higher than those of centrifugal pumps, but their hydraulic efficiency is 85 percent, compared to about 60 to 70 percent for the centrifugal slurry pumps. The flow rate per pump is limited in the case of positive displacement pumps while
FIGURE C11.17   Maximum particle size and pressure capabilities of different types of pumps.

the head developed per pump is limited to about 30 m in the case of centrifugal slurry pumps.

Centrifugal Slurry Pumps.   Centrifugal pumps are extensively used for pumping slurry under relatively low pressure. The main advantages of these pumps are as follows:

1. High flow rates can be achieved with a single unit at a relatively low initial cost. Pumps capable of pumping 25,000 gpm (5680 m^3/h) are available.
2. Very few moving and wearing parts are involved.
3. They are simple to operate and maintain.
4. There is no practical restriction on the maximum size of solids that can be handled.
5. The flow through the pump is pulse-free.
6. They require little space.
7. Valves are not required for the operation of the pump.

Centrifugal pumps have the following shortcomings:

1. The maximum discharge head is limited to less than 130 ft (40 m) for a single-stage pump. With several pumps in series, a maximum pressure of about 750 psi (5.17 MPa) can be achieved.
2. The flow rate of the pump is governed by the system pressure.
3. Attrition of friable solids may occur due to the high velocity of flow through the pump. Attrition can become important if the slurry has to pass through a number of pumps.
4. Seal liquid is required for good packing life. The seal liquid dilutes the slurry. The amount of dilution could become significant when the slurry passes through a number of pumps.
5. Centrifugal slurry pumps are made robust because of the abrasion of parts coming in contact with slurry, resulting in a low pump efficiency.

The centrifugal pump parts exposed to wear from slurry are the casing, impeller, and gland seal. Mechanical shaft seals often are ineffective in slurry installations. A seal that incorporates a liquid flush to keep solids from entering the gland is necessary.

To obtain good service, the casing and impeller should be lined with abrasion-resistant material. Both rubber-lined and ''Ni-hard'' (metal-lined) units are used extensively. The size of the solids to be pumped determines the type of pump to be selected. Rubber-lined pumps are generally used with particles up to about 0.375 in (9.5 mm), and Ni-hard pumps are used for coarser slurries. However, if material with sharp cutting edges is being pumped, such as crushed glass, Ni-hard pumps can be used even for relatively fine solids. Rubber-lined pump parts usually have longer service life with fine materials. Coal is one material for which Ni-hard line pumps have shown better parts life than rubber-lined units.

To obtain good pump parts life, it is good practice to limit the impeller tip speed to less than 4000 ft/min (1220 m/min). The pump parts life on units running faster than this speed drops in proportion to the square of the impeller tip speed.

Reciprocating Pumps. Reciprocating pumps have several desirable features:

- The flow rate of the pump is independent of system pressure.
- They can meet any reasonable system discharge pressure requirement. Pumps capable of producing 2300 psi (15.8 MPa) pressure have been used in magnetite pipelines. Units capable of discharge pressures greater than 5,000 psi (34.5 MPa) are available.
- The overall efficiency of the pump, including drivetrain, is relatively high—on the order of 85 percent.
- Pipeline flow rate can be determined without the use of a flowmeter.

The following disadvantages are associated with this type of unit:

- The maximum flow rate per pump is limited to less than about 3900 gpm. Furthermore, this capacity is only available at relatively low discharge pressures. Therefore, a large number of pumps operating in parallel are needed to handle the high flow rates and working pressures found in large long-distance systems. For example, seven 1,250-hp units are used at each pump station of the Samarco system.
- Initial capital costs and maintenance costs are usually high. Skilled labor is required for operation and maintenance.
- Variable-speed drives are needed to vary flow rates.
- The flow through the pump is pulsating, which requires greater attention to station piping design to avoid vibration and fatigue problems.
- The maximum size of particles that can be pumped is restricted by the check valve seal requirements.

For material with a maximum particle size of less than 0.1 in (2.5 mm) and with discharge pressures up to about 2000 psi (13.8 MPa), either piston or plunger pumps can be used. Slurry with a maximum particle size of 0.1 to 0.25 in (2.5 to 6 mm) may also be handled with these types of pumps if special design pump valves are used.

The decision to use piston or plunger pumps is usually based on the results of a Miller abrasivity test. Material with a Miller number below 30 can be handled using piston pumps, and material with a Miller number above 60 should be pumped with plunger units. Between these values, the type of pump to use is based upon other considerations:

- Piston pumps can be of double-acting design so that about twice the flow rate can be obtained for the same physical pump size.
- Plunger pumps are more adapatable to flushing and lubrication. A flushed stuffing box can prolong parts life. However, a flush fluid free of solids must be provided, and some dilution of the slurry will result.

Piston Pumps. Figure C11.18 shows the fluid end of a conventional piston pump. With such a unit, major wear occurs on the pistons, valves, cylinder liners, piston rods, and packing.

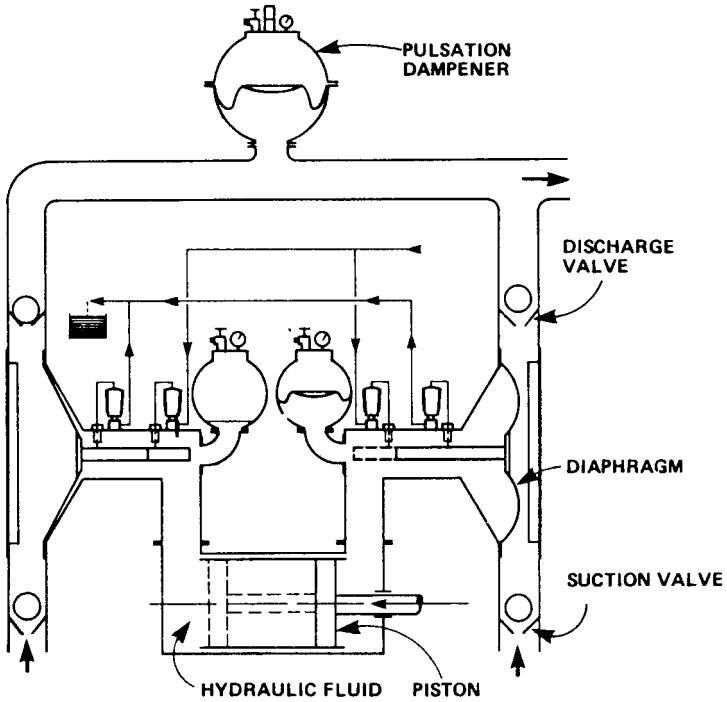
To reduce maintenance, several variations of piston pumps have been developed that limit the number of working parts in contact with the slurry. One such type is the diaphragm pump, the fluid end of which is sketched in Fig. C11.19. By pumping
FIGURE C11.18 Plunger pump fluid end.


FIGURE C11.19 Diaphragm pump fluid end.

hydraulic fluid with a piston pump, the diaphragm is alternately squeezed and expanded. With this type of pump, the valves and diaphragm are the only parts that experience major wear. One disadvantage is the possibility of diaphragm failure. However, this can be minimized through careful pump design by limiting the amount of diaphragm flexing and by selecting the membrane elastomer carefully. In addition, suppliers offer visual and audible monitoring systems to detect diaphragm failure. Units are available that will limit the amount of slurry entering the propelling fluid chamber.

Plunger Pumps. Because abrasive slurries can greatly reduce the life of the pistons and cylinder liners of conventional piston units, plunger pumps are often used. This type of pump maintains a clear liquid barrier between the plunger and packing by means of a flushing system, as shown in Fig. C11.20. Major wear is limited to the plunger, valves, and packing.
FIGURE C11.20   Plunger pump fluid end.

Hydrohoists. The limitation of maximum particle size for positive displacement pumps and the limitation of pump discharge pressure for centrifugal pumps can be eliminated by using a hydrohoist system. Figure C11.21 shows a sketch of a hydrohoist pumping system. The hydrohoist consists of one or more chambers that can be filled with solids either in dry form (lock-hopper) or as a slurry. Once the chamber is filled with solids, water under high pressure is admitted to the chamber to push the solids into the pipeline. A major application is found in vertical transportation of coarse ore from deep mines. The advantages of these devices are as follows:

• Large solids can be pumped under high pressure without having them pass through a number of centrifugal pumps. The attrition of solids is thereby reduced.

• A high-pressure water pump, having relatively high efficiency compared to a centrifugal slurry pump, is used.
FIGURE C11.21   Sketch of a hydrohoist.

- The number of moving parts exposed to slurry is considerably less than that with reciprocating units.
- The life of slurry check valves is extended because of the reduced frequency of operation compared to reciprocating pumps; normally the valves open and close in the presence of water.
- A larger capacity can be obtained with a hydrohoist than with a reciprocating pump operating at the same discharge pressure.

   The disadvantages of the hydrohoist system are as follows:

- A sophisticated control system is needed to open and close the slurry valves.
- The flow rate of this device depends upon the system discharge pressure since a high-pressure centrifugal water pump is used.

Pump Power.   The pump power is computed from the following equation:

$$\text{HP} = \frac{\text{QP}}{F \times \text{efficiency}} \tag{C11.46}$$

where HP = pumping power, kW (hp)
       Q = flow rate, m³/h (gpm)
       P = increase in pressure across the pump, Pa (psi)
       F = conversion factor, 1714 hp/(gpm·psi) {3.6 × 10⁶ kW/[m³/(h·Pa)]}

Example C11.13. Select the type, number, and power of pumps based on the following:

Flow rate	3000 gpm (680 m³/h)
Rise in head across pump(s)	260 ft (80 m)
Specific gravity of slurry	1.5

Solution. The pressure rise across the pumps is 260 ft × 1.5 × 62.4/144 psi = 169 psi (1.177 MPa). Select centrifugal slurry pumps. Assume three pumps operating in series to get a total head rise of 260 ft (80 m).

Assuming a pump efficiency of 70 percent, the power per pump is obained as follows:

$$HP = \frac{3000 \times 169/3}{1714 \times 0.7}$$

$$= 141 \quad \text{Use 150-hp motors.}$$

$$Power = \frac{680(1.17)/3}{3.6(0.7)}$$

$$= 106 \, kW$$

Life of Pump Parts. Typical parts life for the different types of slurry pumps is given in Table C11.5. The actual life depends upon the pump speed, discharge pressure, and abrasivity of the slurry.

TABLE C11.5 Pump Parts Life

	Part life			
Pump part	Piston	Plunger	Diaphragm	Centrifugal
Piston Rod	3000	n/a	n/a	n/a
Plunger sleeve	n/a	700	n/a	n/a
Piston liner	4000	n/a	n/a	n/a
Packing	6000	400	n/a	1500
Diaphragm	n/a	n/a	8000	n/a
Valve seat	1000	800	5000	n/a
Valve body	1000	800	3000	n/a
Valve insert	1000	500	3000	n/a
Impeller	n/a	n/a	n/a	6000
Casing	n/a	n/a	n/a	6000

Selection of Valves

There are many manufacturers and types of valves offered for low-pressure slurry service. These designs are backed by years of experience in the minerals and dredging industries. Selection of valves for use in positive displacement slurry pump stations introduces some new parameters besides those that must be considered in

selecting low-pressure valves. These include vibration of the piping and packing of solids into the void spaces in the valves.

Generally speaking, in high-pressure duty where a full opening is not required, lubricated plug valves have been applied. Depending on the service, the wetted parts of these valves should be hardfaced to minimize abrasive wear during the opening or closing cycle. Gate or ball valves have been used where a full round opening is required. Both types introduce the problem of removing solids from the body cavity after the valve has been operated in slurry. Again, it may be necessary to hardface some wetted parts to extend the valve life.

Slurry valves require regular lubrication and maintenance to remain operable. An important feature in selecting valves is the ease of disassembly for maintenance. Some ball valves, for instance, have to be sent to the factory to renew the seats or seals. Some maintenance problems may simply be a matter of solids finding their way into the valve workings, with the solution simply being disassembly and cleanup of the valve. Some slurries (such as limestone) may have some cementation properties. Therefore, it is good practice to regularly lubricate and exercise valves that are otherwise infrequently used.

Abrasion Control

Pipe abrasion is a major concern in coarse solids pipelines. In temporary systems, the pipeline may be replaced periodically. For example, the phosphate mining industry in Florida replaces temporary steel pipes after about 2 years of operation.[49] Use of special pipes, nonferrous pipes, and steel pipes lined with abrasion-resistant linings can significantly increase the life of pipes carrying coarse solids. Example C11.12 addresses the subject of corrosion-erosion control for long-term service.

Nonferrous Pipes.   For low pressure applications, a number of nonferrous materials can be considered for transporting coarse solids.[50]

Polyethylene.   Ultrahigh-molecular-weight polyethylene has been extensively used for tailings line construction. For sizes up to NPS 14 (DN 350), it is available with pressure ratings up to 250 psi (1725 kPa). This material is a major improvement over unlined carbon steel or wood, and under good conditions it lasts many times longer than the material it replaces.

Polybutylene.   Polybutylene pipe is a flexible thermoplastic pipe that has been developed relatively recently. Depending upon the diameter, it is normally available with pressure ratings up to 200 psi (1380 kPa), although higher-pressure pipes have been made. Polybutylene has two major advantages compared to polyethylene: the tensile strength is higher, and it is less affected by extremes of temperature.

Polyurethane.   This type of pipe has been used for some in-plant systems, in particular, coal cleaning plants. The polyurethane is spun-cast into flanged spools up to NPS 12 (DN 300).

Other Nonferrous Materials.   Polyvinylchloride (PCV) polypropylene and acrylonitrile-butadiene-styrene (ABS) have been made into pipe but have poor wear resistance compared to polyethylene and polybutylene. They should not be considered for long-life slurry applications.

Fiberglass pipe is available with ceramic chips or tile embedded into the inner surface. This material is quite expensive, and once the chips are broken out, the epoxy matrix that holds the chips has very poor wear resistance and the pipe quickly fails. Also, joint systems designed to take high pressure are prone to failure. Abrasive particles attack the groove left at the joint, and early failure may result.

Internally Lined Steel. Many of the materials discussed in the previous section can also be utilized as a lining within a steel outer shell. By utilizing such a system, the inherent pressure limitations of nonferrous materials can be overcome. In most cases, the use of a composite pipe leads to difficulty in joining the pipe sections. Most systems require the use of steel flanges with the lining material serving as the gasket material.

In Situ Lining of Steel Pipe. Two methods of in situ internal lining of welded steel pipe have been developed. In one method a plastic pipe of slightly smaller diameter than the inside diameter of steel pipe is pulled inside, and the annular space between the two pipes is grouted with cement. In another method a high-density polyethylene pipe of slightly larger outside diameter than the inside diameter of the steel pipe is installed by pulling it after compressing it to reduce its outside diameter. The pipe expands and presses against the steel pipe upon release of pulling forces.

These liners are pulled inside the steel pipe, which is welded prior to pulling the liner. The liner can be pulled to a distance of 1 km depending upon the pipe size and the number of bends in the steel pipe.

In either method, best mechanical design and economic results are obtained when lining is planned for in the beginning. In an operating pipeline these lining methods can be used to extend service life.

Instrumentation

The instrumentation used and the major parameters measured and controlled are as follows:

Pressure. Both the suction and discharge pressures at a pump station are normally measured and controlled. Suction pressure is controlled to prevent cavitation. The discharge pressure is controlled so as not to exceed the maximum allowable pressure for the pump unit or the pipeline system. Bourdon-type pressure gages with an isolation diagram are generally used.

Density. The pumping head requirement varies with the changes in slurry density. If the slurry density is not controlled within the pipeline design limits, the pipeline system can be overpressurized or the flow velocity could drop below the deposition critical velocity.

Slurry density is normally measured by radiation gages. Density meters may be needed at each pump station in a multiple-station system. The density meters are normally installed on the suction side of a pump station.

Density is controlled by adding dilution water to high-density slurry. If the density is too low, the slurry can be returned to the preparation plant for concentrating.

Flow Rate. Because slurries are often abrasive by nature, some in-line flow-measuring devices such as orifice plates and pitot tubes are not applicable. For primary slurry flowmetering, magnetic flowmeters are considered the best choice. Ultrasonic flowmeters sometimes are used in applications including oil slurries where magnetic flowmeters are unsuitable.

Slurry Tank Level Measurement. A number of different systems have been used for recording the level in slurry storage tanks.

Conductance probes for level alarms and a pressure sensor mounted in the wall of the tank are used to obtain a rough indication of level of slurry in the tank. This procedure has proved satisfactory although the accuracy of the level measurement with a pressure sensor is affected by changes in slurry density. A way to compensate for this effect is available but not commonly used. Sonic devices provide direct measurement of tank level.

NONMETALLIC PIPING

CHAPTER D1
THERMOPLASTICS PIPING

Dr. Timothy J. McGrath
Principal
Simpson Gumpertz & Heger Inc.
Arlington, Massachusetts

Stanley A. Mruk
Plastics Pipe Consultant
New Providence, New Jersey

SCOPE

This chapter reviews the principal properties and uses of thermoplastics piping, discusses its advantages and limitations, and presents general and basic information on materials, properties, standardization, design, and installation. This information is intended to guide the reader in evaluating the applicability of thermoplastics piping for an intended application; in choosing the appropriate material and product; and in its proper design and installation. References are provided for more detailed information and for further guidance on these and related subjects.

INTRODUCTION

Plastics piping is made from either of two basic groups of synthetic materials, *thermoplastic* and *thermosetting.* Thermoplastics can be softened and reshaped repeatedly by the application of heat. In contrast thermosetting materials are irreversibly *set,* or *cured,* or *hardened* into a permanent shape during factory manufacture. Once *hardened* into their final shape, thermosetting products cannot be softened and therefore may not be reshaped by heating.

Thermoplastic materials include minimal reinforcements, whereas thermosetting resins are almost always combined with reinforcements (such as glass fibers) and sometimes fillers (such as sand) to produce structurally integrated composite constructions. Chapter D2 in this handbook presents information on fiberglass reinforced thermosetting resin piping.

Principal Materials

Thermoplastics account for the lion's share of plastics used for piping. During 1989, over 95 percent of the approximately 7.5 billion pounds (3.75 million metric tons) of plastics that went into pipe, conduit, and fittings consisted of thermoplastics.[1] *Polyvinyl chloride* (PVC) accounted for about three-quarters of all thermoplastic pipe. The second most widely used thermoplastic is *polyethylene* (PE), accounting for about a 15 percent share, followed by *acrylonitrile-butadiene-styrene* (ABS), representing about a 4 percent share. The balance about 6 percent, consists of special-purpose materials, such as chlorinated polyvinyl chloride (CPVC), cross-linked polyethylene (PEX), polybutylene (PB), polypropylene (PP), and various fluorinated polymers, principally polyvinylidene fluoride (PVDF). In 1955, total U.S. shipments of thermoplastic pipe were under 40 million pounds (18,000 metric tons). By 1998, the rate of shipments had increased almost 200 fold, and it is still growing.

More footage of thermoplastic pipe is now being installed than that of all other types of piping materials combined.[2] However, the total dollar value of installed thermoplastic pipe is second to and only about one-quarter of that of the leading material, steel.[3] This is because the principal use of thermoplastics piping is in the smaller sizes. But the very successful track record in these sizes has been leading to increasing acceptance and use of the larger diameters, which currently comprise the fastest growing segment. As of this writing, thermoplastic pipe is available through NPS 60* (DN1500) for pressure uses and NPS 108 (DN 2700) for sewer and drain applications.

The first thermoplastic tubes were made in Germany during the 1930s from a PVC copolymer. Thermoplastics pipe was first manufactured commercially in the United States in 1940 from cellulose acetate butyrate (CAB) and was used by The Southern California Gas Company for distributing natural gas. Volume production commenced in 1948 when PE pipe was first offered for non-code-regulated water service applications. ABS and PVC pipe were first commercially made in the United States in 1949 and 1950, respectively. During the 1940s and 1950s many fundamental advances were introduced in polymer chemistry, materials formulation, and product fabrication technology, which laid the foundation for the thermoplastics pipe industry. Improvements in these areas are still continuing.

However, the start of the evolution of thermoplastics piping as engineering materials is considered to have taken place in 1950 when an American Society for Testing and Materials (ASTM) group for plastics pipe standardization was organized. Soon thereafter the first ASTM standards covering materials, test methods, and piping products began to be issued. At present over 180 ASTM standards define plastic piping, plastic piping materials, test methods, and recommended practices for joining and installation. Numerous plastics piping standards have also been issued by other organizations. A listing of the principal U.S. and Canadian plastic piping product standards is presented in Table D1.1.

Available Products

Plastics pipe and fittings are available in a vast array of materials, diameters, wall thicknesses, and designs. For nonpressure applications special wall constructions are offered—such as double wall, ribbed, and foamed core—which are designed

---

* NPS 60 is size designator for 60-inch pipe. Refer to Chapter A1.

to more economically achieve a desired longitudinal and diametrical pipe stiffness. Most of these products are covered by national standards. Table D1.1, which lists standards that cover principal commercial products, also identifies each product's primary application and gives the range of nominal sizes covered by the standard. As the updating of existing and the writing of new product standards is a dynamic ongoing process, the reader is advised to contact standards-issuing organizations for the latest status. The American Society for Testing and Materials (ASTM),* for example, each year updates a volume of its ''Annual Book of ASTM Standards'' which includes all of its current standards covering plastics piping. The Plastics Pipe Institute (PPI) publishes a periodically updated report, PPI TR-5, which includes a comprehensive listing of North American and International Standards Organization (ISO) standards on thermoplastics piping. There are also many commercially available piping appurtenances, such as identified in Table D1.2, that are fabricated from plastics but which are not covered by any national standard. In addition, some pipe and fitting manufacturers and their distributors can custom-fabricate components that may or may not be shown in product catalogs. These specials include manholes for both infrastructure and industrial applications. Fabricated fittings intended for pressure service are often reinforced by an overwrap with a glass-fiber thermosetting resin composite.

Principal Uses

Thermoplastics piping is routinely used for many common pressure and nonpressure applications. Approximately 80 percent of the newly installed mains and 90 percent of the services for gas distribution are made of PE. Over 90 percent of rural water distribution mains and over 40 percent of municipal mains are made of PVC. Most of the smaller-diameter piping installed for agricultural and turf irrigation is made primarily from PE and PVC. CPVC and PEX piping are increasingly used for hot/cold water distributing piping for residential and other construction. In oil and gas production, significant quantities of PE pipe are used to convey water and well gases. Thermoplastics piping is also frequently used for commercial and industrial applications such as for conveying chilled and process waters, aqueous solutions of corrosive chemicals, slurries, foods, and substances that must remain uncontaminated by metallic ions.

More than half the tonnage of all thermoplastic pipe goes into nonpressure uses. Over 85 percent of the newly installed underground building sewer connections are made of PVC. PVC also accounts for a similar share of the sewer collection mains in sizes NPS 4 through 18 (DN 100 through 450). About 80 percent of new single-family dwellings utilize either PVC or ABS drain, waste, and vent (DWV) piping. Most drainage systems, including those for building foundations, leaching fields, agriculture, and road construction now consist of thermoplastics piping, mostly PE and PVC. And both PVC and PE are increasingly used for larger-diameter sewers, drains and culverts. One of the faster growing applications is the use of PE and PVC pipes of profile wall constructions for drainage, particulalry alongside and under roadways (see Fig. D1.1). Another is the rehabilitation of older sewers, drains, and pressure pipelines by the insertion of new PE or PVC pipes.† In one rehabilitation technology a PE or PVC pipe is deformed when

---

* Societies and associations that write standards or that offer information relating to plastics piping are listed at the end of this chapter.

† Information on the rehabilitation of existing pipelines by the insertion of new themoplastics pipes may be obtained by contacting the North American Society for Trenchless Technology. See previous footnote.

TABLE D1.1 Principal Thermoplastic Piping Standards

Piping material* and product standard†	Subject product, or abbreviated title of standard	Nominal sizes range (in)	Principal applications
ABS, PP and PVC			
ASTM D3311	DWV fittings patterns	1¼–8	Drain, waste & vent
ABS and PVC			
ASTM D2680	ABS and PVC sewer pipe of composite wall construction	4–15	Sewer & drain
ASTM F409	Accessible and replaceable tube and fittings	1¼–1½	Drain, waste & vent
ASTM F480	Thermoplastic water well casing	2–16	Water-well casing
ASTM F1499	Coextruded, composite DWV pipe	1¼–8	Drain, waste & vent
CSA B181.5	Coextruded ABS/PVC DWV pipe	1¼–6	Drain, waste & vent
ABS, PVC & CPVC

manufactured into a "U" shape approximately one-half the diameter of the host pipe. At the installation site, the "U" deformed pipe is pulled through the damaged host pipe and then reformed by a combination of heat and pressure to tightly fit the shape of the host pipe (see Fig. D1.2).

Advantages and Limitations

A number of important performance advantages have sparked the widespread adoption of thermoplastics piping for so many pressure and nonpressure uses. The most universally recognized advantage is the piping's virtual freedom from attack by ambient water and moisture. Thermoplastics piping is not subject to surface attacks in any way comparable to the rusting or environmental corrosion of metals. Thermoplastics, being nonconductors, are immune to the electrochemical-based
Note - Other corrugation profiles are available

FIGURE D1.1 Examples of plastic pipe wall cross sections.
FIGURE D1.2 Deformed and reformed polyethylene liner pipe.

corrosion process induced by electrolytes such as acids, bases, and salts. In addition, plastics pipe materials are not vulnerable to biological attack. In sum, thermoplastics are not subject to corrosion in most environments in both aboveground and underground service. This has resulted in negligible costs for maintenance and external protection such as painting, plastic coating, galvanizing, electroplating, wrapping, and cathodic protection.

Another principal advantage offered by thermoplastics is their lower specific gravity, which results in ease of handling, storage, and installation, as well as in lower transportation costs. The smooth pipe surfaces yield low friction factors and very low tendency to fouling. They also offer very good abrasion resistance, even when conveying slurries that can rapidly abrade harder materials.

High deformation capacity without fracture—or *strainability* (Janson[4])—is another important performance feature, particularly for underground service. In response to earth loading, buried flexible pipes deform (deflect) and thereby activate additional and substantial support from the surrounding soil. This capability to activate additional support by deformation results in a pipe-soil structure that is capable of supporting earth fills and surface live loads of a magnitude that could fracture stronger but less strainable materials.

Thermoplastics piping, particularly in the sizes under around NPS 18 (DN 450), can be competitive in cost to piping of other materials. In the larger sizes, thermoplastics will oftentimes overcome a first-cost disadvantage when consideration is given to their lower operating and maintenance costs and longer life.

The principal limitations of thermoplastics arise from their relatively low strength

and stiffness and greater sensitivity of mechanical properties to temperature. As a result, their primary use is for gravity and lower-pressure applications at near-ambient temperatures. Some plastics qualify for hot water service, and there are some specialty materials that can be used to close to 300°F (149°C). Notwithstanding these restrictions, thermoplastics piping satisfies the performance requirements for a very broad range of applications.

Successful design with thermoplastics requires recognition of their viscoelastic nature. These materials do not exhibit the relatively simple stress/strain relationship that is characteristic of metals. Duration of loading, as well as temperature and environment, can have a profound effect on their stress-strain response, rupture strength, ultimate strain capacity, and other engineering properties. The extent to which duration of loading, temperature, and environment influence ultimate mechanical properties varies not only from one class of thermoplastic material to another (for example, between PVC and PE) but can also significantly differ within the same generic material, depending on the specific nature of the polymer (e.g., molecular weight, molecular weight distribution, degree of branching, and extent of copolymerization with other monomers), the type and quantity of polymer additives and modifiers, and the processing conditions. These factors must be recognized when characterizing the engineering properties of thermoplastic piping, particularly when defining allowable stress, strain, and upper temperature limits; and it goes without saying that for effective design and installation, they must be given consideration by the piping specifier, designer, and user.

Compared to traditional piping materials, thermoplastics have high coefficients of thermal expansion and contraction. For example, the thermal expansion rate can be from 6 to 10 times greater than that of metal pipe. This must be recognized both in design and installation, particularly for aboveground applications where resultant piping reaction may require frequent use of expansion loops or pipe supports. For aboveground piping more attention may also need to be given to proper pipe restraint because the low mass of thermoplastics provides less inertia against piping movements that may be induced by sudden changes in the fluid flow velocity. Additionally, aboveground thermoplastics should be positioned or protected against possible accidental mechanical damage.

Since thermoplastics are combustible, their use in certain locations may be limited by fire safety concerns and regulations. Construction and building codes address these concerns through various requirements, including the placing of thermoplastics piping inside suitable fire-resistant walls and chases and the use of fire stops when pipe penetrates through such structures.

THERMOPLASTIC PIPING MATERIALS

The term *polymer* (from the Greek *poly,* meaning "many," and *mer* meaning "unit") is used to denote the long-chain or network structure of macromolecules that are produced either naturally or that are made by man. The latter are referred to as *synthetic polymers.* Polymers which are the base material for plastics are oftentimes termed *resins.* Plastics are compounds of *resins* and *additives.* As previously explained, plastics are divided into two broad categories, *thermoplastics* and *thermosets.* Since thermoplastics are capable of being softened by heating and hardened by cooling, they can be shaped into articles by operations such as molding or extrusion, which take advantage of this capability.

Additives are incorporated into a thermoplastics composition to achieve specific

purposes during fabrication or service. The precise nature and amounts of these additives depends on the plastic and its inherent properties; the processing method used to convert it to a finished article; and any desired modification of properties to achieve certain aesthetic, performance, or economic objectives. The main kinds of additives that may be used in thermoplastic piping compositions include the following:

Heat stabilizers. To protect the plastic against thermal degradation, particularly during processing

Antioxidants. To protect against oxidation during processing and when in service

Ultraviolet screens, or stabilizers. To protect against ultraviolet radiation in sunlight during outdoor storage and weather-exposed service

Lubricants. To facilitate and improve fabrication by reducing viscosity and lessening frictional drag through dies and other surfaces

Pigments. To give the product a distinctive color

Processing aids. To facilitate material mixing and fusion during processing and thereby optimize the homogenization of material and its properties

Property modifiers. To enhance a particular property such as impact strength or flexibility

Fillers. Most often used to reduce volume cost; however, fillers may also be used to increase stiffness or to modify processing characteristics

Additives are essential components of most thermoplastic piping compositions. They facilitate processing, enhance certain properties, give a product a distinctive appearance and color, and provide required protection during fabrication and service. There are only a few thermoplastics [e.g., certain fluorinated polymers such as polyvinylidene fluoride (PVDF)] that do not require the incorporation of some type of additive because they already have sufficient natural thermal stability and aging and weathering resistance.

The precise nature and quantities of additives that can be used for piping compositions are delimited by their effect on engineering properties, such as rigidity, impact strength, chemical resistance, creep resistance, rupture strength under long-term loading, and fatigue endurance. For example, the use of an inorganic filler can compromise the natural resistance of polymers to very strong acids or bases. Also, too much filler, or use of a filler of a coarser grade, or its inadeqate dispersion can introduce physical discontinuities, or internal faults, that can compromise long-term strength, ductility, toughness, and fatigue endurance. Another example is the excessive use of liquid stabilizers or lubricants, which tends to plasticize the plastic and thereby make it less creep-resistant and more sensitive to temperature.

Additionally, the properties of the base polymer used in a plastics piping composition are not only determined by the chemical elements, or atoms, from which the polymer is made, but are also profoundly influenced by the specific geometrical arrangement by which the polymer's atoms are combined to form a macromolecule. A most important molecular structural parameter is the length of the molecular chain. The longer the chain, the larger and heavier the molecule. Polymers used for engineering applications consist of relatively long molecules in order to yield satisfactory levels of longer-term strength, ductility, and toughness.

Molecule size is denoted by *molecular weight,* which is the sum of the atomic masses of all the elements in the molecule. Since all the molecules in a polymer

are not of the same size, the degree of polymerization is usually expressed by the polymer's *average* molecular weight. The nature of the distribution of molecular sizes also bears a significant influence on a number of physical and mechanical properties. Thermoplastics used for piping applications tend to be of relatively high molecular weight (generally over 100,000) and of relatively narrow molecular weight distribution. However, the molecular weight cannot be so large as to result in a melt viscosity so high as to hinder proper fabrication of the end product.

Another molecular structural parameter is the *length and frequency of shorter molecular chains* that occasionally branch out from the main polymer chain. These branches help determine how closely the polymer molecules can lie next to each other, which has an influence on the polymer's physical and mechanical properties. The length and frequency of polymer branches may be controlled by conditions of chemical reaction, catalysts used, and by the copolymerization with other than the principal monomer. For example, polyethylene pipe polymers are in fact copolymers of ethylene with small amounts of other olefin monomers such as propylene, butene, pentene, and hexene. Although the amount of other monomers used is low, and thereby the polymer still falls under the classification of polyethylene, it is enough to modify the polymer's molecular structure—principally the number of short branches along the linear molecular chains—and thereby exert significant influence on engineering prperties. Many commercial polymers, including polypropylene (PP) and polybutylene (PB), are also partial copolymers.

Chemical geometry, sometimes referred to as *polymer architecture,* also helps determine the relative physical arrangement of molecules to one another and, thereby, the polymer's physical properties. Generally, the long molecules in polymers tend to align themselves near each other in a random symmetry analogous to spaghetti in a bowl. This random arrangement is referred to as the *amorphous state.* The proximity of polymer molecules to one another and their physical entanglement gives rise to mechanical forces that greatly account for a polymer's mechanical properties. PVC and ABS are polymers that are essentially amorphous materials.

Certain other polymers, such as PE, PP, PB, and PVDF, are partly crystalline materials. Portions of their polymer chains organize themselves in close and very well ordered arrangements called *crystallites;* other portions lie in the amorphous regions. The stronger physical bonds in the well-ordered, closely packed crystalline regions have significant influence over mechanical properties such as strength, stiffness, and toughness. The extent of crystallization and the size and nature of the crystalline regions, as well as the nature of the interconnective network of molecules running from one crystalline region to another can all be somewhat controlled by tailoring molecular architecture.

The many possible variations in polymer structure, combined with the different types and amounts of additives that can be used, result in a great diversity of plastic compositions, even within a particular polymer group such as polyvinyl chloride (PVC) or polyethylene (PE). The defining and classifying of such compositions is, understandably, not a simple task. The primary standard plastic material specifications are issued by the American Society for Testing and Materials (ASTM). The first ASTM standards classified plastic materials by a ''Type, Grade, and Class'' system in accordance with three key properties. However, with the growing need to better define plastic materials by more than just three properties, a number of ASTM standards have adopted a cell classification system whereby each of a number of primary properties is given a property cell number depending on the property value. All the resultant property cell numbers (there can be as many as needed) are then listed in a specified order. For example, referring to Table D1.3, in accor-

TABLE D1.3 Primary Properties: Cell classification Limits for PE Piping Materials in Accordance with ASTM D 3350

Property and test method (Note 1)	Cell 0	Cell 1	Cell 2	Cell 3	Cell 4	Cell 5	Cell 6	Cell 7	Cell 8	Cell 9
				Property cell limits						
1. Density ASTM D1505 (g/cc)	Not specified	0.910 to 0.925	0.926 to 0.940	0.941 to 0.955	> 0.955					Specify value
2. Melt index ASTM D1238 (g/10 min)	Not specified	>1.0	0.4 to 1.0	.015 to 0.4	<0.15	(Note 2)	(Note 3)			Specify value
3. Flexural modulus ASTM D790 (psi)	Not specified	< 20.000	20,000 to 40,000	40,000 to 80,000	80,000 to 110,000	110,000 to 160,000	> 160,000			Specify value
4. Yield strength ASTM D638 (psi)	Not specified	< 2,200	2,200 to 2,600	2,600 to 3,000	3,000 to 3,500	3,500 to 4,000	>4,000			Specify value
5. Environmental stress crack resistance	Not specified									Specify value
—Method A ASTM F1473 (min. hrs) (Note 4)						0.15	3	10	30	
—Method B ASTM D1693										
Test condition		A	B	C	C					
Test duration (hrs)		48	24	192	600					
Failure, max (%)		50	50	20	20					
6. Hydrostatic design basis, ASTM D2837 (hrs)	Not specified (Note 5)	800	1,000	1,250	1,600					Specify value

Notes:

(1) To convert psi to Mpa, multiply by 6.90×10^{-3}.

(2) Materials with MI less than Cell 4 but which have a flow rate of <4.0 g/10 min when tested in accordance with D1238, Condition F.

(3) Materials with MI less than Cell 4 but which have flow rate of <0.30 g/10 min when tested in accordance with ASTM D 1238, but at a temperature of 590°F (310°C) and under a total load of 12,480 g).

(4) Test is conducted on compression molded samples, notched to a depth in accordance with Table 1 of F1473, at a load of 350 psi (2.4 Mpa) and at a temperature of 176°F (80°C).

(5) Compositions for which an HDB has not been established are designated as NPR (non-pressure rated).

dance with the cell classification system of ASTM D3350, ''Standard Specification for Polyethylene Plastics Pipe and Fitting Materials,'' Class 234424 polyethylene designates a material with properties that fall within the following range of values:

Property	Requirement
Density:	Cell 2 of property 1 [0.926 to 0.940 g/cm³]
Melt index:	Cell 3 of property 2 [<0.4 to 0.15 g/10 min]
Flexural modulus:	Cell 4 of property 3 [80,000 to <110,000 psi, 550 to 760 MPa]
Tensile strength at yield:	Cell 4 of property 4 [3000 to <3500 psi, 21 to <24 MPa]
Resistance to slow crack growth:	Cell 2 of property 5 [50 percent max failure after 24 hrs, when using test method B, Condition C]
Hydrostatic design basis at 23°C:	Cell 4 of property 6 [1600 psi or 11 MPa]

Although this newer cell-type format is a major improvement in classifying and specifying piping materials by a broader array of significant property and performance characteristics, it may not always be a sufficiently definitive predictor of longer-term performance properties. The manufacturer may have to be consulted for further information. For example, two PE materials with the same ASTM material cell classification may have a strength under long-term loading that responds somewhat differently to increasing temperature, or to fatigue loading, or to chemical environments.

A brief description of the major materials used for thermoplastics piping follows. The principal standard piping products made from these materials, and their applications, are identified in Table D1.1. Nonstandard or specialty piping products are also offered from these materials.

Polyvinyl Chloride (PVC)

In its virgin state PVC is a translucent, colorless, rigid polymer. When PVC was first commercialized it was softened by the addition of plasticizers, and the resultant compositions were primarily used in the manufacture of such items as luggage, upholstery, garden hose, wire coating, floor tiles, and laboratory tubing. Subsequent advances in extrusion and molding equipment, and in the availability of more effective stabilizer and lubrication additives, allowed for the extrusion of the much more viscous, rigid compositions which are the only ones suitable for piping. To differentiate these newer unplasticized compositions from the early plasticized versions they were identified as *uPVC,* or *rigid PVC.* These designations are still often used.

Of the commonly available thermoplastics, rigid PVC offers the highest strength and stiffness at the least volume cost, which accounts for its having become the leading plastic material for both pressure and nonpressure piping. Major uses include water mains; irrigation; drain, waste, and vent (DWV); sewage and drainage; well casing; electric conduit; and power and communications ducting. PVC is available in a much broader range of pipe sizes and wall thicknesses, fittings, valves, and appurtenances than in any other plastic.

PVC piping is joined primarily by two techniques, *solvent cementing* and *elastomeric seals.* Although it can be joined by thermal fusion, its melt viscosity is too high for making reliably strong joints under field conditions.

PVC piping is made only from rigid compounds containing no plasticizers and relatively small quantities of other ingredients. To minimize adverse effects on long-term strength and chemical resistance, minimal quantities of additives are used in pressure pipe compounds. To improve impact strength for conduit and other applications that may be subject to mechanical abuse, small quantities of solid polymeric impact modifiers (but not plasticizers, which are generally liquids) are sometimes incorporated into the composition. When improved stiffness is desired, filler—generally very finely divided calcium carbonate—is added. Combinations of these and other additives can be used to optimize a rigid PVC composition for its intended application. The enhancement of a particular property by the use of additives may often require a trade-off with some other property.

For the defining of rigid PVC compositions based on resultant properties, ASTM has established two material specifications based on the property cell classification system. One of these is ASTM D1784, "Standard Specification for Rigid Poly(Vinyl Chloride) and Chlorinated Poly(Vinyl Chloride) Compounds," which classifies PVC materials in accordance with the nature of the polymer and four primary properties.

TABLE D1.4 Primary Properties: Cell Classification Limits for PVC Materials in Accordance with ASTM D 1784

Property and test method[2]	Property cell limits[1]								
	Cell 0	Cell 1	Cell 2	Cell 3	Cell 4	Cell 5	Cell 6	Cell 7	Cell 8
1. Base resin	Unspecified	Poly (vinyl) homo- polymer	Chlorinated poly(vinyl) chloride	Vinyl copolymer					
2. Min. impact strength (Izod) (ft-lb/in of notch) ASTM D256	Unspecified	<0.65	0.65	1.5	5.0	10.0	15.0		
3. Tensile strength, min. (psi) ASTM D638	Unspecified	<5,000	5,000	6,000	7,000	8,000			
4. Modulus of elasticity, min. (psi) ASTM D638	Unspecified	<280,000	280,000	320,000	360,000 0	400,000 0	440,000 0		
5. Deflection temperature under load (264 psi), min. (°F) [°C]	Unspecified	<131 [55]	131 [55]	140 [60]	158 [70]	176 [80]	194 [90]	212 [100]	230 [110]
Flamability	(3)	(3)	(3)	(3)	(3)	(3)	(3)	(3)	(3)

Notes:

(1) The minimum property value determines the cell number, even though the maximum measured value may fall within a higher cell

(2) Conversion factors to common metric units are as follows:

- psi to Mpa—multiply by 6.90×10^{-3}
- ft-lb/in of notch to J/m of notch—multiply by 53.4

(3) All compounds covered by this specification when tested in accordance with ASTM method D635 shall yield not less than the following result: average extent of burning <25 mm; average time of burning <10 s.

These four primary properties and the cell class ranges established for each are presented in Table D1.4 The requirements for a fifth property, chemical resistance, are presented in Table D1.5 The manner in which a rigid PVC material is identified by this classification system is illustrated by a Class 12454-B PVC material which, according to Tables D1.4 and D1.5, would have to meet the following property requirements:

Property	*Requirement*
Base resin:	Cell 1 of property 1 [poly(vinylchloride) homo- polymer]
Impact strength (Izod):	Cell 2 of property 2 [0.65 ft-lbf/in, minimum, 0.035 N-m/mm]
Tensile strength:	Cell 4 of property 3 [7,000 psi, minimum or 48 MPa]
Modulus of elasticity in tension:	Cell 5 of property 4 [400,000 psi, or 2.8 GPa minimum]
Deflection temperature under load:	Cell 4 of property 5 [158°F (70°C), minimum]
Chemical resistance:	Must meet the minimum requirements listed under Suffix B of Table D1.5

Most PVC pressure pipe is made from materials that meet the minimum requirements of cell 12454-C, which, to maximize long-term strength, generally is formu-

lated with minimal quantities of processing additives and property modifiers. An older ''Type and Grade'' system found in earlier versions of D1784, although technically obsolete, continues to be referenced by a number of piping standards. The newer issues of D1784 include a table (see Table D1.6) that cross-references the former with the new designations.

For pressure pipe applications, the cell classification system of ASTM D1784 is often complemented by one additional material requirement. All PVC pressure

TABLE D1.6 Classification of commercial Types and Grades of Rigid Polyvinyl Chloride Piping Materials: Comparison of former to Newer Designations

Rigid PVC materials	
Type I, Grade 1	12454-B
Type I, Grade 2	12454-C
Type I, Grade 3	11443-B
Type II, Grade 1	14333-D
Type III, Grade 1	13233
CPVC materials	
Type IV, Grade 1	23447-B

pipe standards require that the pipe be made from a formulation with a specified minimum long-term strength that has been established in accordance with ASTM D2837, "Standard Method for Obtaining the Hydrostatic Design Basis for Thermoplastic Pipe Materials." Standards for products intended for the transport of potable water also require that the material meet certain minimum chemical extraction requirements designed to protect water quality. (See discussion in "Effects of Fluids Being Conveyed.")

Most ASTM and a number of other PVC pressure pipe standards identify PVC stress-rated materials by a four-digit number, of which the first two digits designate its type and grade in accordance with the older editions of ASTM D1784 (see Table D1.6) and the last two identify, in hundreds of pounds per square inch, the material's maximum recommended hydrostatic design stress (HDS) for water at 73.4°F (23°C). In accordance with ASTM convention, the maximum HDS is one-half the material's hydrostatic design basis (HDB), which refers to the material's long-term hydrostatic strength (LTHS) category when established in accordance with ASTM D2837. The following list describes the most common PVC stress-rated materials covered by this designation system:

- PVC 1120 is a Type 1, Grade 1 PVC material (minimum cell class 12454-B) with a maximum recommended HDS of 2,000 psi (13.8 MPa) for water at 73.4°F (23°C).

- PVC 2110 is a Type 2, Grade 1 PVC material (minimum cell class 14333-D) with a maximum recommended HDS of 1,000 psi (6.9 MPa).

- PVC 2116 is a Type 2, Grade 1 PVC material (same minimum cell class as above) with a maximum recommended HDS of 1,600 psi (11 MPa).

Since by the ASTM convention the maximum recommended HDS is one-half the material's HDB, it follows that the HDBs for these materials are 4,000 psi (27.6 MPa), 2,000 psi (13.8 MPa), and 3,200 psi (22.1 MPa), respectively.

The Plastics Pipe Institute (PPI) lists a generic PVC 1120 formulation that provides for certain specified alternative choices of ingredients and formulation quantities that have been determined to allow the formulated compounds to satisfy both the short- and long-term requirements established for this material classification. This formulation, which is listed in PPI TR-3, "Policies and Procedures for Developing Recommended Hydrostatic Strengths and Design Stresses for Thermoplastic Pipe Materials," is periodically updated to include any new alternate choices of ingredients that have been validated by means of both short-term and long-term tests.

The other PVC material specification is ASTM D4396, "Standard Specification for Rigid Polyvinyl Chloride (PVC) and Related Plastic Compounds for Non-Pressure Piping Products" As indicated by its title, this specification covers compounds only intended for nonpressure uses. It is similar to D1784 in that it is also based on the cell format and most of the same primary classification properties.

Chlorinated Polyvinyl Chloride (CPVC)

As implied by its name, CPVC is a chemical modification of PVC. It is very similar to PVC in many properties, including strength and stiffness at ambient temperature. But the extra chlorine in CPVC's chemical structure increases this material's maximum operating temperature limit by about 50°F (28°C) above that for PVC. Thus, CPVC can be used up to nearly 200°F (93°C) for pressure uses and up to about

210°F (100°C) for nonpressure applications. Principal uses for CPVC are domestic hot water and cold water piping, residential fire-sprinkling piping, and many industrial applications which can take advantage of its elevated-temperature capabilities and superior chemical resistance.

CPVC materials are also classified by the previously discussed ASTM D1784. Similar to PVC, most CPVC standards that cover pressure-rated products identify stress-rated materials by a four-digit number that combines the older type and grade designation with the material's maximum recommended HDS for water at 73.4°F (23°C). Currently, the only recognized stress-rated CPVC designation is CPVC 4120, signifying a Type IV, Grade 1 material in accordance with D1784 (see Table D1.6), with a maximum recommended hydrostatic design stress of 2,000 psi (13.8 MPa) for water at 73.4°F (23°C) in accordance with ASTM D2837. In addition, most CPVC pipe standards that cover products intended for elevated-temperature service, such as for hot water piping, require that the CPVC material have no less than a recommended HDS of 500 psi (3.5 MPa) (equivalent to an HDB of 1,000 psi or 6.9 MPa) for water at 180°F (82°C).

Polyethylene (PE)

Polyethylene (PE) is possibly the best-known member of the polyolefin family (materials derived from the polymerization of olefin gases including ethylene, propylene, and butylene) because it has penetrated so widely into everyday household uses. PE in its virgin form is a translucent and tough substance with a waxlike feel and appearance. As is the case of the other polyolefins, PE is a partly crystalline and partly amorphous material. The extent to which it crystallizes (which determines many of its resultant properties) is a function of its molecular structure. PE's backbone consists of a long molecular chain, from which short-chain branches occasionally project. The length, type, and frequency of distribution of these branches, as well as other parameters such as molecular weight and molecular weight distribution, determine the degree of crystallinity and the network of molecules that anchor the crystal-like regions to one another. These structural characteristics greatly influence the short- and long-term mechanical properties of PE. The extent to which crystalline regions can form in a PE polymer is reflected by its density—the higher-density materials have more crystalline regions, which results in greater stiffness and tensile strength. However, as the crystallinity increases, there is some accompanying loss in ductility and toughness.

Polyethylene polymers used for piping are classified into three types: a low-density, relatively flexible form; a medium-density, somewhat stiffer and less-flexible form; and a high-density form, which is more rigid and stronger. Most pressure pipe is made of materials of densities lying around the high end of the medium-density PEs and the lower end of the high-density materials. This range has established itself as offering the best balance of toughness, flexibility, and long-term strength. Nonpressure pipe is primarily made from the more rigid, higher-density materials.

PE, which is somewhat less strong and less rigid than PVC at ambient temperature, is the second most used plastic pipe material, primarily because of its toughness, ductility, and flexibility, even at low temperatures. PE pipes do not fracture under the expansive action of freezing water. In an emergency, smaller-diameter PE pipes can be safely ''squeezed-off'' (clamped tightly) by suitable procedures, to shut down the flow of fluids. Also, PE pipe is much less prone to failure by a rapidly running crack. These two last-named characteristics are important reasons why PE pipe is

now used in over 85 percent of all current new installations of piping for gas distribution.

PE pipes also have superior fatigue endurance. This feature, plus their ability to dampen water hammer shock, has led to their use for applications such as in sewer force mains, where repeated cyclic pressure changes tend to occur.

The high strainability and fracture resistance of PE have led to its selection for use in unstable soils and situations where axial bending and diametrical deflection are anticipated. Example installations that utilize this feature are methane collection systems for solid-waste sites, pipes installed by directional trenchless boring techniques, lake and river crossings, and outfall pipes discharging treated effluent into seas and oceans.

PE pipe is also used for the rehabilitation of old pipelines. Lengths of PE pipe which have been joined to the required length by the butt-fusion method are pulled, or sometimes pushed, inside the old line. New rehabilitation procedures have evolved by which, for ease of insertion, the diameter of the liner PE pipe is reduced by a squeeze-down procedure, or by folding the pipe into a U-shape. Once inside the old pipe, the strain memory in the material is relieved by a combination of heating and internal pressure, allowing the PE pipe to reround so that it fits snugly inside the existing pipe (see Fig. D1.2).

The low stiffness of PE permits the coiling of smaller-diameter pipe [generally up to about 4 in (100 mm) although pipe up to NPS 6 (DN 150) diameter has been coiled for special jobs]. The coiled length can be hundreds of feet and sometimes over a thousand feet (300 meters) long, depending on material, wall thickness, and diameter. PE pipe is readily heat-fusible and can be joined to itself or to fittings by the butt-fusion process. PE fittings are also available for joining pipe by the socket fusion and electrofusion processes.

For nonpressure buried pipe applications, such as for stormwater, roadway, and land drainage, various designs of profile wall constructions have been developed which enhance pipe wall stiffness while minimizing material usage (see Figure D1.1). Because of their corrosion resistance, these pipes are displacing metallic drainage piping.

To protect the PE polymer during processing, storage, and service, PE piping compounds contain small quantities of heat stabilizers, antioxidants, and ultraviolet (UV) screens or UV chemical stabilizers. Black PE pipe materials incorporate very finely divided carbon black as both a coloring pigment and to screen the polymer against the potentially damaging UV radiation in sunlight. Nonblack piping compositions include a UV chemical stabilizer in addition to a coloring pigment (usually tan or yellow for gas, blue for water, and orange for communications ducting).

The primary specification for identifying and classifying PE piping materials is ASTM D3350, "Standard Specification for Polyethylene Pipe and Fittings Materials." Standard D3350 employs the cell class format to cover the diversity of materials used for piping. As shown by Table D1.3, this specification classifies PE materials by a matrix of six primary properties and a specified range of cell values for each of these properties. In addition, an ending code letter is used to designate the incorporation of a colorant and UV stabilizer. An example of how PE materials are identified by this system was illustrated under the discussion "Thermoplastics Piping Materials."

A recent addition to ASTM D3350 is a new test for the classifying of PE's resistance to crack growth under sustained tensile loading. The test method used for this purpose is ASTM F1473, "Notch Tensile Test to Measure the Resistance to Slow Crack Growth of Polyethylene Pipe and Resins." Results obtained under this method have been determined to give a more reliable index than the traditional

TABLE D1.7 Classification of Commercial Polyethylene Piping Materials: Comparison of Former to Newer Designations

PE material designation based on type and grade in accordance with former ASTM D1248, plus a code for material's maximum recommended hydrostatic design stress for water, for 73°F	Corresponding minimum cell classification in accordance with cell classification system of ASTM D3350*

PE 3406	PE 324433
PE 3408	PE 334434

* For cells 1 and 6 the resultant values must fall within the limits shown for the particular property cell. For the other properties, material values may fall within or be above the designated cell limits. Refer to Table D 1.3 for the listing of range of property values for each property cell.

stress-crack method (ASTM D 1693) of a PE material's resistance to crack formation and growth when subject to sustained localized intensified stressing, such as can occur in piping applications. A similar method, as follows, which was developed for geomembranes, is also being used to rank the slow-crack growth resistance of PE materials that are intended for nonpressure applications: ASTM D5397, "Standard Test Method for Evaluation of Stress Crack Resistance of Polyolefin Geomembranes Using Notched Constant Tensile Load Test."

Prior to the issuance of ASTM D 3350, most PE piping standards referred to ASTM D1248, "Standard Specification for Polyethylene Plastics Molding and Extrusion Materials," for the defining of material requirements. ASTM D1248 classified PE by type, representing the material's density category, and grade, reflecting a combination of properties, primarily the melt flow or processing characteristics. Similar to PVC, PE piping standards classify PE stress-rated materials by means of a four-digit number, of which the first two digits refer to the older type and grade designation and the last two represent, in hundreds of pounds per square inch, the material's maximum recommended hydrostatic design stress (HDS) for water at 73.4°F (23°C). The following list describes the commonly used PE piping materials in accordance with this traditional designation system:

- PE 2406 is a Type 2 (i.e., medium-density), Grade 4 PE material, in accordance with ASTM D1248, which carries a recommended maximum hydrostatic design stress of 630 psi (4.3 MPa), for water at 73.4°F (23°C). [The "06" in the 2406 designates the 630 psi (4.3 MPa) design stress.]
- PE 3408 is a Type 3 (i.e., high-density), Grade 4 PE material, in accordance with ASTM D1248, which carries a recommended maximum hydrostatic design stress of 800 psi (5.5 MPa) for water at 73.4°F (23°C).

To relate this older designation system to the newer cell system of D 3350, the latter standard includes a cross-reference. The crossovers recognized by the 1993 edition of D 3350 are presented in Table D1.7.

Polybutylene (PB)

Polybutylene is a polyolefin with a stiffness resembling that of low-density polyethylene, but with a long-term strength that is greater than that of high-density polyethyl-

ene (PE). Its most distinctive feature, however, is that the long-term strength is less affected by increasing temperature than that of PE. While most PEs have an upper temperature limit of around 140°F (60°C), the limit for PB is nearly 200°F (93°C).

Major applications for PB pipe and tubing are for water service lines and for uses that take advantage of its improved elevated-temperature strength. They include piping for residential hot and cold water distribution, residential fire sprinklers, and industrial uses such as hot effluent lines.

PB is similar to PE in its chemical resistance and heat fusibility. PB piping materials are covered by ASTM D2581, "Standard Specification for Polybutylene (PB) Plastics Molding and Extrusion Materials." Materials for pressure applications are designated as PB 2110, signifying a Type 2, Grade 1 material in accordance with D2581, and with a recommended maximum HDS of 1,000 psi (6.9 MPa) for water, at 73.4°F (23°C). Hot water piping standards generally require that the PB material also have an established recommended maximum HDS of 500 psi (3.5 MPa) for water at 180°F (82°C).

Cross-Linked Polyethylene (PEX)

Cross-linked polyethylene, as its name implies, is actually a thermoset. It is covered in this chapter because PEX pipe and tubing are made from PE, a thermoplastic, by essentially the same extrusion process used to manufacture all thermoplastic pipes. The only difference is that in the case of PEX a cross-linking of the polymer chains occurs during or soon after pipe extrusion. Cross-linking of PE improves elevated temperature performance, chemical and stress-crack resistance, creep resistance, and abrasion resistance. While most PEs have an upper temperature limit of about 140°F (60°C), PEX piping may be used up to around 200°F (93°C).

Three methods, as follows, are used commercially to cross-link PE piping materials: *silane curing; peroxide curing;* and *radiation.* Silene PEX materials are often referred as *moisture-cured* because they cross-link on exposure of the pipe to water. The pipe is produced by a two-stage process. First, a silene-grafted PE is combined with a catalyst PE concentrate and extruded into pipe using standard extrusion equipment. Then, after the pipe has been extruded, cross-linking is effected by exposing the pipe to moisture.

Peroxide PEX derives its name from the class of chemicals, *peroxides,* that is used to achieve cross-linking. These cross-linking agents are incorporated into the base PE either during or after extrusion. Cross-linking is initiated when the temperature reaches that at which the peroxide decomposes, thereby yielding free-radicals that cross-link the PE.

Radiation PEX pipe is produced by subjecting PE pipe to electromagnetic radiation (gamma radiation) or high-energy electrons (beta radiation).

All three methods are capable of producing equivalent products. PEX pipe is tested to the same performance standards regardless of the manufacturing method. Properties of a PEX material are determined by the properties of the base PE, the stabilizer and additive package, and the degree of cross-linking as determined using method ASTM D2765, "Standard Test Method for Determination of Gel Content and Swell Ratio of Cross-linked Ethylene Plastics." To comply with existing standards PEX piping must be cross-linked to within a range of 65 to 89 percent.

Current PEX piping materials carry a recommended maximum HDS for water of 630 psi (4.3 MPa) at 73.4°F (23°C), and 400 psi (2.8 MPa) at 180°F (82°C). Some

materials are also listed with a recommended maximum HDS of 315 psi (2.2 MPa) at 200°F (93°C).

PEX is also commonly used in PEX-Aluminum-PEX (PEX-Al-PEX) composite pipe. In this pipe PEX inner and outer layers sandwich a thin tubular aluminum reinforcement which significantly enhances the pipe pressure rating.

PEX and PEX-Al-PEX pipes are manufactured in North America in diameters through NPS 2 (DN 50). Their primary applications take advantage of improved elevated temperature performance. These include hot and cold water piping systems, hydronic heating, under-floor or radiant-heating systems, snow-melting systems, and residential fire sprinkler piping.

Polypropylene (PP)

Polypropylene is a polyolefin similar in properties to high-density PE but somewhat harder, more temperature-resistant, and lighter in weight, but less tough. It is also similar to PE in its chemical resistance and heat fusibility. As in the case of PE, PP can be joined to itself by socket fusion, butt fusion, and electrofusion.

Because of its greater stiffness and better tolerance to elevated temperates, PP is sometimes chosen over PE where these qualities are advantageous (e.g., for aboveground piping and for the conveying of hot fluids). A principal application is for corrosive drainage piping, for which PP offers better solvent resistance than either ABS or PVC. A product line of PP corrosive drainage piping made from a flame-retardant grade of material is offered for use in laboratories and hospitals, and for chemical manufacturing.

Another principal application for PP is for conveying corrosive chemicals under pressure. For this application, socket fusion systems of pressure-rated PP pipe and fittings are available through NPS 6 (DN 150). At present there are no consensus standards covering PP pressure pipe; all available products are proprietary.

Polypropylene materials are classified by ASTM D4101, ''Standard Specification for Polypropylene Molding and Extrusion Materials,'' into two types. Type I covers materials that have the highest rigidity and strength but that offer only moderate toughness. Type II covers materials (copolymers of propylene with ethylene or other olefins) which tend to be less rigid and strong but have improved toughness, particularly at lower temperatures. Both types are used for pipe.

Acrylonitrile-Butadiene-Styrene (ABS)

ABS plastics are made by combining styrene-acrylonitrile copolymers with copolymers formed by reacting styrene-acrylonitrile with butadiene. The butadiene copolymers impart toughness, while the acrylonitrile copolymers contribute strength, rigidity, and hardness. The result is a tough, relatively strong plastic that is easy to mold and extrude.

The ABS family covers a wide range of materials. The proportions of the basic components and the way in which they are combined can be varied to produce a wide range of end properties. A major use of ABS for pipe is in the manufacture of drain-waste-vent (DWV) piping, for which it offers good rigidity, temperature resistance, low-temperature toughness, and the ability to make fast-setting solvent cemented joints. ABS has been used for pressure piping, primarily for water service applications, but it has been largely displaced by the stronger, more chemically resistant, and more economical PVC. However, compressed-air piping made from

a proprietary extra-tough, shatter-resistant composition is currently marketed in Europe and the United States.

ABS materials are classified by ASTM D1788, ''Standard Specification for Rigid Acrylonitrile-Butadiene-Styrene (ABS) Plastics,'' in accordance with the cell class format by which each of three properties—impact strength (toughness), tensile stress at yield (short-term strength), and deflection temperature under load (temperature resistance)—is accorded a cell number depending on the property value. The ASTM specification for ABS DWV pipe requires that the material have a minimum cell classification of ABS 2–2–2, which signifies the following minimum properties: notch impact strength of 2 ft-lb/in (0.1 N-m/mm) of notch, 180°F (82°C) deflection temperature, and 4,000 psi (2.8 MPa) tensile strength.

Fluoroplastics

Fluoroplastics designate a broad family of paraffinic polymers that have some or all of the hydrogen replaced by fluorine. The fully fluorinated fluorocarbons include perfluoroalkoxy (PFA), polytrafluoroethylene (PTFE), and fluorinated ethylene propylene (FEP). The partially fluorinated fluoroplastics include ethylene tetrafluoroethylene (ETFE), polychlorotrifluoroethylene (CTFE), ethylenechlorotrifluoroethylene (ECTFE), and polyvinylidene fluoride (PVDF).

Fluorinated polymers have outstanding resistance to chemicals and excellent resistance to solvents. They also offer improved elevated-temperature properties and are very stable and durable. Most members of this family require little or no addition of processing or thermal stabilizers. For this reason they are often specified when exceptional purity of water or other liquids must be maintained. These materials are also very fire resistant.

The various kinds of fluorinated polymers just listed have been used as liners for metal piping to enhance its chemical resistance. Pipe, tubing, and fittings totally made of fluorinated plastics are commercially available, principally from PVDF and PFA, in sizes up to about NPS 6 (DN 150). The pipe is generally joined by means of heat-fused socket fittings. PVDF has good strength, wear resistance, and creep resistance, and can be used over a temperature range from about −100 to 300°F (−70° to 150°C). PFA has somewhat less strength and creep resistance but offers greater toughness and can be used up to over 400°F (200°C).

Fluorinated plastics also have outstanding resistance to weathering and electromagnetic radiation. These materials do not require the use of additives to achieve weathering and ultraviolet resistance. Because of their immunity to radiation, they are used in the reprocessing of nuclear wastes and similar radiation-intensive exposures. And because they are additive-free, these pipes are also used to convey fluids that must remain ultrapure and totally free of metallic ion contamination.

JOINING METHODS

Plastics piping can be joined by different methods (see Table D1.8) depending on the characteristics of the material. For example, ABS, PVC, and CPVC can be solvent cemented. However, polyolefins (PE, PB, and PP) and fluoropolymers cannot be joined by this method because of their high solvent resistance; but they can be readily heat-fused. Both heat fusion and solvent cementing yield monolithic

TABLE D1.8 Common Methods for Joining Thermoplastics Piping

Joining Method	ABS	PVC	CPVC	PE	PEX	PB	PP	PVDF
Solvent cementing	X	X	X	—	—	—	—	—
Heat fusion	—	—	—	X	—	X	X	X
Threading[1]	X	X	X	X	—	—	X	X
Flanged connectors[2]	X	X	X	X	—	X	X	X
Grooved joints[3]	X	X	X	X	—	—	X	X
Mechanical compression[4]	X	X	X	X	X	X	X	X
Elastomeric seal	X	X	X	X	X	X	X	X
Flaring[5]	—	—	—	X	—	X	—	—

Notes:
1. Generally limited to pipes of wall thickness not less than that of Schedule 80.
2. Flanged adapters can be fastened to plastic pipe by means of heat fusion, solvent cementing, or threading.
3. Grooving requires a minimum pipe wall thickness which depends on the material. The pipe manufacturer should be consulted.
4. In most cases internal stiffeners are required to permanently support the pipe against compressive forces generated by these fittings.
5. Not all commercial grades may be flared. Consult the pipe manufacturer for specific recommendations.

joints of maximum strength and of chemical resistance that is not compromised by the introduction of other materials.

In *solvent cementing,* often referred to as *solvent welding,* the mating spigot-socket or saddle-pipe surfaces are readily fused to each other by the softening action of the solvent cement that is placed between the contacting surfaces. Solvent cements achieve bonding by a fusion process, and not by adhesion. Thorough contact of these surfaces with no gaps is essential to the development of good fusion. After initial bonding of the two mating surfaces is achieved, the solvent in the solvent cement gradually migrates and evaporates away. When the solvent is gone the joint is said to have been ''cured'', at which point it achieves its maximum strength. Handling strength is usually achieved in a few minutes. Complete curing may take from hours to longer than a day, depending on the temperature and other conditions. A description of the proper procedure for solvent cementing PVC pipe and fittings is the subject of ASTM Standard Practice D2855.

In *heat fusion* softening of the mating surfaces is achieved by melting. There are two techniques used for achieving the required degree of surface melting. One is to heat with a specially designed heating iron just prior to joining. In the other, the surfaces are first mated and then brought to the proper melt temperature by means of heating wires embedded in the socket. This latter technique, called *electrofusion,* is used with PE piping and also for PP industrial drainage piping.

There are two kinds of heat fusion jointing systems. One of them is the *socket-spigot system,* similar to that used for solvent cementing. In the other the butt ends of pipe and/or fittings are squared off precisely, heated, and then quickly brought together and kept under sufficient pressure until enough cooling has occurred for the development of adequate working strength. Socket fusion is limited to the smaller piping sizes, generally not above 4 in (100 mm). Larger-diameter pipe is heat-fused by the butt-fusion process. Automatic, portable equipment for field joining by butt fusion is available to join all available pressure pipe sizes. ASTM Recommended Practice D2657 covers socket, butt, and saddle heat fusion. The standard recommended practice for electrofusion joining is given by ASTM F1290.

Flanged connections are often used for industrial applications, particularly when making transitions to nonplastic components such as to a metal valve or to a tank outlet, or when it is advantageous to provide for easy removal of a pipe section or other component from a pipeline for cleaning, maintenance, or other purpose. Flange connectors can be applied on the pipe by heat fusion (socket or butt), or solvent cementing, depending on the material. Oftentimes, particularly in the cases of larger-diameter pipes, the use of plastic flanges requires the use of a backup metal flange to ensure even distribution of compressive stresses and optimum fluid tightness. Recommendations regarding proper use of flanges, including bolt tightening limits, are covered by industry manuals and are also available from piping manufacturers.

Much of the pipe used for buried water and sewer lines and drains is joined with *bell-and-spigot connections* that include an elastomeric gasket to seal the joint. The bell, including the gasket cavity, is usually formed during manufacture of the pipe or fitting and is an integral part of the product. Rubber-gasketed connectors facilitate construction and produce tight joints, even when made under foul-weather and poor field conditions, when solvent cementing and heat fusion joining may be adversely affected. ASTM D3112 prescribes requirements for elastomeric joints for nonpressure applications, and D3139 presents requirements for elastomeric joints intended for pressure uses.

Threading is also sometimes used with certain of the more rigid plastics like PVC or CPVC. Molded threads with reduced roots are preferred because cut threads are more notch-sensitive. Molded threaded adapters are available for solvent cementing to PVC and CPVC pipe. If pipe is to be threaded, it is generally recommended that its wall thickness be not less than that corresponding to Schedule 80. Threaded connections of any type are prohibited for gas distribution.

Mechanical compression fittings are also used, particularly when making transition connections to dissimilar materials. Mechanical connectors are the only option for connecting PEX since it cannot be solvent-cemented or heat-fused. ASTM F1807 covers the commonly used metal insert fittings for PEX pipe. In one design, the fitting is inserted inside the PEX pipe, and a copper ring on the outside of the pipe is crimped by means of a tool to achieve the holding strength and to provide the seal.

Many styles of mechanical fittings designed for plastics use *compressed elastomeric gaskets* for sealing. To ensure this seal is not lost through pipe deformation, the design incorporates a metal sleeve that fits inside the plastic pipe to stiffen it against the compression forces. When selecting compression fittings consideration should be given to the fitting's capacity to hold the pipe in place against pull-out forces such as can be generated by thermal contraction or earth settlement. A number of compression fittings, especially for the smaller pipe sizes, are designed to hold the pipe against pull-out forces large enough to cause the pipe to either fail or to permanently stretch by yielding.

DIMENSIONING SYSTEMS

Thermoplastic pipe is made to a number of dimensioning systems based on controlled *outside* diameters. Pipe from all thermoplastic materials is manufactured to the standard outside diameters of iron pipe sizes (IPS) of commercial wrought steel pipe (ASME B36.10). In this diameter system some plastic pipes are offered with wall thicknesses that are the same as those of Schedule 40 and Schedule 80 iron pipes.

Much more common, however, is plastic pipe with outside diameters conforming to IPS standards but with wall thicknesses sized in accordance with the standard dimension ratio (SDR) principle, whereby all pipe sizes in a given SDR series have a uniform ratio of outside diameter to minimum wall thickness. The SDRs adopted by ASTM and other organizations follow the following series: 9; 11; 13.5; 17; 21; 26; and so on. However, nonstandard dimension ratios are also sometimes used, in which case they are identified by the prefix DR. The broad acceptance of the SDR dimension system arises from the fact that certain pipe performance ratings are directly proportional to the ratio of pipe diameter to wall thickness. For example, pipes made from the same material and to the same ratio of diameter to wall thickness have the same pressure rating, and also the same pipe stiffness, irrespective of pipe size.

Other diameter systems to which plastic pipe is made include:

- *Cast-iron (Cl), or ductile-iron (Dl) pipe sizes.* PVC and PE pipes are available in this diameter sizing system to facilitate connections to fittings, valves, and hydrants in water works systems, which generally are made to cast-iron (now ductile-iron) sizes.

- *Copper tubing sizes (CTS).* CTS-sized pipe is made because it can be joined using various compression and flare fittings originally designed for copper tubing. Plastics pipe in CTS sizes is generally used for gas and water services and for hot and cold water piping.

- *Plastic pipe sizes.* Certain products, particularly nonpressure pipes made for sewer and drain applications are available in outside diameter systems that are not a copy of that used by any traditional material.

- *International Standards Organization (ISO) sizes.* Some of the larger-diameter PE pipes are made to an internationally established outside diameter dimensioning system specifically designed for plastics piping.

There is one plastic pipe that is also made to a standard *inside* diameter dimensioning system. PE pressure-rated pipes, up to NPS 6 (DN 150), are made to controlled inside diameters that are the same as the inside diameters of Schedule 40 iron pipe size (IPS). The inside diameter is controlled because this pipe series is designed to be used with insert fittings which must fit snugly inside the pipe, notwithstanding the pipe's wall thickness. The outside diameter of such pipe depends on the thickness of the pipe wall, which is determined by the pipe's pressure rating.

Many manufacturers also make non-standard-sized pipes on special order. Such pipes may be required for a particular situation, such as the sliplining of an existing corroded line with the largest possible plastics pipe that can be pulled into place.

PHYSICAL AND MECHANICAL PROPERTIES

Approximate values of some of the physical and mechanical properties for the more common generic thermoplastic piping materials are given in Table D1.9. The actual property values for a particular commercial grade of material are not accurately predictable from its ASTM classification; they can be significantly affected by the specific nature of the base polymer (e.g., its molecular weight, molecular weight distribution, kind and frequency of branches), the plastic composition (type and amount of additives), and effects of processing (e.g., some anisotropy of proper-

TABLE D1.9 Approximate Values of Physical Properties of Thermoplastic
Piping Materials

- Btu/lb · °F to cal/g · °C—multiply by 1.0

ties and residual stresses may result because of processing conditions). Furthermore, the ultimate properties may also be somewhat influenced by the degree of stress triaxiality and the history of previously applied stresses and strains.

Compared to traditional piping materials, thermoplastics are lighter in weight, have lower heat capacities, are poorer conductors of heat, and have significantly larger coefficients of expansion and contraction. They are also less strong and rigid. However, they offer sufficient rigidity and strength to satisfy the performance requirements of a great many applications, and they are not subject to gradual degradation by rusting and other corrosive processes that commonly afflict most traditional pipe materials. When establishing appropriate values of mechanical design properties such as strength, stiffness, and strain capacity, the special consideration with plastics is over their unique time- and temperature-dependent load-deformation response.

Plastics are viscoelastic materials. Their deformation and strength properties are very significantly affected by temperature and duration of loading. Some of their properties can also be profoundly influenced by service environment. Tensile strength and stiffness values, such as given in Table D1.9 and which have been obtained by means of short-term mechanical tests adapted from metal testing, are not appropriate for design of piping systems that are subjected to longer-term sustained loading. In the case of metals the conventional tensile test is used to define basic properties such as elastic modulus, proportional limit, and yield strength. These are important not only for defining and specifying a metal but they are also basic constants for use in design equations based on elastic theory where strain is

assumed to be proportional to stress. Although very few materials are perfectly elastic, the assumption of such behavior in metals is usually sufficiently close for purposes of engineering design.

The stress-strain response for plastics is curvilinear and can depart greatly from an assumption of proportionality. Furthermore, the viscoelastic nature of plastics results in a relationship between stress and strain that is greatly influenced by elapsed time under load (or by the rate of straining in the case of a tensile test),
FIGURE D1.3 Tensile stress-strain response of a thermoplastic exhibiting ductile behavior at intermediate strain rates. Possible effects of strain rate and temperature are shown.

temperature, and environment. As depicted schematically by Fig. D1.3, the stress-strain response and fracture strength depend on the test conditions. For example, with some thermoplastics a reduction of about two decades in tensile strain rate, or an increase in temperature of around 50°F (28°C) can result in nearly a doubling of the strain response at failure. However, at very low strain rates total strain prior to failure tends to decrease with strain rate. Thus, the strain at failure as measured under the relatively high strain rates in a tensile test is not an accurate index of the elongation at failure, or ductility, under conditions of very low strain rates.

Also, as depicted by Fig. D1.3, the stress-strain response is nonlinear (although near the origin the behavior is fairly linear). Accordingly, plastics have no true elastic constants—such as the elastic modulus or the proportional limit of metals—nor do they have sharply defined yield points. The reported tensile elastic modulus for plastics represents a tangent modulus that is calculated by extending the initial portion of the load-extension curve, as obtained under a specified set of test conditions. Since plastics have no true elastic properties, the propriety of applying the term "elastic modulus," or even "modulus," in describing the stiffness or rigidity of a plastic has been questioned. However, such a "constant" has proven useful both for specification and design when its arbitrary nature and its dependence on duration of loading, temperature, and similar factors is recognized.

Even though plastic's behavior is inelastic, most of the equations for stress analysis (such as for pipe, beams, and pressure vessels) which have been derived on the assumption of elastic behavior can still be used, provided values for strength and stiffness are appropriately established. Thus, property values obtained by means of short-term tests should only be used for predicting response under loads of short duration. Short-term tests, of course, also have important value for the defining and classifying of plastic materials.

To be able to use elastic equations to forecast response under sustained, longer-term loading requires the use of "effective" values of strength and modulus that reflect mechanical behavior under such conditions. The development of longer-term property values usually involves some form of extrapolation protocol. The extrapolating procedures that are used have been borrowed from and are similar to those used with other inelastic engineering materials, such as metals at very high temperatures, which also exhibit a viscoelastic behavior. As will be discussed later, the protocols for plastics for the defining of the effects of duration of loading and temperature on engineering properties generally rely on analysis of information obtained from longer-duration testing, in some cases lasting many thousands of hours.

Viscoelasticity

As the name implies, viscoelastic materials respond to stress as complex aggregates of many different elastic and viscous (fluid) elements. The springs in the highly simplified model of Fig. D1.4 represent the elastic elements of a polymer (e.g., chain rigidity, chemical bonds, and crystallinity), each spring having a different constant that represents a *time-independent* modulus of elasticity. The dashpots represent the fluid elements (e.g., molecules slipping past each other), each one having a different viscosity or *time-dependent* stress-strain response.

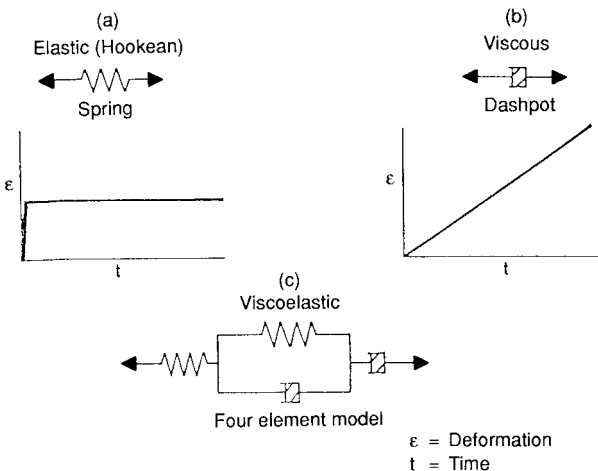
When a load is first applied on this model, it results in an initial, essentially


FIGURE D1.4 Model of viscoelastic behavior.

Creep (constant load)

ε = Deformation
t = Time
Stress relaxation (constant deformation)

s = Stress
t = Time
FIGURE D1.5   Viscoelastic responses.

elastic deformation. As time under load increases, the deformation increases indefinitely but at a gradually diminishing rate (Fig. D1.5). After sufficient time the rate becomes so low that for most engineering purposes one can consider that it is zero. This phenomenon of continuing deformation, which also occurs in concrete, soft metals, wood, and structural metals at very high temperatures, is called *creep.* If the load is removed after a certain time (say, at point t_1 in Fig. D1.5), a rapid initial recovery of the creep strain occurs, followed by a continuing recovery but at a steadily decreasing rate. In this model complete recovery has not been achieved. However, if the creep strain did not cause irreversible structural changes and sufficient time is allowed, the strain recovery will in time be almost complete. The rate and extent of creep strain and its recovery are sensitive to temperature and can also be influenced by environmental effects such as the absorption of solvents or other materials with which the plastic may have come in contact while under stress.

An analogous response of viscoelastic materials is stress relaxation. The load required to maintain a certain initial deformation will tend to gradually relax when that deformation is kept constant (see Fig. D1.5). Initially, stress relaxation occurs rapidly, and then with increasing time it decreases at a decreasing rate toward some ultimate value.

Tensile Creep

Each material has a characteristic stress-strain-time-temperature function. The primary form for characterizing this function is with a family of *tensile creep curves.* Creep curves plotted on Cartesian coordinates (Fig. D1.6) generally show three continuous stages: a first stage marked by large and initial deformation; a second
FIGURE D1.6 Schematic of creep rupture strength of thermoplastics in tension.

stage where deformation continues at a relatively slow and constant rate; and a third stage during which rupture occurs. In ductile plastics third-stage creep usually includes a distinct elongation or yielding just prior to rupture. In nonductile plastics, rupture occurs abruptly during second-stage creep. As illustrated by Fig. D1.7, which has been obtained on a certain pipe grade PE material, tensile creep curves are frequently plotted with log time as the abscissa. Such logarithmic plots allow for a more practical way of representing the information over the time range of engineering interest, and they also facilitate extrapolation of data to longer times. Many mathematical methods have been proposed to describe the creep behavior
FIGURE D1.7 Tensile creep response for high-density polyethylene pipe material.

of plastic materials in terms of stress, strain, and time. One such method, which is contained in an American Society of Civil Engineers standard design practice, presents constants for PVC and PE that have been verified by tests lasting nearly 20 years.[5]

Any point on any creep curve gives a stress-strain ratio. This ratio is usually designated as the *creep modulus, apparent modulus* or, *effective modulus,* and is used for design calculations where the stress is prescribed but the strain is free to vary. Creep modulus curves derived from the creep data in Fig. D1.7 are presented in Fig. D1.8.
FIGURE D1.8   Creep modulus of elasticity versus stress intensity for a high-density polyethylene.

Analogous "stress-relaxation moduli" can be derived from stress-relaxation data. The *stress-relaxation modulus* is the property required for design calculations when the strain is prescribed and the stress is free to vary. However, the numerical difference between the relaxation modulus and the creep modulus is often small when the strain is small and elapsed times under continuous loading or straining are matched. Accordingly, the two can often be used interchangeably for engineering design. A procedure has been proposed to define the range over which the above assumption provides a reasonable approximation.[5] This reference includes a detailed discussion on how viscoelastic properties can be used to model stress-strain response under a variety of time-dependent loading conditions.

The creep modulus for a certain duration of loading is often expressed as a fraction of the modulus of elasticity that has been measured by a particular short-term tensile test. Such a simplified representation (see Table D1.10) assumes that over the range of engineering stresses for which the approximation will be used, creep modulus is independent of stress intensity. The consequence of this simplification is usually small and acceptable for most pipe design. The reciprocal of this fraction, called the *creep factor,* was introduced by Ref. 5 and is used by certain design practices, for example, those of the American Association of State Highway and Transportation Officials (AASHTO) culvert design specifications.[6]

TABLE D1.10   Approximate Ratio of Creep Modulus to Short-Term Modulus as a Function of Duration of Continuous Loading, for 73°F (23°C)

Duration of uninterrupted loading, h	Approximate ratio of creep to short-term modulus*	
	High-density PE	Type I PVC
1	0.80	0.84
100	0.52	0.60
10,000	0.28	0.40
438,000 (50 yrs)	0.22	0.34

* Exact ratio depends on the specific commercial grade of material, stress field, fabrication residual stresses and other factors.

Even though the deformation behavior of plastics is rather complicated, successful design can be simplified by using a creep or an apparent modulus that reasonably reflects response under the anticipated loads. For example, a buried pipe may be subjected to relatively short periods of externally induced high loads, followed by longer periods at lower loading. For such conditions, Boltzman superposition theory can be used to estimate an appropriate creep modulus.[5] More often though, a simpler design check assuming a worse-case condition is all that is required. For example, the wall thickness of a buried pipe is first selected based on pressure rating considerations and then a check is made to ensure that this wall is sufficient to withstand a given combination of traffic (short-term) and soil (long-term) loads. To conduct the design check, it can be assumed that the two loads are simultaneously and continuously present; if the pipe is adequate to this task then no further calculation need be made. While procedures such as this are often used to simplify design, care must be exercised not to make unduly conservative assumptions which could rule out a fully acceptable construction that would be justified by a more refined evaluation.

Allowable Strength When Load is Constant

The relationship between tensile load and time-to-fracture is described by the creep-rupture strength envelope of tensile creep curves (see Fig. D1.6). Each material has a specific envelope depending on the nature of the base polymer and the amount and kinds of additives used in its formulation. To simplify the task of obtaining data from which estimates of a material's long-term strength may be projected, the general practice is to ignore the creep response as a function of stress and time and only track the time-to-fail as a function of the test tensile stress. As is discussed later, excessive deformation under load is seldom, if ever, a factor in delimiting long-term strength.

Stress-rupture data are obtained by means of long-term pressure tests that are conducted on pipe specimens made from the material under evaluation. The use of pipe specimens replicates the combined hoop and axial stresses that are seen by plastic pipe in actual service. Pipe stress-rupture testing is performed in accordance with ASTM D 1598, "Time to Failure of Plastic Pipe Under Constant Internal Pressure." Sufficient pressure versus time-to-fail points are obtained for a set of temperature and test environment conditions to define a hoop stress-rupture envelope through at least 10,000 h. The following relationship, commonly known as the ISO equation (denoting its adoption by the International Standards Organization), is used to calculate the pipe hoop stress generated by the internal test pressure:

$$S = [P/2] \times [D_m/t] \tag{D1.1}$$

where S = hoop stress, psi (MPa)
P = internal pressure, psi (MPa)
D_m = mean pipe diameter, in (mm)
t = minimum pipe wall thickness, in (mm)

The stress-rupture data obtained by testing in accordance with ASTM D1598 are plotted on log stress versus log time-to-fail coordinates. If, as is generally the case for materials that qualify for pressure piping, the data plot along a straight line, the best least-squares line is determined mathematically and then extrapolated to 100,000 h to determine that material's estimated average *long-term hydrostatic strength* (LTHS). The extrapolation procedure used is that of ASTM D 2837, "Obtaining Hydrostatic Design Basis for Thermoplastic Pipe Materials." A material's *hydrostatic design basis* (HDB) is then established by categorizing its estimated average LTHS into one of a series of standard long-term strength values in which the numbers ascend in increments of 25 percent, as follows: 1,000 psi, 1,250 psi, 1,600 psi, 2,000 psi (6.9 MPa 8.6 MPa, 11.0 MPa, 13.8 MPa), and so on. The purpose of categorizing LTHSs into a limited number of standard HDB values is to simplify material standardization and product design. Figure D1.9 illustrates the application of the ASTM D2837 procedure to establish the HDB of a PVC 1120 material.

Every major standard specification for thermoplastic pressure pipe requires that the material from which the pipe is made have an established HDB for the standard condition of water at 73°F (23°C). Piping materials intended for hot water applications are generally required to also have an established HDB for water for 180°F (82°C). Standards covering natural gas piping require evaluation of the HDB with natural gas—which consists of methane, with minor quantities of other gases—as the test medium. However, water may be used in the case of plastics for which it has been shown that the results are essentially equivalent. For most thermoplastics, testing with water or natural gas result in little difference. However, other gaseous
FIGURE D1.9 Application of method ASTM D 2837 to establish the hydrostatic design basis (HDB) for 73°F for a typical PVC 1120 material.

fuels such as propane and butane can make a difference, depending on the degree to which they may be absorbed by the plastic.

For some plastics, particularly those used for industrial applications, there exist stress-rupture data that have been obtained using chemical reagents of special interest.

The Plastics Pipe Institute (PPI) publishes a periodically updated list of thermoplastic pipe materials with HDBs for water which have been established in accordance with ASTM D 2837 and the additional requirements included in PPI TR-3, "Policies and Procedures for Developing Hydrostatic Design bases and Maximum Recommended Hydrostatic Design Stresses for Thermoplastic Piping Materials." Compositions that carry a PPI recommended HDB are listed in PPI TR-4, "HDB Listed Materials." A number of pressure pipe standards require that the material have a PPI listed HDB.

The HDB that is forecast by method ASTM D2837 is predicated on a fundamental assumption: that the straight-line log stress versus log time-to-fail behavior that is defined by the data obtained through at least 10,000 test hours (1.14 years) will continue its straight course through at least the 100,000-h (11.4-year) intercept. To lend confidence to this assumption, certain requirements and procedures, as follows, have been included in method D2837:

- Experimental data must include not less than 18 data points, 4 of which must span not less than 6,000 testing hours.

- At least one data point must span a test time of not less than 10,000 h.

- Statistical analysis of the data must yield a 95 percent lower confidence value for the projected 100,000-h intercept that is not less than 85 percent of the projected mean strength at 100,000 h.

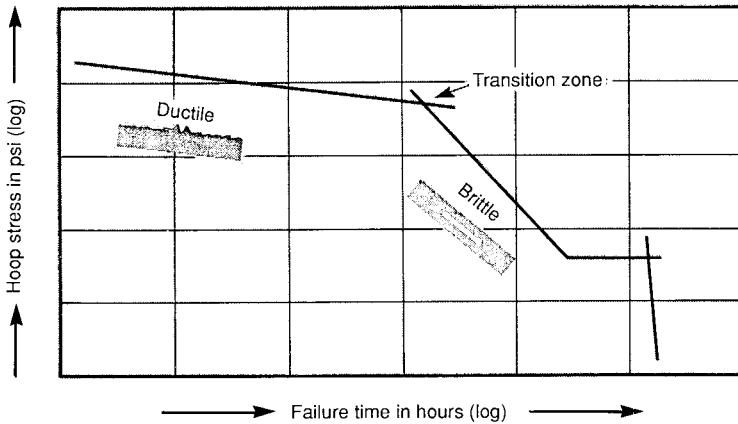
Additional data requirements, particularly when establishing HDBs for elevated temperatures, have been adopted by PPI and are included in the aforementioned PPI TR-3 report.


FIGURE D1.10   Schematic of the stress-rupture behavior of a polyethylene material subject to slow crack growth (first downturn) and chemical degradation (second downturn). Such materials are excluded from pressure service.

In the case of PE pipe compositions there is a further requirement in ASTM D2837 which is designed to validate the assumption that the 73.4°F stress-rupture data obtained through 10,000 h will continue its straight-line course through at least 100,000 h. PE piping materials can only qualify for pressure pipe service when they demonstrate compliance to this validation requirement. The reason for this additional requirement is the finding that PE pipe under long-term load can fail by one of three distinct failure modes, as follows[7] (see Fig. D1.10):

• The first is a ductile failure whereby the specimen ruptures as a consequence of gross yielding at a location subjected to maximum *average tensile stress.* The lower the stress, the longer it takes for yielding to occur. No, or little, irreversible structural damage occurs in the material prior to yielding. When this failure mode controls, the slope of the stress-rupture line is relatively flat.

• The second is a slit failure which is the end result of a slow crack growth mechanism, whereby *localized stress concentrations,* created by minute defects or inclusions in the material, spawn small cracks which then grow, so long as sufficient stress intensity is present. As shown by Fig. D1.10, the strength of PE regresses faster in the brittlelike slow crack zone than is projected by the ductile failure trend. If the transition from ductile to brittlelike failure occurs within the intended design life of a pipe, a forecast of its long-term strength based solely on the earlier ductile behavior can result in an overestimate of a material's actual long-term strength. Accordingly, PE materials used for pressure piping have to have high resistance to this failure mechanism to ensure continuance of the ductile stress-rupture line, and thereby optimum long-term strength.

• The third is the result of a breakdown of the polymer molecule through *oxidative or other degradation.* When this occurs, the polymer's longer-term strength can be severely compromised. For ordinary applications this possibility is precluded by the addition into the pipe composition of appropriate kinds and amounts of stabilizers and antioxidants (see discussion on chemical resistance).

The ASTM D2837 procedure for validating the HDB of PE piping materials is designed to ensure that the material's long-term strength will not be compromised by inadequate resistance to slow crack growth. The procedure used is based on the observation that the time for the onset of the slow crack growth mechanism that leads to brittlelike failure (the first downturn in Fig. D1.10) is greatly accelerated by increasing temperature, and that the rate of acceleration follows basic rate process principles. The extent by which increasing test temperature accelerates the
FIGURE D1.11   Effect of temperature on the time required to reach downturns caused by slow crack growth. This material does not qualify for pressure service.

onset of brittlelike failure is illustrated by Fig. D1.11 By relating the effect of the increased test temperatures on the shortening of the test time required to reach the brittlelike failure zone at a given stress level, one may validate the assumption that the straight-line behavior described by the ambient temperature data will continue its straight-line course through at least 100,000 h. In accordance with current standards, PE materials that do not meet the validation requirement of ASTM D2837 are excluded from pressure pipe applications.

The fracture mechanics process by which slowly growing cracks are incubated and then propagated has been the subject of much investigation in the recent past.[8,9] One result of this work is the development of two new test methods—both based

on measuring the time-to-fail of a notched tensile specimen that is subjected to a constant tensile load at an elevated temperature—that give in relatively short time a good index of a PE's very-long-term resistance to failure by the slow crack growth process. As reported under the discussion of PE piping materials, ASTM D3350, the PE piping material specification, has been recently revised to include this test method as a material performance criterion.

To protect against oxidative degradation, the cause of the second downturn in Figure D1.10, current PE piping formulations include appropriate amounts and types of stabilizer packages. Accelerated aging studies, as well as those conducted on pipe that has been in actual service for many years, indicate that PE can be suitably protected against oxidative degradation over its intended service life when conveying water, gas, and similar fluids.[7]

Other Materials. Downturns in stress-rupture behavior have also been observed in other thermoplastics. A material's susceptibility to ''aging'' by gradual physical and chemical changes created by the stress and environmental conditions to which it is continuously subjected can result, after sufficient time, in a transition in failure mechanism that sometimes—but not always—results in a significant downward shift in its longer-term stress-rupture behavior. In cases where a significant downturn occurs after longer times than the longest test period, a forecast of long-term strength that is based on the earlier observed stress-rupture behavior could result in a significant overestimation of a material's actual long-term strength. While the primary objective of long-term stress-rupture characterization is to establish a reliable estimate of a material's long-term strength, another function of this test is to exclude from pressure piping those materials and formulations that are inadequate for very long-term service when subjected to sustained loading. Longer-term stress rupture testing is a fairly effective test procedure for screening out from pressure applications those materials that are prone to downturning in their stress rupture properties. However, as will be discussed, for more effective screening other information should also be considered.

A plastic material's susceptibility to detrimental ''aging'' that could cause downturns in its very-long-term stress-rupture properties depends on a number of factors, including the nature of the service environments; the polymer's chemical nature (e.g., PVC, PE, PB, and so on); its molecular structure (molecular weight, molecular weight distribution, branching, and so on); the formulation of the plastics composition (kind and amounts of additives, including stabilizers); and quality of manufacture. As an example, significant downturning in stress-rupture properties has been reported in PVC materials of lower molecular weights.[10] The same trend has been observed with PVC formulations that include more than relatively low quantities of finely divided fillers, such as calcium carbonates. For these reasons the policies in PPI TR-3 limit the minimum molecular weight of PVC resins, and the kind and amounts of calcium carbonate that can be used in PVC formulations intended for pressure pipe applications.

Excepting for the special requirement for PE materials that is discussed above, there is no formal general protocol in ASTM D2837 for ensuring for the particular material being analyzed that a significant downturn in stress-rupture properties will not occur sometime beyond the maximum time over which the experimental data were gathered. Therefore, the applicability of this extrapolation method to a plastic material has to be judged in consideration of other information that can give an indication about the possible occurrence of a future downturn. A positive source of confidence is, of course, successful long-term service experience with the kind of plastics for which a long-term forecast is being made. A second one is the

demonstrated continuance of straight line stress-rupture behavior for much beyond the minimum 10,000 h required by ASTM D2837. Certain materials have been on test for well over 10 years. A third one is information gathered from other tests and from actual field experience about the "aging" effects on the material by the physical and chemical environments to which it may be subjected while in service. And a further source is the absence of a downturn during at least the first 10,000 test hours when testing the plastic at a higher temperature, say, about 40°F (22°C) above that for which the HDB is being established. As discussed previously, increasing the test temperature has a profound effect in shifting downturns to much earlier times. Therefore, the absence of a downturn in such an elevated temperature test during the first 10,000 h of testing is taken as a very good indicator that a downturn will not occur for very much longer times at the lower end-use temperature. The listings of HDBs that are issued by PPI have been established with consideration of these various means for enhancing confidence in the forecasts of longer-term strength of thermoplastics piping materials. In many cases manufacturers of plastics piping and of plastics piping materials issue reports that details other information they have accumulated in support of the appropriateness of the long-term strength predicted by method ASTM D2837.

The International Standards Organization (ISO) has recently issued report ISO/TR 9080, "Methods of Extrapolation of Hydrostatic Stress-Rupture Data to Determine the Long-Term Strength of Thermoplastics Pipe Materials."* This ISO method includes mathematically based procedures for the analysis of elevated multitemperature data to give assurance that the projected long-term strength for a lower maximum service temperature will not be compromised by an unanticipated downturn during the pipe's intended service life.

Deformation under Load and Ultimate Strain Capacity

As mentioned earlier, the property of ductility—sometimes referred to as *strainability*—of thermoplastics piping materials is a generally recognized beneficial characteristic of these materials. Their capacity to deform significantly prior to rupturing allows them to shed-off, through localized deformation, stress concentrations that could initiate cracking in less ductile materials. Another benefit of ductility is the soil-pipe interaction that is generated by the flexibility of buried plastics piping.

However, too much creep while under load can lead to performance limitations such as excessive diametrical deformation of pipe under pressure. To ensure that this is not a problem, ASTM D2837 imposes the following limitation: The HDB that is projected by the extrapolation of the stress-rupture data cannot be greater than the sustained stress which would produce a 5 percent diametrical expansion at 100,000 h. For all the presently used stress-rated thermoplastic pipe materials in North America, the 5 percent expansion strength has been determined not to be a limiting factor. Therefore, expansion measurements are not required for these materials.

Although the diametrical expansion at failure of a thermoplastic pipe subjected to a stress equal to its HDB is under 5 percent, it is generally above 3 percent and usually closer to 4 percent. Engineering materials are considered to be ductile when

---

* Copies of ISO standards may be obtained from the American National Standards Institute. See listing of standards writing associations for address.

they are able to deform prior to failure by at least 3 percent. When a material is ductile a localized stress concentration only leads to localized plastic deformations which modify the local geometry and thereby both reduce and redistribute localized stress. If the material is brittle—that is, if it fails after but minimal deformation—localized stress concentrations remain high and can initiate a crack, which once started, is then propagated by the greatly magnified stresses that develop at the bottom of a crack under tension. Therefore, design with ductile materials can be based on *average* or nominal stress due to tension, shear, or bending. All the common design protocols for thermoplastics piping assume ductile behavior. In contrast, design with brittle materials must be based on a combined stress analysis the objective of which is to identify the *maximum* stress, or strain, in consequence of any and all possible loads, that can occur at any point in the piping, but particularly at points that invite the development of multiaxial stress intensification.

Experience has shown that thermoplastic piping materials which exhibit low strain capacity under sustained loading tend to fail in time by cracks that initiate and then slowly grow at points of localized stress concentration. In the case of buried pipes, conditions that can produce localized stress concentrations include stone impingement, shear loading due to differential settlement, excessive bending, and nonrounded corners in fittings. While the occurrence of localized stress intensifications should always be mitigated by proper product design and installation, if the pipe material is too strain-sensitive it can be subject to premature failure even under the best of conditions. Consider the experience with early vintage high-density PE pipe materials such as the one that exhibits the stress-rupture properties depicted by Fig. D1.11 After some time in service, even as long as after 25 years, buried pipes made from such materials have failed by small cracks that were initiated at points of localized stress intensification. As shown by Fig. D1.11, sustained pressure testing of pipes made from such materials revealed that their longer-term strength was compromised by a subsequent downturn in stress-rupture properties. However, the downturn had another important negative consequence: It resulted in a loss of ductility.

In a short-term tensile test, which is conducted at a strain rate of around 20 in/min (500 mm/min), PE piping materials exhibit a total elongation at failure of well over 100 percent, in some cases over 500 percent. As is the case with all plastics, under sustained loading the elongation at failure of PE steadily decreases with increased time-to-failure. But as already mentioned, PEs now considered suitable for pressure applications always fail at deformations not less than about 3 percent, even after the longest time under sustained loading. However, the material for which the data in Figure D1.11 were obtained fails in time at diametrical expansions of under 3 percent, and the longer the time under load, the lower the value. This is shown by Figure D1.12, which compares 68°F (20°C) isometric (constant strain) diametrical expansion curves to the 68°F (20°C) stress-rupture data obtained on this PE material. In the region where the stress-rupture line (band in this case) is parallel to the isometric curves, ductile failure dominates and the diametrical expansion is fairly large. But in the region where the stress-rupture line downturns, brittlelike failures dominate and the diametrical expansion at failure can be as low as 1 percent. So, the effect of a downturn for this PE is not only a reduction in its long-term strength but its transformation from a ductile to a brittlelike-behaving material. As already mentioned, the validation requirement of ASTM D2937 excludes such PEs from pressure pipe service.

All commercial grade thermoplastic piping materials that have demonstrated permanent ductility under conditions of service exhibit stress-rupture characteristics that are free of significant downturns.
FIGURE D1.12 Comparison of the creep-rupture (also referred as stress-rupture) strength to isometric curves (constant strain) for 68°F (20°C) that have been experimentally determined on pipe made from a PE material that exhibits an early downturn in its stress versus time-to-fail characteristics.

Allowable Strain

As explained earlier, when deformation is kept constant during loading time, the load gradually relaxes, reducing—but never completely eliminating—any stress intensity which could generate and propagate cracks. As a result, the long-term strain capacity of a material maintained at constant deformation is somewhat greater than if deformation had been achieved over the same time of loading by free creeping, with no relaxation of loading. However, even though stress relaxation gives somewhat more leeway, materials intended for nonpressure pipe applications must still have a good measure of long-term strain capacity (i.e., ductility); otherwise they will behave over the long-term as brittle materials for which design and installation must anticipate and avoid any and all localized stress intensifications. This is particularly the case for materials used in profile wall construction, the geometry of which tends to produce localized stress risers.

Unlike what has become the generally accepted practice for the qualifying of pressure piping materials, for which evaluation by ASTM D 2837—or, by another suitable procedure that relies on longer-term data—is a controlling requirement, there is no common longer-term test protocol by which to judge the suitability of a plastic for nonpressure service. Recognizing the value of longer-term data some standards for nonpressure piping do require that the pipe material have an established HDB. However, because the HDB test is time consuming and expensive to

run, and because some believe it is excessively demanding for nonpressure piping, the material requirements for many nonpressure pipe standards are based only on the results of shorter-term tests. The particular minimum property requirements for these materials have been established by relating their shorter-term properties to observed quality of longer-term field performance.[13,14] While this approach has generally worked quite well, experience has shown that in some cases it is not as reliable a predictor of adequacy of longer-term strain capacity as is needed. The recent emergence of new testing procedures based on fracture mechanics for the evaluating of the resistance to failure mechanisms that can compromise a materials longer-term strength and ductility promises improved discrimination for the specifying of nonpressure piping materials.[11] As of this writing, the new ASTM notched constant tensile tests that were referenced earlier are also being evaluated for use as an index of the longer-term stress crack resistance of PE materials intended for nonpressure piping.[12]

Resistance to Short-Term Loading

By virtue of the relationship of duration of loading on ultimate strain and ultimate strength, plastics have a certain ability to withstand a higher temporary loading than that indicated by their long-term strength. In short-term loading—such as represented by the higher momentary pressure created by internal pressure waves, or by the temporary added external soil pressure caused by rolling traffic—the limiting stress for long periods of sustained loading can be considerably exceeded, provided the temporary overloading is kept within reasonable limits and its occurrence is sufficiently infrequent so as not cause damage to the plastic by fatigue. Some standards (such as those of AWWA) and a number of design practices give information on the magnitude of infrequent overloading that can be safely tolerated by certain plastic pipes. In cases where the overloading is likely to occur relatively frequently, a pipe's fatigue resistance capabilities need to be considered.

Fatigue Resistance

As with any other engineering material, repeated cyclic stressing of plastics can cause a reduction in their strength through fatigue. Also, brittlelike fracture at points of stress intensification is more likely under cyclic loads than under a simple static load. There is a similarity between the shape of fatigue or *S-N* (stress amplitude versus number of cycles to failure) curves for plastics and those obtained for metals. *S-N* data[15,16] for PVC and PE pipes indicate that fatigue sensitivity varies not only from one plastic to another but can be different within the same plastic family depending on molecular structure, formulation, and fabrication quality. Also, stress risers caused by fitting or joint geometry can magnify the effects of fatigue. By limiting the magnitude of the maximum stress caused by cyclic plus static stresses, or by suppressing the amplitude of the stress change to the "safe" value indicated by *S-N* curves, long service life can be achieved. A number of design practices prescribe such limits.[17,18,20]

Potential Consequence of Failure Mode

The potential failure mode of a plastic pipe may determine the choice of material and/or the limiting service conditions. Some thermoplastics are subject to failure by shattering, which could present a hazard to personnel when the pipe is either used for the aboveground conveying of pressurized gases or when it is pressure

tested with compressed air. For this reason, the Plastics Pipe Institute recommends that no thermoplastic pipe be tested with compressed air or used for aboveground compressed gas service unless it has been evaluated and is specifically recommended by the manufacturer for that service.

Thermoplastic pipe failure can also occur by a rapid crack propagation (RCP) process, whereby axial cracks may travel long distances and at high speeds in a pressurized pipeline. Resistance to RCP has been linked to the absorbed energy in the Charpy impact test, a property highly influenced by temperature. The possibility for the occurrence of RCP increases with increasing pressure and pipe diameter, as well as with decreasing temperature. For certain applications, such as gas distribution, a design objective is to ensure that the selected pipe material in the largest pipe diameter when operating at maximum pressure and minimum temperature will not lead to RCP should the pipe be accidentally damaged. Calculation procedures for evaluating compliance with this objective have been proposed.[19]

CHEMICAL RESISTANCE

A major reason for the broad acceptance of thermoplastics piping is its virtual freedom from attack by ambient moisture and other common corrosives. This applies not only to external surroundings, both below as well as aboveground, but also to the materials being conveyed. Being nonconductors, plastics are immune to galvanic or electrochemical corrosion. The electrical activity of electrolytes such as acids, bases, and salts is of no consequence. Plastics piping is generally durable and not subject to a gradual degradation of material and properties comparable to the rusting of steel, or atmospheric corrosion of copper, or pitting of concrete. Painting, wrapping, lining, and cathodic and other forms of corrosion protection are not required. Maintenance costs are therefore, minimal.

However, as indicated by the abbreviated chemical-resistance guide shown in Table D1.11, for each plastic there are certain substances that can be hostile. Identifying the suitability of a plastic to a specific chemical is inherently more complex than for metals for several reasons. One of these, as previously elaborated, is that even within the same family of plastics the individual members may differ in molecular composition and in the nature and quantity of compounding additives. All of these can affect chemical resistance. Chemical-resistance charts, such as the abbreviated Table D1.11, are not to be considered more than a preliminary guide.

Another reason is that plastics can interact with chemical environments by a number of different mechanisms that can vary in rate, and in degree of impairment of performance properties, depending on concentration, temperature, and stress level. The primary mechanisms are as follows:

- *Chemical attack.* A chemical environment can attack certain active sites on the polymer chain, leading to chain scission and, ultimately, to significant ''aging'' or degradation of the polymer. The rate of attack can determine suitability of the plastic—if very slow, or if arrested by the addition of an appropriate stabilizer, long service life can be realized. Strong oxidizers will attack many plastics. This is why antioxidants are generally included in the stabilization package of many thermoplastic compounds.

- *Solvation.* The absorption by a plastic of an organic solvent is called *solvation.* Its effect may range from a slight swelling and softening, with minor effect on properties, to a complete solution. For example, the solvent cementing of ABS and PVC is based on solvation.

TABLE D1.11 Thermoplastic Piping Materials: Chemical Resistance Guide for Ambient Temperatures (See Note 1)

Notes:

1. G denotes good; L limited resistance; and P poor. These ratings are only for general guidance. For determination of suitability of chemical resistance under the actual anticipated end use conditions more detailed information should be consulted.

2. Stress crack resistant grade of plastic material should be used.

- *Plasticization.* When a liquid hydrocarbon is an imperfect solvent; that is, when it is miscible with a polymer but unable to dissolve it, *plasticization* may result. The plasticizing effect can vary over a wide range, depending on relative miscibilities. Plasticization can significantly compromise mechanical properties, including creep-rupture behavior.

- *Environmental stress-cracking.* Under this mechanism, fracture of the plastic can occur after some time in response to a synergistic action of stress and environment. Stress-cracking agents tend to be strong surface-wetting liquids, such as detergents, surfactants, glycols, and alcohols, which by some mechanism not yet fully identified facilitate the development and growth of microcracks when under stress. Susceptibility to stress-cracking can be mitigated by selecting stress-crack-resistant grades of material.

In all these mechanisms, stress, reagent concentration, and time are important

variables. In addition, temperature has a profound effect on the results. Raising the temperature significantly increases the reaction rates. It also causes a polymer to expand and become more penetrable, more permeable, and more soluble. Forecasting performance at higher temperatures based on lower-temperature results can, therefore, be risky.

Because chemical resistance can be limited by any of the just-noted mechanisms and be affected by many variables, shorter-time ''soak'' tests cannot reliably predict actual performance. Most chemical-resistance charts are, however, based on such information. They should only be considered as an initial guide. A more effective method of evaluating the effects of chemicals, particularly for pressure piping, is creep rupture with the specimen immersed in or in contact with the test environment.

A creep-rupture test method specifically designed for evaluating the chemical resistance of plastics pipe is the subject of ISO Standard ISO 8584. ''Thermoplastic Pipes for Industrial Applications Under Pressure-Determination of the Chemical Resistance Factor and of the Basic Stress.'' Chemical resistance evaluated under this or similar methods is reported by some manufacturers. Successful previews in the same or similar service are also reliable indicators. Lacking this, chemical resistance will be best established by actual service testing. Manufacturers and trade associations can assist in obtaining this information. An advantage of service testing is that it is sure to include some minor chemical component, such as a surfactant, which could influence the final result.

When selecting plastic pipe for a given application, consideration should also be given to the possibility that the quality of the fluid being transported could be affected by permeation of organic pollutants with which the outside of a pipe may be exposed. Thermoplastics, as well as elastomers (such as used in rubber gaskets) and porous materials such as asbestos cement and concrete, may be subject to permeation through the pipe wall by lower molecular weight solvents and other liquid organics, such as petroleum products. Prior to selecting materials for installation in soil or other material that is or can be contaminated by organic solvents, the piping manufacturer should be consulted regarding permeation properties of the pipe walls, fittings, and jointing materials.

Effect on Fluids Being Conveyed

Plastic pipe materials are generally inert to the materials being transported. Because their composition includes minimal or no quantities of materials which can produce dissolved ions, plastics pipes are often used for the transport of pure materials, including deionized water. For food service there are pipes available that have been made from materials approved by the Federal Food and Drug Administration.

Plastic pipe resins are also neutral to potable water. However, because it is possible to formulate pipe with certain ingredients (such as stabilizers, catalysts, or modifiers) that could leach out and adversely impact water quality, most standards and codes require that pipe intended for this service meet the requirements of National Sanitation Foundation Standard 61, ''Drinking Water System Components-Health Effects (November, 1996).''

DESIGN AND INSTALLATION

As discussed earlier, thermoplastics are viscoelastic materials; thus they exhibit a profoundly different stress-strain and stress-rupture response than do elastic materi-

als. Nonetheless, elastic equations used for other types of piping are frequently applicable to thermoplastics piping, provided that their engineering behavior is represented through appropriately derived values of apparent modulus and strength. Since these properties are greatly influenced by the history of the material's exposure to stress as well as by temperature and environment, proper use of traditional elastic equations requires appropriately established or estimated property values. Long-term strength values for certain conditions [such as for water at 73°F (23°C)] are available, and in some cases (i.e., maximum recommended hydrostatic design stress) they may even be part of the product standard. In addition, some codes and suggested design protocols either list or give procedures for arriving at appropriate values of strength, stiffness, and allowable strain. As this is a still developing technology, not all properties for all materials are yet available in a standardized basis. However, for the more frequently used materials, sufficient information for the majority of applications is either available or may be adequately estimated.

While the viscoelasticity of thermoplastics somewhat complicates the process of selecting appropriate material constants, materials with high strain capacity help to facilitate design. Under a great many conditions thermoplastics display a ductilelike behavior: They are able to deform significantly before fracture. This behavior helps to redistribute stresses and preclude failure by localized stress intensification which could initiate cracking in brittlelike materials. Within certain limits, design of thermoplastics piping is based on average stress; localized stress concentrations are generally ignored.

Also, as previously pointed out, the strain capacity of thermoplastics under constant strain (where stresses can gradually decrease through stress relaxation) is often significantly greater than that under constant load (where stresses intensify as the material deforms). Allowable strain limits under constant strain can therefore often be greater than the fracture strains observed under sustained loading. For example, several investigations of PVC and PE pipes subjected to constant deflections over long periods of time show that the materials did not fail at sustained strains of as high as from 5 to 10 percent.[13,14] These same strains corresponded to relatively short lifetimes when the materials were subject to constant load.

One simplification commonly employed in the North American design of flexible buried plastic pipes (the word *flexible* in this instance signifies that the pipe can undergo significant permanent deformation without cracking) assumes that internal pressure (constant load) and external loading (resulting largely in pipe bending stresses relieved by both pipe deformation and stress relaxation) are acting independently. That is, the pipe wall thickness is chosen on the basis of internal fluid pressure, and then a separate analysis is made to ensure that the pipe is sufficiently strong and structurally stable under the external loads acting alone.[17,18] In effect, localized fiber stresses due to bending and other external loadings are neglected. Standard installation practices include recommendations for avoiding localized stress concentrations. For cases where localized strain cannot be avoided and where it may thus limit design, more rigorous design protocols based on a combined loading analysis are available.[5]

There are many potential factors that could cause a material with apparent high strain capacity to shift from the ductilelike to the brittlelike state and as a result, fail at lower-than-expected strains. These can include temperature, environment, duration of loading, nature of loading (unrelieved or relieved by stress relaxation), stress triaxiality, fatigue, scale factors (such as wall thickness), damage (cuts, gouges), stored energy in system (such as residual stresses from manufacture), material imperfections (voids, contaminants), polymer aging, and chemical attack. Judging from the good track record that exists, these influences, although difficult to quantify,

appear to have been adequately considered for typical uses by standards, design protocols, and installation practices. In addition, material requirements and improvements have been evolving that ensure greater durability in pipe products. Furthermore, design practices give recognition to the effects on strength and stiffness and other long-term engineering properties by time, temperature, and environment. Finally, installation recommendations address many of the unique characteristics of plastics that can affect structural integrity and durability. To be sure, the state of the art of thermoplastics piping is still evolving, and considerable work yet remains to be accomplished to further define materials properties and performance limits. Such work is ongoing, and for the latest information the reader is encouraged to refer to the growing literature, particularly to the papers presented at the various conferences that address plastics piping technology.

As demonstrated by the successful record of experience, sufficient information is available to successfully support proper application of thermoplastics over a very broad range of engineering uses. To best realize the performance potential of thermoplastics piping, the user should base materials selection and utilize design and installation practices on information, such as standards and recommended practices, which has been developed under the technical scrutiny of the consensus process of an established professional society or technical association, as well as upon the recommendations and reports issued by industry and independent sources. A number of such references are provided at the end of this chapter.

The following material is an introduction to some of the more basic aspects of the design and installation of thermoplastics piping. More detailed recommendations suitable to a particular product and situation should be sought and followed.

COMMON DESIGN AND INSTALLATION CONSIDERATIONS

Internal Hydraulic Pressure

Thermoplastic pipe is pressure rated by means of the ISO Eq. (D1.1). When rewritten to solve for pressure, this equation takes the form:

$$PR = 2(HDS) \times t/D_m \qquad (D1.2)$$

where PR = pipe pressure rating, psi (MPa)
t = minimum wall thickness, in (mm)
D_m = mean diameter, in (mm)
HDS = HDB $\times$ DF, where HDB is in psi (MPa) units and DF is the pipe design factor

Values of HDS for water at 73°F (23°C) are specified by most ASTM and other standards that cover water and gas applications. The maximum HDS for water is generally determined by multiplying the material's HDB by a design factor (DF) of 0.5. In selecting the appropriate design factor, consideration is given to two general groups of conditions. The first group considers the manufacturing and testing variables, specifically normal variations in the material, manufacture, dimensions, quality of handling techniques, and the accuracy of the long-term strength prediction. The second group considers the application or use, specifically installation, environment, temperature, hazard involved, life expectancy desired, and the degree of reliability selected.

For gas pipe, a DF of 0.32 is prescribed by the federal code. Certain other codes and standards (e.g., those of AWWA) may prescribe specific design factors. A DF smaller than 0.5 is used in applications where greater compensation is advisable for certain anticipated conditions (e.g., surges or temperature), or where the fluid conveyed may have some effect on the pipe material properties. The final determination of the appropriate DF for any given application is up to the discretion of the design engineer.

By assuming that a pipe's outside diameter is equal to $D_m + t$, the previous equation takes the following form:

$$PR = 2(HDS)/(DR - 1) \tag{D1.3}$$

where DR = ratio of average outside pipe diameter to minimum wall thickness

Equation D1.3 is used to compute the pressure rating of DR dimensioned pipe.

There is no equivalent design system for establishing the pressure rating of fittings. Some fitting standards require that fittings have a short-term burst strength, and in some cases a 1000 h strength, that is not less than that of the pipe for which the fitting is intended. This is not always sufficient to ensure that fittings will have long-term strengths that are comparable to that of the pipe. Because of their geometry, the stresses generated by pressure on a fitting body are more complex and not amenable to easy calculations. Furthermore, such complex stress fields tend to result in a faster regression of strength with duration of loading than occurs in the simple cylindrical pipe shape. For these reasons, even if a fitting matches the short-term strength of a pipe, it may become the weak link over the long term. This is more likely the case where there are cyclic pressures that can weaken the material by fatigue, usually at fitting stress risers.

Fittings are also sometimes made from a lower molecular weight or better lubricated compound in order to facilitate molding. Such compounds may have somewhat weaker creep-rupture and fatigue characteristics, which may need to be compensated by thicker walls or by limiting the maximum service conditions of pressure and temperature. For these reasons the designer should not presume that a fitting labeled with a certain schedule (say, Schedule 40 or 80) will have the same pressure rating as the pipe of the same designation. Suggested maximum pressure ratings for PVC fittings Schedule 40 and 80 have been published[20] (see Table D1.12), and these are significantly lower than for pipe. Because of differences in mold design and other factors, it is best for the designer to consult with the fitting manufacturer for fitting pressure-rating recommendations.

AWWA C 907, "AWWA Standard for Polyvinyl Chloride (PVC) Pressure Fittings for Water—4 Inch Through 8 Inch," is distinctive from most other fitting standards in that it requires each molded fitting configuration to be qualified by an accelerated regression pressure testing intended to ensure a minimum long-term pressure strength sufficient for a 150 psi (1.0 MPa) fitting Pressure Class.

Surge Pressure

Transient and regularly recurring surge pressures may cause damage to pipe and fittings by either of two possible effects: The surge exceeds the short-term fracture strength of the pipe or one of the components; or (and this is the more likely possibility) the repetitive changes in pressure exceed the fatigue endurance limit of the pipe or some piping component. Transient or water hammer surges result from sudden changes in velocity. The pressure rise caused by the velocity change

TABLE D1.12 Suggested Maximum Sustained Working Pressures for Water for 73°F (23°C) for Schedule 40 and Schedule 80 PVC Fittings*

Nominal size, in	Schedule 40		Schedule 80	
	Required minimum burst pressure by ASTM D2466 psig	Maximum suggested working pressure psig	Required minimum burst pressure by ASTM D2467 psig	Maximum suggested working pressure psig
½	1910	358	2720	509
¾	1540	289	2200	413
1	1440	270	2020	378

8	500	93	790	148
10	450	84	600	140
12	420	79	580	137

* This table is only intended as a general guide. Appropriate maximum working pressures may vary widely depending on specific fitting design and field conditions, particularly when repetitive surge pressures are present as these may lower the long-term strength because of fatigue effects. The fitting manufacturer should be consulted for recommendations. Source of these suggested values is Ref. 20.

can be estimated by means of the same equations used for calculating the effects of water hammer in other pipes. The only difference is that with plastics the appropriate material modulus is that for the condition of dynamic, instantaneous response (about 150,000 psi (1.0 GPa) and 460,000 psi (3.2 GPa) for high-density PE and PVC, respectively, at 73°F (23°C)). In cases of network piping it is suggested that a complete network analysis be performed for more accurate estimates of possible surge pressures.

Because of the lower stiffness of plastics, the surge pressure rise that occurs from water hammer is significantly lower than for metallic piping. For example, the surge pressure rise for each foot-per-second change in flow velocity is from about 16 to 20 psi (110 to 140 kPa) and 8 to 12 psi (55 to 83 kPa) for PVC and PE, respectively, at 73°F (23°C). The exact value depends on pipe wall thickness—the thicker the wall, the larger the pressure rise. As noted previously, if there is no damage accrued by excessive fatigue, thermoplastic pipes have the capability to withstand momentary pressures that are significantly greater than the pipe's pressure rating. This is due to the stress versus time-to-failure characteristics of thermoplastic pipe materials. However, if the sum of short-term pressure rise plus the sustained working pressure exceed the pipe's short-term burst strength, failure will result.

Entrapped air in a pipeline can produce sudden accelerations of air-separated water columns. The kinetic energy of these fast-moving columns can sometimes be

high enough to fracture the pipe. For this reason, when plastic piping systems are first filled with water, either for operation or testing, they should be filled carefully and relatively slowly to minimize air entrapment. Air should be vented from the high points before the system is pressurized. Other precautions should also be taken, such as carefully laying pipe to grade or using air vent-vacuum relief lines, to minimize the entrapment of air in operating pipelines.

When there exists a frequently recurring pressure surge of significant amplitude—say, over 25 percent of the operating pressure—the designer should evaluate the piping for adequacy of fatigue endurance. The resistance to fatigue varies from material to material. For example, PE pipe is quite tolerant; modern materials can withstand frequent surging up to one-half of the pipe pressure rating even when the pipe is operating at its full rating based on only static pressure considerations. In the case of PVC pipe, which is somewhat more sensitive to effects of fatigue, the following equation has been proposed[15] for estimating the maximum total hoop stress, due to both static and cyclic pressure, that PVC pipe can safely tolerate as a function of the total number of anticipated surge pressure events:

$$S' = \left(\frac{5.05 \times 10^{21}}{C'} \right) \tag{D1.4}$$

where S' = maximum allowable total hoop stress, psi (no safety factor) (for S' in MPa, multiply by 0.0069)

C' = total number of cycles

Resistance to Vacuum and External Pressure

The performance of flexible pipe with thin walls that is made from materials with low modulus of elasticity can sometimes be limited by buckling under vacuum or external pressure. A net external pressure can result from external hydrostatic loading, from internal negative pressure, from the temporary vacuum that may accompany pressure surging, or from a combination of these elements. The buckling resistance of plastic pipes may be estimated using the following adaptation of the elastic buckling equation for thin tubes:

$$P_c = \left(\frac{24EI}{1 - \nu^2} \right) \times \frac{1}{D_m^3} C \tag{D1.5}$$

where P_c = critical buckling pressure, psi (MPa)

E = apparent modulus of elasticity, psi (MPa) (For short-term loading conditions, use the values of E and ν as obtained from short-term tensile tests; for long-term loading, appropriate values as determined from long-term loading tests should be employed)

I = pipe wall moment of inertia, in^4/in (mm^4/mm)

ν = Poisson's ratio (approximately 0.35 to 0.45 for long-term loading)

D_m = mean diameter, in (mm) = diameter to centroid of pipe wall for profile wall pipe

C = ovality correction factor, $(r_0/r_1)^3$, where r_1 is the major radius of curvature of the ovalized pipe, and r_0 is the radius assuming no ovalization

For pipe of solid wall construction, for which $I = t^3/12$, the previous equation is usually expressed as follows:

$$P_c = \left(\frac{2E}{1 - \nu^2}\right) \times \left(\frac{t}{D_m}\right)^3 \times C \qquad (D1.6)$$

where t = pipe wall thickness, in (mm)

According to this equation, pipe made to a constant ratio of diameter to wall thickness has the same resistance to hydraulic collapse, independent of pipe diameter.

For buried pipe, the stiffening effect of embedment can substantially increase the buckling capacity. This is discussed in a later section.

Temperature Effects

As the system temperature increases, thermoplastics piping becomes less rigid, exhibits higher impact strength, and offers lower short- and long-term strength. The opposite effects take place as temperature decreases. The exact effect depends not only on material class but its specific composition. For example, there are PEs suitable for service at temperatures as high as around 160°F (71°C); whereas other PEs might only have sufficient strength through about 120°F (49°C). In the case of fittings, wall thickness and product design also influence the effects of temperature on strength.

The best way to determine the effect of temperature on long-term strength is through stress-rupture testing. PPI TR-4, ''Recommended Hydrostatic Strengths and Design Stresses for Thermoplastic Pipe and Fittings Compounds,'' lists recommended HDBs for various commercial grade thermoplastics for temperatures up to 200°F (93°C). Table D1.13 lists approximate temperature derating factors for some of the more commonly used materials.

Because of its effect on stiffness, increasing temperature also decreases the collapse resistance of plastics pipe. As evident from inspection of Eq. (D1.5), this effect is in direct proportion to the change in the material's apparent modulus of elasticity. This modulus changes with temperature at a rate roughly parallel with the strength derating factors given in Table D1.13.

Other principal effects to be considered in piping design and installation are those resulting from thermoplastics' high coefficient of expansion and contraction. Some potential consequences to be considered include:

1. Piping that is installed hot may cool sufficiently after installation to generate substantial tensile forces. The final connection should be made after the pipe has equilibrated to ambient, or to the desired temperature.
2. Unrestrained pipe may shrink enough to pull out from elastomeric gasket or compression joints. The pipe should be adequately restrained by the use of anchors, or the fitting should be designed to either resist pull-out forces or to tolerate the maximum anticipated pipe movement.
3. Piping exposed to cyclic temperature changes may be susceptible to fatigue damage at points subject to repetitive bending.
4. Pipe installed when ambient temperatures are low may buckle if the compression forces developed on subsequent pipe expansion are not adequately relieved.

TABLE D1.13   Effect of Temperature on Strength and Stiffness of Thermoplastics Pipe: Approximate Temperature Derating Factors[1]

Temperature (°F)	PE	PEX	PB	PVC Type 1	CPVC	PVDF
70	1.0	1.0	1.0	1.0	1.0	1.0
80	0.95	0.95	0.97	0.88	—	0.93

220	NR	NR	NR	NR	NR	0.38
250	NR	NR	NR	NR	NR	0.35
280	NR	NR	NR	NR	NR	0.28

(1) Check with pipe manufacturer for his recommendations for derating factors for the specific composition under consideration.

(2) NR—Not resistant for continuous service at indicated temperature.

CONSIDERATIONS FOR ABOVEGROUND USES

Thermoplastic piping systems in aboveground service must be properly supported to avoid excessive stresses and sagging. Valves and other heavy piping components should be individually supported. Piping should be located, or protected, to avoid mechanical damage. The piping layout should have sufficient flexibility or other means of mitigating excessive bending and axial stresses and fatigue effects induced by repetitive expansion-contraction.

Supports and Anchors

Horizontal runs require the use of hangers that are carefully aligned and are free of rough and sharp edges. Many hangers designed for metal pipe are suitable for thermoplastic pipe as well. These include the shoe, clamp clevis, sling, and roller types. To preclude high localized support pressures, it is generally advisable to modify the hangers by increasing the bearing area by inserting a protective sleeve of plastic between the pipe and the hanger.

Vertical lines must also be supported at intervals to reduce loads on the lower fittings. This can be accomplished by using riser clamps or double bolt clamps located just below a coupling or other fitting to support the pipe. When so located, these provide the necessary support without excessive compression of the pipe.

Anchors are used in thermoplastic piping systems as fixed points from which to direct expansion-contraction and other movements in a defined direction. Their placement is selected to prevent overloading of the piping, particularly at changes of direction where pipe movement could generate excessive bending and axial

stresses. Anchors should be placed as close to elbows and tees as possible. Guides are used to allow axial motion while preventing transverse movement. Both anchors and guides may be used in the control of expansion and contraction of pipelines. They should be of a style and be so located as to prevent overstressing of the pipe. A flexibility analysis can be used to determine suitable arrangements for anchors and guides.

Support Spacing

Support spacing requirements are computed using the same beam deflection equations used for metal piping. The minimum spacing requirement can result from either maximum allowable stress, or maximum allowable pipe deflection considerations for the maximum anticipated service temperature. Maximum beam deflection, or sag, is frequently the controlling factor. Typical support spacing recommendations are presented in Table D1.14.

Expansion-Contraction

There are several methods used for controlling or compensating for axial and bending stresses caused by thermal expansion. Piping runs may include changes in direction which will allow the thermally induced length changes to be taken up safely. Where this method is employed, the pipe must be able to float except at anchor points.

When the piping layout does not include sufficient changes in direction, appropriate expansion loops or offsets have to be provided. The size of the loops and offsets depend on the design (see Fig. D1.13), and the change in length of pipe that has to be accommodated. The dimensions of loops and offsets are calculated using the following equation for cantilevered beams loaded at one end[21]:

$$L = \left[\frac{3}{2} \cdot \frac{E}{S} \right]^{0.5} [D_o(\Delta L)]^{0.5} \tag{D1.7}$$

where L = loop length, in (mm)
E = modulus of elasticity at the working temperature, psi (MPa)
S = maximum allowable stress at the working temperature, psi (MPa)
D_o = outside pipe diameter, in (mm)
ΔL = change in length due to temperature change, in (mm)

Assuming a maximum allowable strain of 0.01, as suggested by a plastics industry publication,[22] the above equation reduces to:

$$L = 12.2[D_o(\Delta L)]^{0.5} \tag{D1.8}$$

For Eq. (D1.7), the convention is to use the short-term apparent modulus in combination with the maximum allowable long-term working stress (often the same value is used as the material's hydrostatic design stress). Since expansion/contraction does not occur instantaneously and since the working stress applies to a condition of constant load where, unlike this situation, there is no stress reduction due to stress relaxation, this combination is conservative. This helps to compensate for other factors, such as fatigue effects caused by repetitive expansion-contraction. Since for most plastics E and S vary with temperature at approximately the same rate,

NONMETALLIC PIPING
FIGURE D1.13   Expansion loops relieve thermal stresses by transforming them to bending stresses. The minimum loop strength L is generally determined by the maximum allowable bending stress or strain.

calculations based on ambient temperature values are generally also appropriate for a fairly wide operating temperature range.

Because the fitting restrains the pipe, a separate check should be made with the manufacturer regarding the fitting's capacity to absorb expansion-contraction stresses and bending moments.

Expansion joints of bellows and piston designs are available and sometimes used. However, piston expansion joints for pressure applications are generally expensive. Proper alignment of piston joints is critical to prevent binding. Bellows-type joints can accept some lateral movement.

CONSIDERATIONS FOR BELOWGROUND USES

Design and installation of thermoplastic pipe for belowground uses recognizes its "flexible" conduit behavior. As noted earlier, the word *flexible* primarily signifies that the pipe has the capacity to sustain significant deflection without failure. Al-

though this value is somewhat arbitrary, a pipe is often considered flexible if it can sustain 2 percent deflection. Conduits that are strong and stiff and that fail at low deformations are classified as *rigid*. Both rigid and flexible piping systems take advantage of soil support to minimize internal stresses and must be designed and installed to avoid stress concentrations and deformations that could result in excessive localized stresses. Thus, the installed buried pipe is actually a pipe-soil system, with both the pipe and the soil contributing to the structural performance. This is an important concept for all types of buried piping systems.

Designing pipe for buried conditions may be different for pressure pipe and nonpressure pipe. The stresses induced by internal pressure are often high relative to those in nonpressure pipe, and the stresses in pressure pipe are constant (subject to creep), while the strains in nonpressure pipe are constant (subject to relaxation, i.e., stresses relax with time). In addition, when subjected to internal pressure, a pipe rerounds, reducing the deflection and bending stresses that result from earth loading.[5]

Thus, for many pressure pipes, a design that meets the requirements of the internal pressure condition can be considered adequate for buried applications, provided the pipe is properly installed in good-quality backfill materials. Although all designers should satisfy themselves to this through calculation checks, in general, if the following conditions are met, a pressure pipe design may be considered adequate for burial without checking the capacity for earth and live loads:

1. Minimum depth of cover of 3 ft (1 m) for live loads up to the magnitude of an AASHTO H20 truck.

2. Maximum depth of burial of 20 ft (6 m).

3. No unusual concentrated or surcharge loads exist.

4. Embedment materials are granular, stable, and compacted to at least 85 percent of maximum standard Proctor density.

5. The pipe is uniformly supported on bedding that is firm but not hard.

6. The pipe is protected from concentrated loads at transitions from soil support to structural support, such as fittings, foundation penetrations, and other connections.

For nonpressure pipe, and for pressure pipe not meeting the just-noted criteria, the following conditions must be met in designing for earth loads:

1. The pipe should not deflect excessively under earth or live loads.

2. The pipe should safely resist maximum wall compressive thrust forces due to external loads.

3. The pipe should not buckle in response to anticipated external soil and hydrostatic loads.

4. The pipe should safely resist bending stresses that result from deflection.

Because of the wide variety of pipe wall profiles and material types, not all of these criteria will be significant for every type of pipe; for instance, resistance to wall compressive thrust forces is important for profile wall pipe, but rarely is significant for solid-wall pipe.

Pipe-Soil System Parameters

The behavior of pipe-soil systems is controlled by two parameters: the *hoop stiffness parameter S_H;* and the *bending stiffness parameter S_B.* These are both ratios of the soil stiffness to the pipe stiffness. An elasticity solution for pipe embedded in an infinite elastic media was developed by Burns and Richard[23] and utilizes these two parameters to describe buried pipe behavior.

The hoop stiffness parameter is defined as:

$$S_H = M_s/\mathrm{PS}_H \qquad (D1.9)$$

where S_H = hoop stiffness parameter
   M_s = constrained modulus of soil, psi (MPa)
   PS_H = pipe hoop stiffness parameter, psi (MPa)

The pipe hoop stiffness parameter is defined as

$$\mathrm{PS}_H = EA/R \qquad (D1.10)$$

where E = pipe material modulus of elasticity, psi (MPa)
   A = pipe wall area per unit length of pipe, in^2/in (mm^2/mm)
   R = radius to centroid of pipe wall, in (mm)

The bending stiffness parameter is defined as:

$$S_B = M_s/PS_B \qquad (D1.11)$$

where S_B = bending stiffness parameter
   M_s = constrained modulus of soil, psi (MPa)
   PS_B = pipe bending stiffness parameter, psi (MPa)

The pipe bending stiffness parameter is defined as

$$\mathrm{PS}_B = EI/R^3 \qquad (D1.12)$$

where I = pipe wall moment of inertia per unit length, in^4/in (mm^4/mm)

The hoop stiffness parameter represents a ratio of the soil stiffness to the pipe extensional stiffness, and the bending stiffness parameter represents the ratio of the soil stiffness to the pipe flexural stiffness. In a detailed analysis the Poisson's ratio of the soil and the pipe material are also important; however, since most design methods are based on simplified models of behavior, and most pipe installation is completed by relatively crude methods, very little accuracy is lost by ignoring this parameter. The contribution of each of the hoop and bending stiffness parameters to the overall pipe soil system is important and bears discussion.

The pipe hoop stiffness parameter represents the change in pipe diameter that results from a radial pressure applied to the perimeter as shown in Fig. D1.14a. This change in diameter results from a reduction in the pipe circumference due to the axial compressive stress produced by the loading. The pipe bending stiffness parameter represents the change in diameter that results from a concentrated load as demonstrated in Fig. D1.14b. This deformation results from flexural stresses produced by the concentrated loading.

$$PS_H = p/(\Delta D/D) = EA/r$$

$$\Delta D = prD/EA$$

b. Pipe Bending Stiffness (Determined in Parallel Plate Test)
FIGURE D1.14   Pipe stiffness parameters.

Soil Stiffness.   While many geotechnical design problems are solved based on the soil strength, represented by the soil friction angle *N,* buried pipe problems are often addressed using soil stiffness as the governing property. The constrained modulus M_s represents the stiffness of an elastic material in a one-dimensional compression test where no lateral strain is allowed. Thus it is often called the *one-dimensional modulus.* In the one-dimensional compression test, the soil stiffness increases with increasing load, as demonstrated in Fig. D1.15 For simplified design methods the slope of the secant from the origin of the curve to the stress that represents the free field soil stress at the level of the pipe springline is used to represent the average soil behavior during backfilling, represented by M_{s1} in Fig. D1.15. For short-term loads, such as live loading, the instantaneous or tangent modulus, represented by M_{s2} in Fig. D1.15, would be appropriate. Table D1.15 presents suggested design values of the constrained modulus[24] based on triaxial compression tests.[25] The testing was conducted on only three types of soils; however Table D1.16 suggests reasonable extensions of the tested soil types to other types based on AASHTO and ASTM soil classification systems. The soil stiffness values
FIGURE D1.15 Constrained modulus, M_s.

proposed in Table D1.15 show an increase in stiffness with increasing depth of fill, which is consistent with known soil behavior. The values also compare well with the more traditional but empirical soil stiffness parameter, the modulus of soil reaction E,[26,27] which is discussed in the section on predicting deflections.

Pipe Flexural Stiffness. Flexible conduits need sufficient flexural stiffness to resist excessive deformation during handling and installation, as well as to maintain shape and structural stability in the final pipe-soil system when subjected to all the loads that can occur during pipe installation and over the intended design life. The parameter most often used to distinguish between rigid and flexible pipe, and the parameter used in many design methods for flexible pipe is *flexural stiffness.* In common practice, the pipe flexural stiffness is expressed in a form which represents the pipe resistance to deflection in a parallel plate test. The parallel plate test is a common quality control test where a pipe is compressed between two parallel plates (Fig. D1.14b). The resistance to deflection is called simply the pipe stiffness:

$$PS = F/\Delta y = PS_B/0.149 = EI/(0.149\ R^3) \qquad (D1.13)$$

where PS = pipe stiffness, lb/in/in (kN/m/m)
$\quad\ F$ = load on the pipe in the parallel plate test, lb/in (kN/m)
$\quad \Delta y$ = change in vertical diameter under load, *F,* in (m)

The parallel plate test is defined in ASTM D2412, "External Loading Properties of Plastic Pipe by Parallel Plate Loading." It is most common to determine the pipe stiffness at a deflection representing a 5 percent decrease in the vertical diameter from the undeformed pipe, but other reference deflection levels are sometimes used. Because of the nonlinear material behavior, and the nonlinear geometric behavior in the test, the reference deflection level will affect the pipe stiffness reported from the test. Minimum short-term pipe stiffness requirements are included in most standards for thermoplastic pipe intended for buried applications. Many such documents offer more than one series of different standard pipe stiffness categories. Categorizing pipes in accordance with pipe stiffness has proven useful to designers and installers. This parameter is an important indicator of a flexible conduit's deformation response, particularly under service loads. However, anticipated performance comparisons based on the pipe stiffness alone cannot always be made for a variety of reasons, including the following:

- Pipe stiffness is a short-term property, which, because of differences in viscoelastic behavior from one material to the next, does not always bear the same relationship to a pipe's long-term stiffness.

TABLE D1.15 Design Values for Constrained Soil Modulus M_S

Stress level (psi)	Soil type and compaction condition (See notes 1 and 2)			
	Sn-100 (psi)	Sn-95 (psi)	Sn-90 (psi)	Sn-85 (psi)
1	2,350	2,000	1,275	470
5	3,450	2,600	1,500	520
10	4,200	3,000	1,625	570
20	5,500	3,450	1,800	650
40	7,500	4,251	2,100	825
60	9,300	5,000	2,500	1,000
Stress level (psi)		Si-95 (psi)	Si-90 (psi)	Si-85 (psi)
1		1,415	670	360
5		1,670	740	390
10		1,770	750	400
20		1,880	790	430
40		2,090	900	510
60		2,300	1,025	600
Stress level (psi)		Cl-95 (psi)	Cl-90 (psi)	Cl-85 (psi)
1		533	255	130
5		625	320	175
10		690	355	200
20		740	395	230
40		815	460	285
60		895	525	345

Notes:
1. The soil types are defined by a two-letter designation that indicates general soil classification, Sn for sands and gravels, Si for silts, and Cl for clays. Specific soil groups that fall into these categories, based on ASTM D 2487 and AASHTO M 145, are listed in Table D1.16.
2. The numerical suffix to the soil type indicates the compaction level of the soil as a percentage of maximum dry density determined in accordance with AASHTO T-99 (ASTM D698).
3. 1 MPa = 145 psi.

TABLE D1.16 Equivalent ASTM and AASHTO Soil Classifications

Basic Soil Type	ASTM D 2487	AASHTO M 145
Sn (Gravelly sand, SW)	SW, SP GW, GP	A1, A3
Si (Sandy silt, ML)	GM, SM, ML also GC and SC with less than 20% passing #200 sieve	A-2-4, A-2-5, A4
Cl (Silty clay, CL)	CL, MH, GC, SC also GC and SC with more than 20% passing #200 sieve	A-2-6, A-2-7, A5, A6

Note: The soil classification listed in parentheses is the type that was tested to develop the constrained soil modulus values in Table D1.15. The correlations to other soil types are approximate.

- Service deflections are controlled more by soil stiffness than by pipe flexural stiffness, which, among other things, means that quality of installation and nature of soil are often more important for controlling ultimate deflection than is pipe stiffness.

- The same pipe stiffness for two pipes does not mean that the pipes have an equivalent resistance to deformation by point loading such as can result from handling and installation (including compaction). Profile-wall pipe will respond differently to point loading than smooth-wall pipe, and even for a solid-wall pipe with the same DR, as pipe diameter increases the pipe's relative resistance to deformation under point loading also increases. This is because resistance to point loading is a result of longitudinal pipe stiffness as well as circumferential pipe stiffness.

To illustrate the last point, consider the example of two pipes, one NPS 6 (DN 150) and the other NPS 60 (DN 1500), each with a pipe stiffness of 60 lb/in/in (410 kN/m/m). A 60-lb load per in (10.5 kN/m) of pipe length applied to either of these two pipes produces the same decrease in vertical diameter, namely NPS 1 (DN 25). Clearly, this NPS 1 (DN 25) deformation is much more significant to the NPS 6 (DN 150) diameter pipe than to the NPS 60 (DN 1500) pipe. In recognition of this, certain larger-diameter standards categorize pipe in accordance with a *ring stiffness constant* (RSC). The RSC is defined as the parallel plate load in pounds per foot of pipe length, which causes a 1 percent reduction in diameter, when measured at 3 percent deflection. Essentially the same test, ASTM D 2412, as used to measure pipe stiffness, is used to measure RSC. The main difference is the form in which the results are expressed. Pipes with equal RSC values will undergo equal percent deflection under equal load. RSC is related to pipe properties by the following relationship:

$$\text{RSC} = 6.44 E I_{\text{ft}}/D^2 \qquad (D1.14)$$

where RSC = ring stiffness constant, lb/ft/percent (kN/m/percent)
D = diameter to centroid of pipe wall, in (m)
I_{ft} = pipe wall moment of inertia per unit length, in^4/ft (m^4/m)

The RSC concept is an adaptation of the *flexibility factor* (FF) which is used by the American Association of State Highway and Transportation Officials (AASHTO)[6] to classify the handling and installation flexibility of flexible conduits, including both thermoplastic and corrugated metal pipe and culvert:

$$FF = D_m^2/EI \tag{D1.15}$$

where FF = flexibility factor, in/lb (m/kN)

  D_m = mean diameter of pipe, in (mm)

The classification of larger-diameter thermoplastic pipe based on the handling and installation flexibility concept recognizes that the ultimate deformation of installed conduit is greatly influenced by the conduit's response to all the short-term loads experienced during handling, placement of bedding, compaction of backfill, and other installation operations. This generally means that as pipe diameter increases, less pipe stiffness (as measured by ASTM D 2412) is required for satisfactory handling and installation. However, after selecting a conduit of adequate wall stiffness based on handling and installation concerns, the designer still has to check for structural adequacy under the anticipated lifetime service loads.

Thermoplastic pipes and conduit for nonpressure buried applications are available in a broad range of wall stiffnesses. As discussed previously, the larger the pipe size, generally the lower the pipe stiffness. Up to about NPS 4 (DN 100) pipe, stiffness is generally above 50 lb/in/in (350 kN/m/m) and can be over 200 lb/in/in (1.4 kN/m/m). In the mid sizes, through about NPS 18 (DN 450), pipe stiffness ranges from about 30 to 60 lb/in/in (210 to 410 kN/m/m). Above this size, values tend to decrease, down to 8 lb/in/in (55 kN/m/m) for the largest sizes.

AASHTO recommends a maximum flexibility factor (FF) of 9.5×10^{-2} in/lb (0.054 m/kN) for both PVC and PE. This value was originally established for corrugated aluminum conduit. This is equivalent to an RSC of about 65 lb/ft/ percent (0.95 kN/m/percent) deflection. RSC's of commercially available larger sizes (NPS 18 through 96) (DN 450 through 2500) PE pipes range from 40 to 120 lb/ft/percent (0.6 to 1.8 kN/m/percent).

Pipe Hoop Stiffness.   The pipe hoop stiffness has not been given significant consideration in buried pipe design. Pipes manufactured from more traditional materials have very high values for the pipe hoop stiffness and thus, for these materials, the parameter does not have a substantial effect on overall pipe behavior. More recently it has been demonstrated that some thermoplastic pipes with low cross-sectional area and low elastic modulus have much lower values for the pipe hoop stiffness, and this can have a significant effect on the pipe performance.

A high value of the hoop stiffness parameter S_H indicates that the hoop compression strain in the pipe can result in significant (1 to 2 percent) shortening of the circumference of the pipe.

Design for Earth Loads

Under vertical earth loads, buried flexible conduits deflect downward vertically and outward horizontally, thereby mobilizing passive lateral soil support for the pipe, which in turn precludes significant further downward deflection. Thus the pipe and surrounding soil interact and behave as a structural system. In this system, pipe deflection is controlled more by soil stiffness than by pipe flexural stiffness, and the soil arching characteristics bear great influence on the system's load-carrying

capacity. Flexible pipe properly installed in stable soils can resist very substantial loads.

Since the pipe and the soil interact, design and installation of buried flexible pipe must always consider both the pipe and the soil around it. If a designer allows different pipes in a specification, the suitability of the backfill and installation specifications should be evaluated for each type of pipe.

One of the advantages of flexible pipe is that the quality of installation can readily be checked via a deflection test after installation is complete. A particular benefit of most thermoplastic pipe is its high strain capacity, which allows it to deform considerably and thereby generate further soil support. To take economic advantage of this benefit, many of the newer larger-diameter thermoplastic pipes are offered with relatively low wall stiffness, which requires that careful attention be given to proper design and installation in order to ensure durable and stable performance. Since the soil and the pipe must always work together to constitute a pipe-soil system, the designer has to consider both when evaluating alternate pipe materials.

Earth Loads on Buried Flexible Pipes. The load acting on a buried pipe consists of *dead load* and *surcharge load.* The dead load is the permanent load from the weight of soil and pavement above the pipe and sometimes, from any surcharge loads applied at the ground surface. Surcharge loads may, or may not, be permanent. Surface-applied wheel loads are called *live loads.*
FIGURE D1.16 Soil prism load.

Earth load is measured as the hoop thrust at the springline of the pipe, and is often characterized as a function of the *soil prism load,* which is the weight of earth directly over the pipe (Fig. D1.16). The weight of the soil prism is modified by the *vertical arching factor* (VAF) to represent the effects of pipe-soil interaction. This is expressed as:

$$W_{sp} = \gamma D_o(H + 0.11 D_O) \qquad (D1.16)$$

where W_{sp} = soil prism load, lb/ft (kN/m)
 γ = soil unit weight, lb/ft^3 (kN/m^3)
 D_o = outside diameter of pipe, ft(m)
 H = depth of fill over top of pipe, ft(m)

and

$$W_p = \text{VAF}(W_{sp}) \qquad (\text{D1.17})$$

where VAF = vertical arching factor
W_p = effective soil load, lb/ft (kN/m)

Flexible pipe are often designed with a vertical arching factor of 1.0 (for reference purposes, rigid pipe installed in embankment conditions are often designed for an arching factor of about 1.4). While VAF = 1.0 is considered conservative for flexible pipe, recent research[28,29] has shown that the VAF can be much lower for some thermoplastic pipe with low moduli of elasticity and low cross-sectional area.

Analysis of the Burns and Richard elasticity solution for buried pipe[30] indicates that the hoop stiffness parameter introduced in the previous subsection, is in fact the most important parameter in controlling the load on buried pipe. The Burns and Richard solution solves for two conditions at the interface between the buried pipe and the soil: (1) full slip—a condition where the interface is frictionless; and (2) no slip—a condition where the interface is fully bonded and shear stresses develop. The Burns and Richard equations for the buried pipe problem can be simplified and expressed in the form of the VAF without significant error as:

$$\text{VAF}_{FS} = 0.76 - 0.71(S_H - 0.7)/(S_H + 1.75) \qquad (\text{D1.18})$$

where VAF_{FS} = vertical arching factor for the full slip solution

and

$$\text{VAF}_{NS} = 1.06 - 0.96(S_H - 0.7)/(S_H + 1.75) \qquad (\text{D1.19})$$

where VAF_{NS} = vertical arching factor for the no-slip solution

The expressions for the VAFs are shown graphically in Fig. D1.17 When computing the VAFs for actual installations, the long-term modulus of elasticity can be used to compute S_H for long-term loads such as earth load, and the short-term modulus of elasticity can be used to compute S_H for short-term loads such as vehicle loads.

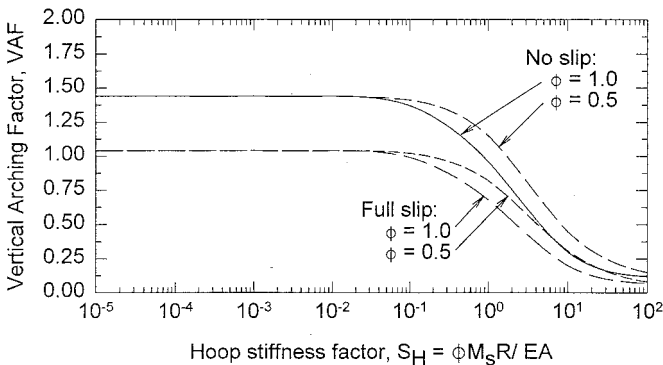
If the value of S_H is low, which is the case for most traditional pipe designs, then the no-slip VAF is a constant value of about 1.4, which is the traditional design value for rigid pipe, and the full-slip VAF is a constant value of about 1.0, which


FIGURE D1.17   Burns and Richard VAF and sensitivity to soil stiffness.

is the traditional design value for flexible pipe. No research has been completed to investigate the actual condition of interface shear for flexible and rigid pipe.

Also demonstrated in Fig. D1.17 is the sensitivity of the VAF to the soil stiffness. The lines labeled "$\phi = 0.5$" represent a reduction of soil stiffness of 50%, relative to the line labeled "$\phi = 1.0$". This indicates that on the steep portion of the curve a loss of 50% of the soil stiffness causes a reduction of about 0.2 in the VAF. A reduction of soil stiffness of 50% is often associated with a reduction in density of about 5% standard Proctor density.

While the described analysis has not yet been adopted into any standards, the theory of elasticity solution of Burns and Richard[23] and field research[28,29] are consistent and suggest that the approach could be used for special installations, such as unusually deep fills. Alternatively, in 1930 Marston published a solution for determining the loads on a buried flexible pipe that is still in use today (ASCE Manual of Practice No. 60[31]). This solution assumes some of the backfill load is carried by the flexible pipe; some is carried by the trench walls; and some by the backfill at the sides of the pipe. Thus in narrow trench installations, the load is substantially less than the soil prism load. This is consistent with trench load theory for rigid pipe.

Surcharge, as well as traffic, railway, aircraft, and other live loads are generally estimated using the same methods and equations employed for other conduits, such as presented in ASCE Manual No. 60[31] and in AASHTO Specifications.[6]

When subjected to the calculated hoop compression forces, a pipe must meet the following criteria:

- *Wall Thrust.* The wall stress due to the hoop compression forces must be less than the limiting strength of the material. Little research has been done on the limiting strength of the plastics materials that are used for buried pipe, and the tension strength is often used as a limiting criteria. AASHTO[6] provides suggested limiting stresses for this purpose. Short-term strength should be used for evaluating short-term load conditions, and long-term strength should be used for evaluating long-term load conditions.

- *General Buckling.* If the hoop compression forces are sufficiently high, the pipe can buckle. This is a function of the pipe flexural stiffness and the soil stiffness. The expression most often used to evaluate this condition[5,6,32] is:

$$N = (1/\text{FS})\, D_o [32 R_w B' E' (EI/D_m^3)]^{0.5} \tag{D1.20}$$

where N = allowable wall thrust, lb/in (kN/m)

$\quad$ FS = factor of safety, often taken as 2.5 to 3.0

$\quad D_m$ = mean diameter of pipe, in (m)

$\quad R_w$ = coefficient for depth of groundwater above top of pipe

$$= 1 - 0.33(H_w/H) \tag{D1.21}$$

$\quad H_w$ = depth of groundwater above top of pipe ($<H$), ft(m)

$\quad H$ = depth of earth cover over top of pipe, ft (m)

$\quad B'$ = coefficient for uniformity of pipe support

$$= 1/(1 + e^{-0.065H})\, [H \text{ in ft}] \tag{D1.22}$$

$\quad E'$ = modulus of soil reaction, psi (MPa)

$\quad E$ and I are as previously defined.

Note that the constrained soil modulus M_s may be used as a direct substitute for the modulus of soil reaction, E'. For trench installations, a method of computing a "composite" value of E' that considers the stiffness of both the backfill soil

and the native soil in the trench wall is presented in AWWA Manual of Practice M45.[32] This is based on the work of Leonhardt.[33,34] This buckling theory was developed based on buckling of a tube supported at discreet locations by a tube. More recently a buckling theory has been proposed based on a continuously supported ring, which more accurately reflects the condition of a buried pipe.[35] This theory is now being reviewed in the scientific community.

- *Local Buckling of Profile Pipe Wall Cross Sections.* Pipe with corrugated cross sections or other profile configurations must be able to carry the hoop compression stresses without local buckling of the thin elements. There are no currently available criteria for evaluating this condition that have consensus support at this time. Successful experience is the best current guide.

Deflection of Flexible Pipe Under Earth Load. As noted, buried flexible pipes deflect (decrease vertical diameter and increase the horizontal diameter) when subjected to earth, live, and surcharge loads. The installation conditions must be designed to assure that the ultimately achieved deflections are within acceptable limits. This will preserve the serviceability of the pipeline and assure that material stress or strain limits are not exceeded. Generally, deflection limits for flexible pipe are limited to between 7.5 and 10 percent decrease in the vertical diameter.

One of the better-known relationships, sometimes called the *Iowa formula,* was developed for flexible metal conduits at Iowa State University.[36,37] A modification of this equation is as follows:

$$\Delta v = D_l K W_{SP}/(EI/R^3 + 0.061E') \tag{D1.23}$$

where Δv = change in vertical diameter, in (m)
D_l = deflection lag factor to account for time effects (typically taken between 1 and 1.5)
K = bedding factor (0.083 to 0.110)
W_{SP} = soil prism load, lb/in (MN/m)
EI/R^3 = pipe flexural stiffness, psi (MPa)
E' = modulus of soil reaction, psi (MPa)

The deflection lag factor accounts for change in load with time and is typically taken at a value of 1 to 1.5. The bedding factor accounts for the width of the bedding support and can vary from 0.083 to 0.110.

The modulus of soil reaction E' is an empirical measure of the stiffness of the soil in resisting pipe deflection and must be obtained empirically by back-calculating it from measured pipe deflections. The most extensive field study to determine E' was conducted by A. Howard of the U.S. Bureau of Reclamation.[26] In this study, data were collected from 113 field installations on different types of flexible pipe buried up to 50 ft (15 m) deep. For this work Howard assumed a prism load, $K = 0.1$, and $D_l = 1.0$; and, in the case of plastic pipes he computed the term EI/R^3 based on the material's short-term apparent modulus. The resultant back-calculated values of E' are tabulated in Table D1.17 in accordance with soil type. This table also identifies soils by the classification system of ASTM D 2321, "Standard Practice for Underground Installation of Thermoplastic Pipe for Sewers and Other Gravity-Flow Applications."

While E' is not a true soil property that can be evaluated by laboratory tests, recent work suggests that the constrained modulus of elasticity, M_s (see earlier discussion) may be directly substituted for E' in the Iowa formula.[23] Making this substitution and rearranging terms shows that the Iowa formula can also be written in terms of the bending stiffness parameter, S_B:

$$\Delta v = D_l K (W_{SP}/M_s)/(S_B + 0.061) \tag{D1.24}$$

TABLE D1.17 Bureau of Reclamation Recommendations for $E'^{(26)}$

Backfill type (ASTM D2487)	E' for degree of compaction of bedding, psi[3]			
	Dumped	Slight <85% Proctor <40% relative density	Moderate 85–95% Proctor 40–70% relative density	High >95% Proctor >70% relative density
Fine-grained soils (liquid limit > 50) CH, MH, CH-MH	No data available; consult a competent soils engineer; otherwise, use $E' = 0$			
Fine-grained soils (liquid limit < 50) CL, ML, ML-CL, with less than 25% coarse-grained particles	50	200	400	1,000
Fine-grained soils (liquid limit < 50) CL, ML, ML-CL, with more than 25% coarse-grained particles *Coarse-grained soils with fines*, GM, GC, SM, SC[1] with more than 12% fines	100	400	1,000	2,000
Coarse-grained soils with little or no fines GW, GP, SW, SP with less than 12% fines	200	1,000	2,000	3,000
Crushed Rock	1,000	3,000		
Accuracy in terms of percent deflection[2]	±2%	±2%	+1%	±0.5%

[1] Or any borderline soil beginning with one of these symbols (i.e., GM-GC, GC-SC).
[2] For ±1% accuracy and predicted deflection of 3%, actual deflection would be between 2% and 4%.
[3] 1 MPa = 145 psi
Notes:
A. Values applicable only for fills less than 50 ft (15 m).
B. Table does not include any safety factor.
C. For use in predicting initial deflections only; appropriate deflection lag factor must be applied for long-term deflections.
D. If bedding falls on the borderline between two compaction categories, select lower E' value or average the two values.
E. Percent Proctor based on laboratory maximum dry density from ASTM D-698.

This expression of the Iowa formula clearly shows that deflection is controlled by the soil stiffness far more than by the pipe stiffness. Designers should understand that design of buried pipe installations is actually more a design of the backfill and installation procedures than of the pipe. The significance of this is that the installation process is critical to proper performance.

Another significant aspect of Eq. (D1.24) is that the deflection will not go to infinity even if the pipe stiffness goes to zero. The apparent implication that pipe stiffness is insignificant to controlling deflection and overall pipe performance is not correct for two reasons:

- The pipe stiffness not only contributes to deflection control as predicted in the Iowa formula; it also controls the variability of deflection (i.e., the standard deviation) which is relatively independent of the average deflection predicted by the Iowa formula. NCHRP Report 225[38] demonstrated this for a wide range of pipe stiffnesses. Deflection variability is also a function of the compaction effort required to densify a soil. Variability will be reduced with backfill materials that densify easily, such as crushed stone and coarse gravel, and increased for soils that are moisture sensitive and require increased compaction effort to reach adequate density, such as silts and fine sands.

- If the pipe stiffness is too low, the buckling criterion noted above will control the design.

Various other methods have been proposed for estimating deflection, for example by Watkins,[39] Gaube,[40] and Brown and Lytton.[41] Recently, more precise approaches to forecasting deflection have been made possible by the application of computer-run finite element analysis programs that utilize soil models that incorporate true nonlinear soil behavior.[42]

Longitudinal Effects.   In pressure pipe, changes in direction such as elbows and tees-result in longitudinal forces in the pipeline. These can be controlled by the use of thrust blocks, which result in minimal longitudinal stresses, or with restrained joints, which can develop significant longitudinal forces in the pipe. Most pressure pipe has adequate longitudinal capacity for this loading. Buried pipe is not specifically designed for longitudinal stresses due to uneven bedding. Uniform support due to proper installation is relied upon to avoid this condition.

INSTALLATION

Concurrent with the development of structural design methods for thermoplastics, installation practices dedicated to these materials have also been developed. Noteworthy among these are ASTM D 2774, "Underground Installation of Thermoplastic Pressure Piping," ASTM D 2321, "Underground Installation of Thermoplastic Pipe for Sewers and Other Gravity-Flow Applications," and ASTM F 1668 "Construction Procedures for Buried Plastic Pipe."

A commentary on the installation issues that are critical to the long-term performance of flexible nonpressure plastics pipe has been offered by T. J. McGrath.[31] Howard has published a book devoted to pipe installation issues.[27] Installation as well as design recommendations are also issued by various professional and trade associations. A number of these references are identified in the following section.

A significant development in pipe installation practice is the use of *controlled*

low-strength materials (CLSM, also known as *flowable fill*) for pipe backfill. CLSM is a mixture of sand, cement, fly ash, and water with excellent flow characteristics such that vibration is not required to place it around and under a pipe or other obstructions in a trench. Strengths are low, sometimes as low as 35 psi (240 kPa) at 28 days, in order to assure that the material can be excavated in the event that an encased utility requires a repair. In 1997 ASTM held a three-day symposium on the subject of CLSM, with many papers devoted to its use around pipes.[43] One benefit of CLSM is that shrinkage is minimal after placement; thus, if used to backfill an entire trench the settlement and pavement damage that often occurs with soil backfill can be avoided.

Pipe installation can be difficult if ground conditions are poor, and it is also expensive to provide full-time inspection of pipe-laying crews. Therefore, a key step in quality control of pipe installations is to check the pipe deflection levels after the installation is complete. This should be a standard part of all pipe installation specifications.

SOURCES OF ADDITIONAL INFORMATION

On New Developments

The inroads that thermoplastics piping has made in fuel gas distribution, sewer, water, agricultural, and highway drainage, and in various industrial uses has generated many studies regarding the durability and engineering performance of these materials. Topics of particular recent interest relate to the use of these materials for larger-diameter applications for which certain limits of performance, such as maximum depth of burial, buckling resistance, and compressive wall strength are often design limiting. A reader interested in these topics, as well as in the general state of the art, should consult the proceedings of the following periodically held symposia and conferences:

Proceedings of International Conferences on Pipeline Design and Installation, American Society of Civil Engineers, 345 East 47th Street, New York, NY 10017.

Proceedings of the Symposium on Buried Plastic Pipe Technology, American Society for Testing & Materials, 100 Bar Harbor Drive, West Conshohocken, PA 19428.

Proceedings of the Fuel Gas Plastic Pipe Symposium, American Gas Association, 1515 Wilson Boulevard, Arlington, VA 22209.

Proceedings of the National Conference on Flexible Pipes, Center for Geotechnical and Groundwater Research, Ohio University, Athens, OH 45701.

Proceedings of the International Conferences on Plastics Pipe, Plastics and Rubber Institute, 11 Hobart Place, London, England SW1W OHL.

Publications Related to Standards

The following publications contain much information that is useful for all applications of plastics piping, particularly with respect to design and installation:

ASME Guide for Gas Transmission and Distribution Piping Systems. Available

from American Society of Mechanical Engineers, United Engineering Center, 345 East 47th Street, New York, NY 10017, (212) 705-7722.

AGA Plastic Pipe Manual for Gas Service. Available from American Gas Association, 1515 Wilson Boulevard, Arlington, VA 22209, (703) 841-8454.

Maintenance of Operation of Gas Systems, November, 1970, Army TM5–654; NAVFAC-MO–220; Air Force AFM 91–6. Available from Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402.

Associations

Various trade and technical associations issue reports, manuals, and lists of references on properties, design, and installation of plastics piping. A listing of current literature offerings may be obtained by contacting these organizations at the following addresses:

Thermoplastic pipe (industrial gas distribution, sewerage, water, and general uses): The Plastics Pipe Institute, 1825 Connecticut Ave., N.W., Suite 680, Washington, DC 20009.

Thermoplastics pipe (plumbing applications): Plastics Pipe & Fittings Association, 800 Roosevelt Road, Building C, Suite 20, Glen Ellyn, IL 60137.

PVC piping (water distribution, sewerage, and irrigation): Uni-Bell PVC Pipe Association, 2655 Villa Creek Drive, Suite 155, Dallas, TX 75234.

''No-Dig'' methods for the rehabilitation of existing buried pipelines: North American Society for Trenchless Technology, 435 North Michigan Avenue, Suite 1717 Chicago, IL 60611.

Codes

Thermoplastics piping for plumbing, heating, cooling and ventilating, sewer, water, fire protection, gas distribution, and other hazardous materials may be subject to the provisions of a code or other regulation. Nearly all plumbing codes allow plastics piping for certain applications. The major model building and plumbing codes from which most such codes are derived are issued by the following organizations:

BOCA: National Building Code, BOCA National Mechanical Code, and BOCA National Plumbing Code. Building Officials and Code Administrators, International, Inc., 4051 West Flossmoor Road, Country Club Hills, IL 60478.

CABO: One and Two Family Dwelling Code. Council of American Building Officials, 5203 Leesburg Pike, Falls Church, VA 22041.

IAPMO: Uniform Plumbing Code. International Association of Building and Mechanical Officials, 20001 Walnut Drive South, Walnut, CA 91789–2855.

ICBO: Uniform Building Code and Uniform Mechanical Code. International Conference of Building Officials, 5360 South Workman Mill Road, Whittier, CA 90601.

PHCC: National Standard Plumbing Code. National Association of PlumbingHeating-Cooling Contractors, P.O. Box 6808, Falls Church, VA 22040.

SBCI: SBCCI Southern Building Code, SBCCI Southern Standard Plumbing Code, and SBCCI Southern Standard Mechanical Code. Southern Building Code Congress International, 900 Montclair Road, Birmingham, AL 35213.

Plastics piping for other applications may also be covered by other codes, such as the following:

American National Standards Institute

ANSI B31.3 Chemical Plant and Petroleum Refinery Piping. Thermoplastic Piping

ANSI B31.8 Gas Transmission and Distribution Piping Systems. ANSI Z223, National Fuel Gas Code.

Department of Transportation, Hazardous Materials Board, Office of Pipeline Safety Operations

Code of Federal Regulations (CFR), Title 49, Part 192. Transportation of Natural Gas and Other Gas by Pipeline: Minimum Federal Safety Standards.

Code of Federal Regulations (CFR), Title 49, Part 195. Transportation of Liquids by Pipeline, Minimum Federal Safety Standards.

The National Fire Protection Association (Quincy, MA) Model Codes

NFPA 30 Flammable and Combustible Liquids Codes.

NFPA 54 National Fuel Gas Code.

NFPA 70 National Electrical Code.*

NFPA 70A Electrical Code for One and Two Family Dwellings.

NFPA 34 Outdoor Piping.

NFPA 13D, Standard for the Installation of Sprinkler Systems in One and Two Family Dwellings and Manufactured Homes.

Some standards and various jurisdictions and authorities require that before a pipe may be used for certain applications, it first must be approved for that use by a recognized, or specifically designated, organization. Organizations and approval programs for plastic pipe include the following:

For potable water:

NSF International, NSF Building, Post Office Box 1468, Ann Arbor, MI 48106.

Canadian Standards Association, 178 Rexdale Boulevard, Rexdale, Ontario, Canada, M9W 1R3

For drain, waste, and vent:

NSF International and Canadian Standards Association (see above).

For meat- and food-processing plants:

U.S. Department of Agriculture, 14th and Independence S.W., Room 0717 South, Washington, DC 20250.

---

* National Electrical Code is a registered trademark of the National Fire Protection Association, Quincy, MA 02269.

For fire protection systems, including fire sprinklers:

Underwriters Laboratories Inc., 333 Pfingsten Road, Northbrook, IL 60062.

Factory Mutual Research Corporation, 1151 Boston-Providence Turnpike, Post Office Box 688, Norwood, MA 02062.

For underground gasoline and petroleum lines:

Underwriters Laboratories Inc. (see above).

For water pipe:

American Water Works Association, Denver, CO.

CHAPTER D2
FIBERGLASS PIPING SYSTEMS

Carl E. Martin

Fibercast Company
Sand Springs, Oklahoma

Fiberglass reinforced plastic (FRP) piping systems have been successfully used for over fifty years in applications requiring the corrosion resistance of plastics and the strength of metallic systems. FRP piping is readily available in a wide range of types, sizes, and wall thicknesses to meet numerous design requirements. The knowledgeable piping designer can design a successful project by using established standards and criteria. This chapter is intended to provide insight into the standards and criteria available for both aboveground and underground fiberglass piping systems.

TYPICAL APPLICATIONS

Fiberglass piping is used in most industries requiring corrosion-resistant pipe. FRP is used in vent and liquid applications which operate from −40° to 300° F (−40° to 149°C). Fiberglass piping can be constructed of resin which is resistant to acids, caustics or solvents. Abrasion-resistant materials can be added to the FRP piping inside diameter liner and outside cover for excellent slurry wear resistance. Fiberglass pipe is readily available in ½ through 144 inch sizes (DN15 through 3600). Table D2.1 is a brief list of the many applications and industries where fiberglass pipe has been used successfully.

TABLE D2.1 Typical Fiberglass Pipe Applications by Industry

Applications	Industry

STANDARDS

The American Society for Testing and Materials (ASTM), American Petroleum Institute (API), British Standard (BS), Deutsche Norm (DIN), and International Organization for Standardization (ISO) publish fiberglass pipe and fittings test methods (see Table D2.2) and standard product specifications (see Table D2.3). The American Society of Mechanical Engineers (ASME) and British Standard publish pressure piping codes (see Table D2.4). Quality fiberglass pipe manufacturers produce products to one or more applicable standards.

RESINS

The resin used in the manufacture of fiberglass pipe, fittings, and adhesives provides for the corrosion resistance of the system. The resin is also used to bond the reinforcing glass together. The glass along with the resin in FRP piping provides for the physical properties of the composite structure. As with the metals used to make pipe, each resin system used in the manufacture of fiberglass pipe has particular strengths and weaknesses.

Custom fiberglass equipment and fiberglass pipe larger than NPS16 (DN 400) are generally made from polyester or vinyl ester resins because of the ease of handling large quantities of this type of resin. Some small-diameter pipe is made from polyester or vinyl ester resins, but most NPS 1 through 16 (DN 25 through 400) pipe are manufactured from epoxy resin systems which are easier to handle in mass-production processes. For special corrosion- or flame-resistant applications outside the capabilities of polyester, vinyl ester, or epoxy resins, pipe made from furan resins or phenolic resins is available.

Epoxy Resins

The chemical resistance and physical properties of an epoxy resin system depend upon both components of the system: the *basic resin* and the *curing or cross-linking agent*. Two general types of epoxy resins are in common usage today: *bisphenol-A epoxies* and *epoxy novolacs*. The bisphenol epoxies are much more widely used because they are more economical and easier to handle during fabrication. The epoxy novolacs are employed where increased temperature resistance and/or better solvent resistance are required. Both types of epoxies can be cured with a great variety of curing agents, and the choice of curing agent has much influence on the properties of the final product. The two most common resin systems used in the

manufacture of epoxy fiberglass pipe are bisphenol epoxies cured with aromatic amines and bisphenol epoxies cured with aromatic anhydrides.

In the NPS 1- through 16 (DN 25 through 400) range, bisphenol epoxies cured with aromatic amines produce pipe with the balance of physical, chemical, and economic properties that is needed for most fiberglass piping applications. Pipe made from these resin systems has an upper temperature limit of 250°F (121°C) and is resistant to salt solutions and rather severe alkaline and solvent exposures. Dilute acids are also handled with this type of pipe. If increase solvent resistance is required, an epoxy novolac resin system is recommended.

In the NPS 2- through 16 (DN 50 through 400) range, bisphenol epoxies cured with aromatic anhydrides are used to manufacture pipe for use in oil field and water handling applications where the chemical resistance of an aromatic amine cured epoxy resin is not required. When used within the temperature and chemical limits of the resin system, these pipes give excellent service. These pipes have an upper temperature limit of approximately 150°F (66°C) and are less chemical resistant than pipe made from aromatic amine cured epoxy resin systems. Anhydride-cured resin systems have no resistance to alkaline solutions and are rapidly attacked by water at temperatures above the rated temperature.

Neither of these epoxy resin systems is resistant to strong mineral acids or strong oxidizers.

Polyester Resins

The chemical resistance and physical properties of commercially available polyesters and vinyl esters—a special class of chemical-resistant polyesters—are uniform for a given resin because all of these resins are cured using styrene as the cross-linking agent. When one knows of a successful application of particular polyester or vinyl ester resin, one need not be concerned about the curing agent. During the manufacture of fiberglass pipe, an *initiator* or *catalyst* is added to the styrene-polyester mixture to cause the two components to react and solidify. In almost all chemical services the choice of initiator system is of no consequence. However, the choice of initiator system has been found to affect the chemical resistance of fiberglass pipe in some extremely aggressive chemical services such as hot, wet chlorine, or sodium hypochlorite.

Fiberglass pipe are generally manufactured from any of four types of chemical-resistant polyester resins: vinyl esters and isophthalic, chlorendic, and bisphenol-A fumarate polyesters. Each particular resin has different chemical, physical, and economic properties, and the choice of resin is critical.

Vinyl Ester Resins. Until the development of vinyl ester resins, it was not practical to mass produce small-diameter polyester pipe. Now, however, NPS 1 through 16 (DN 25-400) pipe manufactured from vinyl ester resins is commercially available from several manufacturers. Pipe made from these resins has good physical strength and, in general, better impact strength than other chemical-resistant polyesters. These resins have excellent resistance to oxidizers and strong mineral acids and good resistance to alkaline environments. Standard vinyl esters are limited to 200° to 225°F (93 to 107°C) in most applications, while more costly high-performance vinyl esters are suitable for general use up to 250°F (121°C), and in some special applications have been used in temperatures as high as 350°F (177°C).

Bisphenol-A Fumarate Polyester Resins. The bisphenol-A fumarate polyester is the original high-volume, commercially available, chemical-resistant polyester resin.

This type of resin has been produced for over 35 years and, until the advent of vinyl ester resins, was the resin most widely used in the manufacture of chemical-resistant fiberglass products. The chemical resistance of this type of resin is roughly equivalent to that of vinyl ester resins at temperatures up to 250°F (121°C), but bisphenol-A fumarate resins are more rigid than vinyl esters, and this makes them unsuitable for the manufacture of small-diameter pipe on mass-production equipment. The rigidity of this resin is the major reason for its displacement by vinyl esters from its former position as the most widely used chemical-resistant resin. In large-diameter pipe and large reaction vessels, resin rigidity is not a disadvantage, and this resin is still used in the manufacture of this type equipment, especially when it is to be used in services where this resin has proven successful in past applications.

Chlorendic Polyester Resins. The chlorendic polyester resins have a chlorinated backbone in their molecular structure which makes them particularly well-suited for elevated-temperature applications, up to 350°F (177°C). In most resin classifications there is an increase in rigidity when chemical structure changes are made to give increased temperature performance to the resin. Chlorendic resins follow this general rule and are more rigid than bisphenol-A fumarate resins. The molecular structure of chlorendic resins gives them excellent resistance to concentrated mineral acid and highly oxidizing environments, but poor resistance to alkaline solutions. The solvent resistance of these resins is very good when compared to other polyesters.

Isophthalic Polyester Resins. The isophthalic polyesters are the least expensive and least chemical resistant of the corrosion-resistant polyester resins. For service temperatures up to 180°F (82°C), these resins generally have good resistance to water, dilute acids, and very weak alkaline solutions, and good resistance to petroleum solvents such as gasoline and oil. There are many grades of isophthalic polyester resins. It is important to choose an isophthalic polyester which is compatible with the service being handled.

Other Resins

Furan resins are difficult to work with, and this presently limits their application to systems which require the unique blend of superior acid, alkali, and solvent resistance at temperatures up to 300°F (149°C) offered by these resins. However, furan resins are not suitable for handing oxidizing services.

Phenolic resins also require special processing techniques which limit their economical application to systems that require superior acid and solvent resistance at temperatures to 300°F (149°C). Phenolic resins are often used in flame-resistant duct applications.

MANUFACTURING PROCESSES

Hand Layup

Hand layup or *contact molding* is the simplest method used to make fiberglass pipe and fittings. The part is made over a male mold which forms the inside diameter of the piping component. Glass veil or synthetic nexus is saturated with resin, then

applied to the mold, creating a 10 to 20 mil (0.25 to 0.50 mm) thick resin-rich inner surface for the part. This inner liner contains about 90 percent resin and is very corrosion resistant and somewhat abrasion resistant. Most hand layup pipes and fittings have from 50 to 250 mil (1.3 to 6.4 mm) thick corrosion barriers. The corrosion barrier is created by saturating fiberglass mat with resin and then applying it over the resin-rich inner surface. The mat layers contain about 60 percent resin. The corrosion barrier or liner thickness is the total thickness of the veil, nexus, and mat layers. The structural strength of the piping component is created in the reinforced wall of the part. The reinforcement is created by saturating mat or alternating layers of mat and woven roving with resin and applying to the outer surfaces of the corrosion barrier. The number of layers and type of reinforcing glass used depends on the strength requirements for the part. A corrosion barrier can be applied to the outer surface of the part for applications requiring corrosion or abrasion-resistance on the outside diameter.

Hand layup pipe and fittings are typically used in severe or critical applications. As the name implies, hand layup parts are made using manual operations and are usually more expensive than machine-made fiberglass parts. Hand layup parts used for severe and critical applications are also made with up to 10:1 safety factors, which also adds to cost. Hand layup piping is usually provided with plain ends and is joined using butt and wrap joints.

Filament Winding

Filament-wound fiberglass pipe and fittings are machine-made products made on a rotating male mold. The mold forms the inside diameter of the part. Filament-wound parts are made with or without resin-rich interior corrosion barriers. Corrosion barriers are made the same as with the hand layup process but may be applied by hand or by the machine. The reinforced wall for filament-wound pipe and fittings is made by drawing glass roving through a resin bath or with a resin-impregnated tape. The resin-saturated roving or tape is placed on the outside of the corrosion barrier by a fiber placement head (see Figure D2.1a). The fiber placement head
FIGURE D2.1a   The filament winding process.
FIGURE D2.1b   Continuous filament winding process.

travels in relation to the rotating mold to properly position the reinforcement on the part. The roving or tape-on filament-wound pipe is usually placed on the part at a helical angle. This angle is normally optimized for maximum internal pressure ratings but may be changed for improved pipe stiffness, axial strength, or unsupported span spacing. The number of layers of reinforcement used on filament wound parts is determined by the strength requirements for the part. A barrier can be added to the exterior of filament-wound products for corrosion or abrasion protection.

Another manufacturing process, known as the *continuous filament winding process,* is used for some fiberglass piping products. The advantages of this process are that the pipe is produced continuously and glass angles can be changed to optimize strength (see Fig. D2.1b). The longitudinal glass heads rotate around the tube passing through the center, which is also rotating. Changing one or both speeds of rotation and the rate at which the tube is travelling will change the angle at which the glass is applied. Typically, the goal is to apply the glass nearly longitudinally as this best utilizes the high tensile strength of the glass. The circumferential glass is applied at fixed stations with an application angle of approximately 87°. Glass applied circumferentially will optimize the hoop strength of the pipe as, again, the high tensile strength of the glass is best utilized. The number of longitudinal and circumferential layers can be changed as well to produce a product which has high hoop strength, with more circumferential layers, or longitudinal strength, with more longitudinal layers.

Filament-wound pipe and fittings are used in a broad range of applications. Filament-wound pipe is available with thin walls suitable for light duty applications through very heavy walls suitable for severe or critical applications. The installed cost of filament-wound pipe and fittings can be competitively priced against many metallic and thermoplastic piping systems required in difficult piping applications. Filament-wound pipe and fittings are available with the complete range of joining methods.
FIGURE D2.2 The centrifugal casting process.

Centrifugal Casting

Centrifugal casting is used to make both glass-fiber-reinforced thermosetting resin pipe and glass-fiber-reinforced plastic mortar pipe. Centrifugal casting is not used to make fiberglass fittings. In the centrifugal casting process the pipe is made inside a steel mold tube which can be rotated at high speeds, creating significant centrifugal force (see Fig. D2.2), Glass-fiber-reinforced thermosetting resin pipe is made by first positioning fiberglass fabrics in the mold tube. The mold is then rotated while a controlled amount of resin is injected into the tube. The very high centrifugal forces of the spinning tube drive the resin through the glass fibers and displace any air in the fibers. Excess resin is injected into the tube which forms a pure resin corrosion and abrasion barrier on the pipe inside diameter. The mold is heated, which aids in the cure of the pipe. A corrosion barrier can be added to the outer surface of the pipe if required for the application.

Centrifugal cast glass-fiber-reinforced thermosetting resin pipe is used in a broad range of applications. It is available with medium walls suitable for moderate applications to heavy walls suitable for severe or critical applications. The installed cost of centrifugal cast pipe can be competitively priced against many metallic and thermosetting piping systems required in difficult piping applications. Centrifugally cast glass-fiber-reinforced thermosetting resin pipe is typically joined with straight socket adhesive, flanged, butt and wrap, threaded, or mechanical joints.

Centrifugal cast glass-fiber-reinforced plastic mortar pipe is made by dispensing a silica and resin mortar mix into a rotating mold tube. The mortar mix creates the reinforced wall of the pipe. The corrosion liner is created by dispensing a mixture of chopped glass and resin into the inside diameter of the resin mortar mix.

Centrifugal cast glass fiber reinforced plastic mortar pipe is used mainly in buried applications but can be used above grade. Mortar pipe has excellent hoop and axial compressive strength, which makes it ideal for tunneling applications. Centrifugal cast glass-fiber-reinforced plastic mortar pipe is typically joined with mechanical joints. Flanged and butt and wrap joints are also available.

Press Molded

Press molding is used to make fittings but not pipe. In this process a mixture of resin, chopped glass, and fillers, called *premix,* is placed in matched metal mold.

The mold is usually closed by a hydraulic press which forces the premix to take the shape of the mold. The mold is heated to accelerate the cure of the part.

Since press molding of fittings is highly automated, press-molded fittings are usually lower in cost than fittings made by other methods. Press-molded fittings can be very corrosion-resistant but typically have heavy walls to achieve desired physical strength. Press-molded fittings are available with bell and spigot, straight socket, and flanged joints.

Resin Transfer Molding

Resin transfer molding is used to make fiberglass fittings only. Resin transfer molded fittings are made by placing glass, veil, and nexus into a mold. After the mold is closed, resin is injected into the mold and cured. Resin transfer molding applications include the outer shell for double contained fiberglass piping systems.

Mitered

Special, low-volume, and large-diameter fiberglass fittings are often made from mitered pipe. The mitered pipe is joined with a butt and wrap joint to form the fitting. Mitered fittings are typically provided with plain ends for butt and wrap joints.

JOINING SYSTEMS

Fiberglass piping is available with a wide range of joining systems to fit the particular application. Available are bell and spigot joints, straight-socket joints, flanged joints, butt wrap joints (also known as butt and strap joints), O-ring joints, bell and spigot joints, threaded joints, and mechanical joints. See Fig. D2.3.

Bell and Spigot Joint

Tapered bell and spigot joints are available in all sizes of fiberglass piping. They include a matched taper for an interference fit which gives a very high strength, thin glue line. The joints are adhesively bonded, usually with a two-part adhesive which is supplied by the piping manufacturer. Tapered bell and spigot joints are used in both low- and high-pressure applications. These joints are typically stronger in pressure and axial tensile capability than the pipe being joined. Bell and spigot joints do require field tapering of joints which are used in less than full length. Specialized field tapering tools are available from the pipe manufacturers. A special type of threaded and bonded tapered bell and spigot joint is also available. The threads in the tapered interference joint are used to hold the joint together during the cure time. This type of joint is claimed to be highly reliable.

Straight-Socket Adhesive Joints

Straight-socket adhesive joints are available (in sizes from NPS 1 through 16 (DN 25 through 400). Some manufacturers limit these joints to NPS 14 (DN 350). The

FIGURE D2.3 Fiberglass pipe joining systems.

socket in the fitting is essentially straight but may include a slight taper for centering purposes. This type of joint is adhesively bonded. A land in the bottom of each fitting used in this type of piping system ensures accurate laying lengths and close-tolerance piping. Adhesively bonded straight-socket joints are typically stronger in pressure and axial tensile capabilities than the fittings in the piping system.

Flanged Joint

Flanged joints are available in all fiberglass pipe sizes. The flanges are available with industry standard bolt patterns such as ANSI, DIN, ISO, or JSI bolt patterns. Flanges are typically used to connect to other piping systems and equipment or for piping systems which must be opened for inspection or cleaning. Fiberglass flanges are also available in vanstone style.

Butt and Wrap Joint

Butt and wrap joints are available in all sizes of fiberglass piping. Butt and wrap joints are used almost exclusively in hand lay-up piping systems or in filament-wound piping systems larger than NPS 14 (DN 350) or NPS 16 (DN 400), depending upon manufacturer. A butt and wrap joint is used to join two pieces of plain-end pipe or a pipe and fitting. The joint is made by first placing a corrosion barrier, similar to the corrosion barrier used in the pipe and fittings, on the interior or exterior of the pipe. After the corrosion barrier is formed, the mechanical strength of the system is ensured by using saturated reinforcement which is laid up out of mat and woven roving.

O-Ring Bell and Spigot Joint

O-ring bell and spigot joints are available in NPS 14 (DN 350) and larger sizes of filament-wound pipe and all sizes of polymer concrete pipe. O-ring and bell and spigot joints do require restraining the pipe from axial loads, therefore, it is used mostly for buried pipe. O-ring bell and spigot joints are quick and easy to install, but there is a limited availability of fittings in this style of joint.

Threaded Joint

Threaded joints are available in API eight round and ten round EUE (External Upset) and NPT (Nominal Pipe Taper) threads. The EUE threads are available in 1½ through 7 in nominal sizes and are mainly used for high-pressure line pipe and downhole tubing. The 8 round and 10 round threads conform to API standard B. Fittings are available with the EUE threads for couplings, flanges, elbows, tees, crosses, plugs, and adapters only. NPT threads are typically available in NPS 1 to 6 (DN 25 to 150) sizes. Pressure is limited to 450 psi (3105 kPa) depending on the pipe size. Threaded adaptors for NPT threads are readily available. There are also special coarse threads available on some fiberglass piping systems for quick makeup.

Mechanical Joint

Mechanical joints using O-rings for sealing purposes are available in NPS 2 (DN 50) through NPS 36 (DN 900). One type of mechanical joint uses a retainer pin made of either metal cable or thermoplastic rod to retain the axial loads. Also available are mechanical joints which use coarse threads to retain the axial loads. The mechanical joint with threads is fully reusable.

RESISTANT PROPERTIES

Chemical Resistance

The chemical resistance and life expectancy of fiberglass piping systems is dependent on many factors including type of resin, curing agent, liner material, liner thickness, fillers, and cure profiles. When assessing the suitability of a system, the chemical resistance of the pipe, fittings, and joining materials must be considered. With all of the above variables to consider, the piping manufacturer should be contacted for recommendations for specific applications. The piping manufacturer will need to have the following information for their evaluation.

- Chemicals and concentrations
- Temperatures, operating and upset
- Frequency of use
- Other factors which may determine suitability for use:

  Spills or upsets

  Low or static flow in dilute solvent lines

  Mixing of chemicals which may react in the line

  Steam cleaning

  Abrasives

Table D2.5 is provided as a preliminary guideline only. The temperature ratings range shown is compiled from published information from several manufacturers.

Abrasion Resistance

Fiberglass piping systems with typical corrosion barriers are somewhat abrasion resistant. They can typically handle slurries with particle sizes less than 100 mesh (150 micron) at fluid velocity below 6 ft/sec (1.8 meter/sec). The abrasion resistance can be improved by adding fillers such as fine silica, silicon carbide, or ceramic to the piping's interior or exterior barriers. Table D2.6 shows the ability of different resins and abrasion-resistant additives to resist surface wear. (The lower the wear index, the better is the resistance to wear.) Wear resistance of fiberglass fittings can be improved by using long-radius fittings.

TABLE D2.5 Maximum Temperature Ratings Range by Chemical and Resin Class

Service/Fluid		Epoxy	Vinyl ester	Novolac VE	Furan	Isophthalic
Acetic acid	°F	75–100	100–210	150–215	225	170
	°C	24–93	38–99	66–102	107	77
Acetone	°F	75–180	125–150	100–200	AMB	NR
	°C	24–82	52–66	38–93	AMB	NR
Acrylic acid	°F	100–120	75–100	100–100	NT	NR
	°C	38–49	24–38	38–38	NT	NR
Adipic acid	°F	225–250	75–200	100–210	NT	NL
	°C	107–121	24–93	38–99	NT	NL
Air	°F	210–300	200–360	225–450	NL	NL
	°C	99–149	93–182	107–232	NL	NL
Alcohol-ethyl	°F	120–180	75–150	80–150	NT	NL
	°C	49–82	24–66	27–66	NT	NL
Alcohol, isopropyl	°F	100–180	80–150	100–150	NT	NL
	°C	38–82	27–66	38–66	NT	NL
Alcohol-methyl	°F	75–150	100–150	100–150	NT	NL
	°C	24–66	38–66	38–66	NT	NL
Alcohol-methyl isobutyl	°F	100–150	100–150	120–150	NT	NL
	°C	38–66	38–66	49–66	NT	NL
Alcohol, secondary butyl	°F	100–175	120–150	120–150	NT	NL

The piping manufacturer should be contacted for recommendations for specific abrasive applications. The following information will be needed to make the best recommendation:

- Particle size
- Percent solids
- Particle hardness
- Flow velocity
- Continuous or intermittent service

Flame Resistance

Flame-resistant fiberglass piping has been developed that is readily avaliable. These systems usually use phenolic resins or brominated vinyl ester resins with antimony trioxide fillers. ASTM E-84 tunnel test flame spread ratings below 25 can be achieved with both resin systems. Phenolic systems also provide for low smoke generation. Intunescent coatings can also be applied to increase flame resistance.

Weather Resistance

Fiberglass piping systems have been successfully used from the north slope of Alaska to the Sahara desert. Fiberglass piping is less prone to ultraviolet or cold embrittlement and cracking than thermoplastic piping systems. Fiberglass piping also has operating temperature capabilities in excess of ambient temperatures. Surfaces of fiberglass piping systems exposed to sunlight will experience ultraviolet degradation of the resin. This degradation is a surface effect which stops as soon as the glass fibers are exposed. Long-term testing of fiberglass piping typically shows no effect on the physical strength of the components. The surface appearance of the pipe will deteriorate with ultraviolet exposure. The surface can be protected with a resin-rich veil surface, paint, or ultraviolet inhibitors.

PHYSICAL PROPERTIES

The physical properties of fiberglass pipe are dependent on resin type, glass type, manufacturing method, glass orientation, and cure profile. Actual properties may vary significantly between pipes that appears to be similar; therefore the manufacturer's published data should be used for all engineering calculations. Table D2.7 is provided as preliminary information only. Since FRP physical properties are dependent on glass orientation, unit stress and elastic modulus are also dependent on orientation of the load. Fig. D2.4 shows simplified load orientations along with the ASTM standard test method used to measure unit stress and elastic modulus.

TABLE D2.7 Typical Ultimate Physical Properties for Fiberglass Pipe

Property at 75°F (24°C)	Filament-wound epoxy pipe		Centrifugally cast epoxy pipe		Filament-wound vinyl ester pipe		Centrifugally cast vinyl ester pipe		Filament-wound isophthalic pipe

BENEFITS AND LIMITATIONS OF FIBERGLASS PIPING SYSTEMS

Fiberglass pipe offers a number of benefits compared to other piping materials, but it also has some significant limitations. The piping designer should review the benefits and limitations when making the piping material selection.

Corrosion Resistance

Fiberglass piping can be manufactured with resins selected to optimize corrosion resistance for a particular application. Corrosion resistance is generally good compared to competitive materials but may have some concentration and temperature limitations.

Installed Cost

The installed cost of FRP pipe is competitive with stainless steel, lined steel, and high-end thermoplastic systems (see Table D2.8 and Fig. D2.5).

TABLE D2.8   Total Material and Labor Cost Index* (Average for Pipe Installed in Process Areas, Inside Buildings, and Outside Buildings, Fiberglass = 1.0)

FIGURE D2.5 Piping material and labor (total cost index).

Unsupported Spans

The spans for fiberglass systems can actually be longer than both steel and thermo-plastic systems (see Table D2.9 and Fig. D2.6), further reducing the installed cost on aboveground systems.

TABLE D2.9 Support Spacing In Feet at 60°F (Specific Gravity = 1.00)

NPS (DN)	PVC Schedule 80	Steel standard wall	Fiberglass process pipe
1″ (25)	6.0	7.0	12.3

10″ (250)	12.0	22.0	26.7
FIGURE D2.6   Support spacing (feet at 60°F).

Thermal Expansion

The thermal expansion of fiberglass pipe is comparatively low (see Table D2.10 and Fig. D2.7) and can be easily controlled using the inherent strength of fiberglass.

Flow Loss

Fiberglass pipe has a smooth bore which typically remains smooth throughout the life of the system. The smooth bore significantly reduces flow loss in both pumped and drainage systems. Flow loss can significantly affect the life cycle cost of pumped systems and pipe size requirements for drainage systems (see Table D2.11 and D2.12).

TABLE D2.10 Piping System Thermal Expansion, Uninsulated Pipe (inches/100 feet)

Temperature change degrees F	PVC	CPVC	Carbon steel	Stainless steel	Typical fiberglass pipe

PRESSURE RATINGS

Fiberglass piping is available with a wide range of both internal and external pressure ratings depending on its intended application (see Tables D2.13 through D2.16). Pipe larger than NPS 16 (DN 400) is usually custom-made for the system pressure requirements. The piping system internal pressure rating is usually limited by the joining method and fittings, not the pipe. Long-term pressure ratings are extrapolated to a 50-year life expectancy using regression analysis (see Table D2.17).

TABLE D2.13 Fiberglass Process Piping (Internal & External Pressure Ratings for Pipe Manufactured According to ASTM D 2996 or ASTM D 2997)

NPS (DH)	Units	Internal pressure rating ranges*				External pressure rating ranges*

ABOVEGROUND DESIGN

Anchors Guides and Supports

It is important that an aboveground fiberglass piping system be properly anchored, guided, and supported. Anchors, guides, and supports must be selected which protect the piping components from point loads. Point loading can cause significant damage which will affect the life of the system. Figures D2.8 through D2.11 show typical hanger, support, guide, and anchor details.

Design Equations and Criteria

Design equations and criteria have been developed for fiberglass piping used in aboveground systems. These equations and criteria are conservative and have resulted in many numerous successful piping installations. Most of the fiberglass piping manufacturers publish technical information based on these equations and criteria.

Finite element computer design programs based on ASME design criteria are also used to design fiberglass piping systems. Use of one of these computer programs should be considered when designing complex systems. The manufacturer's published data should be used whenever doing design calculations or computer design.

Minimum Fiberglass Pipe Support Width.   Fiberglass pipe can be damaged by point loads at hangers, supports, anchors, or guides. Hangers, supports, anchors, or guides should be selected which provide a minimum of 120° contact and a maximum bearing stress of 85 psi (6.0 kg/cm^2). Fiberglass pipe should be protected when used with support rollers, U-bolts, or flat supports such as angle iron or I-Beams (see Figs. D2.8 through D2.11). Eq. (D2.1) or Table D2.18 can be used to determine minimum fiberglass pipe support widths.

$$W = \frac{\sqrt{3}/2 * F}{\text{OD} * Sb} \tag{D2.1}$$

where W = minimum support width, in (cm)
   F = weight on support, lbs (kg)
  OD = pipe outer diameter, in (cm)
   Sb = allowable bearing stress 85 psi (5.98 kg/cm^2)
     Based on 120° of contact.

TABLE D2.18 Minimum Support Width for 120° Contact

Pipe size		Minimum support width	
NPS	DN	in.	mm
1	25	⅞	22.4
1½	40	⅞	22.4
2	50	⅞	22.4
3	80	1¼	31.8
4	100	1¼	31.8
6	150	1½	38.1
8	200	1¾	44.5
10	250	1¾	44.5
12	300	2	50.8
14	350	2	50.8

Note: Table is based on fluid specific gravity of 1.25 and typical maximum spans for filament wound fiberglass pipe at 75°F (24°C).

Example D2.1: 36 in nominal diameter pipe carrying 1.25 specific gravity fluid

F = weight of pipe plus weight of fluid times span length (32.5 lbs/ ft + 550 lbs/ft) * 25 ft = 14,560 lbs

OD = 36.75"

$$W = \frac{\sqrt{3}/2 * 14560}{36.75 * 85} \Rightarrow 4.04''$$

TABLE D2.19   Deflection Coefficients, f, for Various Span Configurations

1 Span	2 Span	3 Span	4 Span
N—N f = 0.013	N—N—N f = 0.0069	N—N—N—N 1 2 1 f1 = 0.0069 f2 = 0.0026	N—N—N—N—N 1 2 2 1 f1 = 0.0065 f2 = 0.0031
F—N f = 0.0054	F—N—N 1 2 f1 = 0.0026 f2 = 0.0054	F—N—N—N 1 2 2 f1 = 0.0026 f2 = 0.0054	F—N—N—N—N 1 2 2 2 f1 = 0.0026 f2 = 0.0054
N—F f = 0.06	F—N—F f = 0.0026	F—N—N—F 1 2 1 f1 = 0.0026 f2 = 0.0031	F—N—N—N—F 1 2 2 1 f1 = 0.0026 f2 = 0.0031
	F—F—F f = 0.0026	F—F—F—F f = 0.0026	F—F—F—F—F f = 0.0026

Where: F = fixed securely,   N = not fixed

Support Spacing for Fiberglass Pipe.   Fiberglass pipe support spacing is determined using beam deflection equations. Deflection is normally limited to ½ in (1.27 cm). The resulting pipe bending stress is normally well below the allowable bending stress. Maximum pipe span based on deflection can be calculated using the following equation along with Table D2.20.

$$L = \left(\frac{d * Eb * I}{f * W} \right)^{0.25} \tag{D2.2}$$

where L = unsupported span length, in (cm)
d = allowable midpoint deflection, in (cm)
Eb = bending modulus of elasticity, psi (kg/cm^2)
l = pipe moment of inertia, in^4 (cm^4)
f = deflection coefficient. Table D2.19
W = weight of pipe and fluid, lbs/in (kg/cm)

Example D2.2: HPS 14 (DN 350) Pipe with Supports Securely Fixed,

$$d = 0.5 \text{ in}$$
$$Eb = 2 \times 10^6 \text{ psi}$$
$$I = 226.12 \text{ in}^4$$
$$f = 0.026$$
$$W = 7.08 \text{ lbs/in}$$

$$L = \left(\frac{0.5 * 2 \times 10^6 * 226}{0.0026 * 7.08} \right)^{0.25} \Rightarrow 333''$$

TABLE D2.20 Typical Fiberglass Pipe Maximum Support Spacing

Nominal pipe size, NPS (DN)	1 (25)	1½ (40)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10 (250)	12 (300)	14 (350)
Support spacing, ft (m)	12½ (3.8)	14½ (4.4)	15 (4.6)	17½ (5.3)	19 (5.8)	21½ (6.6)	24½ (7.5)	26½ (8.1)	28 (8.5)	29 (8.8)

Note: Based on 4 span fixed continuous beam with a fluid specific gravity of 1. Use the following multipliers for other conditions.

Specific gravity	Span multiplier	Beam type	Span multiplier
1.25	0.95	Simple support, 1 Span	0.669
1.50	0.90	Continuous beam, 3 Span	0.783
2.00	0.84	Continuous beam, 4 Span	0.795

Thermal Expansion Calculation.   Fiberglass pipe expands at from 1¼ times to twice the rate of steel pipe due to changes in temperature. The wide variation in thermal expansion is due to the different constructions used to make different types of fiberglass pipe. The following equation is used to calculate thermal expansion. Refer to Table D2.21.

TABLE D2.21   Typical Fiberglass Pipe Thermal Expansion, $C_t = 10.2 \times 10^{-6}$ in/in/°F (18.3×10^{-6} in/cm/cm/°C)

Temperature change, °F	25	50	75	100	125	150	175	200	225
Length change, in./100 ft.	0.31	0.61	0.92	1.22	1.53	1.84	2.14	2.45	2.75
Temperature change, °C	14	28	42	56	69	83	97	111	125
Length change, cm/30.5 m.	0.79	1.55	2.34	3.10	3.89	4.67	5.44	6.22	6.99

$$L_c = C_t * L * T_c \qquad \text{(D2.3)}$$

where L_c = length change, in (cm)
   C_t = coefficient of thermal expansion, in/in/°F (cm/cm/°C)
   L = Length of pipe between anchors, in (cm)
   T_c = temperature change, °F (°C)

Example D2.3: NPS 14 (DN 350) Pipe

$Ct = 10.2 \times 10^{-6}$ in/in/°F
$L = 2400$ inches $L_c = 10.2 \times 10^{-6} * 2400 * 100 \Rightarrow 2.44$ inches
$T_c = 100$ °F

Restrained End Loads.   Fiberglass pipes' low linear coefficient of thermal expansion, low compressive modulus of elasticity, and high compressive strength makes it practical to restrain the pipe to control thermal expansion. The following equation is used to determine the restrained end load for fiberglass pipe. Refer to Table D2.22 for typical heavy wall fiberglass pipe restrained end loads at rated compressive loads at 100°F (56°C) change in temperature.

$$E_L = C_t * E * A * T_c \qquad (D2.4)$$

where E_L = thermal end load, lbs (kg)
      C_t = coefficient of thermal expansion, in/in/°F (cm/cm/°C)
      E = axial compressive modulus for expansion, psi (kg/cm^2) axial tensile
            modulus for contraction
      A = reinforced cross-sectional area, in^2 (cm^2)
      T_c = temperature change, °F (°C)

Example D2.4: NPS 14 (DN 350) Pipe

$Ct = 10.2 \times 10^{-6}$ in/in/°F
$E = 2.01 \times 10^6$ psi
$A = 9.4$ in^2
$T_c = 100$ °F
$E_L = 10.2 \times 10^{-6} * 2.0 \times 10^6 * 9.4 * 100 \Rightarrow 19,200$ lbs

TABLE D2.22   Typical Heavy Wall Fiberglass Pipe Restrained End Loads and Rated Compressive Loads at 100°F (55.6°C) Temperature Change

Nominal pipe size, NPS (DN)	1 (25)	1½ (40)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10 (250)	12 (300)	14 (350)
Restrained load, lbs × 10³ (kg × 10³)	0.83 (.37)	1.40 (.64)	1.60 (.73)	2.86 (1.3)	3.91 (1.8)	6.53 (3.0)	9.88 (4.5)	13.5 (6.1)	16.7 (7.6)	19.2 (8.7)
Rated compressive load, lbs × 10³ (kg × 10³)	2.99 (1.4)	5.23 (2.4)	5.36 (2.4)	9.94 (4.5)	14.4 (6.5)	22.1 (10)	34.8 (15)	44.8 (22)	57.7 (26)	69.8 (32)

Guide Spacing.   When a fiberglass piping system is restrained to control thermal expansion, guides must be used to prevent pipe buckling. The following equation should be used to determine maximum guide spacing:

$$Lg = 0.262 * \left(\frac{Eb * I}{C_t * E * A * T_c} \right)^{0.5} \qquad (D2.5)$$

where L_g = maximum distance between guides, ft (m)
      E_b = bending modulus of elasticity, psi (kg/cm^2)

l = pipe moment of inertia, in^4 (cm^4)
C_t = coefficient of thermal expansion, in/in/°F (cm/cm/°C)
E = axial compressive modulus for expansion, psi (kg/cm^2)
A = cross-sectional area, in^2 (cm^2)
T_c = temperature change, °F (°C)

Example D2.5: 14″ Pipe

$$Eb = 2 \times 10^6 \text{ psi}$$
$$L = 226.12 \text{ in}^4$$
$$Ct = 8.9 \times 10^{-6}$$
$$E = 2.1 \times 10^6$$
$$A = 12.912$$
$$T_c = 100 \text{ °F}$$

$$Lg = 0.262 * \left(\frac{2 \times 10^6 * 226}{8.9 \times 10^{-6} * 2.1 \times 10^6 * 12.912 * 100} \right)^{0.5} \Rightarrow 36 \text{ feet.}$$

Table D2.23 provides typical guide spacing for pipe sizes NPS l through 14 (DN 25 through 350).

TABLE D2.23 Typical Guide Spacing for Restrained Epoxy Pipe, Feet (meter)

Nominal pipe size, in (mm)	1 (25)	1½ (40)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10 (250)	12 (300)	14 (350)
Temperature change										
50°F (28°C)	5.0 (1.5)	7.7 (2.3)	8.6 (2.6)	13 (3.9)	17 (5.3)	25 (7.7)	32 (9.9)	40 (12)	46 (14)	59 (18)
100°F (56°C)	3.5 (1.1)	5.4 (1.7)	6.1 (1.9)	9.2 (2.8)	12 (3.6)	18 (5.4)	23 (7.1)	29 (8.7)	34 (10)	42 (13)
150°F (84°C)	2.9 (0.9)	4.4 (1.3)	5.0 (1.5)	7.4 (2.3)	10 (3.0)	14 (4.4)	19 (5.8)	24 (7.2)	28 (8.5)	34 (10)
200°F (111°C)	2.4 (0.7)	3.8 (1.2)	4.3 (1.3)	6.5 (2.0)	8.5 (2.6)	12 (3.8)	17 (5.1)	21 (6.3)	24 (7.4)	30 (9.0)

Changes of Direction and Expansion Loops. Thermal expansion in fiberglass piping systems is often controlled using changes of directional or expansion loops. The low thermal expansion, low beam-bending modulus of elasticity, and high beam-bending strength of fiberglass pipe makes changes of direction and expansion loops very practical methods of thermal expansion control. The following cantilevered beam equations are used to determine the minimum leg lengths needed, based on allowable pipe stress or elbow bending moments. Minimum leg lengths based on pipe stress and elbow bending moments should be determined, and the longer of the leg lengths used.
FIGURE D2.12   Offset leg sizing diagram.

Leg length based on pipe allowable bending stress (see Figs. D2.12 and D2.13):

$$A = \sqrt{\frac{K * L * E * \mathrm{OD}}{S}} \tag{D2.6}$$

where A = deflected pipe length, in (cm)
 K = cantilevered beam constant
   = 0.75 for expansion loops
   = 1.50 for directional changes
 L = length change, in (cm)
 E = pipe-bending modulus of elasticity, psi (kg/cm^2)
 OD = pipe outer diameter, in (cm)
 S = pipe allowable bending stress (minimum 8:1 safety factor), psi (kg/cm^2)
FIGURE D2.13   Loop leg sizing diagram.

Leg length based on 90° elbow allowable bending moment:

$$A = \sqrt{\frac{12 * L * E * I}{M}} \tag{D2.7}$$

where I = pipe reinforcement moment of inertia, in⁴ (cm⁴)

M = 90° elbow allowable bending moment, lb-in (kg-cm)

Table D2.24 provides typical expansion versus leg length.
FIGURE D2.14 Typical expansion joint installation.

TABLE D2.25   Distance from Expansion Joint to Primary and Secondary Guides
(See Figure D2.14)

Nominal pipe size, NPS (DN)	1 (25)	1½ (40)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10 (250)	12 (300)	14 (350)
Primary guide, "A", inches (mm)	5 (127)	8 (203)	10 (254)	12 (305)	16 (406)	24 (610)	32 (813)	40 (1016)	48 (1219)	56 (1422)
Secondary guide, "B", inches (mm)	18 (457)	30 (762)	36 (914)	42 (1067)	56 (1422)	84 (2134)	112 (2845)	140 (3556)	168 (4267)	196 (7518)

Expansion Joints.   The thermal expansion loads and allowable loads for fiberglass pipe are relatively low when compared to metallic pipe. Therefore expansion joints selected for use with fiberglass pipe must have low activation forces. The following equation can be used to determine the maximum allowable expansion joint activation load:

$$Pcr = \frac{\pi^2 * Ec * I}{Lg^2} \qquad (D2.8)$$

Where Pcr = critical buckling force of pipe, lbs (kg)
Ec = axial compressive modulus, psi (kg/cm^2)
l = pipe moment of inertia, in^4 (cm^4)
L_l = guide spacing interval, in (cm)

A primary and secondary guide should be used with expansion joints to give the joint proper alignment (see Fig. D2.14). Typically the primary guide is 4 nominal pipe diameters away from the joint and the secondary guide is 14 diameters away from the joint. Refer to Table D2.25.

BELOWGROUND DESIGN

Buried fiberglass pipe is treated as a flexible system where the pipe, trench walls, and bedding material work together to form a complete pipe support system. The elements of this system can best be defined by considering a section of buried flexible pipe and the loads acting on it. These loads, the *dead load* (*backfill*) and the *live loads* (*vehicle traffic*), act downward on the pipe, tending to deflect it into an oval shape. If the bedding material at the sides of the pipe is compacted sufficiently, it will resist the pipe movement and minimize the deflection to an acceptable amount. For this reason, the specification of the pipe, the construction of the trench, and selection of bedding materials must be closely coordinated and controlled.

Burial Design

The fiberglass pipe industry uses Chapter 5 American Water Works Association (AWWA) manual M45 as the design basis for buried pipe systems and Chapter 6

for installation guidelines. AWWA M45 Buried Pipe Design addresses internal pressure, surge pressure, external pressure, head losses, pipe properties, ring bending, deflection, soil loads, wheel loads, combined loading, modulus of soil reaction, buckling, and installation guidelines.

Trench Design

Fiberglass pipe is typically installed in trenches which provide from 2 ft to 20 ft (0.61 to 6.1 m) of cover when backfilled. Special designs have been developed for burial of pipe outside of this range. Trench design will vary depending on pipe diameter and specifications, type of soil, backfill, water table levels, and expected live wheel loads. (See Table D2.26 and Figs. D2.15 through D2.17). During installation it

TABLE D2.26 Nominal Trench Widths*

Nominal pipe size NPS (DN)	Minimum width earth excavation Inches (mm)	Maximum width Inches (mm)
2 (50)	18 (450)	26 (660)
3 (75)	18 (450)	27 (690)
4 (100)	18 (450)	28 (710)
6 (150)	20 (500)	30 (760)
8 (200)	23 (580)	32 (810)
10 (250)	25 (635)	34 (860)
12 (300)	28 (710)	36 (910)
14 (350)	31 (790)	38 (960)
16 (400)	33 (840)	40 (1010)
18 (450)	36 (910)	42 (1070)
20 (500)	39 (990)	44 (1120)
24 (600)	44 (1120)	48 (1220)
30 (750)	52 (1320)	56 (1420)
36 (900)	60 (1520)	64 (1630)
42 (1050)	66 (1680)	70 (1780)
48 (1200)	72 (1830)	80 (2030)
54 (1400)	78 (1980)	86 (2240)
60 (1500)	84 (2130)	96 (2440)
72 (1800)	96 (2440)	108 (2740)

* Trench widths may be wider depending on soil conditions.
FIGURE D2.15   Trench shape and bedding for soft and medium consistency soil with sheeting or shoring.
FIGURE D2.16   Trench shape and bedding for granular type soils (sand, etc.).
FIGURE D2.17   Wide trench for very soft consistency soils.
FIGURES D2.18 and D2.19.   Flat trench bottom.

is very important that voids are eliminated around the bottom of the flexible fiberglass pipe. The bottom of the trench can be shaped to conform to the bottom ¼ pipe diameter, or, if flat, the bedding material carefully placed and tamped by hand to ensure complete pipe support (see Fig. D2.18 and D2.19).

Bedding Materials

Selection and compaction of bedding materials is critical to the success of a fiberglass buried pipe installation (see Table D2.27). Proper bedding will help prevent excessive deflection of the flexible fiberglass pipe. Bedding materials particle sizes should

TABLE D2.27   Bedding Material for Burial of FIBERCAST® Pipe

Type	Typical names	Description*	Unified soils classification system	Degree of compaction required†
1	Crushed rock or pea gravel	¾″ max. size with less than 50% passing No. 4 sieve	GW, GP	80–85%
2	Sand	Coarse or medium sand, moist	SW, SP	90–95%
3	Gravel, sand, clay and gravel, sand silt mixtures	Coarse grained soils 5% and 12% fines	GW-GM, GW-GC, SW-SM, GP-GM, SP-SM, GP-GC, SW-SC, SP-SC	85–90%
4	Silty gravels, clayey gravels, silty sands, clayey sands	Coarse grained soils more than 12% fines—low compressibility	GM, GC, SM, SC	90–95%

* All types have a maximum particle size of ¾ inch.
† Compaction required: Standard Proctor Density per ASTM D 698.
FIGURE D2.20   Typical Class "A" bedding.

be smaller than 3 times the pipe wall thickness to prevent point loading fracturing of the pipe walls.

High Water Table Areas

Areas with high water tables are usually coincident with very poor soil conditions. In most of these areas, it will be necessary to use crushed rock or pea gravel as the bedding and backfill material. In addition, a permeable, synthetic support fabric may be needed as a trench liner to prevent migration of the backfill material into the native soil.

In extreme cases such as soft clay and other plastic soils, it may be necessary to use "Class A" bedding (see Fig. D2.20). If the depth of the pipe cover is less than 1 pipe diameter, tiedowns or concrete encasement is recommended to prevent pipe flotation.

CONNECTION TO OTHER EQUIPMENT AND PIPING MATERIAL

Fiberglass pipe can be connected to other equipment and piping materials using flanges, threaded joints, and grooved adaptors. For flanges it is preferred to connect to flat-faced flanges. When connecting to flat-faced flanges, a full face gasket of 60 to 70 durometer Shore A hardness is usually used. Other specialty-type gaskets can be used, but the piping manufacturer should be contacted for compatibility. Fiberglass flanges can be damaged if excessive torque is applied to the flange or if the proper torque sequence is not followed. Again, the piping manufacturer should be contacted for information on maximum torque and torque sequence. In some cases a flat-faced flange cannot be used, such as on raised-face flanged pumps, valves, and other equipment. When connecting to a raised-face flange you can use a filament-wound fiberglass flange, a hard spacer ring, a steel backup ring, or machine the mating flange so that it is flat-faced. The hard spacer ring is used to fill the gap outside the raised face to prevent bolt loads from bending and breaking the fiberglass flange. In connecting with a flange to other equipment and piping materials, make sure the boltholes line up with the other system and have the same bolt hole pattern. Fiberglass flanges are available in a number of different hole

patterns to match the connecting equipment. Fiberglass flanges should use a flat washer under all nuts and bolts used to make up the flange. Threaded joints are also used to connect to other equipment and piping materials. Threaded joints are typically available in NPT thread or 8 and 10 round EUE threads. Before making up threads in a fiberglass piping a system, make sure that all bonded joints are fully cured. Thread lube should be used which will not harden to seal the threads. Field threading of fiberglass piping is possible on some systems, and the manufacturer should be contacted for threading details. Grooved adapters are also available to make up to existing equipment and other piping materials. Fiberglass pipe connections to pumps and other equipment that involve vibration, shock loads, or other mechanical movement should include flexible connectors. Rotating equipment such as pumps can induce extreme vibration in the system if the natural frequency is reached. Flexible connectors used with fiberglass piping systems should have low activation forces due to the flexibility of the fiberglass pipe. When connecting to tanks the wall movement of the tank should be a consideration. Avoid direct connection between two tanks using fiberglass pipe. A change of direction should be utilized or a flexible connector to allow for tank wall movement.

INSULATION AND HEAT TRACING

It is common practice to use insulation and heat tracing for freeze protection in maintaining fluid temperature in fiberglass piping systems. The excellent insulating property of fiberglass piping may eliminate the need for additional insulation or heat tracing in some systems. The low conductivity of fiberglass piping should be considered when designing the system heat tracing and insulation. The additional weight and temperature of heat tracing and insulation should be considered when designing the unsupported spans for the piping system. The heat tracing used should not exceed the maximum temperature rating of the piping system. The maximum heat tracing temperature should also be used in all design calculations. It is very important that hot spots be avoided in the piping system, or damage to the fiberglass pipe can result. When using steam heat tracing, insulation can be placed between the heat tracing and the pipe to prevent hot spots. Thermally conductive tape designed for use with heat tracing can also be used to avoid hot spots in the piping. The most common form of heat tracing fiberglass pipe is with self-regulating electrical tape. Heat tracing should be spiraled around the pipe or run parallel down opposite sides of the pipe to prevent bowing of the system. Care should be taken when designing a system with heat tracing so that the flexibility inherent in a fiberglass piping system does not overstress the heat trace. Refer to Chap. B6.

PAINTING FIBERGLASS PIPING

Fiberglass piping systems can be painted to change the color of the piping or to coat a dulled surface. Fiberglass piping may become dull due to ultraviolet exposure from sunlight or from exposure to chemicals or chemical vapors. Fiberglass piping may have an exterior wax or silicone coating which will prevent adherence of the paint unless the piping is properly prepared. The piping can be prepared by sanding, sandblasting, or allowing it to weather until it has a dull surface. After the piping

has been sanded or sandblasted, the surface must be cleaned in preparation for painting. Some paints may require primer before painting. Also, the paint must be compatible with the environment the pipe will be exposed to. Consult the paint manufacturer for details. Paints which have been found to work well with fiberglass piping systems are two component epoxies, two component urethanes, or alkyd enamels.

HYDROSTATIC TESTING

Fiberglass piping systems should always be tested prior to being put into service. It is very important that good hydrostatic test procedures be followed to prevent personal injury or property damage during the test. On aboveground systems all guides and supports must be in place prior to hydrostatic testing. On buried applications the piping should be partially backfilled, with the joints exposed prior to testing. Large or complex systems should be tested in subsections. One of the reasons for doing this is to confirm that proper fabrication techniques have been followed prior to fabricating the complete systems. If the piping system does not have any connections for testing, tie-ins may be required. These can be flange connections, threaded, or grooved connections. The connections can be cut off after the test. For drainage systems expandable plugs can be used for low-pressure testing, but because of the smooth bore of fiberglass piping, testing may be limited to less than five psi on larger diameters. The test pressure used should not exceed 1½ times the rated operating pressure of the lowest rated component of the piping system. If vacuum testing is used, the test should not exceed the external pressure rating of the piping system. The hydrostatic test can be either static or cyclic. For a static test the pressure is maintained in the system for 1 to 8 hours. For a cyclic test it is usually recommended that the pipe be cycled 10 times, from zero psi to 1½ times the rated operating pressure. Then the pipe has static pressure for a minimum of 1 hour. Water should be introduced into the system through a NPS 1 (DN 25) inlet for pipe up to NPS 14 (DN 350) and a NPS 2 (DN 50) inlet for pipe larger than NPS 14 (DN 350). While the water is being introduced, air must be bled from all the high points in the system to prevent the storage of energy which could result in damage to the system. Air can also be removed by using a small pig in the system. When filling and bleeding the system open and close valves slowly to prevent surges of water hammer, which can produce very high internal pipe pressures. When pressurizing the system, raise the pressure no more than 100 to 200 psi (690 to 1380 kPa) per minute. After the test pressure is reached, the system should be monitored for rises in pressure due to sunlight exposure, ambient temperature changes, or wind conditions. During the test when there is water in the system, freezing must be prevented in cold weather. Should leaks occur when the pipe is being tested, release the pressure immediately and repair the leak prior to retesting. When draining the system after the test, all the high points should be vented to prevent vacuum damage in systems not rated for a full vacuum operation.

Fiberglass downhole tubing requires some special precautions because the exterior of the pipe or tubing is normally pressurized with annular testing. If the tubing has a packer on the bottom of the strain, which is normal, the annular test pressure can increase the tensile load on the tubing if the packer moves. The combination

of the annular test pressure and any fluid differential pressure must not exceed the external pressure rating of the tubing.

AIR TESTING

A hydrostatic test should be used instead of air or compressed gas pressure tests if possible. When air or compressed gas is used for testing, tremendous amounts of energy can be stored in the system. Many fiberglass pipe manufactures do not recommend air testing. If a failure occurs, the energy may be released catastrophically, which can result in property damage and personal injury. In cases where system contamination or fluid weight prevents the use of hydrostatic testing, air testing may be used with extreme caution. To reduce the risk of air testing, pressurize the system to no more than 15 psi (103.5 kPa). When pressurizing the system with air or compressed gas, the area surrounding the piping must be cleared of personnel to prevent injury. Hold air pressure for 1 hour, then reduce the pressure to one-half the original pressure. Personnel can then enter the area to perform a soap test of all joints. Again, extreme caution must be exercised during air testing to prevent property damage or personal injury.

SAMPLE SPECIFICATION FOR STANDARD WALL EPOXY FIBERGLASS PROCESS PIPING SYSTEMS

1.0 SCOPE

1.1 This specification covers requirements for machine-made NPS1 through NPS16 diameter fiberglass reinforced epoxy thermosetting resin processing piping for chemical petroleum, and industrial applications.

2.0 REFERENCED STANDARDS

2.1 ASTM D 1599   Standard Test Method for Short-Time Hydraulic Failure Pressure of Plastic Pipe, Tubing, and Fittings.

2.2 ASTM D 2105   Standard Test Method for Longitudinal Tensile Properties of ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe and Tube.

2.3 ASTM D 2412   Standard Test Method for Determination of External Loading Characteristics of Plastic Pipe by Parallel-Plate Loading.

2.4 ASTM D 2992   Standard Practice for Obtaining Hydrostatic or Pressure Design Basis for ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe and Tube.

2.5 ASTM D 2996   Standard Specification for Filament Wound ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe.

2.6 ASTM D 2997   Standard Specification for Centrifugal Cast ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe.

2.7 ASTM D 3567   Standard Practice for Determining Dimensions of ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe and Fittings.

2.8 ASME B31.3   Process Piping.

3.0   PIPE

3.1   The pipe shall be manufactured from epoxy resin to meet or exceed one of the following ASTM Standard Specifications for ''Fiberglass'' Pipe:

	Manufacturing Method	**ASTM Designation**	**Designation Code***
A.	Filament Wound	ASTM D 2996	RTRP 11FF1-3122
B.	Centrifugal Cast	ASTM D 2997	RTRP 21CW-4252

  * Typical Designation Code May vary with product selected.

3.2   The pipe shall have a minimum 30 mil** thick epoxy resin liner as determined per ASTM D-3567. The liner shall have a minimum 65 percent by weight resin content.

  ** Liner thickness may vary by application.

3.3   The pipe shall have a minimum reinforced wall thickness per Table 1. Reinforced wall thickness shall be determined per ASTM D 3567. The reinforced wall shall have a minimum 45 percent by weight continuous glass roving content. Only epoxy resin shall be used in the reinforced wall.

TABLE 1

Nominal size NPS (DN)	1 (25)	1½ (40)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10 (250)	12 (300)	14 (350)	16 (400)
Reinforced wall*** in (mm)	0.055 (1.4)	0.065 (1.7)	0.070 (1.8)	0.070 (1.8)	0.090 (1.8)	0.090 (2.3)	0.120 (3.0)	0.140 (3.6)	0.165 (4.2)	0.170 (4.3)	0.225 (5.7)

  *** The reinforced wall may vary by application.

4.0   FITTINGS AND ADHESIVE

4.1   The pipe, fittings, and adhesive shall be produced by the same manufacturer. The piping, including joining method, shall have been commercially available from the manufacturer for a minimum of 5 years.

4.2   The piping system, including pipe, fittings, and joints, shall have a minimum pressure rating of 150 psig (1035 kPa) at 200°F (93°C). (Pressure and Temperature rating may vary by application.)

5.0   QUALITY ASSURANCE

5.1   Inspection for shipping damage shall be performed at the job site prior to piping installation. Damaged pipe and fittings shall not be used.

6.0   INSTALLATION

Installation, including joining, burial, anchoring, guiding, and supporting, shall be per the manufacturer's recommendations.

7.0   FABRICATOR CERTIFICATION

All fiberglass piping field joints shall be made by fabricators who have been certified by the piping manufacturer. Certification by the manufacturer shall be in compliance with ASME B31.3 section A328.2 for the type of joint being made.

SAMPLE SPECIFICATION FOR STANDARD WALL VINYL ESTER FIBERGLASS PROCESS PIPING SYSTEMS

1.0 SCOPE

1.1 This specification covers requirements for machine-made NPS 1 through NPS 16 diameter fiberglass reinforced vinyl ester thermosetting resin process piping for chemical petroleum, and industrial applications.

2.0 REFERENCED STANDARDS

2.1 ASTM D 1599   Standard Test Method for Short-Time Hydraulic Failure Pressure of Plastic Pipe, Tubing, and Fittings.

2.2 ASTM D 2105   Standard Test Method for Longitudinal Tensile Properties of ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe and Tube.

2.3 ASTM D 2412   Standard Test Method for Determination of External Loading Characteristics of Plastic Pipe by Parallel-Plate Loading.

2.4 ASTM D 2992   Standard Practice for Obtaining Hydrostatic or Pressure Design Basis for ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe and Tube.

2.5 ASTM D 2996   Standard Specification for Filament Wound ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe.

2.6 ASTM D 2997   Standard Specification for Centrifugal Cast ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe.

2.7 ASTM D 3567   Standard Practice for Determining Dimensions of ''Fiberglass'' (Glass-Fiber-Reinforced Thermosetting-Resin) Pipe and Fittings.

2.8 ASME B31.3   Process Piping.

3.0 PIPE

3.1 The pipe shall be manufactured from vinyl ester resin to meet or exceed one of the following ASTM Standard Specifications for ''Fiberglass'' Pipe:

	Manufacturing Method	**ASTM Designation**	**Designation Code***
A.	Filament Wound	ASTM D 2996	RTRP 12EE1-2112
B.	Centrifugal Cast	ASTM D 2997	RTRP 22BU-4222

* Typical Designation Code May vary with product selected.

3.2 The pipe shall have a minimum 50 mil** thick vinyl ester resin liner as determined per ASTM D 3567. The liner shall have a minimum 65 percent by weight resin content.

** Liner thickness may vary by application.

3.3 The pipe shall have a minimum reinforced wall thickness per Table 1. Reinforced wall thickness shall be determined per ASTM D 3567. The reinforced wall shall have a minimum 45 percent by weight continuous glass roving content. Only vinyl ester resin shall be used in the reinforced wall.

TABLE 1

Nominal size NPS (DN)	1 (25)	1½ (40)	2 (50)	3 (80)	4 (100)	6 (150)	8 (200)	10 (250)	12 (300)	14 (350)	16 (400)
Reinforced wall*** in (mm)	0.075 (1.9)	0.080 (2.0)	0.085 (2.2)	0.090 (2.3)	0.090 (2.3)	0.110 (2.8)	0.130 (3.3)	0.150 (3.8)	0.160 (4.1)	0.160 (4.1)	0.200 (5.1)

*** The reinforced wall may vary by application.

4.0   FITTINGS AND ADHESIVE

4.1   The pipe, fittings, and adhesive shall be produced by the same manufacturer. The piping, including joining method, shall have been commercially available from the manufacturer for a minimum of 5 years.

4.2   The piping system, including pipe, fittings, and joints, shall have a minimum pressure rating of 150 psig (1035 kPa) at 175°F (79°C). (Pressure and Temperature rating may vary by application.)

5.0   QUALITY ASSURANCE

5.1   Inspection for shipping damage shall be performed at the job site prior to piping installation. Damaged pipe and fittings shall not be used.

6.0   INSTALLATION

Installation, including joining, burial, anchoring, guiding, and supporting, shall be per the manufacturer's recommendations.

7.0   FABRICATOR CERTIFICATION

All fiberglass piping field joints shall be made by fabricators who have been certified by the piping manufacturer. Certification by the manufacturer shall be in compliance with ASME B31.3 section A328.2 for the type of joint being made.

GLOSSARY

Catalyst.   The chemical added to vinyl ester resins which cause them to harden. Usually Methyl Ethyl Ketone Peroxide (MEKP).

Centrifugal Casting.   A process for making pipe in which resin and fiberglass are placed into the interior of a spinning rotary mold, forming the pipe through centrifugal force.

Chopped Fiber.   Continuous glass fibers cut into short (0.125 to 2.0 in or 3 to 50 mm) lengths.

Chopped Strand Mat.   Coarse fabric sheets made from chopped strands randomly placed and held together by resin binders.

Cure.   The hardening of a thermoset resin system by the action of heat or chemical action.

Cure Time.   The time it take for a resin system to reach full strength.

Curing Agent.   Any of a number of chemicals added to epoxy resin to cause it to harden. Aromatic amine curing agents are commonly used for high-temperature corrosion service. Anhydride cured epoxy resins are typically used for less stringent applications.

Epoxy Resin.   A thermosetting resin used in caustic, solvent, salt, and some acid solutions.

Fabmat.   A combination of woven roving and chopped strand mat held together with resin binders. Usually used for making contact molded fittings and butt weld joints.

Filament. A single fiber of glass (e.g., a monofilament).

Gel Time. The time it takes for a resin system to harden so flow will not occur.

Hardener. Any of a number of chemicals added to resin which cause hardening to occur.

Liner. The resin-rich interior surface of the pipe or fitting. The liner provides the corrosion resistance for chemical service.

Nexus. Porous surfacing mat of synthetic used to provide a resin-rich layer or liner.

Novolac Resin. A premium epoxy vinyl ester resin used in a broad range of corrosive applications.

Reinforcement. Typically fibers of glass used to provide strength and stiffness to a composite material.

Resin. The polymer or plastic material used to bind the glass fibers together in fiberglass pipe and fittings.

Roving. A collection of one or more strands of glass filaments. The typical form of glass fiber used in the manufacture of filament-wound pipe.

Thermoset Resin. A resin cured by heat or chemical additives. Once cured, a thermoset resin cannot be remelted.

Veil. Surfacing mat of porous fabric made from filaments. Used to provide a resin-rich layer or liner.

Vinyl Ester Resin. A thermosetting resin used in strong acids, chlorine, and oxidizing agents.

Woven Roving. Coarse clothlike material made by weaving fiberglass roving.

TABLE E2.1 Principal Properties of Commercial Pipe (in U.S. Customary Units) (*Continued*)

Notes: The following formulas were used in the computation of the values shown in the table:

Weight† of pipe per foot (pounds)	$= 10.6802t(D - t)$
Weight of water per foot (pounds)	$= 0.3405d^2$
Square feet outside surface per foot	$= 0.2618D$
Square feet inside surface per foot	$= 0.2618d$
Inside area (square inches)	$= 0.785d^2$
Area of metal (square inches)	$= 0.785(D^2 - d^2)$
Moment of inertia (inches⁴)	$= 0.0491(D^4 - d^4)$
	$= A_M R_g^2$
Elastic section modulus (inches³)	$= \dfrac{0.0982(D^4 - d^4)}{D}$
Plastic section modulus	$= \dfrac{(D^3 - d^3)}{6}$
Radius of gyration (inches)	$= 0.25\sqrt{D^2 + d^2}$

A_M = area of metal (square inches)
d = inside diameter (inches)
D = outside diameter (inches)
R_g = radius of gyration (inches)
t = pipe wall thickness (inches)

* Schedule numbers: Standard weight pipe and Schedule 40 are the same in all sizes through 10 in; from 12 in through 24 in, standard weight pipe has a wall thickness of ⅜ in. Extra-strong weight pipe and Schedule 80 are the same in all sizes through 8 in; from 8 in through 24 in, extra-strong weight pipe has a wall thickness of ½ in. Double extra-strong weight pipe has no corresponding schedule number.

a: ANSI/ASME B36.10 Steel Pipe Schedule Numbers.
b: ANSI/ASME N36.10 Steel Pipe Nominal Wall Thickness Designations.
c: ANSI/ASME B36.19 Stainless Steel Pipe Schedule Numbers.

† The ferritic stainless steels may be about 5 percent less and the austenitic stainless steels about 2 percent greater than the values shown in this table which are based on weights for carbon steel.

TABLE E2.1M Principal Properties of Commercial Pipe (Metric Data)

TABLE E3.2 Diameter and Wall-Thickness Tolerances for Seamless Hot-Finished Mechanical Tubing of Carbon and Alloy Steel (AISI)*

Specified size, OD, in.	Ratio of wall thickness to OD	OD tolerance		Wall thickness tolerance, %							
				0.109 in. and under		Over 0.109 to 0.172 in., incl.		Over 0.172 to 0.203 in., incl.		Over 0.203 in.	
		Over	Under	Over	Under	Over	Under	Over	Under	Over	Under
Under 3	All wall thicknesses	0.023	0.023	16.5	16.5	15	15	14	14	12.5	12.5
3–5½, excl.	All wall thicknesses	0.031	0.031	16.5	16.5	15	15	14	14	12.5	12.5
5½–8, excl.	All wall thicknesses	0.047	0.047	. . .	. . .	. .	. .	14	14	12.5	12.5
8–10¾, incl. . . .	5% and over	0.047	0.047	. . .	. . .	. .	. .	. .	. .	12.5	12.5
8–10¾, incl. . . .	Under 5%	0.063	0.063	. . .	. . .	. .	. .	. .	. .	12.5	12.5

* The common range of sizes of hot-finished tubes is 1½ to and including 10¾ in outside diameter with wall thickness not less than 0.095 in (no. 13 BWG) or 3 percent or more of the outside diameter. For sizes under 1½ or over 10¾ in outside diameter, the tolerances are commonly negotiated between the purchaser and producer.

[1] For tolerances closer than those indicated, availability and applicable tolerances for tubing less than ³⁄₁₆ in OD or larger than 10¾-in. OD, the producer should be consulted.

[2] For those tubes with inside diameter less than ½ in (or less than ⅝ in when the wall thickness is more than 20 percent of the outside diameter), which are not commonly drawn over a mandrel, note[4] is not applicable. Unless otherwise agreed upon by the purchaser and producer, the wall thickness may vary 15 percent over and under that specified, and the inside diameter is governed by the outside diameter and wall-thickness tolerances shown.

[3] For tubes with inside diameter less than ½ in (or less than ⅝ in when the wall thickness is more than 20 percent of the outside diameter), which can be produced by the rod or bar mandrel process, the tolerances are as shown in the above table except that the wall-thickness tolerances are 10 percent over and under the specified wall thickness.

[4] Many tubes with inside diameter less than 50 percent of outside diameter, with wall thickness more than 25 percent of outside diameter, with wall thickness over 1¼ in or weighing more than 90 lb/ft are difficult to draw over a mandrel. Unless otherwise agreed upon by the purchaser and producer the inside diameter may vary over or under by an amount equal to 10 percent of the wall thickness and the wall thickness may vary 12½ percent over and under that specified.

[5] Tubing have a wall thickness less than 3 percent of the outside diameter cannot be straightened properly without a certain amount of distortion. Consequently, such tubes, while having an average outside diameter and inside diameter within the tolerances shown in the above table, require an ovality tolerance of 0.5 percent over and under nominal outside diameter, this being in addition to the tolerances indicated in the above table.

Note: No allowance has been made for age, differences in diameter, or any abnormal condition of interior surface. Any factor of safety must be estimated from the local conditions and the requirements of each particular installation.

Source: Friction loss, h_f, is derived from Darcy-Weisbach equations. (*Hydraulic Institute Engineering Data Book,* Table IIIB-4).

APPENDIX E4M
FRICTION LOSS FOR WATER IN METERS PER 100 METERS OF PIPE

Troy J. Skillen
Mechanical Engineer
Bechtel Power Corporation
Frederick, Maryland

Example E4M.1:

Calculate hf in NPS 4 (DN 100) steel-schedule 40 pipe in meters per 100 m with flow of 100 gallons per minute (gpm).

(1 U. S. gallon = 3.7853 liters).

Refer to Table E1.5 in App. E1.

From App. E4:

hf per 100 ft of length of pipe = 0.624 ft (for 100 gpm)

100 ft = 30.48 m

hf in 100 ft length of pipe   = 0.624 ft

or   = 0.624 * 0.0348 m = 0.190 m

hf in 30.48 m length of pipe = 0.190 m

hf in 100 m length of pipe $= \dfrac{0.190 \text{ m}}{30.48} * 100 \text{ m}$

or   = 0.623 m

Example E4M.2:

Calculate hf in NPS 6 (DN 150) steel-schedule 40 pipe in meters per 100 m with flow of 1000 gallons per minute (gpm).

(1 U. S. gallon = 3.7853 liters).

Refer to Table E1.5 in App. E1.

From App. E4:

hf per 100 ft of length of pipe = 6.17 ft (for 100 gpm)

100 ft = 30.48 m

hf in 100 ft length of pipe	= 6.17 ft
or	= 6.17 * 0.0348 m = 0.215 m

hf in 30.48 m length of pipe = 0.215 m

hf in 100 m length of pipe $= \dfrac{0.215 \text{ m}}{30.48} * 100 \text{ m}$

or $= 0.705$ m

Example E4M.3:

Calculate hf in NPS 24 steel-schedule 40 pipe in meters per 100 m with flow of 60,000 gallons per minute (gpm).

(1 U. S. gallon = 3.7853 liters).

Refer to Table E1.5 in App. E1.

From App. E4:

hf per 100 ft of length of pipe = 22.3 ft (for 60,000 gmp)

100 ft = 30.48 m

hf in 100 ft length of pipe	= 22.3 ft
or	= 22.3 * 0.0348 m = 0.776 m

hf in 30.48 m length of pipe = 0.776 m

hf in 100 m length of pipe $= \dfrac{0.776 \text{ m}}{30.48} * 100 \text{ m}$

or $= 2.55$ m

APPENDIX E5

PIPE, TUBE, AND FITTING MATERIAL SPECIFICATIONS ACCEPTABLE FOR ASME B31, PRESSURE PIPING CODE, AND ASME BOILER AND PRESSURE VESSEL CODE

(1) For materials acceptable for use in ASME I and/or ASME III applications, use ASME specifications (e.g., SB 160) in lieu of ASTM specifications (e.g., B 160). The ASME specifications for nonferrous materials are prefixed by SB, whereas ASTM specifications are prefixed by B.

(2) For limitations or additional requirements on use of these material specifications, refer to the applicable Code.

Note: (3) Refer to code for acceptable grades, class, temper, and/or UNS Number.

(1) For materials acceptable for use in ASME I and/or ASME III applications, use ASME specifications (e.g., SB 247) in lieu of ASTM specifications (e.g., B 247). The ASME specifications for nonferrous materials are prefixed by SB, whereas ASTM specifications are prefixed by B.

(2) For limitations or additional requirements on use of these material specifications, refer to the applicable Code.

Note: (3) Refer to code for acceptable grades, class, temper, and/or UNS Number.

APPENDIX E6
INTERNATIONAL PIPING MATERIAL SPECIFICATIONS

R. Peter Deubler, P.E.
Technical Director
Shaw Fronek Company
Englewood, NJ

This appendix lists material specifications of different countries. It includes correlating specifications for different piping materials, grades, classes, types, and other categories. Since each country's specifications are unique, no two specifications are identical. The equivalency determination of material produced to one specification to material produced to another specification will vary based upon the criteria utilized. Therefore this table provides only a cross-reference and does not consider which specifications are equivalent.

Specific gravity of water at 60°F = 1.00.
Weight per gallon is based on 7.48052 gallons per cubic foot.

Molecular weight, specific gravity, individual gas constant, and specific heat values were abstracted from, or based on, data in Table 24 of Mark's *Standard Handbook for Mechanical Engineers* (seventh edition).

Weight density values were obtained by multiplying density of air by specific gravity of gas. For values at 60°F, multiply by 1.0154.

Natural gas values are representative only. Exact characteristics require knowledge of specific constituents.

GENERAL NOTE:
   Coefficient A is the instantaneous coefficient of thermal expansion $\times 10^{-6}$ (in./in./°F). Coefficient B is the mean coefficient of thermal expansion $\times 10^{-6}$ (in./in./°F) in going from 70°F to indicated temperature. Coefficient C is the linear thermal expansion (in./ft) in going from 70°F to indicated temperature.

TABLE E8.1 Nominal Coefficients of Thermal Expansion for Ferrous Materials (*Continued*)

Notes:
(1) Material Group A consists of:

Plain carbon steels	¾Ni–½Mo–⅓Cr–V	½Ni–½Cr–¼Mo–V
Carbon–manganese steel	¾Ni–1Mo–¾Cr	¾Ni–½Cu–Mo
½Ni–½Mo–V	¾Ni–½Cr–½Mo–V	¾Cr–¾Ni–Cu–Al
¾Ni–½Mo–Cr–V	1Ni–½Cr–½Mo	¾Cr–½Ni–Cu

(2) Material Group B consists of:

Carbon–silicon steels	½Cr–½Mo	1Cr–⅕Mo
C–½Mo	½Cr–⅕Mo–V	1Cr–⅕Mo–Si
½Cr–½Ni–⅕Mo	1Cr–½Mo	1¾Cr–½Mo–Cu

(3) Material Group C consists of:

C–Mn–Si steels	¼Cr–½Mo	3Cr–1Mo
½Cr–¼Mo–Si	1¼Cr–½Mo–Si	
1Cr–½Mo–V	2Cr–½Mo	

(4) Material Group D consists of:

Mn–¼Mo	Mn–½Mo–¼Ni	Mn–½Mo–¾Ni
Mn–½Mo	Mn–½Mo–½Ni	

(5) Material Group E consists of:

1¼Ni–1Cr–½Mo	2Ni–¾Cr–⅓Mo	3½Ni–1¾Cr–½Mo–V
1¾Ni–¾Cr–¼Mo	2Ni–1Cu	
2Ni–¾Cr–¼Mo	2½Ni and 3½Ni	

(6) Includes N grades also

Notes:

(1) Material Group A consists of the following carbon–molybdenum steels:

C–½Mo	Mn–¼Mo
Mn–½Mo	Mn–V

(2) Material Group B consists of the following Ni steels:

¾Ni–½Mo–Cr–V	1Ni–½Cr–½Mo
½Ni–½Mo–V	¾Ni–1Mo–¾Cr
¾Ni–½Mo–⅓Cr–V	½Ni–½Cr–¼Mo–V
¾Cr–¾Ni–Cu–Al	2Ni–1Cu
¾Cr–½Ni–Cu	2½Ni
¾Ni–½Cu–Mo	3½Ni

(3) Material Group C consists of the following ½–2Cr steels:

½Cr–½Mo
1Cr–½Mo
1¼Cr–½Mo–Si
1¼Cr–½Mo
2Cr–½Mo

(4) Material Group D consists of the following 2¼–3Cr steels:

2¼Cr–1Mo
3Cr–1Mo

(5) Material Group E consists of the following 5–9Cr steels:

5Cr–½Mo
5Cr–½Mo–Si
5Cr–½Mo–Ti
7Cr–½Mo
9Cr–Mo

(6) Material Group F consists of the following chromium steels:

12Cr–Al
13Cr
15Cr
17Cr

(7) Material Group G consists of the following austenitic steels:

18Cr–8Ni	18Cr–10Ni–Cb
18Cr–8Ni–N	18Cr–18Ni–2Si
16Cr–12Ni	20Cr–6Ni–9Mn
18Cr–13Ni–3Mo	22Cr–13Ni–5Mn
16Cr–12Ni–2Mo–N	23Cr–12Ni
18Cr–3Ni–13Mn	25Cr–20Ni
18Cr–10Ni–Ti

APPENDIX E9
PIPING-RELATED COMPUTER PROGRAMS AND THEIR CAPABILITIES

Anthony W. Paulin

President
Paulin Research Group
Woodlands, TX 77302

Computer technology and world standards for the conduct of engineering practice continue to evolve at a rapid pace. In this appendix, over 40 piping-related programs are listed, together with several that relate to machinery and equipment closely associated with piping. It is beyond the scope of this handbook to identify those programs that are compliant to the codes and standards mentioned in Chap. A4, or to ISO-9000, or other standards. It is customary for software users to ascertain the state of compliance to the relevant codes of the programs they use. This is done in contract negotiations with the software vendors.

The trend today is toward more integrated systems of management, design, manufacturing, and construction. Some of the software listed in this appendix is suitable for use in some integrated systems, and some is incapable of such use at present. It is beyond the scope of this handbook to address integrated systems that include CAD/CAM modules such as FORAN, HICADEC, ISDP, NAPA, and TRIBON. Similarly, software that primarily supports management and nontechnical functions is mentioned only if it has some technical value for the piping designer.

Changing codes, hardware, operating systems, computer languages, rapid evolution of the Internet, and improvements in integrating systems necessitate continuing review of software capabilities.

Programs for use in the piping and pressure-vessel areas are described in this appendix. The information was provided by courtesy of the software vendors.

The programs listed in Tables E9.1 through E9.14 may undergo considerable changes in the future. The user is cautioned to check and verify applicability of the computer program and its version prior to using.

TABLE E9.1 Pipe Stress Analysis Programs

Program title	Applications/capabilities	Contact
ADL Pipe	Windows 95 GUI version of well-respected software program. Nuclear Class 1 Piping Analysis, extensive piping code library and features.	Research Engineers 714-974-2500 *info@reiusa.com*
AutoPipe	Windows 95 GUI version with graphical model building, including options cut, copy and paste, multiple loadings, wave loads, and nonlinear pipe/soil interaction. 2-way interface with PlantFLO, PULS, AutoPLANT Designer, PDS, and PASCE.	Rebis 510-933-2525 *info@rebis.com.*
CAESAR II	Established Windows-based program for the design and analysis of above and below ground piping and pipe and structure systems. Windows-based, with CADWorx bidirectional link.	COADE, Inc. 281-890-4566 *query@coade.com.*
PipePak	Easy-to-use, quick static and dynamic analysis of complex piping networks.	Algor, Inc. 412-967-2700 *info@algor.com.*
Simflex	Nonnuclear piping applications for weight, pressure, thermal, occasional, and dynamic loads. Established, thorough program using keyword input for simplified piping modeling.	Peng Engineering 713-462-7390 *lcpeng@aol.com.*
Triflex	Piping stress, design, and analysis. Includes code compliance reports for many international piping codes. Linear and nonlinear modeling of pipe, structure, equipment and soils.	AAA Technology & Specialties Co., Inc. 713-849-3366 *info@aaatech.com.*
CAEPipe	Windows 95, NT/DOS version, performs static and dynamic analyses and checks for code compliance (ASME, B31, British, Canadian, Swedish). (WRC, NEMA, API, etc.) Year 2K compliant. Versions available for nuclear applications.	SST Systems, Inc. 408-452-8111 *info@sstusa.com*
Pipestress (DOS/Unix)	Performs static & dynamic analysis of nuclear and nonnuclear piping systems. Can be provided with data translators. For advanced Nuclear Piping Stress Analysis (including, Nuclear QA, class 1/2/3).	SST Systems, Inc. 408-452-8111 *info@sstusa.com*
NuPipe	For nuclear as well as nonnuclear applications for weight, pressure, thermal, occasional, and dynamic loads.	Nuclear Services Corp. Campbell, CA
ME 101	For nuclear as well as nonnuclear applications for weight, pressure, thermal, occasional, and dynamic loads.	Bechtel Software, Inc. 50 Beale Street San Francisco, CA 94105-1595 415-768-8947 *bsi@bechtel.com*
T Pipe	For nuclear as well as nonnuclear applications for weight, pressure, thermal, occasional, and dynamic loads.	PMB Systems Engineering, Inc. 500 Sansome Street San Francisco, CA 94111 415-986-4166
Super Pipe	For nuclear as well as nonnuclear applications for weight, pressure, thermal, occasional, and dynamic loads.	EDS Nuclear, Inc. San Francisco, CA

TABLE E9.2 Computer-Aided Design and Drafting

Program title	Applications/capabilities	Contact
AutoPLANT 97	3D CAD plant design and modeling software. Object-oriented technology with external database links, spec-driven fitting-to-fitting polyline routing and component placement.	Rebis 510-933-2525 *info@rebis.com.*
AutoSTAAD/ Pro	Model generation, verification drafting, and detailing within AutoCAD.	Research Engineers 714-974-2500 *info@reiusa.com*
CADWorx/ Pipe	AutoCAD-based, intuitive piping CAD package with bidirectional transfer link to CAESAR II. Operates in 2d, 3d, ortho, iso, or solid modes. Auto-routing, BOM's.	COADE, Inc. 281-890-4566 *query@coade.com.*
Intergraph Plant Design System 6.3 (PDS[tm])	Market-leading interactive piping design, specification, P&ID, clash-detection and ISO-creation software. (1997–54.3% market share according to Daratech, Inc.) PDS Runs on Windows NT Operating System.	Intergraph Corporation 800-260-0245 *Fjoop@ingr.com*
MiniCAD	General purpose 2D and 3D CAD program that includes a complete library of piping and process–design symbols.	Diehl Graphsoft, Inc. 410-290-5114 *marketing@ diehlgraphsoft.com*
Multi-Steel	Structural steel–drafting and modeling application. 2D frames can be combined into 3D models, and contains seven steel-section libraries. Links for stress analysis and for CAD imports to AutoPLANT.	Rebis 510-933-2525 *info@rebis.com.*
PPP-Pro Bundle	Complete piping and structural–design and drafting programs and symbol libraries for use with AutoCAD.	CAD Technology Corp. 704-369-3979
Solid Pipe Designer	AutoCAD-based 3D solid modeling of process piping systems designed specifically for sanitary, high purity, HVAC and general piping systems used in the semiconductor, pharmaceutical, biotechnology, food, beverage, and dairy industries.	UHP Process Piping, Inc. 972-247-8530 *gary.greer@uhppp.com*
Vessel Drafting Program	Automatically generates fabrication/as-built drawings of pressure vessels and heat exchangers.	Codeware 281-497-5705 *john@codeware.com*
Multi-Frame	3D structural analysis and design software system.	Formation Design Systems, Inc. 408-440-0702 *info@formsys.com*
PlantSpace	Object-oriented software. 3D CAD Software.	Jacobus 800-724-8741 *info@jacobus.com*

TABLE E9.3 Heat-Exchanger Programs

Program title	Applications/capabilities	Contact
Iris* Exchanger	Interactive and graphical design & analysis of TEMA shell and tube heat exchangers.	EDAC, Inc. 281-437-1155 *iris@edacsoft.com*
B-Jac Hetran	Thermal design of shell & tube heat exchangers, single phase, condensers, vaporizers, falling film evaporators, and thermosiphons supported.	Aspen Tech 804-897-4150 *info@aspentech.com*
B-Jac Teams	Mechanical design of shell & tube heat exchangers. ASME, Codap, ADM Codes. Detailed cost estimating and drawings.	Aspen Tech 804-897-4150 *info@aspentech.com*
HTRI Programs	Eleven programs for the rating and simulating of air- and liquid-cooled exchangers, condensers, reboilers & fire heaters. Single- and two-phone applications and tube-bundle vibrations.	Heat Transfer Research, Inc. 409-260-6200 *htri@htri-net.com*
TRI*Therm	Performs thermodynamic design and rerating of shell and tube heat exchangers. Handles 2-phase fluids with integral VLE module. Has built-in fluid property database.	AAA Technology & Specialties Co., Inc. 713-849-3366 *info@aaatech.com*
TRI*AC	Performs forced air–cooled heat exchanger design & analysis with built-in fluid property & VLE.	AAA Technology & Specialties. Co., Inc. 713-849-3366 *info@aaatech.com*
Compress 6.0	Windows 95 NT version for design, rating, cost analysis, drafting of ASME Section VIII pressure vessels and heat exchangers.	Codeware 281-497-5705 *john@codeware.com*

TABLE E9.4   Network Fluid Flow Programs

Program title	Applications/capabilities	Contact
AFT Impulse 1.0.	Windows-based, transient fluid-flow analysis. Drag & drop model construction, cavitation, and multipipe interaction.	Applied Flow Technology 719-686-1000 *info@aft.com.*
AFT Fathom 3.0	Windows-based, steady-state incompressible flow analysis. Drag & drop model construction with integrated heat-transfer analysis.	Applied Flow Technology 719-686-1000 *info@aft.com*
BOS Fluids	Steady-state and transient liquid and gas simulator for 3D piping geometries. Computes unbalanced forces due to valve closure and acoustic frequencies.	Paulin Research Group 281-363-3790 *info@paulin.com.*
Pipe-Flo	Windows-based. Unlimited size version of Pipe-Flo Lite. Performs steady-state line sizing, pump selection, etc. Interacts with orifice- and compressor-sizing programs.	Engineered Software, Inc. 800-786-8545 *Sales@ eng-software.com*
PlantFLOW	Steady-state piping flow analysis in 3D for gas or liquid systems; includes heat transfer, gas equations of state, and graphical model building.	Rebis 510-933-2525 *info@rebis.com.*
AFT Arrow	Windows-based. Steady-state compressible fluid-flow analysis. Drag & drop model construction. Models complex gas networks.	Applied Flow Technology 719-686-1000 *info@aft.com*

TABLE E9.5 Pressure-Vessel Design Programs

Program title	Applications/capabilities	Contact
Advanced Pressure Vessel	ASME Section VIII Div. 1 pressure-vessel calculations. Ability to perform nozzle-loading calculations per WRC-107.	Computer Engineering, Inc. 800-473-1976 *Sales@ computereng.com*
CodeCalc	ASME Section VIII, Div. 1 vessel and heat-exchanger component analysis and design. TEMA, WRC 107, and some piping components. Windows-based.	COADE, Inc. 281-890-4566 *Query@coade.com*
Compress	32 bit Windows, 3D graphic ASME Section VIII Div. 1 and TEMA designs for vertical and horizontal pressure vessels. Produces hypertext-linked output reports.	Codeware 281-497-5705 *john@codeware.com.*
Iris*Calc	ASME Section VIII, Div. 1 Interactive design and analysis of pressure-vessel and heat-exchanger components.	EDAC, Inc. 281-437-1155 *iris@edacsoft.com.*
Iris*Vessel	ASME Section VIII, Div. 1 Interactive and graphical design of vertical and horizontal pressure vessels.	EDAC, Inc. 281-437-1155 *iris@edacsoft.com*
PV Elite	Designs and rates multicomponent vertical and horizontal vessels subject to a variety of loadings. Designs per ASME Section VIII, Div. 1 and 2, and BS 5500. Windows-based.	COADE, Inc. 281-890-4566 *query@coade.com.*
Vessel Coster	Estimates material and labor for pressure-vessel fabrication. Includes complete design ability and is written in Visual Basic for Windows.	Codeware 281-497-5705 *john@codeware.com*

TABLE E9.6   Specialty Finite Element Analysis Program

Program title	Applications/capabilities	Contact
FE/Pipe	Specialty brick, shell, beam, and axisymetric finite element program specializing in ASME Code output reports, automatic input, stress intensification, flexibility, and allowable load computation for nozzles and supports on pressure vessels and piping.	Paulin Research Group 281-363-3790 *info@paulin.com.*

TABLE E9.7   Structural Steel Evaluation Programs

Program title	Applications/capabilities	Contact
FrameWorks Plus	Design steel structures in both 2D and 3D. Provides integration with 3rd-party analysis tools, including GTSTRUDL and STAAD. Runs on Windows NT operating system.	Intergraph Corporation 800-260-0245 *fjoop@ingr.com*
QSE	Imported from Europe, provides analysis and design modules for frame structures. Incorporates many European and American codes for both steel and concrete.	Research Engineers 714-974-2500 *info@reiusa.com*
STAAD-III	Multimedia version allows audio-visual clips and walk-thrus, analysis, design, and verification, taking full advantage of Windows functionality. Full AISC code checking.	Research Engineers 714-974-2500 *info@reiusa.com*
STAAD/Pro	Next level of STAAD-III. Model development, analysis, design, drafting, & component design.	Research Engineers 714-974-2500 *info@reiusa.com*

TABLE E9.8 Flow Analysis Tools Programs

Program title	Applications/capabilities	Contact
C-Max	32-bit Windows-based software for flow-system analysis. Includes compressor, pump, pipe, fan, blower, and energy-conservation modules. Windows-based calculation includes evaluation of energy costs.	Unicade, Inc. 425-747-0353 *unicade@unicade.com*
Con-Flow	Selects, evaluates, and analyzes control valves using catalogs available on disk. Windows-based.	Engineered Software, Inc. 800-786-8545 *Sales@ eng-software.com*
Crane Companion	Windows version of Crane Technical Paper 410.	Crane Valve Group 630-226-4900 *www.cranevalve.com*
Ori-Flow	Sizes and analyzes flat-plate orifices, nozzles- and venturi tubes for fluid-metering applications. Windows-based.	Engineered Software, Inc. 800-786-8545 *sales@ eng-software.com*
PETS	Process engineering tools—Single- and two-phase pressure drops, orifice sizing, RV sizing, tray hydraulics, and more. Windows-based, and automates many repetitive flow-related calculations.	Stratus Engineering 281-335-7138 *dfsstratus@aol.com*
Pipe-Flo Lite	For small systems, up to 25 pipelines. Steady-state flow analysis and sizing of pumps and connected piping. Windows interface.	Engineered Software, Inc. 800-786-8545 *Sales@ eng-software.com*
Pipe-Flow-Stock	Provides balanced pressure and flow calculations for piping systems used in the pulp and paper industry. Uses TAPPI method for pressure drop calculation. Windows-based.	Engineered Software, Inc. 800-786-8545 *Sales@ eng-software.com*
Pump-Flow	Selects, evaluates, and analyzes centrifugal pumps using manufacturers' pump catalogs available on disk. Over 40 manufacturers to choose from. Windows-based.	Engineered Software, Inc. 800-786-8545 *Sales@ eng-software.com*
BOS Fluids	2d CFD applications for horizontal vessels, tanks, and slug loads. Developed slug-velocity diagrams.	Paulin Research Group 281-363-3790 *info@paulin.com*

TABLE E9.9 Tank Programs

Program title	Applications/capabilities	Contact
E-Tank	Designs API 650 & 620 tanks, UL 142 tanks, and rates per API 653. Comprehensive reports are generated.	Techdata 281-497-5705 *www.techdat.com*
Tank	Designs or rerates API 650/653 storage tanks. Addresses wind girders, conical roofs, stainless-steel materials, allowed fluid heights, and remaining corrosion allowance.	COADE, Inc. 281-890-4566 *query@coade.com*

TABLE E9.10 Computational Fluid Dynamics Programs

Program title	Applications/capabilities	Contact
CFD-ACE+	Advanced computing environment for modeling flow, turbulence, conjugate heat transfer, and associated physics. Highly automated parametric geometry and grid generation with high accuracy numerics.	CFD Research Corp. 205-726-4800 *info@cfdrc.com*
COMIG	Detailed blade-geometry design for centrifugal impellers and rotors. Allows fluid-dynamic designer to produce highly efficient blade shapes.	Northern Research & Engineering Corporation 781-935-9050 *sales@nrec.com*
Phoenix	Simulates laminar, turbulent, thermal- and chemically reactive flows. Includes particle tracking, multiphase flow, non-Newtonian fluids, and user programmability.	Phoenics North America 770-996-8656 *adamgreen@* *sprynet.com.*
PREDIG	Performance prediction of centrifugal compressors. Produces performance maps based on overall geometry and fluid characteristics.	Northern Research & Engineering Corporation 781-935-9050 *sales@nrec.com*
VISIUN	Computational Fluid Dynamics analysis tool for turbomachinery. Specialized, full 3D, Navier-Stokes analysis of internal flows, including two frame-of-reference analyses of rotating-stationary interactions.	Northern Research & Engineering Corporation 781-935-9050 *sales@nrec.com*
BOS Fluids	Simplified 2d models for horizontal vessels, tanks, and some slug applications.	Paulin Research Group 281-363-3790 *info@paulin.com*

TABLE E9.11 Thermal and Power System Process Programs

Program title	Applications/capabilities	Contact
QTPro[2]	General-purpose "handbook" for thermodynamics and heat-transfer calculations related to the power and cogeneration industries.	Thermoflow, Inc. 978-579-7999 *info@thermoflow.com*
Thermoflex	General-purpose modeling of thermal and power-system processes for both the power and cogeneration industries.	Thermoflow, Inc. 978-579-7999 *info@thermoflow.com.*

TABLE E9.12 Maintenance Programs

Program title	Applications/capabilities	Contact
Avert	Designed to manage maintenance, repair, inspection, and testing data for pressure safety–relief valves. Includes Process Safety Management requirements of OSHA 1910.119.	Avert Systems 403-261-3931 *avert@telusplanet.net*

TABLE E9.13 Welding Programs

Program title	Applications/capabilities	Contact
Welding Pro-Write	Creates and maintains WPS, PQR, and WPQ in accordance with ASME Section IX. Welder management included. Also includes ASME Code checking.	Computer Engineering, Inc. 800-473-1976 *sales@ computereng.com.*

TABLE E9.14 Measurement Programs

Program title	Applications/capabilities	Contact
Conduit Corrosion Monitor	Integrates with Krautkramer Branson Pipe+ database, and has direct integration with a number of KB instruments. Provides access to many standard databases and is ANSI SQL–compliant. Windows design.	Conduit Limited Inc. 713-447-8290 *conduit@iapc.net*

APPENDIX E10
INTERNATIONAL STANDARDS AND SPECIFICATIONS

Soami D. Suri, P.E.
Senior Engineer
Bechtel Power Corporation
Frederick, Maryland

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings

Numbers	Title
BSI BS 21	1985 Amd 1 Pipe Threads for Tubes and Fittings Where Pressure-Tight Joints Are Made on the Threads (Metric Dimensions) AMD 6633; Dec. 21, 1990
BSI BS 61	1969 Amd 1 Threads for Light Gauge Copper Tubes and Fittings
BSI BS 143 & 1256	1986 Amd 2 Malleable Cast Iron and Cast Copper Alloy Threaded Pipe Fittings (AMD 6632) Dec. 21, 1990 (Partially Replaced by BS EN 10242: 1995 but Remains Current)
BSI BS 143 & 1256	1986 Amd 3 Malleable Cast Iron and Cast Copper Alloy Threaded Pipe Fittings (AMD7692) April 15, 1993 (Partially Replaced by BS EN 10242: 1995 but Remains Current)
BSI BS 143 & 1256	1986 Amd 4 Malleable Cast Iron and Cast Copper Alloy Threaded Pipe Fittings (AMD 8467) Sept. 15, 1995 (E) (Partially Replaced by BS EN 10242: 1995 but Remains Current)
BSI BS 806: ENQ CASE 4	1989 Design and Construction of Ferrous Piping Installations for and in Connection with Land Boilers Enquiry Cases: Enquiry Case 4: EFW Alloy Pipe for Wet Steam Application
BSI BS 806: ENQ CASE 6	1991 Design and Construction of Ferrous Piping Installations for and in Connection with Land Boilers Enquiry Cases: Enquiry Case 6: Use of Buttwelding Pipe Fittings
BSI BS 806: ENQ CASE 7	1991 Design and Construction of Ferrous Piping Installations for and in Connection with Land Boilers Enquiry Cases: Enquiry Case 7: Testing of Pipe Bends
BSI BS 949: PART 3	1993 Screwing Taps Part 3: Specification for Pipe Thread Taps (E)
BSI BS 949: PART 3	1993 Amd 1 Screwing Taps Part 3: Specification for Pipe Thread Taps AMD 7927; Sept. 15, 1993; (E)
BSI BS 949: PART 3	1982 Screwing Taps: Part 3: Specification for Taps for Pipe Threads (G Series, Rp Series and Rc Series)
BSI BS 1042: SEC 1.2	1989 Methods of Measurement of Fluid Flow in Closed Conduits: Pt 1: Pressure Differential Devices: Section 1.2: Specification for Squared-Edged-Orifice Plates and Nozzles (with Drain Holes, in Pipe Below 50 mm Diameter, as Inlet and Outlet Devices) and other Orifice Plates
BSI BS 1042: SEC 1.6	1993 Measurement of Fluid Flow in Closed Conduits Part 1: Pressure Differential Devices Section 1.6: Method of Measurement of Pulsating Fluid Flow in a Pipe, by Means of Orifice Plates, Nozzles or Venturi Tubes (ISO TR 3313: 1992) (Q)

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
BSI BS 1113: ENQ CASE 5	1988 Design and Manufacture of Water-Tube Steam Generating Plant (Including Superheaters, Reheaters and Steel Tube Economizers) Enquiry Case 5: British Standard Forging and Pipe Materials
BSI BS 1127: PART 2	1990 Screwing Dies and Dienuts Part 2: Hand-and-Machine-Operated Circular Screwing Dies for Taper Pipe Threads; R Series
BSI BS 1127: PART 3	1990 Screwing Dies and Dienuts Part 3: Hand-and-Machine-Operated Circular Screwing Dies for Parallel Pipe Threads; G Series
BSI BS 1387	1987 Amd 1 Screwed and Socketed Steel Tubes and Tubulars and for Plain End Steel Tubes Suitable for Welding or for Screwing to BS 21 Pipe Threads (AMD 5830) May 31, 1989
BSI BS 1600	1991 Dimensions of Steel Pipe for Petroleum Industry (Q)
BSI BS 1600	1991 Amd 1 Dimensions of Steel Pipe for the Petroleum Industry (AMD 7204) June 15, 1992 (Q)
BSI BS 1640: PART 1	1962 Amd 3 Steel Butt-Welding Pipe Fittings for the Petroleum Industry Part 1: Wrought Carbon and Ferritic Alloy Steel Fittings
BSI BS 1640: PART 2	1962 Amd 3 Steel Butt-Welding Pipe Fittings for the Petroleum Industry Part 2: Wrought and Cast Austenitic Chromium-Nickel Steel Fittings
BSI BS 1640: PART 3	1968 Amd 1 Steel Butt-Welding Pipe Fittings for the Petroleum Industry Part 3: Wrought Carbon and Ferritic Alloy Steel Fittings
BSI BS 1640: PART 4	1968 Steel Butt-Welding Pipe Fittings for the Petroleum Industry Part 4: Wrought and Cast Austentic Chromium-Nickel Steel Fittings
BSI BS 1740: PART 1	1971 Amd 3 Wrought Steel Pipe Fittings (Screwed BSP Threads) Part 1: Metric Units (AMD 6240) May 31, 1990
BSI BS 1965: PART 1	1963 Amd 2 Butt-Welding Pipe Fittings for Pressure Purposes Part 1: Carbon Steel
BSI BS 2051: PART 1	(OBSOLESCENT) 1973 Amd 2 Tube and Pipe Fittings for Engineering Purposes Part 1: Copper and Copper Alloy Capillary and Compression Tube Fittings for Engineering Purposes
BSI BS 2051: PART 2	(OBSOLESCENT) 1984 Tube and Pipe Fittings for Engineering Purposes Part 2: Specification for Olive Type Copper Alloy Compression Tube Fittings
BSI BS 2494	1990 Elastomeric Seals for Joints in Pipework and Pipelines

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings (*Continued*)

Numbers	Title
BSI BS 2779	1986 Pipe Threads for Tubes and Fittings Where Pressure-Tight Joints are Not Made on the Threads (Metric Dimensions)
BSI BS 2782: PT11: METH 1103A&B	1995 Plastic Piping and Ducting Systems-Injection-Moulded Thermoplastics Fittings—Test Method for Visually Assessing Effects of Heating (V)
BSI BS 2782: PT11: METH 1103V	1995 Plastic Piping and Ducting Systems—Thermoplastic Pipe and Fittings—Determination of Vicat Softening Temperature (VST) (See BS EN 727) (V)
BSI BS 2782: PT11: METH 1108T	1997 Plastics Piping Systems—Polyethylene (PE) Tapping Tees—Test Method for Impact Resistance of an Assembled Tapping Tee Also Known as BS EN 1716: 1997; (V)
BSI BS 2782: PT11: METH 1112L, M, N, Q	1996 Plastic Piping Systems—Thermoplastics Piping Systems for Buried Non-Pressure Applications—Test Methods for Leaktightness of Elastomeric Sealing Ring Type Joints (V)
BSI BS 2782:PT11: METH 1114F	1995 Plastics Piping and Ducting Systems—Injection-Moulded Thermoplastics Fittings for Pressure Piping Systems—Test Method for Maximum Deformation by Crushing (See BS EN 802) (V)
BSI BS 2782: PT11: METH 1123B	1995 Plastics Piping Systems—Mechanical Joints Between Fittings and Polyolefin Pressure Pipes—Test Method for Leaktightness Under Internal Pressure of Assemblies Subjected to Bending (SEE BS EN 713) (V)
BSI BS 2782: PT11: METH 1123B	1995 Amd 1 Plastics Piping Systems—Mechanical Joints Between Fittings and Polyolefin Pressure Pipes—Test Method for Leaktightness Under Internal Pressure of Assemblies Subjected to Bending (AMD 8876) Oct. 15, 1995 (SEE BS EN 713) (V)
BSI BS 2782: PT11: METH 1123F	1995 Thermoplastics Piping Systems—Non-End-Load-Bearing Elastomeric Sealing Ring Type Joints Between Pressure Pipes and Moulded Fittings—Test Method for Leaktightness Under Internal Hydrostatic Pressure without End Thrust (See BS EN 714) (V)
BSI BS 2782: PT11: METH 1123G	1995 Thermoplastics Piping Systems—End-Load-Bearing Joints Between Small Diameter Pressure Pipes and Fittings—Test Method for Leaktightness Under Internal Water Pressure, Including End Thrust (See BS EN 715) (V)
BSI BS 2782: PT11: METH 1123J	1995 Plastics Piping Systems—Injection-Moulded Thermoplastics Fittings for Elastic Sealing Ring Type Joints for Pressure Piping—Test Methods for Resistance to Short-Term Internal Pressure Without End Thrust (See BS EN 803) (V)

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
BSI BS 2782:PT11: METH 1123K	1995 Plastics Piping Systems—Injection-Moulded Socket Fittings for Solvent-Cemented Joints for Pressure Piping—Test Method for Resistance to a Short-Term Internal Hydrostatic Pressure (See BS EN 804) (V)
BSI BS 2782:PT11: METH 1123W	1996 Plastic Piping Systems-Elastomeric Sealing Ring Type Joints and Mechanical Joints for Thermoplastic Pressure Piping-Test Method for Leaktightness Under External Hydrostatic Pressure (V)
BSI BS 2782:PT12: METH 1123A&B	1997 Plastics Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Test Methods to Prove the Leaktightness of the Wall Under Short-Term Internal Pressure (V)
BSI BS 2782:PT12: METH 1123C	1996 Plastics Piping Systems—Joints for Glass Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Test Methods for Leaktightness and Resistance to Damage of Flexible and Reduced-Articulation Joints (V)
BSI BS 3506	1969 Amd 2 Unplasticized PVC Pipe for Industrial Purposes
BSI BS 3799	1974 Amd 2 Steel Pipe Fittings, Screwed and Socket-Welding for the Petroleum Industry (AMD 5518) March 31, 1987
BSI BS 3867	(OBSOLESCENT) 1987 Method of Specifying Outside Diameters and Pressure Ratings for Pipe of Thermoplastics Materials (Inch Series) Partially Superseded by BS ISO 11922-2: 1997, BS 2782: Part 11: Method 1121 C: and BS ISO 4065: 1996
BSI BS 3908: PART 1	1965 Amd 1 Methods for Sampling and Analysis of Lead and Lead Alloys Part 1: Sampling of Ingot Lead, Lead Alloy Ingots, Sheet Pipe, and Cable Sheathing Alloys
BSI BS 3958: PART 4	1982 Thermal Insulating Materials Part 4: Bonded Preformed Man-Made Fibre Pipe Sections
BSI BS 4346: PART 1	1969 Amd 5 Joints and Fittings for Use With Unplasticized PVC Pressure Pipes Part 1: Injection Moulded Unplasticized PVC Fittings for Solvent Welding for Use with Pressure Pipes, Including Potable Water Supply
BSI BS 4346: PART 2	1970 Amd 3 Joints and Fittings for Use with Unplasticized PVC Pressure Pipes Part 2: Mechanical Joints and Fittings Principally of Unplasticized PVC
BSI BS 4346: PART 3	1982 Amd 1 Joints and Fittings for Use with Unplasticized PVC Pressure Pipes Part 3: Solvent Cements

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings
(*Continued*)

Numbers	Title
BSI BS 4728	(OBSOLESCENT) 1971 Determination of the Resistance to Constant Internal Pressure of Thermoplastics Pipe Replaced by BS EN 921: 1995
BSI BS 4991	1974 Amd 2 Propylene Copolymer Pressure Pipe
BSI BS 5254	1976 Amd 2 Polypropylene Waste Pipe and Fittings (External Diameter 34.6 mm, 41.0 mm and 54.1 mm) (AMD 4438) Dec. 30, 1983
BSI BS 5255	1989 Thermoplastics Waste Pipe and Fittings
BSI BS 5391: PART 1	1976 Acrylonitrile Butadiene-Styrene (ABS) Pressure Pipe Part 1: Pipe for Industrial Uses
BSI BS 5392: PART 1	1976 Acrylonitrile Butadiene-Styrene (ABS) Fittings for use With ABS Pressure Pipe Part 1: Fittings for Use with Pipe for Industrial Uses
BSI BS 5422	1990 Method for Specifying Thermal Insulating Materials on Pipes, Ductwork and Equipment (In Temperature Range 40 Degrees Celsius to +700 Degrees Celcius)
BSI BS 5480	1990 Glass Reinforced Plastics (GRP) Pipes, Joints and Fittings for use for Water Supply or Sewerage
BSI BS 5481	1977 Amd 2 Unplasticized PVC Pipe and Fittings for Gravity Sewers
BSI BS 5500: ENQ CASE 112	1996 Enquiry Case: Case 112: Use of API 5L Pipe Material (Q)
BSI BS 5556	(OBSOLESCENT) 1978 General Requirements for Dimensions and Pressure Ratings for Pipe of Thermoplastics Materials (Metric Series) Replaces BS 4159: 1967; Partially superseded by BS ISO 11922-1: 1997, BS 2782: Part 11: Method 1121B and BS ISO 4065
BSI BS 5608	1993 Preformed Rigid Polyurethane (PUR) and Polyisocyanurate (PIR) Foams for Thermal Insulation of Pipework and Equipment (E)
BSI BS 5608	1986 Preformed Rigid Polyurethane (PUR) and Polyisocyanurate (PIR) Foams for Thermal Insulation of Pipework and Equipment
BSI BS 5627	1984 Amd 1 Plastic Connectors for Use With Horizontal Outlet Vitreous China WC Plans
BSI BS 5844	1980 Measurement of Fluid Flow: Estimation of Uncertainty of a Flow rate Measurement
BSI BS 5970	1992 Thermal Insulation of Pipework and Equipment (in the Temperature Range −100 Degrees C to +870 Degrees C)
BSI BS 5970	1981 Amd 1 Thermal Insulation of Pipework and Equipment (in the Temperature Range −100 Degrees C to +870 Degrees C)

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
BSI BS 6209	1982 Solvent Cement for Non-Pressure Thermoplastics Pipe Systems
BSI BS 6281: PART 3	1982 Devices Without Moving Parts for the Prevention of Contamination of Water by Backflow Part 3: Pipe Interrupters of Nominal Size up to and Including DN 42
BSI BS 6362	1990 Stainless Steel Tubes Suitable for Screwing in Accordance with BS 21 Pipe Threads for Tubes and Fittings Where Pressure-Tight Joints are Made on the Threads
BSI BS 7605: PART 2	1992 Agricultural Irrigation Equipment Part 2: Specification for Emitting Pipe Systems (ISO 9261: 1991)
BSI BS 7677	1993 Classification of Imperfections in Pipe Joint Rings (ISO 9691: 1992)
BSI BS 7838	1996 Corrugated Stainless Steel Semi-Rigid Pipe and Associated Fittings for Low Pressure Gas Pipework of up to 28 mm (R)
BSI BS 7892	1997 Bitumen Seal Coatings on Cement Mortar Linings in Ductile Iron Pipes and Fittings (W)
BSI BS 8010: PART 1	1989 Pipelines Part 1: Pipelines on Land: General (Replaces BS CP 2010: Part 1: 1966)
BSI BS EN 253	1995 Preinsulated Bonded Pipe Systems for Underground Hot Water Networks—Pipe Assembly of Steel Service Pipes, Polyurethane Thermal Insulation and Outer Casing of Polyethylene (E)
BSI BS EN 253	1991 Preinsulated Bonded Pipe Systems for Underground Hot Water Networks—Pipe Assembly of Steel Service Pipes, Polyurethane Thermal Insulation and Outer Casing of High Density Polyethylene
BSI BS EN 448	1995 Preinsulated Bonded Pipe Systems for Underground Hot Water Networks—Fitting Assemblies of Steel Service Pipes, Polyurethane Thermal Insulation and Outer Casing of Polyethylene (E)
BSI BS EN 476	1998 General Requirements for Components Used in Discharge Pipes, Drains and Sewers for Gravity Systems (R)
BSI BS EN 489	1995 Preinsulated Bonded Pipe Systems for Underground Hot Water Networks—Joint Assembly for Steel Service Pipes, Polyurethane Thermal Insulation and Outer Casing of Polyethylene (E)
BSI BS EN 681-1	1996 Elastomeric Seals—Material Requirements for Pipe Joint Seals Used in Water and Drainage Applications Part 1: Vulcanized Rubber (E)

Numbers	Title
BSI BS EN ISO 12185	1996 Methods of Test for Petroleum and Its Products Part 365: Crude Petroleum and Petroleum Products—Determination of Density—Oscillating U-Tube Method (ISO 12185: 1996) (W)
BSI BS ISO 8434-1	Metallic Tube Connections for Fluid Power and General Use–Part 1: 24 Degrees Compression Fittings (E)
BSI BS ISO 8434-2	1994 Metallic Tube Connections for Fluid Power and General Use–Part 2: 37 Degrees Flared Fitting (E)
BSI BS ISO 8434-3	1995 Metallic Tube Connections for Fluid Power and General Use–Part 3: O-Ring Face Seal Fittings (E)
BSI BS ISO 8434-4	1995 Metallic Tube Connections for Fluid Power and General Use–Part 4: 24 Degree Cone Connector with O-Ring Weld-On Nipples (E)
BSI B 27	1991 Copper-Zinc-Aluminium-Nickel-Silicon Alloy Tube
BSI 4L 54	1986 Amd 1 Tube of 99% Aluminium (Cold Drawn: Seamless: Tested Hydraulically) (Not exceeding 12 mm Wall Thickness) (AMD 5994) Aug. 31, 1988 (Replaces BS 3L 54: 1971)
BSI 4L 56	1986 Amd 1 Tube of Aluminium–2¼% Magnesium Alloy (Temper Designation–0) (Seamless: Tested Hydraulically) (Not Exceeding 12 mm Wall Thickness) (AMD 5993) Aug. 31, 1988 (Replaces BS 3L 56: 1971)
BSI 3L 63	1971 Tube of Aluminium-Copper-Magnesium-Silicon-Manganese Alloy (Solution Treated and Precipitation Treated) (Cu 4.4, Mg 0.5, Si 0.7, Mn 0.8)
BSI L 105	1971 Tube of Aluminium-Copper-Magnesium-Silicon-Manganese Alloy (Solution Treated and Aged at Room Temperature) (Not Exceeding 10 mm Wall Thickness) (Cu 4.4, Mg 0.5, Si 0.7, Mn 0.8) (Replaces BS 2L 62: 1961)
BSI L 114	1971 Tube of Aluminium-Magnesium-Silicon-Manganese Alloy (Solution Treated and Precipitation Treated)
BSI 2L 116	(OBSOLESCENT) 1985 Tube of 99% Aluminium (Cold Drawn: Seamless: Not Tested Hydraulically) (Not Exceeding 12 mm Wall Thickness) Replaces BS L 116: 1973)
BSI L 117	1975 Amd 1 Tube of Aluminium-Magnesium-Silicon-Copper-Chromium Alloy (Solution Treated and Artifically Aged: Not Tested Hydraulically) (Not Exceeding 10 mm Thickness) (Mg 1.0, Si 0.6, Cu 0.28, Cr 0.2)

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
BSI L 118	1975 Amd 2 Tube of Aluminium-Magnesium-Silicon-Copper-Chromium Alloy (Solution Treated and Artificially Aged: Tested Hydraulically) (Not Exceeding 10 mm Thickness) (Mg 1.0, Si 0.6, Cu 0.28, Cr 0.2)
BSI 2L 503	(OBSOLESCENT) 1973 Tube of Magnesium-6 Per Cent Aluminium-Zinc Alloy
BSI 2L 509	(OBSOLESCENT) 1973 Tube of Magnesium–1¼% Zinc-Zirconium Alloy (Suitable for Welding by Inert-Gas Shielded Arc Techniques) (Zn 1.25, Zr 0.6) (S)
BSI 5T 2	(OBSOLESCENT) 1972 4/1 Nickel-Chromium Steel Tube (1300 N/Square mm) Replaces BS 4T 2: 1948
BSI 4T 45	(OBSOLESCENT) 1972 Carbon-Manganese Steel Tube (700 N/Square mm) (Tube 12.5 mm Outside Diameter and Greater) (Weldable) (Replaces BS 3T 45: 1948)
BSI 3T 53	1980 Chromium-Molybdenum Steel Tube (700 Mpa) (Tube 12.5 mm Outside Diameter and Greater) (Weldable) (Replaces BS 2T 53: 1972)
BSI 2T 57	(OBSOLESCENT) 1972 4/1 Nickel-Chromium Steel Tube (1150 N/Square MM) (Replaces BS T 57: 1948)
BSI 3T 60	1980 Chromium-Molybdenum Steel Tube (1150 MPa) (Maximum Wall Thickness 8 mm) (Replaces BS 2T 60: 1972)
BSI T 64	(OBSOLESCENT) 1972 Carbon-Manganese Steel Tube (550 N/Square mm) (Tube Less than 12.5 mm Outside Diameter) (Weldable) (Replaces BS 3T 35: 1948)
BSI 2T 66	1980 18/10 Chromium-Nickel Corrosion-Resisting Steel Tube (Niobium Stabilized: 550 MPa) (Weldable)
BSI 2T 66	1980 Amd 1 18/10 Chromium-Nickel Corrosion-Resisting Steel Tube (Niobium Stabilized: 550 Mpa) (Weldable) (AMD 6853) Nov. 29, 1991 (Replaces BS T 66: 1972)
BSI T 67	(OBSOLESCENT) 1972 18/10 Chromium-Nickel Corrosion-Resisting Steel Tube (Titanium mm) (Weldable) (Replaces BS T 55: 1948)
BSI 2T 68	1980 Cold Drawn 18/10 Chromium-Nickel Corrosion-Resisting Steel Tube (Niobium Stabilized: 800 N/Square mm) (Weldable) (Replaces BS T 68: 1972)
BSI T 69	(OBSOLESCENT) 1972 Cold Drawn 18/10 Chromium-Nickel Corrosion-Resisting Steel Tube (Titanium Stabilized: 800 N/Square MM) (Weldable) (Replaces BS T 58: 1948)

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
BSI T 72-73	1977 18/10 Chromium-Nickel Corrosion Resisting Steel Tube for Hydraulic Purposes (Niobium/Titanium Stabilized: 550 MPa)
BSI T 72-73	1977 Amd 1 18/10 Chromium-Nickel Corrosion Resisting Steel Tube for Hydraulic Purposes (Niobium/Titanium Stabilized: 550 MPa) (AMD 6852) Dec. 24, 1991
BSI T 74	(OBSOLESCENT) 1972 Low Carbon 18/10 Chromium-Nickel Corrosion-Resisting Steel Tube (500 N/Square mm)
BSI T 75	(OBSOLESCENT) 1972 Low Carbon 17/12 Chromium-Nickel-Molybdenum Corrosion-Resisting Steel Tube (500 N/Square MM)
BSI T 76	1978 Amd 1 Chromium-Molybdenum Steel Tube (770 MPa) (Weldable)
BSI T 77	1980 Chromium-Molybdenum Steel Tube (900 MPa) (Weldable) Replaces BS T 65: 1972
BSI BS 65	1991 Vitrified Clay Pipes, Fittings and Ducts, Also Flexible Mechanical Joints for Use Solely with Surface Water Pipes and Fittings
BSI BS 65	1991 Amd 1 Vitrified Clay Pipes, Fittings and Ducts, Also Flexible Mechanical Joints for Use Solely with Surface Water Pipes and Fittings (AMD 8622) May 15, 1995 (R)
BSI BS 78: PART 2	(OBSOLESCENT) 1965 Amd 1 Cast Iron Spigot and Socket Pipes (Vertically Cast) and Spigot and Socket Fittings Part 2: Fittings (Partially Superseded by BS 4772)
BSI BS 416: PART 1	1990 Discharge and Ventilating Pipes and Fittings, Sand-Cast or Spun in Cast Iron Part 1: Specification for Spigot and Socket Systems
BSI BS 416: PART 2	1990 Discharge and Ventilating Pipes and Fittings, Sand-Cast or Spun in Cast Iron Part 2: Specification for Socketless Systems
BSI BS 437	1978 Amd 1 Cast Iron Spigot and Socket Drain Pipes and Fittings (Replaces BS 1130: 1943)
BSI BS 567	1973 Amd 1 Asbestos-Cement Flue Pipes and Fittings, Light Quality (AMD 5963) April 28, 1989
BSI BS 835	1973 Amd 1 Asbestos-Cement Flue Pipes and Fittings, Heavy Quality
BSI BS 2598: PART 3	1980 Glass Plant, Pipeline and Fittings Part 3: Pipeline and Fittings of Nominal Bore 15 to 150 mm: Compatibility and Interchangeability
BSI BS 2598: PART 4	1980 Glass Plant, Pipeline and Fittings Part 4: Glass Plant Components

TABLE E10.B1   British Standards and Specifications for Pipe, Tube, and Fittings

Numbers	Title
BSI BS 2760	1973 Amd 1 Pitch-Impregnated Fibre Pipes and Fittings for Below and Above Ground Drainage (AMD 2675) June 30, 1978 (R)
BSI BS 2782: PT 11: METH 1103D	1997 Plastics Piping and Ducting Systems—Polyolefin Pipes and Fittings—Determination of Oxidation Induction Time Also Numbered as BS EN 728: 1997; (V)
BSI BS 2782: PT 11: METH 1104A	1994 Plastics Piping Systems—Plastic Pipes and Fittings—Determination of Opacity (V)
BSI BS 2782: PT 11: METH 1107A	1996 Plastics Piping and Ducting Systems—Plastic Pipes and Fittings—Method of Exposure to Direct (Natural) Weathering (V)
BSI BS 2782: PT 11: METH 1121A	1996 Thermoplastics Materials for Pipes and Fittings for Pressure Applications—Classification and Designation—Overall Service (Design) Coefficient (See BS EN ISO 12162) (V)
BSI BS 2782: PT 11: METH 1123H	1995 Thermoplastics Piping Systems—End-Load Bearing Mechanical Joints Between Pressure Pipes and Fittings—Test Method for Resistance to Pull Out Under Constant Longitudinal Force (See BS EN 712) (V)
BSI BS 2782: PT 11: METH 1140A	1995 Plastics Piping and Ducting Systems—Pipes and Fittings of Unplasticized Poly(Vinyl Chloride) (PVC_U)—Specimen Preparation for Determination of the Viscosity Number and Calculation of the K-Value (See BS EN 922) (V)
BSI BS 2782: PT 12: METH 1209A&B	1996 Plastics Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Determination of the Resistance to Chemical Attack from the Inside of a Section in a Deflated Condition (V)
BSI BS 2782: PT 12: METH 1220A to C	1995 Plastics Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Methods of Regression Analyses and Their Use (E) Supplement 1: Guide to Functional Performance Values; IEC 977: 1989
BSI BS 4514	1983 Amd 1 Unplasticized PVC Soil and Ventilating Pipes, Fittings and Accessories
BSI BS 4622	(OBSOLESCENT) 1970 Amd 3 Grey Iron Pipes and Fittings (Replaces BS 78: Part 1 1961)
BSI BS 4625	1970 Amd 2 Prestressed Concrete Pressure Pipes (Including Fittings)
BSI BS 4660	1989 Unplasticized Polyvinyl Chloride (PVC-V) Pipes and Plastics Fittings of Nominal Sizes 110 to 160 for Below Ground Gravity Drainage and Sewerage

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
BSI BS 4660	1989 Amd 1 Unplasticized Polyvinyl Chloride (PVC-V) Pipes and Plastic Fittings of Nominal Sizes 110 to 160 for Below Ground Gravity Drainage and Sewerage AMD 9132 July 15, 1996 (R)
BSI BS 4825: PART 1	1991 Stainless Steel Tubes and Fittings for the Food Industry and Other Hygienic Application Part 1: Specification for Tubes (Q)
BSI BS 4825: PART 1	1972 Amd 1 Stainless Steel Pipes and Fittings for the Food Industry Part 1: Pipes
BSI BS 4825: PART 2	1991 Stainless Steel Tubes and Fittings for the Food Industry and Other Hygienic Application Part 2: Specification for Bends and Tees (Q)
BSI BS 4825: PART 2	1973 Stainless Steel Pipes and Fittings for the Food Industry Part 2: Bends and Tees
BSI BS 4825: PART 3	1991 Stainless Steel Tubes and Fittings for the Food Industry and Other Hygienic Application Part 3: Specification for Clamp Type Couplings (Q)
BSI BS 4825: PART 3	1976 Stainless Steel Pipes and Fittings for the Food Industry Part 3: Clamp Type Couplings
BSI BS 4825: PART 4	1991 Stainless Steel Tubes and Fittings for the Food Industry and Other Hygienic Application Part 4: Specification for Threaded (IDF Type) Couplings (Q)
BSI BS 4825: PART 4	1977 Stainless Steel Pipes and Fittings for Food Industry Part 4: Screwed Type Couplings
BSI BS 4825: PART 5	1991 Stainless Steel Tubes and Fittings for the Food Industry and Other Hygienic Application Part 5: Specification for Recessed Ring Joint Type Couplings (Replaces BS 1864: 1966)
BSI BS 4962	1989 Plastic Pipe and Fittings for Use as Subsoil Field Drains
BSI BS 4962	1989 Amd 1 Plastic Pipes and Fittings for Use as Subsoil Field Drains (AMD 9131) July 15, 1996 (R)
BSI BS 5114	1975 Amd 2 Performance Requirements for Joints and Fittings for Use With Polyethylene Pipes (AMD 5336) July 31, 1987
BSI BS 5911: PART 2	1982 Amd 1 Precast Concrete Pipes and Fittings for Drainage and Sewerage Part 2: Inspection Chambers and Street Gullies
BSI BS 5911: PART 100	1988 Amd 1 Precast Concrete Pipes and Fittings for Drainage and Sewerage Part 100: Unreinforced and Reinforced Pipes and Fittings with Flexible Joints (AMD 6269) Dec. 22, 1989 (Supersedes BS 5911: Part 1 1981)

TABLE E10.B1 British Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
BSI BS 5911: PART 100	1988 Amd 2 Precast Concrete Pipes, Fittings and Ancillary Products Part 100: Specification for Unreinforced and Reinforced Pipes and Fittings with Flexible Joints (AMD 7588) April 15, 1993 (R)
BSI BS 5911: PART 101	1988 Precast Concrete Pipes and Fittings for Drainage and Sewerage Part 101: Glass Composite Concrete (GCC) Pipes and Fittings with Flexible Joints (Replaces DD 76: Part 1: 1981)
BSI BS 5911: PART 103	1994 Precast Concrete Pipes and Ancillary Concrete Products Part 103: Specification for Prestressed Non-Pressure Pipes and Fittings with Flexible Joints (Replaces BS 5178: 1975) (R)
BSI BS 5911: PART 110	1992 Precast Concrete Pipes, Fittings and Ancillary Products Part 110: Specification for Ogee Pipes and Fittings (Including Perforated)
BSI BS 5911: PART 110	1992 Amd 1 Precast Concrete Pipes, and Ancillary Concrete Products Part 110: Specification for Ogee Pipes and Fittings (Including Perforated) (AMD 8155) March 15, 1994 (R)
BSI BS 5911: PART 114	1992 Precast Concrete Pipes, Fittings and Ancillary Products Part 114: Specification for Porous Pipes (Supersedes BS 1194: 1969)
BSI BS 5911: PART 120	1989 Precast Concrete Pipes and Fittings for Drainage and Sewerage Part 120: Reinforced Jacking Pipes with Flexible Joints
BSI BS 5911: PART 120	1989 Amd 1 Precast Concrete Pipes, Fittings and Ancillary Products Part 120: Specification for Reinforced Jacking Pipes with Flexible Joints (AMD 9020) March 15, 1996 (R)
BSI BS 5911: PART 200	1989 Precast Concrete Pipes and Fittings for Drainage and Sewerage Part 200: Unreinforced and Reinforced Manholes and Soakaways of Circular Cross Section
BSI BS 5955: Part 8	1990 Code of Practice for Plastics Pipework (Thermoplastics Materials) Part 8: Installation of Thermoplastics Pipes and Associated Fittings for Use in Domestic Hot and Cold Water Services and Heating Systems
BSI BS 6076	1996 Polymeric Film for Use as a Protective Sleeving for Buried Iron Pipes and Fittings (For Site and Factory Application) (E)
BSI BS 6076	1981 Tubular Polyethylene Film for use as Protective Sleeving for Buried Iron Pipes and Fittings
BSI BS 6087	1990 Amd 1 Flexible Joints for Grey or Ductile Cast Iron Drain Pipes and Fittings (BS 437) and for Discharge and Ventilating Pipes and Fittings (BS 416) (AMD 6357) June 28, 1991 (R)

Numbers	Title
BSI BS EN 723	1996 Copper and Copper Alloys—Combustion Method for Determination of Carbon on the Inner Surface of Copper Tubes or Fittings (V)
BSI BS EN 922	1995 Plastics Piping and Ducting Systems—Pipes and Fittings of Unplasticized Poly (Vinyl Chloride) (PVC-U)—Specimen Preparation for Determination of the Viscosity Number and Calculation of the K-Value (V)
BSI BS EN 969	1996 Ductile Iron Pipes, Fittings, Accessories and Their Joints for Gas Pipelines—Requirements and Test Methods (Replaces BS 4772: 1988) (E)
BSI BS EN 1056	1996 Plastic Piping and Ducting Systems—Plastic Pipes and Fittings—Method for Exposure to Direct (Natural) Weathering (V)
BSI BS EN 1119	1996 Plastics Piping Systems—Joints for Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Test Methods for Leaktightness and Resistance to Damage of Flexible and Reduced-Articulation Joints (V)
BSI BS EN 1120	1996 Plastics Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Determination of the Resistance to Chemical Attack from the Inside of a Section in a Deflected Condition (V)
BSI BS EN 1229	1997 Plastics Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings—Test Methods to Prove the Leaktightness of the Wall Under Short-Term Internal Pressure (V)
BSI BS EN 10242	1995 Threaded Pipe Fittings in Malleable Cast Iron (Partially Replaces BS 143 & 1256: 1986) (E)
BSI BS ISO 10931-3	1996 Plastic Piping Systems for Industrial Applications—Poly (Vinylidene Fluoride) Part 3: Fittings (V)

TABLE E10.B2   British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets

Numbers	Title
BSI BS 10	(OBSOLESCENT) 1962 Amd 4 Flanges and Bolting Pipes, Valves and Fittings
BSI BS 848 PART 4	1997 Fans for General Purposes Part 4: Dimensions ISO 13351: 1996 (Q)
BSI BS 1560 SEC 3.1	1989 Steel Pipe Flanges and Flanged Fittings (Nominal Sizes Half an Inch to 24 Inch) for The Petroleum Industry Part 3: Steel, Cast Iron and Copper Alloy Flanges Section 3.1: Steel Flanges
BSI BS 1560 SEC 3.1	1989 Amd 1 Circular Flanges for Pipes, Valves and Fittings (Class Designated) Part 3: Steel, Cast Iron and Copper Alloy Flanges Section 3.1: Specification for Steel Flanges (AMD 7557) June 15, 1993 (Q)
BSI BS 1560 SEC 3.1	1989 Amd 2 Circular Flanges for Pipes, Valves and Fittings (Class Designated) Part 3: Steel, Cast Iron and Copper Alloy Flanges Section 3.1: Specification for Steel Flanges (AMD 8593) July 15, 1995 (Q)
BSI BS 1560 SEC 3.2	1989 Steel Pipe Flanges and Flanged Fittings (Nominal Sizes Half an Inch to 24 Inch) for the Petroleum Industry Part 3: Steel, Cast Iron and Copper Alloy Flanges Section 3.2: Cast Iron Flanges
BSI BS 1560 SEC 3.3	1989 Steel Pipe Flanges and Flanged Fittings (Nominal Sizes Half an Inch to 24 Inch) for the Petroleum Industry Part 3: Steel Cast Iron and Copper Alloy Flanges Section 3.3: Copper Alloy and Composite Flanges
BSI BS 2782 PT 12: METH1224F	1997 Plastics Piping System—Glass—Reinforced Thermosetting Plastics (GRP) Components—Test Methods to Prove the Design of the Bolted Flange Joints Also Known as BS EN 1450: 1997: (V)
BSI BS 3293	1960 Amd 1 Carbon Steel Pipe Flanges (OVER 24 in Nominal Size) for the Petroleum Industry
BSI BS 4504 SEC 3.1	1989 Amd 2 Circular Flanges for Pipes, Valves and Fittings (PN Designated) Part 3: Steel Cast Iron and Copper Alloy Flanges Section 3.1 Steel Flanges (AMD 6334) Jan. 31, 1991
BSI BS 4504 SEC 3.1	1989 Amd 3 Circular Flanges for Pipes, Valves and Fittings (PN Designated) Part 3: Steel, Cast Iron and Copper Alloy Flanges Section 3.1 Steel Flanges (AMD 7555) June 15, 1993 (Supersedes BS 4504 Part 1 1969)
BSI BS 4504 SEC 3.3	1989 Amd 1 Circular Flanges for Pipes, Valves and Fittings, (PN Designated Part 3: Steel, Cast Iron and Copper Alloy Flanges) Section 3.3 Specification for Copper Alloy and Composite Flanges (AMD 6274) Nov. 30, 1989
BSI BS 4581	1970 Amd 4 Dimensions for Flanges for the Mounting of Plain Grinding Wheels Renumbered as BS 4581: Part 1: 1970 Per AMD 4393; March 30, 1984

TABLE E10.B2 British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
BSI BS 4581 PART 2	1984 Flanges for Mounting Grinding Wheels on Grinding Machine Tools Part 2: Specification for Dimensions and Materials of Flanges for Grinding Wheels of Less Than 76.2 mm Bore
BSI BS 4882	1990 Bolting for Flanges and Pressure Containing Purposes (Q)
BSI BS 5500 ENQ CASE 17	1979 Enquiry Cases Case 17: Split Ring Flanges
BSI BS 5500 ENQ CASE 36	1995 Enquiry Cases Case 36: Loose Flanges Split Across a Diameter and Keyed into the Back of a Component (Q)
BSI BS 5500 ENQ CASE 36	1993 Enquiry Case Case 36: Loose Flanges Split Across a Diameter and Keyed into the Back of a Component (Q)
BSI BS 5500 ENQ CASE 36	1981 Enquiry Case Case 36: Loose Flanges Split Across a Diameter and Keyed into the Back of a Component
BSI BS 5500 ENQ CASE 58	1995 Enquiry Case Case 58: Bolted Flanges Complying with ANSI B 16.5 Issue 2: (Q)
BSI BS 5500 ENQ CASE 58	1984 Enquiry Case Case 58: Bolted Flanges Complying with ANSI B 16.5
BSI BS 5500 ENQ CASE 100	1993 Enquiry Case Case 100: Domed and Bolted Ends with Full Face Flange
BSI BS 5500 ENQ CASE 117	1996 Enquiry Case Case 117: Flanges Fitted with Swing Bolts and Clamps (Q)
BSI BS 5587	1978 Amd 1 Coated Abrasives Flap Wheels with Incorporated Flanges or Separate Flanges. Designation and Dimensions
BSI BS 5840 PART 1	1980 Valve Mating Details for Actuator Operation Part 1: Flange Dimensions and Characteristics
BSI BS 6276	1987 Dimensions and Identification Code for Mounting Flanges and Shaft Ends for Hydraulic Fluid Power Pumps and Motors
BSI BS 6339	1983 Dimensions for Circular Flanges for General Purpose Industrial Fans
BSI BS AU 211	1987 Dimensions of Four-Hole Flanges for Gear-Driven Air Compressors for Commercial Vehicles and Buses
BSI BS AU 214A PART 1	1987 Amd 1 Gearbox Flanges Part 1: Dimensions of Cross-Tooth Gearbox Flanges, Type T, for Commercial Vehicles and Buses (Formerly BS AU 214: 1987)
BSI BS AU 214 PART 2	1988 Gearbox Flanges Part 2: Dimensions for Type A Gearbox Flanges for Commercial Vehicles and Buses
BSI BS AU 214 PART 3	1988 Gearbox Flanges Part 3: Dimensions for Type S Gearbox Flanges for Commercial Vehicles and Buses

TABLE E10.B2 British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
BSI BS AU 259	1995 Components for Commercial Vehicles and Buses—Cross-Tooth Propeller Shaft Flanges, Type T (ISO 12667: 1993) (E)
BSI BS MA 9	(OBSOLESCENT) 1970 Amd 3 Flanges, Bolting and Gaskets for Exhaust Gas Piping for Diesel Engines and Boiler Uptakes
BSI BS EN 1092-2	1997 Flanges and Their Joints—Circular Flanges for Pipes, Valves, Fittings and Accessories, PN Designated Part 2: Cast Iron Flanges Supersedes BS 4504: Section 3.2: 1989; (Q)
BSI BS EN 1450	1997 Plastics Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Components—Test Methods to Prove the Design of Bolted Flanged Joints Also Known as BS 2782: Part 12: Method 1224 F: 1997; (V)
BSI BS EN 3149	1997 Shank Nuts-Installation Holes, 60 Degree Swage, Flanges-Design Standard (S)
BSI BS EN 60154-1	1996 Flanges for Waveguides Part 1: General Requirements (IEC 154-1: 1982) (S)
BSI BS EN 60154-2	1997 Flanges for Waveguides Part 2: Relevant Specifications for Flanges for Ordinary Rectangular Waveguides Renumbers BS 6569: Part 2: 1985; (S)
BSI BS EN 60264-5-1	1997 Packaging of Winding Wirest 5.1: Cylindrical Barrelled Delivery Spools with Conical Flanges—Basic Dimensions IEC 60264-5-1: 1997; (E)
BSI BS EN ISO 5210	1996 Industrial Valves—Multi-Turn Valve Actuator Attachments Supersedes Section 3 of BS 5840: Part 1: 1980 and Section 3 of BS 5840: Part 2: 1982 (E)
BSI BS ISO 666	1996 Machine Tools—Mounting of Plain Grinding Wheels by Means of Hub Flanges Supersedes BS 4581: Part 1: 1970; (F)
BSI BS ISO 7299	1996 Diesel Engines—End-Mounting Flanges for Fuel Injection Pumps (E)
BSI BS ISO 12129-2	1995 Plain Bearings–Part 2: Tolerances on Form and Position and Surface Roughness for Shafts, Flanges and Thrust Collars (E)
BSI PD 6438	1969 Review of Present Methods for Design of Bolted Flanges for Pressure Vessels
BSI BS 57	(OBSOLESCENT) 1951 Amd 3 B.A. Screws, Bolts and Nuts
BSI BS 64	1992 Normal and High Strength Steel Bolts and Nuts for Railway Rail Fishplates (Q)
BSI BS 64	1992 Amd 1 Normal and High Strength Steel Bolts and Nuts for Railway Rail Fish Plates (AMD 8210) July 15, 1994 (Q)

TABLE E10.B2 British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
BSI BS 325	(OBSOLESCENT) 1947 Amd 3 Black Cup and Countersunk Bolts and Nuts
BSI BS 916	(OBSOLESCENT) 1953 AMD 4 Black Bolts, Screws and Nuts
BSI BS 1083	(OBSOLESCENT) 1965 Amd 2 Precision Hexagon Bolts, Screws and Nuts (B.S.W. and B.S.F. Threads)
BSI BS 1768	(OBSOLESCENT) 1963 Amd 3 Unified Precision Hexagon Bolts, Screws and Nuts (UNC and UNF Threads) Normal Series
BSI BS 1769	(OBSOLESCENT) 1951 Amd 7 Unified Precision Hexagon Bolts, Screws and Nuts (UNC and UNF Threads) Heavy Series
BSI BS 2485	1987 Tee Slots, Tee Bolts, Tee Nuts and Tenons
BSI BS 3692	(OBSOLESCENT) 1967 Amd 1 ISO Metric Precision Hexagon Bolts, Screws and Nuts
BSI BS 3692	(OBSOLESCENT) 1967 Amd 2 ISO Metric Precision Hexagon Bolts, Screws and Nuts Metric Units (AMD 8227) November 15, 1994 (E)
BSI BS 4190	(OBSOLESCENT) 1967 AMD 2 ISO Metric Black Hexagon Bolts, Screws and Nuts
BSI BS 4190	(OBSOLESCENT) 1967 AMD 3 ISO Metric Black Hexagon Bolts, Screws and Nuts (AMD 8226) Nov. 15, 1994 (E)
BSI BS 4395 PART 1	1969 Amd 2 High Strength Friction Grip Bolts and Associated Nuts and Washers for Structural Engineering Part 1: General Grade (E)
BSI BS 4395 PART 2	1969 Amd 2 High Strength Friction Grip Bolts and Associated Nuts and Washers for Structural Engineering Part 2: Higher Grade Bolts and Nuts and General Grade Washers (E)
BSI BS 4933	(OBSOLESCENT) 1973 ISO Metric Black Cup and Countersunk Head Bolts and Screws with Hexagon Nuts (E)
BSI BS 6040	1981 Nomenclature for Bolts, Screws, Nuts and Accessories
BSI BS 6293 PART 2	1994 Aerospace-MJ Threads Part 2: Limit Dimensions for Bolts and Nuts (ISO 5855-2: 1988) (S)
BSI BS 6293 PART 2	1982 MJ Threads for Aerospace Construction Part 2: Dimensions for Bolts and Nuts
BSI BS 6322 PART 1	1982 Tolerances for Fasteners Part 1: Tolerances of Bolts, Screws and Nuts with Thread Diameter MW 1.6 mm and MV 150 mm and Product Grades A, B and C

TABLE E10.B2   British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
BSI BS 6322 PART 2	1982 Tolerances for Fasteners Part 2: Tolerances of Bolts, Screws and Nuts with Thread Diameters from 1 mm up to 3 mm and Product Grade F, for Fine Mechanics
BSI BS 6322 PART 3	1992 Tolerances for Fasteners Part 3: Specification for Tolerances of Plain Washers for Bolts, Screws and Nuts with Nominal Thread Diameters from 1 mm up to and Including 150 mm. Product Grades A and C (ISO 4759-3: 1991)
BSI BS 6322 PART 3	1982 Tolerances for Fasteners Part 3: Tolerances of Washers for Metric Bolts, Screws and Nuts with Thread Diameters from 1 mm up to and including 150 mm. Product Grades A and C.
BSI BS 7670 PART 1	1993 Steel Nuts and Bolts for Resistance Projection Welding Part 1: Specification for Dimensions and Properties (E)
BSI BS 7670 PART 1	1993 Amd 1 Steel Nuts and Bolts for Resistance Projection Welding Part 1: Specification for Dimensions and Properties (AMD 8215) July 15, 1994 (E)
BSI BS 7670 PART 2	1997 Steel Nuts and Bolts for Resistance Projection Welding Part 2: Specification for Welding of Weld Nuts and Weld Bolts Supersedes BS 2996: 1958; (E)
BSI BS EN 20225	1992 Fasteners—Bolts, Screws, Studs and Nuts—Symbols and Designations of Dimensions (ISO 225: 1983) (Replaces BS 6565: 1985)
BSI BS EN 28839	1992 Mechanical Properties of Fasteners—Bolts, Screws, Studs and Nuts Made of Non-Ferrous Metals (ISO 8839: 1986) (E)
BSI 2A 58	(OBSOLESCENT) 1962 Amd 4 Steel Hexagonal Nuts (B.S.F. Threads) for Shear Bolts for Aircraft (Replaces BS A57 and A58: 1952)
BSI 3A 100	1991 General Requirements for Bolts and Free Running Nuts of Tensile Strength not Exceeding 1249 MPa (Supersedes 2A 100: 1968) (S)
BSI 3A 100	1991 Amd 1 General Requirements for Bolts and Free Running Nuts of Tensile Strength not Exceeding 1249 MPa (AMD 7661) April 15, 1993 (S)
BSI 2A 110	1962 Amd 4 Steel Nuts (Unified Hexagons and Unified Threads) for Shear Bolts for Aircraft (Replaces BS A 109 and A 110: 1954)
BSI HR 650	1972 Amd 2 High Expansion Heat-Resisting Steel Bar and Wire for the Manufacture of Bolts, Studs, Set Screws and Nuts (Ni 25.5, Cr 15, Ti 2, Mn 1.5, Mo 1.25, Si 0.7, V 0.3) (Limiting Ruling Section 20 mm)

TABLE E10.B2 British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
BSI 2S 147	1976 0.5 Per Cent Nickel-Chromium-Molybdenum Steel Bars for the Manufacture of Forged Bolts and Forged Nuts (Replaces BS S 147: 1969)
BSI 2S 147	1976 Amd 1 0.5 Per Cent Nickel-Chromium-Molybdenum Steel Bars for the Manufacture of Forged Bolts and Forged Nuts (AMD 6836) Nov. 29, 1991 (Replaces BS S 147: 1969)
BSI 2S 149	1976 1.75 Per Cent Nickel-Chromium-Molybdenum Steel Bars for the Manufacture of Forged Bolts and Forged Nuts (Replaces BS S 149: 1972)
BSI 2S 149	1976 Amd 1 1.75 Per Cent Nickel-Chromium-Molybdenum Steel Bars for the Manufacture of Forged Bolts and Forged Nuts (AMD 6837) Nov. 29, 1991 (Replaces BS S 149: 1972)
BSI S 158	1977 1 Per Cent Chromium-Molybdenum Steel Bars for the Manufacture of Forged Bolts and Forged Nuts
BSI PD 7300	1979 Nuts and Bolts: Recommended Drawing Ratios for School and Colleges. Teacher's Notes
BSI BSD 3063	(OBSOLESCENT) 1965 Amd 1 Dimensions of Gaskets for Pipe Flanges
BSI BS 3381	1989 Spiral Wound Gaskets for Steel Flanges to BS 1560 (Q)
BSI BS 4255 PART 1	1986 Rubber Used in Performed Gaskets for Weather Exclusion from Buildings Part 1: Non-Cellular Gaskets
BSI BS 4332	1989 Phenol-Formaldehyde Resin-Bonded Cork Jointing
BSI BS 7076 PART 1	1989 Dimensions of Gaskets for Flanges to BS 1560 Part 1: Non-Metallic Flat Gaskets (Replaces BS 1560: Part 2: 1970)
BSI BS 7076 PART 2	1989 Dimensions of Gaskets for Flanges to BS 1560 Part 2: Metallic Ring-Joint Gaskets for Use with Steel Flanges (Replaces BS 1560: Part 2 and BS 1970)
BSI BS 7076 PART 2	1989 Amd 1 Dimensions of Gaskets for Flanges to BS 1560 Part 2: Specification for Metallic Ring-Joint Gaskets for Use with Steel Flanges (AMD 8592) June 15, 1995 (Replaces BS 1560: Part 2 and BS 1970) (Q)
BSI BS 7076 PART 3	1989 Dimensions of Gaskets for Flanges to BS 1560 Part 3: Specification for Non-Metallic Envelope Gaskets (Replaces BS 1560: Part 2: 1970)
BSI BS 7076 PART 4	1989 Dimensions of Gaskets for Flanges to BS 1560 Part 4: Corrugated, Flat or Grooved Metallic and Filled Metallic Gaskets (Replaces BS 1560: Part 2: 1970)

TABLE E10.B2 British Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
BSI BS MA 9	(OBSOLESCENT) 1970 Amd 3 Flanges, Bolting and Gaskets for Exhaust Gas Piping for Diesel Engines and Boiler Uptakes
BSI BS EN 1514-1	1997 Flanges and Their Joints—Dimensions of Gaskets for PN-Designated Flanges Part 1: Non-Metallic Flat Gaskets with or without Inserts Supersedes BS 4865: Part 1: 1989; (E)
BSI BS EN 1514-2	1997 Flanges and Their Joints—Dimensions of Gaskets for PN-Designated Flanges Part 2: Spiral Wound Gaskets for Use with Steel Flanges Supersedes BS 4865: Part 2: 1989; (E)
BSI BS EN 1514-3	1997 Flanges and Their Joints—Dimensions of Gaskets for PN-Designated Flanges Part 3: Non-Metallic PTFE Envelope Gaskets Supersede BS 4865: 1989: (E)
BSI BS EN 1514-4	1997 Flanges and Their Joints—Dimensions of Gaskets for PN-Designated Flanges Part 4: Corrugated, Flat or Grooved Metallic and Filled Metallic Gaskets for use with Steel Flanges Supersedes BS 4865: Part 4: 1989; (E)

TABLE E10.B3 British Standards and Specifications for Valves

Numbers	Title
BSI BS 341: PART 1	1991 Transportable Gas Container Valves Part 1: Specification for Industrial Valves for Working Pressures up to and Including 300 Bar (Supersedes BS 341: Part 2-1963) (E)
BSI BS 341: PART 1	1991 Amd 1 Transportable Gas Container Valves Part 1: Specification for Industrial Valves for Working Pressures up to and Including 300 Bar (AMD 7641) May 15, 1993
BSI BS 759: PART 1	1984 Amd 1 Valves, Gauges and Other Safety Fittings for Application to Boilers and to Piping Installation for and in Connection with Boilers Part 1: Specification for Valves, Mounting and Fittings
BSI BS 1123: PART 1	1987 Safety Valves, Gauges and Fusible Plugs for Compressed Air or Inert Gas Installations Part 1: Code of Practice for Installation
BSI BS 1212 PART 1	1990 Float Operated Valves (Excluding Floats) Part 1: Piston Type Float Operated Valves (Copper Alloy Body) (Excluding Floats)
BSI SI 1212 PART 2	1990 Float Operated Valves (Excluding Floats) Part 2: Diaphragm Type Float Operated Valves (Copper Alloy Body) (Excluding Floats)
BSI BS 1212 PART 3	1990 Float Operated Valves Part 3: Specification for Diaphragm Type Float Operated Valves (Plastic Bodied) for Cold Water Services Only (Excluding Floats)
BSI BS 1212 PART 4	1991 Float Operated Valves Part 4: Specification for Compact Type Float Operated Valves for WC Flushing Cisterns (Including Floats)
BSI BS 1319	1976 Amd 2 Medical Gas Cylinders, Valves and Yoke Connections (AMD 4603) June 29, 1984
BSI BS 1414	1975 Amd 2 Steel Wedge Gate Valves (Flanged and Butt-Welding Ends) for the Petroleum, Petrochemical and Allied Industries (AMD 6562) Aug. 31, 1990
BSI BS 1415: PART 1	1976 Amd 2 Mixing Valves Part 1: Non-Thermostatic, Non-Compensating Mixing Valves
BSI BS 1415: PART 2	1986 Mixing Valves Part 2: Thermostatic Mixing Valves
BSI BS 1552	1995 Open Bottomed Taper Plug Valves for 1st, 2nd and 3rd Family Gases up to 200 mbar (E)
BSI BS 1552	1995 Amd 1 Open Bottomed Taper Plug Valves for 1st, 2nd and 3rd Family Gases up to 200 mbar AMD 9622; Sept. 1997; (E)
BSI BS 1552	1989 Manual Shut-off Valves for Use with 1st, 2nd and 3rd Family Gases
BSI BS 1655	1950 Amd 2 Flanged Automatic Control Valves for the Process Control Industry (Face to Face Dimensions)

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 1868	1975 Amd 1 Steel Check Valves (Flanged and Butt-Welding Ends) for the Petroleum, Petrochemical and Allied Industries (AMD 6563) July 31, 1990
BSI BS 1873	1975 Amd 1 Steel Globe and Globe Stop and Check Valves (Flanged and Butt-Welding Ends) for the Petroleum, Petrochemical and Allied Industries (AMD 6564) July 31, 1990
BSI BS 1963	1990 Pressure Operated Relay Valves for Domestic, Commercial and Catering Gas Appliances
BSI BS 2080	(OBSOLESCENT) 1989 Face-To-Face, Centre-To-Face, End-To-End and Centre-To-End Dimensions of Valves (Partially Superseded by BS EN 558: Part 1: 1994 and BS EN 558: Part 2: 1994)
BSI BS 2080	(OBSOLESCENT) 1989 Face-To-Face, Centre-To-Face, End-To-End and Centre-To-End Dimensions of Valves (AMD 8434) May 15, 1995 (Partially Superseded by BS EN 558: Part 1: 1994 and BS EN 558: Part 2: 1994)
BSI BS 2456	1990 Floats (Plastics) for Float Operated Valves for Cold Water Services
BSI BS 2782: PT 11: METH 1101A	1981 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1101A: Measurement of Dimensions of Pipes
BSI BS 2782: PT 11: METH 1106A	1983 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1106 A: Assessment of Pigment Dispersion in Polyolefin Pipes and Fittings: Microtome Method
BSI BS 2782: PT 11: METH 1108A	1989 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1108 A: True Impact Rate (TIR) Boundaries of Pipes (Read in Conjunction with BS 2782: Part 0)
BSI BS 2782: PT 11: METH 1109A	1989 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1109 A: Resistance to Environmental Stress Cracking of Polyethylene Pipes and Fitting for Non-Pressure Applications
BSI BS 2782: PT 11: METH 1110	1989 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1110: Tensile Properties of Dumb-Bell Specimens from PVC Gutter Profiles or Pipes for Non-Pressure Applications Read in Conjunction with BS 2782: Part 0
BSI BS 2782: PT 11: METH 1112 A	(OBSOLESCENT) 1989 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1112 A: Leaktightness of Thermoplastic Pipes and Fittings for Non-Pressure Applications Superseded by BS EN 1053: 1996; Read in Conjunction with BS 2782: Part 0

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 2782: PT 11: METH 1121B	1997 Methods of Testing Plastics Part 11: Pipes, Fittings and Valves Method 1121 B: Thermoplastic Pipes for the Conveyance of Fluids—Nominal Outside Diameters and Nominal Pressures—Metric Series ISO 161-1: 1996; (V)
BSI BS 2782; PT 11: METH 1121C	1997 Methods of Testing Plastics Part 11: Pipes, Fittings and Valves Method 1121 C: Thermoplastic Pipes for the Conveyance of Fluids—Nominal Outside Diameters and Nominal Pressures—Inch-Based Series ISO 161-2: 1996; Together with BS ISO 4065 and BS ISO 11922-2
BSI BS 2782: PT 11: METH 1121H	1996 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1121 H: Thermoplastic Pipes for Transport of Liquids under Pressure—Calculation of Head Losses (ISO/TR 10501: 1993) (V)
BSI BS 2782: PT 11: METH 1127P	1997 Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1127P: Thermoplastic Pipes for the Conveyance of Fluids—Resistance to Internal Pressure—Test Method ISO 1167: 1996; (V)
BSI BS 2782: PT 11: METH 1131	1992 Thermoplastic Valves-Torque-Test Method (ISO 8233: 1988)
BSI BS 2782: PT 11: METH 1132	1992 Thermoplastic Valves–Fatigue Strength-Test Method (ISO 8659: 1989)
BSI BS 2782: PT 11: METH 1133A	1997 Plastic Piping Systems—Valves for Polyethylene (PE)-Piping Systems—Test Methods fo Leaktightness Under and after Bending applied to the Operating Mechanism. Also Known as BS EN 1680: 1997; (V)
BSI BS 2782: PT 11: METH 1133B	1997 Plastic Piping Systems—Thermoplastics Valves–Test Methods for the Integrity of a Valve After Temperature Cycling under Bending Also Numbered as BS EN 1704: 1997; (V)
BSI BS 2782: PT 11: METH 1133C	1997 Plastic Piping Systems—Thermoplastics Valves–Test Method for Integrity of a Valve After an External Blow Also Known as BS EN 1705: 1997; (V)
BSI BS 2782: PT 11: METH 1133E	1997 Plastic Piping Systems—Polyethylene (PE) Valves–Test Method for Resistance to Thermal Cycling Also Numbered as BS EN 12119: 1997; (V)
BSI BS 2782: PT 11: METH 1134A	1997 Plastic Piping Systems—Thermoplastics Valves–Test Methods for Resistance to Internal Pressure and Leaktightness Also Numbered as BS EN 917: 1997; (V)
BSI BS 2782: PT 11: METH 1150E	Methods of Testing Plastics Part 11: Thermoplastic Pipes, Fittings and Valves Method 1150E: Plastic Pipe and Fittings—Preparation of Test Piece Assemblies between a Polyethylene (PE) Pipe and Electrofusion Fitting ISO 11413: 1996 (V)

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 2782: PT12: METH 1211A–F	1997 Plastic Piping Systems—Glass-Reinforced Thermosetting Plastics (GRP) Pipes—Determination of Apparent Initial Circumferential Tensile Strength Also Numbered as BS EN 1394: 1997; (V)
BSI BS 2879	1980 Amd 3 Draining Taps (Screw-Down Pattern)
BSI BS 3457	1973 Material for Water Tap and Stopvalve Seat Washers
BSI BS 4062: PART 1	1982 Valves for Hydraulic Fluid Power Systems Part 1: Methods for Determining Pressure Differential Pressure/Flow Characteristics
BSI BS 4062: PART 2	1990 Valves for Hydraulic Fluid Power Systems Part 2: Methods for Determining Performance
BSI BS 5041: PART 1	1987 Amd 1 Fire Hydrant System Equipment Part 1: Landing Valves for Wet Risers (AMD 5912) Sept. 30, 1988
BSI BS 5041: PART 1	1975 Fire Hydrant System Equipment Part 1: Landing Valves for Wet Risers
BSI BS 5041: PART 2	1987 Amd 1 Fire Hydrant System Equipment Part 2: Landing Valves for Dry Risers (AMD 5776) July 29, 1988
BSI BS 5041: PART 2	1976 Fire Hydrant System Equipment Part 2: Landing Valves for Dry Risers
BSI BS 5041: PART 4	1975 Amd 1 Fire Hydrant Systems Equipment Part 4: Boxes for Landing Valves for Dry Risers
BSI BS 5150	1990 Cast Iron Gate Valves
BSI BS 5151	1974 Amd 2 Cast Iron Gate (Parallel Slide) Valves for General Purposes (Replaces BS 3948: 1965)
BSI BS 5152	1974 Amd 4 Cast Iron Globe and Globe Stop and Check Valve for General Purposes AMD 6042; July 31, 1989; Replaces BS 3961: 1965; (Q)
BSI BS 5153	1974 Amd 3 Cast Iron Check Valves for General Purposes (AMD 6067) July 31, 1989 (Replaces BS 4090: 1966)
BSI BS 5154	1991 Copper Alloy Globe, Globe Stop and Check, Check and Gate Valves
BSI BS 5155	1984 Amd 1 Butterfly Valves
BSI BS 5155	1984 Amd 2 Butterfly Valves (AMD 6990) May 1, 1992
BSI BS 5156	1985 Amd 1 Diaphragm Valves for General Purposes (AMD 6513) June 29, 1990
BSI BS 5157	1989 Steel Gate (Parallel Slide) Valves
BSI BS 5158	1989 Cast Iron Plug Valves
BSI BS 5159	1974 Amd 2 Cast Iron and Carbon Steel Ball Valves for General Purposes
BSI BS 5160	1989 Steel Globe Valves, Globe Stop and Check Valves and Lift Type Check Valves

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 5163	1986 Amd 2 Predominantly Key-Operated Cast Iron Gate Valves for Waterworks Purposes (AMD 6057) July 31, 1989
BSI BS 5351	1986 Amd 3 Steel Ball Valves for the Petroleum, Petrochemical and Allied Industries (AMD 6271) Sept. 28, 1990 (E)
BSI BS 5352	1981 Amd 2 Steel Wedge Gate, Globe and Check Valves 50 mm and Smaller for the Petroleum, Petrochemical and Allied Industries (AMD 6560) Aug. 31, 1990 (Supersedes BS 2995: 1996)
BSI BS 5353	1989 Steel Plug Valves
BSI BS 5672	1991 Designation of the Direction of Rotation of Cylinders and Valves in Cylinder Heads, and Definition of Right-Hand and Left-Hand in-Line Engines and Locations on an Engine for Reciprocating Internal Combustion Engines (ISO 1204: 1990) (Replaces BS 5673: 1979, BS 5674: 1979)
BSI BS 5793: PART 1	1989 Industrial-Process Control Valves Part 1: Specification and Terminology for Control Valves (IEC 534-1: 1987) (Q)
BSI BS 5793: SEC 3.2	1985 Industrial Process Control Valves Part 3: Dimensions Section 3.2: Face-to-Face Dimensions for Flangeless Control Valves Except Wafer Butterfly Valves
BSI BS 5793: PART 4	1987 Industrial Process Control Valves Part 4: Inspection and Routine Testing
BSI BS 5793: PART 5	1984 Industrial Process Control Valves Part 5: Specification for Marking
BSI BS 5793: PART 6	1986 Industrial Process Control Valves Part 6: Mounting Details for Attachment of Positioners to Control Valve Actuators
BSI BS 5793: SEC 8.1	1986 Industrial Process Control Valves Part 8: Noise Considerations Section 8.1: Method for Laboratory Measurement of Noise Generated by Aerodynamic Flow Through Control Valves
BSI BS 5834 PART 2	1983 Surface Boxes, and Guards for Underground Stopvalves for Gas and Waterworks Purposes Part 2: Small Surface Boxes (Replaces BS 1426 and 3461: 1969)
BSI BS 5834 PART 3	1985 Surface Boxes, and Guards for Underground Stopvalves for Gas and Waterworks Purposes Part 3: Large Surface Boxes
BSI BS 5944: PART 4	1984 Measurement of Airborne Noise From Hydraulic Fluid Power Systems and Components Part 4: Method of Determining Sound Power Levels from Valves Controlling Flow and Pressure
BSI BS 5995	1980 Methods of Test for Electrohydraulic Servovalves

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 6282: PART 1	1982 Devices with Moving Parts for the Prevention of Contamination of Water by Backflow Part 1: Check Valves of Nominal Size up to and Including DN 54
BSI BS 6282: PART 2	1982 Devices with Moving Parts for the Prevention of Contamination of Water by Backflow Part 2: Terminal Anti-Vacuum Valves of Nominal Size up to and Including DN 54
BSI BS 6282: PART 3	1982 Devices with Moving Parts for the Prevention of Contamination of Water by Backflow Part 3: In-Line Anti-Vacuum of Nominal Size up to and Including DN 42
BSI BS 6282: PART 4	1982 Devices with Moving Parts for the Prevention of Contamination of Water by Backflow Part 4: Combined Check and Anti-Vacuum Valves of Nominal Size up to and Including DN 42
BSI BS 6283: PART 1	1991 Safety and Control Devices for Use in Hot Water Systems Part 1: Specification for Expansion Valves for Pressure up to and Including 10 Bar
BSI BS 6283: PART 1	1982 Safety Devices for Use in Hot Water Systems Part 1: Specification for Expansion Valves for Pressures up to and Including 10 Bar (R)
BSI BS 6283: PART 2	1991 Safety and Control Devices for Use in Hot Water Systems Part 2: Specification for Temperature Relief Valves for Pressures from 1 Bar to 10 Bar
BSI BS 6283: PART 2	1982 Safety Devices for Use in Hot Water Systems Part 2: Specification for Temperature Relief Valves for Pressure up to and Including 10 Bar
BSI BS 6283: PART 3	1991 Safety and Control Devices for Use in Hot Water Systems Part 3: Specification for Combined Temperature and Pressure Relief Valves for Pressures from 1 Bar to 10 Bar
BSI BS 6283: PART 3	1982 Safety Devices for Use in Hot Water Systems Part 3: Specification for Combined Temperature and Pressure Relief Valves for Pressures up to and Including 10 Bar
BSI BS 6283: PART 4	1991 Safety and Control Devices for Use in Hot Water Systems Part 4: Specification for Drop-Tight Pressure Reducing Valves of Nominal Size up to and Including DN 50 for Supply Pressures up to and Including 12 Bar
BSI BS 6494: PART 2	1986 Hydraulic Fluid Power Valve Mounting Devices Part 2: Four-Port and Five-Port Servo Valves
BSI BS 6494: PART 3	1989 Hydraulic Fluid Power Valve Mounting Surfaces Part 3: Pressure-Relief Valves
BSI BS 6494: PART 4	1989 Hydraulic Fluid Power Valve Mounting Surfaces Part 4: Clamping Dimensions of Four-Port Sizes 03 and 05, Modular Stack Valves and Directional Control Valves

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 6494: PART 6	1989 Hydraulic Fluid Power Valve Mounting Surfaces Part 6: Pressure-Control Valves (Excluding Pressure-Relief Valves), Sequence Valves, Unloading Valves, Throttle Valves and Check Valves
BSI BS 6675	1986 Servicing Valves (Copper Alloy) for Water Services
BSI BS 6683	1985 Amd 1 Installation and Use of Valves (AMD 6604) April 30, 1991 (E)
BSI 6697	1986 Electrohydraulic Proportional Control Valves
BSI 6755: PART 1	1986 Testing of Valves Part 1: Production Pressure Testing Requirements (Replaces the Requirements for Production Pressure Testing in BS 5146: Part 1: 1974 and BS 5146: Part 2: 1984)
BSI 6755: PART 2	1987 Amd 2 Testing of Valves Part 2: Specification for Fire Type-Testing Requirements (AMD 6712) June 28, 1991 (Replaces BS 5146: Part 1: 1974 and BS 5146: Part 2: 1984)
BSI BS 6759: PART 1	1984 Amd 1 Safety Valves Part 1: Specification for Safety Valves for Steam and Hot Water (AMD 5493) March 31, 1987 (Replaces BS 759; Part 2: 1975)
BSI BS 6759: PART 1	1984 Amd 2 Safety Valves Part 1: Specification for Safety Valves for Steam and Hot Water (AMD 8272) Feb. 15, 1995 (Q)
BSI BS 6759: PART 2	1984 Amd 1 Safety Valves Part 2: Specification for Safety Valves for Compressed Air or Inert Gases (AMD 5494) March 31, 1987 (Replaces BS 1123: Part 2: 1975)
BSI BS 6759: PART 2	1984 Amd 2 Safety Valves Part 2: Specification for Safety Valves for Compressed Air or Inert Gases AMD 9276; Jan. 15, 1997; (Q)
BSI BS 6759: PART 3	1984 Amd 1 Safety Valves Part 3: Specification for Safety Valves for Process Fluids
BSI BS 6759: PART 3	1984 Amd 2 Safety Valves Part 3: Specification for Safety Valves for Process Fluids (AMD 8273) Feb. 15, 1995 (Q)
BSI BS 6821	1988 Methods for Aerodynamic Testing of Dampers and Valves
BSI BS 7296: PART 1	1990 Cavities for Hydraulic Fluid Power Cartridge Valves Part 1: Two-Port Slip-in Valves
BSI BS 7350	1990 Double Regulating Globe Valves and Flow Measurement Devices for Heating and Chilled Water Systems
BSI BS 7350	1990 Amd 1 Double Regulating Globe Valves and Flow Measurement Devices for Heating and Chilled Water Systems (AMD 6865) Dec. 24, 1991

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS 7389: PART 1	1990 Pneumatic Fluid Power Valve Mounting Surfaces Part 1: Five Port Directional Control Valves (Without Electrical Connector)
BSI BS 7403: PART 9	1995 Full-Flow Lubricating Oil Filters for Internal Combustion Engines Part 9: Method for Test for Inlet and Outlet Anti-Drain Valves (ISO 4548-9: 1995) (E)
BSI BS 7438	1991 Steel and Copper Alloy Wafer Check Valves, Single Disc, Spring-Loaded Type
BSI BS EN 488	1995 Preinsulated Bonded Pipe Systems for Underground Hot Water Networks—Steel Valve Assembly for Steel Service Pipes, Polyurethane Thermal Insulation and Outer Casing of Polyethylene (E)
BSI BS EN 558-1	1996 Industrial Valves—Face-to-Face and Centre-to-Face Dimensions of Metal Valves for Use in Flanged Pipe Systems Part 1: PN-Designated Valves (F)
BSI BS EN 558-2	1996 Industrial Valves—Face-to-Face and Centre-to-Face Dimensions of Metal Valves for Uses in Flanged Piping Systems Part 2: Class-Designated Valves (F)
BSI BS EN 561	1995 Gas Welding Equipment—Quick-Action Couplings with Shut-off Valves for Welding, Cutting and Allied Processes (F)
BSI BS EN 736-1	1995 Valves—Terminology Part 1: Definition of Type of Valves (V)
BSI BS EN 736-2	1997 Valves—Terminology Part 2: Definition of Components of Valves (E)
BSI BS EN 816	1997 Sanitary Tapware—Automatic Shut-off Valves PN 10 (R)
BSI BS EN 917	1997 Plastic Piping Systems—Thermoplastic Valves–Test Methods for Resistance to Internal Pressure and Leaktightness Also Numbered as BS 2782: Part 11: Methods 1134A and B: 1997; (V)
BSI BS EN 1092-2	1997 Flanges and Their Joints—Circular Flanges for Pipes, Valves, Fittings and Accessories, PN Designated Part 2: Cast Iron Flanges Supersedes BS 4504: Section 3.2: 1989; (Q)
BSI BS EN 1112	1997 Shower Outlets for (PN 10) Sanitary Tapware (L)
BSI BS EN 1680	1997 Plastic Piping Systems—Valves for Polyethylene (PE) Piping Systems–Test Method for Leaktightness Under and After Bending Applied to the Operating Mechanism. Also Known as BS 2782: Part 11: Method 1133 A: 1997; (V)
BSI BS EN 1704	1997 Plastics Piping Systems—Thermoplastics Valves–Test Method for the Integrity of a Valve After Temperature Cycling under Bending Also Numbered as BS 2782: Part 11: Method 1133B: 1997; (V)

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS EN 1705	1997 Plastics Piping Systems—Thermoplastics Valves–Test Method for the Integrity of a Valve After an External Blow Also Known as BS 2782: Part 11: Method 1133C: 1997; (V)
BSI BS EN 12119	1997 Plastics Piping Systems—Polyethylene (PE) Valves–Test Method for Resistance to Thermal Cycling. Also Numbered as BS 2782: Part 11: Method 1133E: 1997; (V)
BSI BS EN 28233	1992 Thermoplastics Valves–Torque-Test Method (ISO 8233: 1988) (Also numbered BS 2782: Part 11: Method 1131: 1992)
BSI BS EN 28659	1992 Thermoplastics Valves–Fatigue Strength-Test Method (ISO 8659: 1989) (Also Numbered BS 2782: Part 11: Method 1132: 1992)
BSI B EN 60534-1	1993 Amd 1 Industrial-Process Control Valves Part 1: Control Valve Terminology and General Considerations (IEC 534-1: 1987) (AMD 7815) July 15, 1993 (Formerly BS 5793: Part 1: 1989) (Q)
BSI BS EN 60534-2-1	1993 Amd 1 Industrial-Process Control Valves Part 2: Flow Capacity Section 1: Sizing Equations for Incompressible Fluid Flow Under Installed Conditions (AMD 7816) July 15, 1993 (Formerly BS 5793: Part 2: Section 2.1: 1979. Replaces BS 4740: Part 1: 1971) (Q)
BSI BS EN 60534-2-2	1993 Amd 1 Industrial-Process Control Valves Part 2: Flow Capacity Section 2: Sizing Equations for Incompressible Fluid Flow Under Installed Conditions (AMD 7817) July 15, 1993 (Formerly BS 5793: Section 2.2: 1981. Replaces BS 4740: Part 2: 1971) (Q)
BSI BS EN 60534-2-3	1993 Amd 1 Industrial-Process Control Valves Part 2: Flow Capacity Section 3: Test Procedures (IEC 534-2-3: 1983) (AMD 7818) July 15, 1993 (Formerly BS 5793: Section 2.3: 1993) (Q)
BSI BS EN 60534-8-2	1993 Amd 1 Industrial-Process Control Valves Part 8: Noise Considerations Section 2: Laboratory Measurement of Noise Generated by Hydrodynamic Flow Through Control Valves (IEC 534-8-2: 1991) (AMD 7819) July 15, 1993 (Formerly BS 5793: Section 8.2: 1991) (Q)
BSI BS EN 60534-8-3	1996 Industrial-Process Control Valves Part 8: Noise Considerations Section 3: Control Valve Aerodynamic Noise Prediction Method (IEC 534-8-3: 1995) (Q)
BSI BS EN 60534-8-4	1994 Industrial-Process Control Valves Part 8: Noise Considerations Section 8.4: Prediction of Noise Generated by Hydrodynamic Flow (IEC 534-8-4: 1994) (Q)

TABLE E10.B3 British Standards and Specifications for Valves *(Continued)*

Numbers	Title
BSI BS EN 60730-2-8	1995 Automatic Electrical Controls for Household and Similar Use Part 2: Particular Requirements Section 2.8: Electrically Operated Water Valves, Including Mechanical Requirements (Partially Replaces BS 3955: 1986) (L)
BSI BS EN 60730-2-8	1995 Amd 1 Automatic Electrical Controls for Household and Similar Use Part 2: Particular Requirements Section 2.8: Electrically Operated Water Valves, Including Mechanical Requirements AMD 9680; Nov. 15, 1997; Read in Conjunction with BS EN 60730-1: 1995; (L)
BSI BS EN ISO 5210	1996 Industrial Valves—Multi-Turn Valve Actuator Attachments Supersedes Section 3 of BS 5840: Part 1: 1980 and Section 3 of BS 5840: Part 2: 1982 (E)
BSI BS ISO 4401	1994 Hydraulic Fluid Power—Four-Port Directional Control Valves—Mounting Surfaces (E)
BSI BS ISO 6263	1997 Hydraulic Fluid Power—Compensated Flow-Control Valves Mounting Surfaces Supersedes BS 6494: Part 5: 1989; (E)

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings

Numbers	Title
DIN 76 PT 2	Thread Run-Outs and Thread Undercuts for Pipe Threads Conforming to ISO 228 Part 1—1984
DIN 259 PT 1	Whitworth Pipe Threads: Parallel Internal and Parallel External Screw Threads; Nominal Dimensions (Not to Be Used for New Design Projects)
DIN 259 PT 2	Whitworth Pipe Threads; Parallel Internal and Parallel External Screw Threads; Tolerances (Not to Be Used for New Design Projects)
DIN 259 PT 3	Whitworth Pipe Threads; Parallel Internal and Parallel External Screw Threads; Limiting Dimensions (Not to Be Used for New Design Projects)
DIN 431	Pipe Nuts with Thread in Accordance with DIN ISO 228 Part 1—1982
DIN 906	Hexagon Socket Pipe Plugs—1992
DIN 909	Hexagon Head Pipe Plugs—1992
DIN 1389 PT 1	Connectors for Water Closets; Dimensions
DIN 1389 PT 2	Connectors for Water Closets; Principles of Construction and Testing
DIN 1986-4	Site Drainage Systems; Use of Sewer Pipes and Fittings Made of Different Materials
DIN 1988 PT 3	Drinking Water Supply Systems; Pipe Sizing (DVGW Code of Practice)—1988
DIN 2406	Pipelines; Symbols; Pipe Classes—1968
DIN 2559 PT 1	Edge Preparation for Welding; Directions Regarding Edge Forms; Fusion Welding of Butt Joints in Steel Tubes
DIN 2559 PT 2	Edge Preparation for Welding; Matching of Inside Diameter for Circumferential Welds on Seamless Pipes
DIN 2559 PT 3	Weld Preparation; Inside Diameters of Steel Pipes Required for Circumferential; Butt Welding
DIN 3567	Pipe Brackets for NW 20 to 500—1963
DIN 3568	Clamping Plates for the Suspension of Pipes on I and IP Steel Beams
DIN 3570	Steel Strap for Tubes of NW 20 to 500
DIN 3575	Hanger Straps with Welding End for Pipe Hanging—1962
DIN 3853	Solderless and Soldered Pipe Unions; Threaded Ends for Union Nuts; Design Sheets—1982
DIN 3858	Whitworth Pipe Threads for Pipe Couplings; Parallel Internal Threads and Taper External Threads; Thread Dimensions—1988
DIN 3861	Solderless Pipe Unions; Cutting Rings; Design and Type W Bore Shape—1982

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN 3867	Solderless Pipe Unions with Cutting Ring; Thrust Collars for Butt Joints—1982
DIN 3870	Soldered and Solderless Pipe Couplings; Coupling Nuts—1985
DIN 3872	Solderless Pipe Couplings with Cutting Ring; Coupling Nuts for Butt Joints—1985
DIN 3904	Olive Type Compression Couplings; Male Stud Elbows
DIN 3907	Olive Type Compression Couplings; Male Stud Tees (Stud Branch)
DIN 3908	Solderless Compression Couplings with Olive; Equal Tees
DIN 3911	Solderless Compression Couplings with Olive; Elbow Bulkhead Compression Couplings
DIN 3914	Olive Type Compression Couplings; Male Stud Tees (Stud Run)
DIN 3952	Solderless Compression Couplings with Olive; Male Stud Elbow Assemblies
DIN 3953	Solderless Compression Couplings with Olive; Male Stud Tee (Stud Branch) Assemblies
DIN 3954	Solderless Compression Couplings with Olive; Male Stud Tee (Stud Run) Assemblies
DIN 4060	Elastomer Seals for Pipe Joints in Drain and Sewers; Requirements and Testing—1988
DIN 4922 PT 1	Steel Filter Pipes for Drilled Wells with Slot Perforation and Fishing; (Butt Strap Joint)
DIN 4941	Screw Threads for Drill Pipes for Seamless Drill Pipes for Water and Rock Drillings According to the Percussion Drilling and Core Drilling Method
DIN 7632	Compression Couplings with Spherical Liner; Reducers
DIN 7639	Compression Couplings with Spherical Liner; Equal Tees
DIN 8975 PT 9	Refrigeration Plants; Safety Principles for Design, Equipment and Installation; Flexible Pipe Elements in the Refrigerant Circuit
DIN 16928	Pipes of Thermoplastic Materials; Pipe Joints, Elements for Pipes, Laying; General Directions—1979
DIN 16962 PT 1	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines Types 1 and 2; Bends of Segmental Construction for Butt-Welding; Dimensions—1980

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN 16962 PT 2	Pipe Joint Assemblies and Fittings for Types 1 and 2 Polypropylene (PP) Pressure Pipes; Tees and Branches Produced by Segment Inserts and Necking for Butt Welding; Dimensions—1983
DIN 16962 PT 3	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines; Types 1 and 2; Bends Formed from Pipe for Butt-Welding; Dimensions—1980
DIN 16962 PT 5	Pipe Joint Assemblies and Fittings for Types 1 and 2 Polypropylene (PP) Pressure Pipes; General Quality Requirements and Testing—1989
DIN 16962 PT 6	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines; Types 1 and 2; Injection Moulded Elbows for Socket-Welding; Dimensions—1980
DIN 16962 PT 7	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines; Types 1 and 2; Injection Moulded Tee Pieces for Socket-Welding; Dimensions—1980
DIN 16962 PT 8	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines; Types 1 and 2; Injection Moulded Sockets and Caps for Socket-Welding; Dimensions—1980
DIN 16962 PT 9	Pipe Joint Assemblies and Fittings for Types 1 and 2 Polypropylene (PP) Pressure Pipes; Injection Moulded Reducers and Nipples for Socket Welding; Dimensions—1983
DIN 16962 PT 10	Pipe Joint Assemblies and Fittings for Types 1 to 3 Polypropylene (PP) Pressure Pipes; Injection-Moulded Fittings for Butt Welding; Dimensions—1989
DIN 16962 PT 11	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines; Types 1 and 2; Turned and Pressed Reducing Sockets for Butt-Welding; Dimensions—1980
DIN 16962 PT 13	Pipe Joint Assemblies and Fittings for Type 1 and Type 2 Polypropylene (PP) Pressure Pipes; Pipe Couplings; Dimensions—1987
DIN 16963 PT 1	Pipe Joints and Elements for High Density Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Pipe Bends of Segmental Construction for Butt-Welding; Dimensions—1980
DIN 16963 PT 2	Pipe Joint Assemblies and Fittings for Types 1 and 2 High Density Polyethylene (HDPE) Pressure Pipes; Tees and Branches Produced by Segment Inserts and Necking for Butt Welding; Dimensions—1983
DIN 16963 PT 3	Pipe Joints and Elements for High Density Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Pipe Bends for Butt-Welding; Dimensions—1980

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
DIN 16963 PT 5	Pipe Joint Assemblies and Fittings for High Density Polyethylene (PE-HD) Pressure Pipes; General Quality Requirements and Testing—1989
DIN 16963 PT 6	Pipe Joint Assemblies and Fittings for High Density Polyethylene (PE-HD) Pressure Pipes; Injection-Moulded Fittings for Butt Welding; Dimensions—1989
DIN 16963 PT 7	Pipe Joints Assemblies and Fittings for High Density Polyethylene (PE-HD) Pressure Pipes; Fittings for Resistance Welding; Dimensions—1989
DIN 16963 PT 8	Pipe Joints and Elements for High Density Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Injection-Moulded Elbows for Socket-Welding; Dimensions—1980
DIN 16963 PT 9	Pipe Joints and Elements for High Density Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Injection-Moulded Tee Pieces for Socket-Welding, Dimensions—1980
DIN 16963 PT 10	Pipe Joints and Elements for High Density Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Injection-Moulded Sockets and Caps for Socket-Welding; Dimensions—1980
DIN 16963 PT 13	Pipe Joints and Elements for High Pressure Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Turned and Pressed Reducing Sockets for Butt-Welding; Dimensions—1980
DIN 16963 PT 14	Pipe Joint Assemblies and Fittings for Types 1 and 2 High-Density Polyethylene (HDPE) Pressure Pipes; Injection Moulded Reducers and Nipples for Socket Welding; Dimensions—1983
DIN 16963 PT 15	Pipe Joint Assemblies and Fittings for High-Density Polyethylene (PE-HD) Pressure Pipes; Pipe Couplings; Dimensions—1987
DIN 16966 PT 1	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joint Assemblies; Fittings: General Quality Requirements and Testing—1988
DIN 16966 PT 2	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joints; Elbows; Dimensions—1982
DIN 16966 PT 4	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joints; Tees; Nozzles; Dimensions—1982
DIN 16966 PT 5	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joints; Reducers; Dimensions—1982
DIN 16966 PT 8	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joints; Laminated Joints; Dimensions—1982

(Continued)

Numbers	Title
DIN 16970	Adhesives for Bonding Pipes and Pipe System Elements of Rigid PVC; General Quality Requirements and Testings—1970
DIN 19532	Pipelines of Unplasticized Polyvinyl Chloride (Rigid PVC, PVC-U) for Drinking Water Supply; Pipes; Pipe Joints; Pipeline Parts; DVGW Technical Rule—1979
DIN 19559 PT1	Measurement of Flow of Waste Water in Open Channels and Gravity Conduits; General Information
DIN 28065	Thermal Shock Resistance of Enamelled Steel Appliances and Pipe Fittings for Process Engineering Applications—1993
DIN 86041 PT 1	Welding Flanges for Tanks and Sea Boxes; Nominal Pressure 10 and 16
DIN EN 253	Preinsulated Bonded Pipe Systems for Underground Hot Water Networks; Pipe Assemblies of Steel Service Pipes, Polyurethane Thermal Insulation and Polyethylene Outer Casing—1994
DIN EN 448	Preinsulated Bonded Pipe Systems for Underground Hot Water Networks; Fitting Assemblies of Steel Service Pipes, Polyurethane Thermal Insulation and Polyethylene Outer Casing—1994
DIN EN 476	General Requirements for Components Used in Discharge Pipes, Drains and Sewers for Gravity Systems; Supersedes DIN 19543: 1982-08, DIN 19549: 1989-02, DIN 19550: 1987-10 and DIN 19550-2: 1990-05
DIN EN 489	Preinsulated Bonded Pipe Systems for Underground Hot Water Networks; Joint Assemblies for Steel Service Pipes with Polyurethane Thermal Insulation and Polyethylene Outer Casing—1994
DIN EN 681-1	Materials Requirements for Elastomeric Pipe Joint Seals Used in Water and Drainage Applications; Vulcanized Rubber—1996; Supersedes Parts of DIN 4060, December 1988 Edition
DIN EN 911	Elastomeric Sealing Ring Type Joints and Mechanical Joints for Thermoplastics Pressure Piping; Test Method for Leaktightness under External Hydrostatic Pressure—1995
DIN EN 1277	Thermoplastics Piping Systems for Buried Non-Pressure Applications; Test Methods for Leaktightness of Elastomeric Sealing Ring Type Joints—1996
DIN EN 1716	Polyethylene (PE) Tapping Tees; Test Method for Impact Resistance of an Assembled Tapping Tee

TABLE E10.D1   DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN EN 10242	Threaded Pipe Fitting in Malleable Cast Iron English Version of DIN EN 10242 (Supersedes DIN 2950, April 1983 Edition)—1995
DIN 1478	Turnbuckles Made from Steel Tube or Round Steel Bar—1975
DIN 7340	Tubular Rivets; Made from Tube—1993
DIN 28187	Tube-To-Tube-Sheet Joints in Tubular Heat Exchangers—1991
DIN 52613	Thermal Insulation Testings; Determination of Thermal Conductivity by the Tube Method—1977
DIN EN 754-1	Aluminium and Aluminium Alloy Cold Drawn Rod/Bar and Tube Part 1: Technical Conditions for Inspection and Delivery—1997; Together with DIN 755-1 Supersedes DIN 1746-2 and DIN 1747-2
DIN EN 754-2	Aluminium and Aluminium Alloy Cold Drawn Rod/Bars and Tube Part 2: Mechanical Properties—1997; Together with DIN 755-2 Supersedes DIN 1746-1 and 1747-1
DIN EN 754-3	Aluminium and Aluminium Alloy Cold Drawn Rod/Bar and Tube; Round Bars: Tolerances on Dimensions and Form; (Supersedes DIN 1798, September 1986 Edition)—1996
DIN EN 754-4	Aluminium and Aluminium Alloy Cold Drawn Rod/Bar and Tube; Square Bars: Tolerances on Dimensions and Form; (Supersedes DIN 1796, September 1986 Edition)—1996
DIN EN 754-5	Aluminium and Aluminium Alloy Cold Drawn Rod/Bar and Tube; Rectangular Bars: Tolerances on Dimensions and Form; (Supersedes DIN 1769, September 1986 Edition)—1996
DIN EN 754-6	Aluminium and Aluminium Alloy Cold Drawn Rod/Bar and Tube; Hexagonal Bars: Tolerances on Dimensions and Form; (Supersedes DIN 1797, September 1986 Edition)—1996
DIN EN 755-1	Aluminium and Aluminium Alloy Extruded Rod/Bar, Tube and Profiles Part 1: Technical Conditions for Inspection and Delivery—1997; Replaces DIN 1748-2 February 1983; and Together with DIN EN 754-1 August 1997 Replaces DIN 1746-2 and 1747-2 February 1983
DIN EN 755-2	Aluminium and Aluminium Alloy Extruded Rod/Bar, Tube and Profiles Part 2: Mechanical Properties—1997; Supersedes DIN 1748-1 February 1983; Together with DIN EN 754-2 August 1997 Supersedes DIN 1746-1 January 1987 and DIN 1747-1 February 1983

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN EN 755-3	Aluminium and Aluminium Alloy Extruded Rod/Bar, Tube and Profiles; Round Bars: Tolerances on Dimensions and Form—1995 (Supersedes DIN 1799, September 1986 Edition)
DIN EN 755-4	Aluminium and Aluminium Alloy Extruded Rod/Bar, Tube and Profiles; Square Bars: Tolerances on Dimensions and Form—1995 (Supersedes DIN 59700, August 1986 Edition)
DIN EN 755-5	Aluminium and Aluminium Alloy Extruded Rod/Bar, Tube and Profiles; Rectangular Bars: Tolerances on Dimensions and Form—1995 (Supersedes DIN 1770, September 1987 Edition)
DIN EN 755-6	Aluminium and Aluminium Alloy Extruded Rod/Bar, Tube and Profiles; Hexagonal Bars: Tolerances on Dimensions and Form—1995 (Supersedes DIN 59701, August 1986 Edition)
DIN EN 10232	Metallic Materials; Tube (In Full Section) Bend Test—1994
DIN EN 10233	Metallic Materials; Tube Flattening Test—1994 (Supersedes DIN 50136, June 1979 Edition)
DIN EN 10234	Metallic Materials; Tube Drift Expanding Test—1994 (Supersedes DIN 50135, August 1965 Edition)
DIN EN 10235	Metallic Materials; Tube Flanging Test—1994 (Supersedes DIN 50139, November 1965 Edition)
DIN EN 10236	Metallic Materials; Tube Ring Expanding Test—1994 (Supersedes DIN 50137, June 1979 Edition)
DIN EN 10237	Metallic Materials; Tube Ring Tensile Test—1994 (Supersedes DIN 50138, May 1979 Edition)
DIN 1230 PT 1 (W)	Vitrified Clayware for Sewers; Socket Pipes and Fittings; Dimensions (Intended to be Superseded by DIN EN 295-4, May 1995 Edition)
DIN 1230 PT 2 (W)	Vitrified Clayware for Sewers; Socket Pipes and Fittings; Technical Delivery Conditions
DIN 1230 PT 6 (W)	Clayware for Sewerage; Pipes and Fittings without Sockets; Dimensions (Intended to be Superseded by DIN EN 295-4, May 1995 Edition)
DIN 1230 PT 7 (W)	Clayware for Sewerage; Pipes and Fittings without Sockets; Technical Delivery Conditions
DIN 2353	Compression Fittings and Couplings—1991
DIN 2470 PT 1	Steel Gas Pipelines for Permissible Working Pressures up to 16 Bar; Pipes and Fittings—1987
DIN 2605-2	Steel Butt-Welding Pipe Fittings Part 2: Elbows and Bends for Use at Full Service Pressure—1995
DIN 2605 PT 1	Steel Butt-Welding Pipe Fittings; Elbows and Bends with Reduced Pressure Factor—1991

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN 2609	Steel Butt-Welding Pipe Fittings; Technical Delivery Conditions—1991
DIN 2614	Cement Mortar Linings for Ductile Iron and Steel Pipes and Fittings; Application, Requirements and Testing—1990; Superseded in Part By DIN EN 545, January 1995 Edition
DIN 2615 PT 1	Steel Butt-Welding Pipe Fittings; Tees with Reduced Pressure Factor—1992; Together with DIN 2615 Part 2, May 1992 Edition, Supersedes DIN 2615, June 1964 Edition
DIN 2615 PT 2	Steel Butt-Welding Pipe Fittings; Tees for Use at Full Service Pressure—1992; Together with DIN 2615 Part 1, May 1992 Edition, Supersedes DIN 2615, June 1964 Edition
DIN 2616 PT 1	Steel Butt-Welding Pipe Fittings; Eccentric Reducers with Reduced Pressure Factor—1991
DIN 2616 PT 2	Steel Butt-Welding Pipe Fittings; Reducers for Use at Full Service Pressure—1991
DIN 2617	Steel Butt-Welding Pipe Fittings; Caps—1991
DIN 2618	Butt-Welding Steel Fittings; Welding Saddles; Nominal Pressure 16—1968
DIN 2619	Butt-Welding Steel Fittings; Bends for Welding; Nominal Pressure 16—1968
DIN 2826	Clamp Type Coupling Assemblies for Use with DN 15 to DN 50 Steam and Hot Water Hoses Rated For Pressures up to 18 Bar
DIN 2848	Lined Steel Flanged Pipes and Steel or Cast Iron Flanged Fittings Rated for a Pressure of 10 Bar (PN 10)—1993; Supersedes July Edition and DIN 2848 Parts 10 to 12, January 1982 Editions
DIN 2856	Capillary Solder Fittings; Assembly Dimensions and Testing
DIN 2873	Enamelled Steel Flanged Pipes and Fittings Rated for 10 Bar (PN 10)—1993
DIN 2874	Steel Flanged Pipes and Steel and Cast Iron Flanged Fittings Lined with PTFE or PFA; Technical Delivery Condition—1993
DIN 2875	Steel Flanged Pipes and Flanged Fittings Lined with Soft or Hard Rubber; Technical Delivery Conditions—1993
DIN 2876	Enamelled Steel Flanged Pipes and Fittings; Technical Delivery Conditions—1993
DIN 2950	Malleable Cast Iron Fittings
DIN 2980	Screwed Steel Pipe Fittings—1977

TABLE E10.D1   DIN Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
DIN 2981	Threaded Steel Pipe Fittings; Fittings with Long Screw Thread—1982
DIN 2982	Screwed Steel Pipe Fittings; Parallel Nipples; Taper Nipples—1977
DIN 2983	Screwed Steel Pipe Fittings; Bends—1977
DIN 2986	Threaded Steel Pipe Fittings; Sockets—1977
DIN 2987 PT 1	Threaded Steel Pipe Fittings; Crosses, Tees, Elbows—1977
DIN 2987 PT 2	Threaded Steel Pipe Fittings; Reducing Tees and Elbows—1977
DIN 2988	Reducing Sockets; Threaded Steel Pipe Fittings—1977
DIN 2990	Threaded Steel Pipe Fittings; Hexagon Nipples; Bushings—1977
DIN 2991	Threaded Steel Pipe Fittings; Plugs, Caps—1977
DIN 2993	Threaded Steel Pipe Fittings; Pipe Unions—1977
DIN 2999 PT 1	Pipe Threads for Tubes and Fittings; Parallel Internal Thread and Taper External Thread; Thread Dimensions—1983
DIN 2999 PT 2	Whitworth Pipe Threads for Tubes and Fittings; Cylindrical Internal Thread and Conical External Thread; Gauging System and Use of Gauges—1973
DIN 2999 PT 3	Whitworth Pipe Threads for Tubes and Fittings; Gauge Dimensions—1973
DIN 2999 PT 4	Pipe Threads for Tubes and Fittings; Sizes for Taper Screw Limit Plug Gauges for Parallel Internal Thread—1986
DIN 2999 PT 5	Whitworth Pipe Threads for Tubes and Fittings; Cylindrical Screw Limit Ring Gauges for Gauging Conical External Threads; Sizes—1973
DIN 2999 PT 6	Whitworth Pipe Threads for Tubes and Fittings; Conical Screw Check Plugs; Sizes—1975
DIN 3871	Male Fittings for Use with Compression Couplings—1995
DIN 3942	Compression Fittings and Couplings; Swivel Type Male Stud Elbows with 24 Degree Cone and O-Ring and with Type W Port as in DIN 3861—1994
DIN 3943	Compression Fittings and Couplings; Swivel Type Male Stud Tees (Stud Branch) with 24 Degree Cone and O-Ring and with Type W Port as in DIN 3861—1994
DIN 3944	Compression Fittings and Couplings; Swivel Type Male Stud Tees (Stud Run) with 24 Degree Cone and O-Ring and with Type W Port as in DIN 3861—1994

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN 3945	Compression Fittings and Couplings; Swivel Type Adaptors with 24 Degree Cone and O-Ring and with Type W Port as in DIN 3861—1994
DIN 4032	Concrete Pipes and Fittings; Dimensions; Technical Conditions of Delivery—1981
DIN 7591	Water Fittings for Domestic Installation; Screwed Unions with Flat Gasket for Hose Connection on Either Side, Designed for Nominal Pressure 10—1981
DIN 7593	Water Fittings for Domestic Installation; Screwed Unions with Flat Gasket for Connection to Copper Tube on Either Side, Designed for Nominal Pressure 10—1981
DIN 8063 PT 1	Pipe Joint Assemblies and Fittings for Unplasticized Polyvinyl Chloride (U-PVC) Pressure Pipelines; Dimensions of Socket Bends—1986
DIN 8063 PT 2	Pipe Joints and Pipe Fittings for Pipes Under Pressure Made of Unplasticized Polyvinyl Chloride (Rigid PVC); Bends Made by Injection Moulding for Bonding; Dimensions—1980
DIN 8063 PT 3	Pipe Joints and Pipe Fittings for Pipes Under Pressure Made of Unplasticized Polyvinyl Chloride (Rigid PVC); Screwed Pipe Joints; Dimensions—1980
DIN 8063 PT 4	Pipe Joint Assemblies and Fittings for Unplasticized Polyvinyl Chloride (PVC-U) Pressure Pipes; Bushings, Flanges, Seals, Dimensions—1983
DIN 8063 PT 5	Pipe Joint Assemblies and Fittings for Unplasticized Polyvinyl Chloride (PVC-U) Pressure Pipes; General Quality Requirements and Testing—1990
DIN 8063 PT 6	Pipe Joints and Pipe Fittings for Pipes Under Pressure Made of Unplasticized Polyvinyl Chloride (Rigid PVC); Injection Moulded Elbows for Bonding; Dimensions—1980
DIN 8063 PT 8	Pipe Joints and Pipe Fittings for Pipes Under Pressure Made of Unplasticized Polyvinyl Chloride (Rigid PVC); Injection Moulded Sockets, Caps and Nipples for Bonding; Dimensions—1980
DIN 8063 PT 11	Pipe Joints and Pipe Fittings for Pipes Under Pressure Made of Unplasticized Polyvinyl Chloride (Rigid PVC); Sockets with Primary Element of Copper-Zinc Alloy (Brass) for Bonding; Dimensions—1980
DIN 8063 PT 12	Pipe Joint Assemblies and Fittings for Unplasticized Polyvinyl Chloride (U-PVC) Pressure Pipelines; Dimensions of Flanged and Socket Fittings—1987
DIN 8076 PT 1	Thermoplastics Pressure Pipelines; Metal Compression Fittings for Polyethylene (PE) Pipes; General Quality Requirements; Testing—1984

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
DIN 8906	PN 40 Flared Flange Solderless Compression Couplings for Use in Refrigerating Systems
DIN 8912	Coupling Nuts and Screwed Plugs for Use with PN 40 Flared Flange Solderless Compression Couplings in Refrigerating Systems
DIN 8914	90 Degree Tapered Seal Rings and Caps for Use with PN 40 Flared Flange Solderless Compression Couplings in Refrigerating Systems
DIN 16450	Nomenclature and Symbols for Fittings for Use with Unplasticized Polyvinyl Chloride (PVC-U) Pressure Pipes—1994
DIN 16451 PT 1	Ductile Iron (GGG) Fittings for Use with Unplasticized Polyvinyl Chloride (PVC-U) Pressure Pipes; Technical Delivery Conditions—1994
DIN 16451 PT 2	Ductile Iron (GGG) Fittings for Use with Unplasticized Polyvinyl Chloride (PVC-U); Pressure Pipes; Dimensions—1994
DIN 16867	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipes, Fittings and Joints for Use in Chemical Pipelines; Technical Delivery Conditions—1982
DIN 16961 PT 1	Thermoplastics Pipes and Fittings with Profiled Outer and Smooth Inner Surfaces; Dimensions—1989
DIN 16961 PT 2	Thermoplastics Pipes and Fittings with Profiled Outer and Smooth Inner Surfaces; Technical Delivery Conditions—1989
DIN 16967 PT 2	Glass Fibre Reinforced Epoxy Resin (EP-GF) Pipe Fittings and Joints; Elbows; Tees; Dimensions—1982
DIN 19522 PT 1	Cast Iron Spigot (SML) Drainpipes and Fittings; Dimensions—1983
DIN 19522 PT 2	Cast Iron Spigot (SML) Drainpipes and Fittings; Technical Delivery Conditions—1983
DIN 19530 PT 1	Steel Socket Pipes and Fittings for Sewers; Dimensions—1983
DIN 19530 PT 2	Steel Socket Pipes and Fittings for Sewers; Technical Delivery Conditions—1983
DIN 19531	Unplasticized Polyvinyl Chloride (PVC-U) Socket Pipes and Fittings for Discharge Systems Inside Buildings; Dimensions and Technical Delivery Conditions—1987
DIN 19535 PT 1	High Density Polyethylene (HDPE) Pipes and Fittings for Hot-Water Resistant Drains and Sewers Inside Buildings; Dimensions—1988 (Together with DIN 19535 Part 2, April 1987 Edition, Supersedes DIN 19535, March 1977 Edition, Withdrawn in January 1986)

TABLE E10.D1 DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN 19535 PT 2	High Density Polyethylene (HDPE) Pipes and Fittings for Hot-Water Resistant (HT) Drains and Sewers Inside Buildings; Technical Delivery Conditions—1987 (Supersedes Parts of the March 1977 Edition of DIN 19535, Withdrawn in January 1986)
DIN 19537 PT 1	High Density Polyethylene (HDPE) Pipes and Fittings for Drains and Sewers; Dimensions—1983
DIN 19537 PT 2	High Density Polyethylene (HDPE) Pipes and Fittings for Drains and Sewers; Technical Delivery Conditions—1988
DIN 19538	Chlorinated Polyvinyl Chloride (CPVC) Pipes and Fittings with Sockets for Hot Water Resistant (HT) Sanitary Pipework Inside Buildings; Dimensions, Technical Delivery Conditions—1980
DIN 19565 PT 1	Centrifugally Cast and Filled Polyester Resin Glass Fibre Reinforced (UP-GF) Pipes and Fittings for Buried Drains and Sewers; Dimensions and Technical Delivery Conditions—1989; Partially Superseded by DIN EN 1115-3, November 1996 Edition, and DIN EN 1115-5, November 1996 Edition
DIN 19800 PT 1	Asbestos Cement Pipes and Fittings for Pressure Pipelines; Pipes; Dimensions—1973
DIN 19800 PT 3	Asbestos Cement Pipes and Fittings for Pressure Pipelines; Joint Assemblies; Dimensions—1979
DIN 19850-1	Fibre Cement Pipes and Fittings for Drains and Sewers; Part 1: Dimensions of Pipes, Branches and Bends—1996
DIN 24147 PT 1	Fittings for Use in Air Distribution Systems; Overview and Dimensions—1993
DIN 24147 PT 2	Fittings for Use in Air Distribution Systems; Bends
DIN 24147 PT 3	Fittings for Use in Air Distribution Systems; Gusseted Bends
DIN 24147 PT 4	Fittings for Use in Air Distribution Systems; Tapers
DIN 24147 PT 6	Fittings for Use in Air Distribution Systems; 90 Degree and 45 Degree Branches (Tees and Angled Branches)
DIN 24147 PT 7	Fittings for Use in Air Distribution Systems; Reducers with 90 Degree Branch and Crosses (June)
DIN 28600	Ductile Iron Pressure Pipes and Fittings for Gas and Water Pipelines; Technical Delivery Conditions—1983 (Superseded in Part by DIN EN 545, January 1995 Edition, and DIN EN 969, November 1995 Edition)

TABLE E10.D1   DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN 28603	Ductile Cast Iron Pipes and Fittings; Spigot and Socket Joints; Connecting Dimensions and Masses—1982
DIN 28624	Ductile Iron Collars for Use with Gas and Water Pipes; Dimensions and Mass (Superseded in Part by DIN EN 545, and DIN EN 969, November 1995 Edition)
DIN 28631	Ductile Iron Spigot and Socket Fittings with Branch for Gas and Water Pipelines; Dimensions and Requirements—1996
DIN 28633	Ductile Iron Double Spigot Fittings with Branch for Gas and Water Pipelines; Dimensions and Requirements—1996
DIN 28645	Ductile Iron Double-Flanged Tapers for Use with Gas and Water Pipes; Dimensions and Mass (Superseded in Part by DIN EN 545, January 1995 Edition, and DIN EN 969, November 1995 Edition)
DIN 30670	Polyethylene Coatings for Steel Pipes and Fittings; Requirements and Testing—1991 (Supersedes July 1980 Edition)
DIN 30673	Bitumen Coatings and Linings for Steel Pipes, Fittings and Vessels—1986
DIN 53769 PT 1	Testing of Glass Fibre Reinforced Plastics Pipes; Determination of the Longitudinal Shear Strength of Type B Pipe Fittings—1988
DIN 53769 PT 6	Testing of Glass Fibre Reinforced Plastics Pipes; Testing of Pipes and Fittings Under Pulsating Internal Pressure—1989
DIN 86086	Copper-Nickel Alloy Welding Pipe Fittings; Technical Delivery Conditions—1990
DIN EN 295-4	Vitrified Clay Pipes and Fittings and Pipe Joints for Drains and Sewers; Requirements for Special Fittings, Adaptors and Compatible Accessories—1995 (Intended to Supersede DIN 1230 PT 1 and DIN 1230 PT 6, February 1992 Editions)
DIN EN 295-6	Vitrified Clay Pipes and Fittings and Pipe Joints for Drains and Sewers; Requirements for Vitrified Clay Manholes—1995 (Supersedes DIN 1230 PT 9, November 1990 Edition)
DIN EN 295-7	Vitrified Clay Pipes and Fittings and Pipe Joints for Drains and Sewers; Requirements for Vitrified Clay Pipes and Joints for Pipe Jacking—1995
DIN EN 295 PT 5	Vitrified Clay Pipes and Fittings and Pipe Joints for Drains and Sewers; Requirements for Perforated Vitrified Clay Pipes and Fittings—1994

TABLE E10.D1   DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN EN 545	Ductile Iron Pipes, Fittings, Accessories and Their Joints for Water Pipelines; Requirements and Test Methods—1995 (Supersedes Parts of DIN 2614, February 1990 Edition, DIN 28600 and DIN 28610 PT 1 January 1983 Editions, DIN 28614, DIN 28615 PT 1, DIN 28615 PT 2, DIN 28622, DIN 28623, DIN 28624, DIN 28625, DIN 28626, DIN 28628, DIN 28629, DIN 28630, DIN 28632, DIN 28634, DIN 28637, DIN 28638)
DIN EN 578	Plastics Piping Systems; Plastics Pipes and Fittings; Determination of the Opacity—1993
DIN EN 588-1	Fibre-Cement Pipes for Drains and Sewers; Pipes, Joints and Fittings for Gravity Systems—1996
DIN EN 598	Ductile Iron Pipes, Fittings, Accessories and Their Joints in Sewerage Applications; Requirements and Test Methods—1994 (Supersedes DIN 19690, DIN 19691, DIN 19692 PT 1, and DIN 19692 PT 2, July 1978 Editions)
DIN EN 607	PVC-U Eaves Gutters and Fittings; Definitions, Requirements and Testing—1995 (Supersedes DIN 18469 May 1988 Edition)
DIN EN 639	Requirements for Concrete Pressure Pipes Including Joints and Fittings—1994 (Together with DIN EN 640, December 1994 Edition, Supersedes DIN 4035, July 1990 Edition)
DIN EN 640	Reinforced Concrete Pressure Pipes and Distributed Reinforcement Concrete Pressure Pipes (Non-Cylinder Type), Including Joints and Fittings—1994 (Together with DIN EN 639, December 1994 Edition, Supersedes DIN 4035, July 1990 Edition)
DIN EN 641	Reinforced Concrete Pressure Pipes, Cylinder Type, Including Joints and Fittings—1994
DIN EN 642	Prestressed Concrete Pressure Pipes, Cylinder and Non-Cylinder Types, Including Joints, Fittings and Specific Requirements for Prestressing Steel for Pipes—1994
DIN EN 705	Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings; Methods for Regression Analyses and Their Use—1994
DIN EN 713	Mechanical Joints Between Fittings and Polyolefin Pressure Pipes; Test Method for Leaktightness Under Internal Pressure of Assemblies Subjected to Bending—1994
DIN EN 714	Not End-Loadbearing Elastomeric Sealing Ring Type Joints Between Thermoplastic Pressure Pipes and Fittings; Test Method for Leaktightness Under Internal Hydrostatic Pressure without End Thrust—1994

TABLE E10.D1   DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN EN 715	End-Load Bearing Joints Between Small Diameter Thermoplastics Pressure Pipes and Fittings; Test Method for Leaktightness Under Internal Water Pressure, Including End Thrust—1994
DIN EN 723	Combustion Method for Determination of Carbon on the Inner Surface of Copper Tubes or Fittings—1996
DIN EN 727	Thermoplastics Pipes and Fittings; Determination of Vicat Softening Temperature (VST)—1995
DIN EN 728	Plastics Piping and Ducting Systems; Polyolefin Pipes and Fittings; Determination of Oxidation Induction Time—1997
DIN EN 763	Injection-Moulded Thermoplastics Pipe Fittings; Test Method for Visually Assessing Effects of Heating—1994
DIN EN 802	Injection-Moulded Thermoplastics Fittings for Pressure Piping Systems; Test Method for Maximum Deformation by Crushing—1994
DIN EN 803	Injection-Moulded Thermoplastics Fittings for Elastic Sealing Ring Type Joints for Pressure Piping; Test Method for Resistance to a Short-Term Internal Pressure without End Thrust—1994
DIN EN 804	Injection-Moulded Plastics Socket Fittings for Solvent-Cemented Joints for Pressure Piping; Test Method for Resistance to a Short-Term Internal Hydrostatic Pressure—1994
DIN EN 922	Unplasticized Polyvinyl Chloride (PVC-U) Pipes and Fittings; Specimen Preparation for Determination of the Viscosity Number and Calculation of the K-Value—1995
DIN EN 969	Ductile Iron Pipes, Fittings, Accessories and Their Joints for Gas Pipelines; Requirements and Test Methods—1995 (Supersedes DIN 28610 PT 2, January 1983 Edition, and Parts of DIN 28600 and DIN 28610 PT 1, January 1983 Editions, DIN 28614, DIN 28615 PT 1, DIN 28615 PT 2, DIN 28622, DIN 28623, DIN 28624, DIN 28625, DIN 28626, DIN 28628, DIN 28629, DIN 28630, DIN 28632, DIN 28634, DIN 28637)
DIN EN 1056	Plastic Pipe and Fittings; Method for Exposure to Direct (Natural) Weathering—1996
DIN EN 1115-3	Piping Systems for Underground Drainage and Sewerage Under Pressure Made of Glass-Reinforced Thermosetting Plastics (GRP) Based on Unsaturated Polyester (UP) Resin; Fittings—1996; Supersedes Parts of DIN 19565-1, March 1989 Edition

TABLE E10.D1   DIN Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
DIN EN 1119	Joints for Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings; Testing for Leaktightness and Resistance to Damage of Flexible and Reduced-Articulation Joints—1996
DIN EN 1120	Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings Determination of the Resistance to Chemical Attack from the Inside of a Section in a Deflected Condition—1996
DIN EN 1229	Glass-Reinforced Thermosetting Plastics (GRP) Pipes and Fittings; Test Methods to Prove the Leaktightness of the Wall Under Short-Term Internal Pressure—1996
DIN LN 29855	Fitting Assembly, Ring Locked, for Solderless Pipe Fittings with Coupling Sleeves; Flareless; Complete Fitting—1974
DIN LN 29856	Unions, Ring Locked for Solderless Pipe Fittings with Coupling Sleeves; Flareless—1974
DIN LN 29859	Unions, Ring Locked for Solderless Pipe Fittings with Coupling Sleeves; Flareless; Directions for Installation—1974
DIN 16962 PT 4	Pipe Joint Assemblies and Fittings for Types 1 and 2 Polypropylene (PP) Pressure Pipes; Adaptors for Fusion Jointing, Flanges and Sealing Elements; Dimensions—1988
DIN 16963 PT 4	Pipe Joint Assemblies and Fittings for High-Density Polyethylene (PE-HD) Pressure Pipes; Adaptors for Fusion Jointing, Flanges and Sealing Elements; Dimensions—1988
DIN 16966 PT 6	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joint Assemblies; Collars, Flanges, Joint Rings, Dimensions

TABLE E10.D2 DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets

Numbers	Title
DIN 2500	Flanges; General Information; Survey—1966
DIN 2501 PT 1	Flanges; Mating Dimensions—1972
DIN 2505 (D)	Flanged Joint Calculation January
DIN 2512	Flanges; Tongue and Groove; Nominal Pressures 10 to 160; Design Sizes; Rings—1975
DIN 2513	Flanges; Projection and Recess; Nominal Pressures 10 to 100; Design Dimensions—1966
DIN 2514	Flanges; Projection with Groove and Recess; Nominal Pressures 10 to 40; Design Dimensions—1975
DIN 2519	Steel Flanges; Technical Conditions of Delivery—1966
DIN 2526	Flanges; Types of Contact Surfaces—1975
DIN 2527	Blank Flanges; Nominal Pressure 6 to 100—1972
DIN 2528	Steel Flanges; Technical Delivery Conditions—1991
DIN 2543	Cast Steel Flanges; Nominal Pressure 16—1977
DIN 2558	Plain Face Oval Screwed Flanges; Nominal Pressure 6—1975
DIN 2561	Oval Screwed Flanges with Socket; Nominal Pressure 10 and 16—1975
DIN 2566	Screwed Flanges with Socket; Nominal Pressure 10 and 16—1975
DIN 2573	Plain Face Flanges for Brazing or Welding; Nominal Pressure 6—1975
DIN 2576	Flanges, Slip-on Type for Brazing or Welding; Nominal Pressure 10—1975
DIN 2627	Welding Neck Flanges; Nominal Pressure 400—1975
DIN 2628	Welding Neck Flanges; Nominal Pressure 250—1975
DIN 2629	Welding Neck Flanges; Nominal Pressure 320—1975
DIN 2630	Welding Neck Flanges; Nominal Pressure 1 and 2.5—1975
DIN 2631	Welding Neck Flanges; Nominal Pressure 6—1975
DIN 2632	Welding Neck Flanges; Nominal Pressure 10—1975
DIN 2633	Welding Neck Flanges; Nominal Pressure 16—1975
DIN 2634	Welding Neck Flanges; Nominal Pressure 25—1975
DIN 2635	Welding Neck Flanges; Nominal Pressure 40—1975
DIN 2636	Welding Neck Flanges; Nominal Pressure 64—1975
DIN 2637	Welding Neck Flanges; Nominal Pressure 100—1975
DIN 2638	Welding Neck Flanges; Nominal Pressure 160—1975
DIN 2641	Lapped Flanges; Welding Neck Flanges; Plain Collars; Nominal Pressure 6—1975
DIN 2642	Slip-on Flanges; Upturned Welding Flanges; Plain Collars; Nominal Pressure 10—1975

TABLE E10.D2 DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
DIN 2655	Lapped Flanges; Plain Collars; Nominal Pressure 25—1975
DIN 2656	Lapped Flanges; Plain Collars; Nominal Pressure 40—1975
DIN 2673	Loose Flanges with Welding Neck; Nominal Pressure 10—1962
DIN 2693	Sealing Rings for Flanges with Groove; Nominal Pressures from 10 to 40—1967
DIN 2695	Diaphragm Packings and Diaphragm Weld Seals for Flanged Connections; Nominal Pressure 64 to 400
DIN 3337	Connections for Part-Turn Valve Actuator Attachment; Dimensions of Driving Components and Flanges—1985
DIN 6352 PT 1	Chuck Backplates with 1:4 Locating Taper; Basic Flanges—1968
DIN 8063 PT 4	Pipe Joint Assemblies and Fittings for Unplasticized Polyvinyl Chloride (PVC-U) Pressure Pipes; Bushings, Flanges, Seals; Dimensions—1983
DIN 16872	Glass Fibre Reinforced Polyester Resin (UP-GRP) Flanges; for Use for Thermoplastics Pipe Fittings; Dimensions—1993
DIN 16962 PT 4	Pipe Joint Assemblies and Fittings for Types 1 and 2 Polypropylene (PP) Pressure Pipes; Adaptors for Fusion Jointing, Flanges and Sealing Elements; Dimensions—1988
DIN 16962 PT 12	Pipe Joints and Elements for Polypropylene (PP) Pressure Pipelines; Types 1 and 2; Bushes, Flanges and Seals for Socket-Welding; Dimensions—1980
DIN 16963 PT 4	Pipe Joint Assemblies and Fittings for High-Density Polyethylene (PE-HD) Pressure Pipes; Adaptors for Fusion Jointing, Flanges and Sealing Elements; Dimensions—1988
DIN 16963 PT 11	Pipe Joints and Elements for High Density Polyethylene (HDPE) Pressure Pipelines; Types 1 and 2; Bushes, Flanges and Seals for Socket-Welding; Dimensions—1980
DIN 16966-7	Glass Fibre Reinforced Polyester Resin (UP-GRP) Pipe Fittings and Joint Assemblies; Requirements for and Testing of Bushes, Flanges, and Flanged and Laminated Joints—1995
DIN 16966 PT 6	Glass Fibre Reinforced Polyester Resin (UP-GF) Pipe Fittings and Joint Assemblies; Collars, Flanges, Joint Rings, Dimensions—1982
DIN 28031	Flanges for Welding for Use on Unalloyed and Stainless Steel Vessels Not Subject to Pressure—1989

TABLE E10.D2 DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
DIN 28032	Flanges for Welding for Use on Unalloyed Steel Pressure Vessels—1989
DIN 28034	Weld-Neck Flanges for Use on Unalloyed Steel Pressure Vessels—1989
DIN 28036	Flanges for Welding for Use on Stainless Steel Pressure Vessels—1989
DIN 28038	Flanges for Welding, with Cylindrical Hub, for Use on Stainless Steel Pressure Vessels—1989
DIN 28117	PN 10 to PN 40 Loose Flanges—1990
DIN 28122	Blank Flanges with Stainless Steel Facing, of Nominal Sizes DN 125 to DN 500 and Rated for Nominal Pressures PN 10 to PN 40—1987
DIN 28141	Connecting Flanges for Unalloyed and Stainless Steel Mixing Vessels for Use in Process Engineering—1992
DIN 28404	Vacuum Technology; Flanges; Dimensions—1984
DIN 28614	Ductile Iron Pipes with Cast-On Flanges for Use with Gas and Water Pipelines; Dimensions and Mass—1990 (Superseded in Part by DIN EN 545, January 1995 Edition, and DIN EN 969, November 1995 Edition)
DIN 28615 PT 1	Ductile Iron Pipes with Welded-On Flanges for Use With Gas and Water Pipelines; Dimensions and Mass—1990 (Together with the January 1990 Edition of DIN 28615 Part 2, Supersedes the March 1976 Edition of DIN 28615) (Superseded in Part by DIN EN 545, January 1995 Edition, and DIN EN 969, November 1995 Edition)
DIN 28615 PT 2	Ductile Iron Pipes with Screwed-On Flanges for Use With Gas and Water Pipelines; Dimensions and Mass—1990 (Together with the January 1990 Edition of DIN 28615 Part 1, Supersedes the March 1976 Edition of DIN 28615) (Superseded in Part by DIN EN 545, January 1995 Edition, and DIN EN 969, November 1995 Edition)
DIN 28646	Ductile Iron Blank Flanges for Use with Gas and Water Pipes; Dimensions and Mass—1990 (Superseded in Part by DIN EN 545, January 1995 Edition, and DIN EN 969, November 1995 Edition)
DIN 86037 PT 1	Loose Flanges and Welded Stub Ends for Pipes of Forged Copper Alloys; Nominal Pressures 10, 16 and 25; Summary—1978
DIN 86037 PT 2	Loose Flanges and Welded Stub Ends for Pipes of Forged Copper Alloys; Nominal Pressures 10, 16 and 25; Welded Stub Ends—1978
DIN 86037 PT 3	Loose Flanges and Welded Stub Ends for Pipes of Forged Copper Alloys; Nominal Pressures 10, 16 and 25; Loose Flanges—1978

TABLE E10.D2 DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
DIN 86041 PT 1	Welding Flanges for Tanks and Sea Boxes; Nominal Pressure 10 and 16—1976
DIN 86041 PT 2	Welding Flanges for Outboard Connections; Nominal Pressure 10, 16, 40, 160—1977
DIN 86042	Dummy Hole Plates (Spectacle Flanges); Mating Dimensions According to Nominal Pressure 10 and 16—1978
DIN 13 PT 13	ISO Metric Screw Threads; Selected Sizes for Screws, Bolts and Nuts from 1 to 52 mm Screw Thread Diameter and Limits of Sizes—1983
DIN 13 PT 51	ISO Metric Screw Threads; External Threads for Transition Fits; Tolerances, Limit Deviations, Limits of Size
DIN 74 PT 3	Counterbores (Holes) for Hexagon Bolts and Nuts—1991
DIN 103 PT 7	ISO Metric Trapezoidal Screw Threads; Limiting Sizes for Bolt Threads from 8 to 100 mm Nominal Diameter
DIN 103 PT 8	ISO Metric Trapezoidal Screw Threads; Limiting Sizes for Bolt Threads from 105 to 300 mm Nominal Diameter
DIN 125 PT 1	Product Grade A Washers with a Hardness up to 250 HV Designed for Use with Hexagon Head Bolts and Nuts—1990
DIN 125 PT 2	Product Grade A Washers with a Hardness up to 300 HV Designed for Use with Hexagon Head Bolts and Nuts—1990
DIN 126	Product Grade C Washers; Designed for Use with Hexagon Head Bolts and Nuts—1990
DIN 186	T-Head Bolts with Square Neck—1988
DIN 188	T-Head Bolts with Double Nib—1987
DIN 261	T-Head Bolts—1987
DIN 267 PT 3	Fasteners; Technical Delivery Conditions; Property Classes for Carbon Steel and Alloy Steel Bolts and Screws; Conversion of Property Classes—1983
DIN 267 PT 12	Bolts, Screws, Nuts and Similar Threaded and Formed Parts; Technical Conditions of Delivery; Self-Tapping Screws
DIN 267 PT 25 (P)	Fasteners; Technical Delivery Conditions; Torsion Testing of M 1 to M 10 Bolts and Screws—1984
DIN 267 PT 27	Fasteners; Adhesive-Coated Steel Screws, Bolts and Studs; Technical Delivery Conditions—1990
DIN 267 PT 28	Fasteners; Steel-Screws, Bolts and Studs with Locking Coating; Technical Delivery Conditions—1990

TABLE E10.B2 DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
DIN 478	Square Head Bolts with Collar—1985
DIN 479	Square Head Bolts with Short Dog Point—1985
DIN 480	Square Head Bolts with Collar and Oval Half Dog Point—1985
DIN 522	Metal Washers; Technical Delivery Conditions
DIN 603	Mushroom Head Square Neck Bolts—1981
DIN 604	Flat Countersunk Nib Bolts—1981
DIN 605	Flat Countersunk Square Neck Bolts with Long Square—1981
DIN 607	Cup Head Nib Bolts—1981
DIN 608	Flat Countersunk Square Neck Bolts with Short Square—1981
DIN 609	Hexagon Fit Bolts—1995
DIN 610	Hexagon Fit Bolts with Short Threaded Dog Point
DIN 649	T-Slots for T-Head Bolts—1987
DIN 787	Tee Bolts May; ISO 299: 1987—1991
DIN 797	Special Foundation Bolts—1970
DIN 798	Special Foundation Nuts for Special Foundation Bolts According to DIN 797
DIN 931 PT 2	M 42 to M 160x6 Hexagon Head Bolts; Product Grade B—1987
DIN 931 SUPPL. 1	Hexagon Head Bolts with Shank; Masses—1986
DIN 974 PT 2	Diameters of Counterbores (Holes) for Hexagon Bolts and Nuts—1991
DIN 976-1	Metric Thread Stud Bolts—1995
DIN 976-2	Metric Interference-Fit Thread Stud Bolts—1995
DIN 1441	Washers; Type Coarse for Bolts—1974
DIN 2507	Bolts, Screws and Nuts for Pipelines—1986
DIN 2510 PT 3	Bolted Connections with Reduced Shank; Stud-Bolts—1971
DIN 6921	Hexagon Flange Bolts
DIN 6922	Hexagon Flange Bolts with Reduced Shank
DIN 7349	Plain Washers for Bolts with Heavy Clamping Sleeves—1974
DIN 7500-1	Thread Rolling Screws for ISO Metric Screw Thread; Dimensions, Requirements and Testing
DIN 7992	T-Head Bolts with Large Head—1970
DIN 17111	Low Carbon Unalloyed Steels for Bolts, Nuts and Rivets; Technical Conditions of Delivery—1980
DIN 17240	Heat Resisting and Highly Heat Resisting Materials for Bolts and Nuts; Quality Specifications—1976

TABLE E10.B2   DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets
(Continued)

Numbers	Title
DIN EN 20225	Fasteners Bolts, Screws, Studs and Nuts; Symbols and Designations for Dimensioning (ISO 225: 1983)—1992 (Supersedes DIN ISO 225, January 1984 Edition)
DIN EN 20273	Fasteners; Clearance Holes for Bolts and Screws (ISO 273: 1979) (Supersedes DIN ISO 273, September 1979 Edition)—1992
DIN EN 20898-7	Mechanical Properties of Fasteners; Torsional Test and Minimum Torques for Bolts and Screws with Nominal Diameters 1 mm to 10 mm (ISO 898-7: 1992)—1995
DIN EN 20898 PT 1	Mechanical Properties of Fasteners; Bolts, Screws and Studs (ISO 898-1: 1988)—1992 (Supersedes DIN ISO 898 Part 1, January 1989 Edition)
DIN EN 24014	Hexagon Head Bolts; Product Grades A and B; (ISO 4014: 1988)—1992 Supersedes DIN 931 Part 1, September 1987 Edition, and DIN ISO 4014, September 1989 Edition)
DIN EN 24015	Hexagon Head Bolts with Reduced Shank; (Shank Diameter = Pitch Diameter; Product Grade B (ISO 4015: 1979)—1991
DIN EN 24016	Hexagon Head Bolts Product Grade C (ISO 4016: 1988)—1992 (Supersedes DIN 601 September 1987 Edition, and DIN ISO 4016, October 1989 Edition)
DIN EN 26157 PT 1	Fasteners; Surface Discontinuities; Bolts, Screws and Studs Subject to General Requirements (ISO 6157-1: 1988)—1991 (Together with the December 1991 Edition of DIN EN 26157 Part 3, Supersedes October 1984 Edition of DIN 267 Part 19)
DIN EN 26157 PT 3	Fasteners; Surface Discontinuities; Bolts, Screws and Studs Subject to Special Requirements (ISO 6157-3: 1988)—1991 (Together with the December 1991 Edition of DIN EN 26157 Part 1, Supersedes October 1984 Edition of DIN 267 Part 19)
DIN EN 28765	Hexagon Head Bolts with Metric Fine Pitch Thread; Product Grades A and B (ISO 8765: 1988)—1992 (Supersedes DIN 960, January 1990 Edition, and DIN ISO 8765, January 1990 Edition)
DIN EN 28839	Mechanical Properties of Fasteners; Nonferrous Metal Bolts, Screws, Studs and Nuts (ISO 8839: 1986)—1991 (Supersedes February 1981 Edition of DIN 267 Part 18)
DIN LN 29962	Bolts and Accessories; Additional Procurement Data for Special Designs and Arrangement of Code Letters in Characteristic Blocks—1976
DIN LN 65010 PT 1	Specification for Screws and Bolts of Unalloyed and Low-Alloy Steel with Minimum Tensile Strength up to 900N/mm^2—1968

TABLE E10.D2 DIN Standards and Specifications for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
DIN LN 65010 PT 2	Specification for Screws and Bolts of Unalloyed and Low-Alloy Steel with Minimum Tensile Strength up to 900N/mm^2, Minimum Ultimate Tensile Loads, Proof Loads—1968
DIN LN 65018 PT 1	Manufacturer's Acceptance Certificate for Screws and Bolts—1968
DIN LN 65019	Bolts, Countersunk Head with TORQ-Set Recess—1977
DIN 2696	Lenticular Gaskets and Lenticular Seals for ND 64 to ND 400 Flanged Connections—1972
DIN 2698	Corrugated Steel Sheet Gaskets Incorporating Asbestos Ropes for ND 25 to ND 250 Flanged Connections—1972
DIN 3535 PT 6	Synthetic Fibre and Graphite Based Gasket Materials for Use with Gas Valves, Gas Appliances and Gas Pipework
DIN 7603	Ring Seals and Gaskets—1994
DIN 8914	90 Degree Tapered Seal Rings and Caps for Use with PN 40 Flared Flange Solderless Compression Couplings in Refrigerating Systems
DIN 28040	Gaskets for Use with Flanged Joints—1989
DIN 28090-1	Static Seals for Flanged Connections; Characteristic Values and Test Methods
DIN 28090-2	Static Seals for Flanged Connections; In-Process Testing of Sheet Gasket Materials
DIN 28090-3	Static Seals for Flanged Connections; Chemical Resistance of Sheet Gasket Materials
DIN 87107	Gaskets for Non-Return Flaps in Accordance with DIN 87101—1975
DIN EN 1514-1	Flanges and Their Joints Dimensions of Gaskets for PN-Designated Flanges Part 1: Non-Metallic Flat Gaskets with or without Inserts August; Supersedes DIN EN 2690 and DIN 2692 May 1966 and DIN 2691 November 1971—1997
DIN EN 1514-2	Flanges and Their Joints Dimensions of Gaskets for PN-Designated Flanges Part 2: Spiral Wound Gaskets for Use with Steel Flanges—1997
DIN EN 1514-3	Flanges and Their Joints Dimensions of Gaskets for PN-Designated Flanges Part 3: Non-Metallic PTFE Envelope Gaskets—1997
DIN EN 1514-4	Flanges and Their Joints Dimensions of Gaskets for PN-Designated Flanges Part 4: Corrugated, Flat or Grooved Metallic and Filled Metallic Gaskets for Use with Steel Flanges—1997

TABLE E10.D3 DIN Standards and Specifications for Valves

Numbers	Title
DIN 475 PT 1	Widths Across Flats for Bolts, Screws, Valves and Fittings—1984
DIN 477 PT 1	Gas Cylinder Valves Rated for Test Pressures up to 300 Bar; Types, Sizes and Outlets—1990; Superseded in Part by DIN EN 629-1—August 1996 Edition
DIN 477 PT 5	Gas Cylinder Valves Rated for Test Pressures up to 450 Bar; Types, Sizes and Outlets—1990
DIN 1690 PT 10	Technical Delivery Conditions for Castings of Metallic Materials; Supplementary Requirements for Steel Castings Used for Heavy-Duty Valves—1991
DIN 1997 PT 1	Shut-Off Valves for Site Drainage Systems; Backflow Gates for Non-Faecal Sewage; Requirements, Design Principles and Materials—1984
DIN 1997 PT 2	Shut-Off Valves for Site Drainage Systems; Backflow Gates for Non-Faecal Sewage; Testing—1984
DIN 3158	Valves for Use in Refrigerating Systems; Safety Requirements, Testing and Marking—1987
DIN 3202 PT 2	End-To-End and Centre-To-End Dimensions of Valves; Weld-On Valves—1982
DIN 3202 PT 4	Face-To-Face and Centre-To-Face Dimensions of Valves; Valves With Female Thread Connection—1982
DIN 3202 PT 5	Face-To-Face and Centre-To-Face Dimensions of Valves; Valves for Connection With Compression Couplings—1984
DIN 3230 PT 1	Technical Conditions of Delivery for Valves; Enquiry, Order and Delivery—1974
DIN 3230 PT 2	Technical Conditions of Delivery for Valves; General Requirements—1974
DIN 3230 PT 3	Technical Delivery Conditions for Valves; Compilation of Test Methods—1982
DIN 3230 PT 4	Technical Conditions of Delivery for Valves; Valves for Potable Water Service; Requirements and Testing—1977
DIN 3230 PT 5	Technical Delivery Conditions; Valves for Gas Installations and Gas Pipelines; Requirements and Testing—1984
DIN 3230 PT 6	Technical Delivery Conditions for Valves; Requirements and Methods of Test for Valves for Use with Flammable Liquids—1987
DIN 3239 PT 2	Weld-On Ends of Valves for Socket Welding—1978
DIN 3266 PT 1	Valves for Drinking Water Installations on Private Premises; PN 10 Pipe Interrupters, Pipe Disconnectors, Anti-Vacuum Valves—1986

TABLE E10.D3 DIN Standards and Specifications for Valves *(Continued)*

Numbers	Title
DIN 3266 PT 2	Valves for Drinking Water Installations on Private Premises; PN 10 Pipe Interrupters, Pipe Disconnectors, Anti-Vacuum Valves; Testing—1987
DIN 3339	Valves; Body Component Materials—1984
DIN 3352 PT 1	Gate Valves; General Information—1979
DIN 3352 PT 2	Cast Iron Gate Valves with Metallic Seat and Inside Screw Stem—1988
DIN 3352 PT 3	Cast Iron Gate Valves with Metallic Seat and Outside Screw Stem—1988
DIN 3352 PT 4	Cast Iron Gate Valves with Elastomeric Obturator Seatings and Inside Screw Stem—1986
DIN 3352 PT 6	Gate Valves of Unalloyed and Low-Alloyed Steel with Internal Stem Thread—1979
DIN 3352 PT 7	Gate Valves of Unalloyed and Low-Alloyed Steel with External Stem Thread—1979
DIN 3352 PT 9	Gate Valves of Heat-Resistant Steel—1979
DIN 3352 PT 10	Gate Valves of Stainless Steel—1979
DIN 3352 PT 11	Flanged Copper Alloy Gate Valves—1981
DIN 3352 PT 12	Socket End Copper Alloy Gate Valves—1981
DIN 3352 PT 13	Double-Socket Cast Iron Gate Valves with Elastomeric Obturator Seat and Inside Screw Stem—1987
DIN 3354 PT 1	Butterfly Valves; General Data
DIN 3354 PT 2	Butterfly Valves; Soft Material Seat Seal Cast Iron Tight Butterfly Shutoff Valves with Flanged Ends
DIN 3354 PT 3	Butterfly Valves; Soft Material Seat Seal Steel or Cast Steel Tight Butterfly Shutoff Valves with Flanged Ends or Weld-on-Ends
DIN 3354 PT 4	Butterfly Valves; Metallic Seat Seal Steel or Cast Steel Tight Butterfly Shutoff Valves with Flanged Ends or Weld-on Ends
DIN 3356 PT 1	Globe Valves; General Data—1982
DIN 3356 PT 2	Globe Valves; Cast Iron Stop Valves—1982
DIN 3356 PT 3	Globe Valves; Unalloyed Steel Stop Valves—1982
DIN 3356 PT 4	Globe Valves; High Temperature Steel Stop Valves—1982
DIN 3356 PT 5	Globe Valves; Stainless Steel Stop Valves—1982
DIN 3357 PT 1	Metal Ball Valves; General Requirements and Methods of Test—1989
DIN 3357 PT 2	Full Bore Steel Ball Valves—1981
DIN 3357 PT 3	Reduced Bore Steel Ball Valves—1981

TABLE E10.D3 DIN Standards and Specifications for Valves *(Continued)*

Numbers	Title
DIN 3357 PT 4	Full Bore Nonferrous Metal Ball Valves—1981
DIN 3357 PT 5	Reduced Bore Nonferrous Metal Ball Valves—1981
DIN 3357 PT 6	Full Bore Cast Iron Ball Valves
DIN 3357 PT 7	Reduced Bore Cast Iron Ball Valves
DIN 3381	Safety Devices for Gas Supply Installations Operating at Working Pressures up to 100 Bar; Pressure Relief Governors and Safety Shut-Off Devices
DIN 3399	Gas Low-Pressure Cut-Off Valves; Safety Requirements, Testing—1986
DIN 3441 PT 1	Unplasticized Polyvinyl Chloride (PVC-U) Valves; Requirements and Testing—1989
DIN 3441 PT 2	Unplasticized Polyvinyl Chloride (PVC-U) Valves; Ball Valves; Dimensions—1984
DIN 3441 PT 3	Unplasticized Polyvinyl Chloride (PVC-U) Valves; Diaphragm Valves; Dimensions—1984
DIN 3441 PT 4	Valves of Rigid PVC (Unplasticized or Rigid Polyvinyl Chloride); Y-Valves (Inclined-Seat Valves), Dimensions—1978
DIN 3441 PT 5	Unplasticized Polyvinyl Chloride (PVC-U) Valves; PN 6 and PN 10 Wafer Type Bufferfly Valves; Dimensions—1984
DIN 3441 PT 6	Unplasticized Polyvinyl Chloride (UPVC) Valves; Gate Valves with Inside Screw Stem Dimensions—1988
DIN 3442 PT 1	Polypropylene (PP) Valves; Requirements and Testing—1987
DIN 3442 PT 2	Fittings of PP (Polypropylene); Ball Valves; Dimensions—1980
DIN 3442 PT 3	Polypropylene (PP) Valves; Diaphragm Valves; Dimensions—1987
DIN 3475	Spheroidal Graphite Cast Iron Valves and Fittings Provided with Internal Corrosion Protection by means of Enamelling, for Use in Drinking Water Supply Systems; Requirements and Testing—1993
DIN 3476	Corrosion Protection of Water Valves and Pipe Fittings by Epoxy Powder or Liquid Epoxy Resin Linings; Requirements and Testing—1996
DIN 3500	PN 10 Piston Type Gate Valves for Use in Drinking Water Supply Systems—1990
DIN 3502	Stop Valves for Drinking Water Supplies on and in Private Property; Straight Pattern Globe Valves with Oblique Bonnet, Rated for Nominal Pressure PN 10—1985

TABLE E10.D3 DIN Standards and Specifications for Valves *(Continued)*

Numbers	Title
DIN 3512	Stop Valves for Drinking Water Supplies on and in Private Property; Straight Pattern Globe Valves with Vertical Bonnet, Rated for Nominal Pressure PN 10—1985
DIN 3535 PT 5	Rubber/Cork and Rubber/Cork Synthetic Fibre Based Gasket Materials for Use With Gas Valves, Gas Appliances and Gas Pipework; Safety Requirements and Testing—1993
DIN 3535 PT 6	Synthetic Fibre and Graphite Based Gasket Materials for Use with Gas Valves, Gas Appliances and Gas Pipework—1994
DIN 3536	Lubricants for Gas Valves and Controls; Requirements, Testing—1982, Superseded in Parts By EN 377
DIN 3537 PT 3	Gas Stop Valves Rated for Pressures up to 4 Bar; Requirements and Acceptance Testing for Laboratory Valves—1992
DIN 3543 PT 1	Metal Tapping Valves; Requirements, Testing—1984
DIN 3543 PT 4	High Density Polyethylene (HDPE) Tapping Valves for HDPE Pipes; Dimensions—1984
DIN 3544 PT 1	High Density Polyethylene (HDPE) Valves; Tapping Valves; Requirements and Test—1985
DIN 3840	Valve Bodies; Strength Calculation in Respect of Internal Pressure
DIN 3852 PT 1 (S)	Stud Ends and Tapped Holes with Metric Fine Pitch Thread, for Use with Compression Couplings, Valves and Screw Plugs; Dimensions—1992: Superseded in Part by DIN 3852 Part 11, May 1994 Edition
DIN 3852 PT 2 (S)	Stud Ends and Tapped Holes with Pipe Thread, for Use with Compression Couplings, Valves and Screw Plugs; Dimensions—1991: (Superseded in Part by DIN 3852 Part 11, May 1994 Edition)
DIN 3852 PT 3	Type F Stud Ends and Type W Tapped Holes with Metric Fine Pitch Thread, for Use with Compression Couplings, Valves and Screw Plugs, Sealed by O-Ring; Dimensions
DIN 3852 PT 11	Stud Ends and Tapped Holes for Use with Compression Couplings; Valves and Screw Plugs Type E Stud End Dimensions—1994; Supersedes Parts of DIN 3852 Part 1, February 1992 Edition, and DIN 3852 Part 2, November 1991 Edition
DIN 17480	Valve Materials; Technical Delivery Conditions (May)
DIN 19208	Flow Measurement; Mating Dimensions and Application of Shut-Off Valves for Differential Pressure Transducers and Differential Pressure Piping—1988

TABLE E10.D3 DIN Standards and Specifications for Valves *(Continued)*

Numbers	Title
DIN 19578 PT 1	Stop Valves for Site Drainage Systems; Anti-Flooding Valves for Faecal Sewage Systems; Requirements—1988
DIN 19578 PT 2	Stop Valves for Site Drainage Systems; Anti-Flooding Valves for Faecal Sewage Systems; Testing and Inspection—1988
DIN 30677 PT 1	External Corrosion Protection of Buried Valves; Normal Duty Coatings—1991
DIN 30677 PT 2	External Corrosion Protection of Buried Valves; Heavy-Duty Thermoset Plastics Coatings—1988
DIN 32509	Hand-Operated Shut-Off Valves for Welding, Cutting and Allied Processes; Designs, Safety Requirements, Testing—1985
DIN 42560	Transformers; Throttle-Valves NW 80; Dimensions; Tightness Testing—1971
DIN 45635 PT 50	Measurement of Noise Emitted by Machines; Airborne Noise Measurement, Enveloping Surface Method; Valves—1987
DIN 74279	Compressed-Air Braking Systems; Overflow Valves—1977
DIN 86500	Valves and Gate Valves with Screwed Connections; Survey of Types for Shipbuilding—1968
DIN 86501	Gunmetal Screwed-Bonnet Type Shut-Off Valves with Non-Soldered Cutting Ring–Type Pipe Unions—1973
DIN 86502	Gunmetal Screwed Bonnet Non-Return Valves with Non-Soldered Pipe Unions with Cutting Ring—1973
DIN 86511	Shut-Off Valves, Screwed-Bonnet Type of Gun Metal with 25 Deg. Taper Bushing Pipe Unions for Brazing
DIN 86512	Shut-Off Check Valves, Screwed-Bonnet Type of Gun Metal with 25 Deg. Taper Bushing Pipe Unions for Brazing
DIN 86528	Tab Washers for Screwed Bonnet Valves—1973
DIN 86545 (W)	Vent Valve; R ¼″; NP 16; up to 110 Deg. C
DIN 86551	Steel Screwed Bonnet Valves with 25 Deg. Taper-Bushing Type Pipe Unions
DIN 86552	Steel Screwed Bonnet Valves with Non-Soldered Cutting Ring-Type Pipe Unions—1973
DIN 86720	Bronze Wedge-Type Flat-Sided Gate Valves with Screwed Bonnet and Flanges; ND 16; NW 20 to 100—1968
DIN 87107	Gaskets for Non-Return Flaps in Accordance with DIN 87101
DIN 87901	Sniffle Valves for Pumps; Size R ⅜″ to R ¾″; ND 16 up to 100 Deg. C—1967

TABLE E10.D3 DIN Standards and Specifications for Valves *(Continued)*

Numbers	Title
DIN EN 488	Preinsulated Bonded Pipe Systems for Underground Hot Water Networks; Valve Assemblies for Steel Service Pipes with Polyurethane Thermal Insulation and Outer Polyethylene Casing
DIN EN 558-1	Face-to-Face and Centre-to-Face Dimensions of Metal Industrial Valves for Use in Flanged Pipe Systems; PN-Designated Valves—1995 (Supersedes DIN 3202 PT 1, September 1984 Edition)
DIN EN 558-2	Face-to-Face and Centre-to-Face Dimensions of Metal Industrial Valves for Use in Flanged Pipe Systems; Class-Designated Valves—1995
DIN EN 736-1	Valves; Terminology; Types of Valves
DIN EN 917	Plastic Piping Systems Thermoplastic Valves Test Methods for Resistance to Internal Pressure and Leaktightness
DIN EN 1092-2	Circular Flanges for Pipes, Valves, Fittings and Accessories, PN Designated Part 2: Cast Iron Flanges; Supersedes DIN 2532 02–1976; DIN 2533 02–1976; DIN 28604 01–1990; DIN 28605 01–1990; DIN 28606 01–1990; and 28607 01–1990 and also Supersedes Part of DIN 2500 08–1966
DIN EN 1680	Valves for Polyethylene (PE) Piping Systems; Test Method for Leaktightness Under and After Bending Applied to the Operating Mechanism
DIN EN 1704	Thermoplastics Valves; Test Method for the Integrity of a Valve After Temperature Cycling Under Bending
DIN 1705	Plastic Piping Systems; Thermoplastics Valves; Test Method for the Integrity of a Valve After an External Blow
DIN EN 28233	Thermoplastics Valves; Torque Test (ISO 8233: 1988)
DIN EN 28659	Thermoplastics Valves; Testing of Fatigue Strength (ISO 8659: 1989)

TABLE E10.J1 Japanese Standards and Specifications for Pipe, Tube, and Fittings

Numbers	Title
JIS A 5302	Concrete Pipes and Reinforced Concrete Pipes
JIS A 5303	Reinforced Spun and Centrifugal Reinforced Concrete Pipes
JIS A 5314	Mortar Lining for Ductile Iron Pipes (Errata–1995)
JIS A 5322	Reinforced Spun-Concrete Pipes with Socket
JIS A 5333	Core Type Prestressed Concrete Pipes
JIS A 5350	Fiberglass Reinforced Plastic Mortar Pipes (Errata–1995)
JIS A 5405	Asbestos Cement Pipes
JIS G 3429	Seamless Steel Tubes for High Pressure Gas Cylinder
JIS G 3439	Seamless Steel Oil Well Casing, Tubing and Drill Pipe
JIS G 3441	Alloy Steel Tubes for Machine Purposes
JIS G 3442	Galvanized Steel Pipes for Water Service
JIS G 3443	Coated Steel Pipes for Water Service; (Erratum)
JIS G 3444	Carbon Steel Tubes for General Structural Purposes: (Errata–March 1996)
JIS G 3445	Carbon Steel Tubes for Machine Structural Purposes
JIS G 3446	Stainless Steel Pipes for Machine and Structural Purposes
JIS G 3447	Stainless Steel Sanitary Pipes
JIS G 3448	Light Gauge Stainless Steel Pipes for Ordinary Piping
JIS G 3451	Fittings of Coated Steel Pipes for Water Service; Errata–1996
JIS G 3452	Carbon Steel Pipes for Ordinary Piping
JIS G 3454	Carbon Steel Pipes for Pressure Service
JIS G 3455	Carbon Steel Pipes for High Pressure Service
JIS G 3456	Carbon Steel Pipes for High Temperature Service
JIS G 3457	Arc Welded Carbon Steel Pipes
JIS G 3458	Alloy Steel Pipes
JIS G 3459	Stainless Steel Pipes (Errata–1995)
JIS G 3460	Steel Pipes for Low Temperature Service
JIS G 3465	Seamless Steel Tubes for Drilling
JIS G 3466	Carbon Steel Square Pipes for General Structural Purposes
JIS G 3468	Large Diameter Welded Stainless Steel Pipes
JIS G 3469	Polyethylene Coated Steel Pipes
JIS G 3471	Corrugated Steel Pipes and Sections
JIS G 3474	High Tensile Strength Steel Tubes for Tower Structural Purposes
JIS G 3491	Asphalt Protective Coatings for Steel Water Pipe R (1983)

TABLE E10.J1 Japanese Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
JIS G 3492	Coal-Tar Enamel Protective Coatings for Steel Water Pipe R (1983)
JIS G 4903	Seamless Nickel-Chromium-Iron Alloy Pipes
JIS G 5201	Centrifugally Cast Steel Pipes for Welded Structure
JIS G 5202	Centrifugally Cast Steel Pipes for High Temperature and High Pressure Service
JIS G 5525	Cast-Iron Soil Pipes and Fittings; Errata–1996
JIS G 5526	Ductile Iron Pipes
JIS G 5527	Ductile Iron Fittings
JIS G 5528	Epoxy-Powder Coating for Interior of Ductile Iron Pipes and Fittings
JIS H 0502	Method of Eddy Current Testing for Copper and Copper-Alloy Pipes and Tubes
JIS H 0515	Eddy Current Inspection of Titanium Pipes and Tubes
JIS H 0516	Ultrasonic Inspection of Titanium Pipes and Tubes
JIS H 3300	Copper and Copper Alloy Seamless Pipes and Tubes
JIS H 3320	Copper and Copper Alloy Welded Pipes and Tubes
JIS H 3401	Pipe Fittings of Copper and Copper Alloy
JIS H 4080	Aluminum and Aluminum Alloy Seamless Pipes and Tubes
JIS H 4090	Aluminum and Aluminum Alloy Welded Pipes and Tubes
JIS H 4202	Magnesium Alloy Seamless Pipes and Tubes
JIS H 4311	Lead and Lead Alloy Tubes for Common Industries
JIS H 4312	Polyethylene Lining Lead Pipes for Water Supply
JIS H 4552	Nickel and Nickel Alloy Seamless Pipe and Tubes
JIS H 4630	Titanium Pipes for Ordinary Piping
JIS H 4635	Titanium-Palladium Alloy Pipes for Ordinary Piping
JIS K 6739	Unplasticized Polyvinyl Chloride Pipe Fittings for Drain R (1980)
JIS K 6741	Unplasticized Polyvinyl Chloride (PVC) Pipes
JIS K 6742	Unplasticized Polyvinyl Chloride Pipes for Water Works; (Errata–April 1995)
JIS K 6743	Unplasticized Polyvinyl Chloride Pipe Fittings for Water Works
JIS K 6761	Polyethylene Pipes for General Purposes
JIS K 6762	Polyethylene Pipes for Water Works; (Errata–April 1995)
JIS K 6763	Polyethylene Pipe Fittings for Water Works
JIS K 6769	Crosslinked Polyethylene (XPE) Pipes
JIS K 6770	Crosslinked Polyethylene (XPE) Pipe Fusion Fittings

TABLE E10.J1 Japanese Standards and Specifications for Pipe, Tube, and Fittings
(Continued)

Numbers	Title
JIS K 6774	Polyethylene Pipes for the Supply of Gaseous Fuels
JIS K 6775	Polyethylene Pipe-Fittings for the Supply of Gaseous Fuels
JIS K 6776	Chlorinated Polyvinyl Chloride (CPVC) Pipes for Hot and Cold Water Supply
JIS K 6777	Chlorinated Polyvinyl Chloride (CPVC) Pipe Fittings for Hot and Cold Water Supply
JIS K 6778	Polybutene (PB) Pipes
JIS K 6779	Polybutene (PB) Pipe-Fittings
JIS K 6897	Polytetrafluoroethylene Pipes
JIS R 1201	Clay Pipes
JIS R 1511	Conical Flanged Straight Pipes of Acid Proof Porcelains for Chemical Industry
JIS R 1512	Conical Flanged 90 Degree Bent Pipes of Acid Proof Porcelains for Chemical Industry
JIS R 1513	Conical Flanged 45 Degree Bent Pipes of Acid Proof Porcelains for Chemical Industry
JIS R 1514	Conical Flanged Tee Pipes of Acid Proof Porcelains for Chemical Industry
JIS R 1534	Metal Joint For Conical Flange Pipes of Acid Proof Porcelains for Chemical Industry
JIS R 3511	Ampoule Pipe
JIS S 2080	Exhaust Pipes for Burning Appliances
JIS S 3025	Supply and Exhaust Pipes for Oil Burning Appliances
JIS S 3028	Oil Discharge Copper Pipe for Oil Burning Appliances
JIS T 7101	Medical Gas Pipeline Systems
JIS T 9211	Pipes for Endoskeletal Type of Lower Limb Prostheses
JIS B 2301	Screwed Type Malleable Cast Iron Pipe Fittings
JIS B 2302	Screwed Type Steel Pipe Fittings
JIS B 2311	Steel Butt-Welding Pipe Fittings for Ordinary Use
JIS B 2312	Steel Butt-Welding Pipe Fittings
JIS B 2313	Steel Plate Butt-Welding Pipe Fittings
JIS B 2316	Steel Socket-Welding Pipe Fittings
JIS B 2321	Aluminium and Aluminium Alloy Butt-Welding Pipe Fittings
JIS B 2351	25 MPa (250 kgf/cm^2) Bite Type Tube Fittings for Hydraulic Use; (Errata–1994)
JIS B 2354	Crosslinked Polyethylene (XPE) Pipe Clamp Type Fittings
JIS B 6164	Compression Type Tube Fittings for Machine Tools Edition 1
JIS B 8381	Pneumatic System—Flexible Tubes—Tube Fittings

Numbers	Title
JIS C 8380	Plastic Coated Steel Pipes for Cable—Ways
JIS D 3607	Automotive Diesel Engines–Steel Tubes for High-Pressure Fuel Injection Pipes
JIS E 4106	Railway Rolling Stock—Screwed Type Pipe Fittings
JIS E 4308	Railway Rolling Stock—Air Filters
JIS F 0014	Glossary of Terms of Shipbuilding (Hull Part—Piping)
JIS F 0301	Schemes Thermal Insulation of Piping for Small Ships
JIS F 0414	Internal Wirings and Pipings of Marine Engine Control Console
JIS F 0506	Application of Copper Pipes for Marine Use
JIS F 0507	Small Ships—Steel Pipes—Application
JIS F 2007	Mooring Pipes
JIS F 2030	Single Point Mooring Pipes
JIS F 3001	Hinged Caps of Sounding Pipes
JIS F 3002	Deck Pieces for Sounding Pipes R (1977)
JIS F 3016	Ships' Cast Iron Pipe Sleeve Type Expansion Joints
JIS F 3017	Ships' Cast Steel Pipe Sleeve Type Expansion Joints
JIS F 3993	Discharge Pipes for Dredger
JIS F 3994	Floaters of Discharge Pipes for Dredger
JIS F 3995	Rubber Sleeves for Dredger Discharge Pipes
JIS F 7008	Standard Specification of Thermal Insulation for Piping
JIS F 7101	Pipes of Ships' Machinery—Standard Velocity of Flow
JIS F 7102	Application for Gaskets and Packings to Piping System in Machinery Space
JIS F 7435	Brass 30 K Unions with Bite Joint(s) for Marine Use
JIS F 7436	Copper Tube 10 K Brazed Unions for Marine Use
JIS F 7437	Copper Tube 10 K Screwed Unions for Marine Use
JIS F 7438	Steel Pipe 10 K Welding Type Unions for Marine Use
JIS F 7439	Steel Pipe 10 K Screwed Unions for Marine Use
JIS F 7440	Copper Pipe 20 K Brazed Type Unions for Marine Use
JIS F 7441	Copper Pipe 20 K Screwed Unions for Marine Use
JIS F 7442	Steel Pipe 40 K Welded Unions for Marine Use
JIS F 7443	Steel Pipe 40 K Screwed Unions for Marine Use
JIS F 7444	Steel Pipe 100 K Welded Unions for Marine Use
JIS F 7445	Steel Pipe 100 K Screwed Unions for Marine use
JIS B 0151	Iron and Steel Pipe Fittings—Vocabulary
JIS B 2303	Screwed Drainage Fittings Edition 1
JIS B 8602	Pipe Flanges for Refrigerants; (Errata–1994)
JIS B 8607	Flare Type and Brazing Type Fittings for Refrigerants

TABLE E10.J2 Japanese Standards for Flanges, Bolts, Nuts, and Gaskets

Numbers	Title
JIS B 1189	Hexagon Bolts with Flange
JIS B 1190	Hexagon Nuts with Flange
JIS B 1451	Rigid Flanged Shaft Couplings
JIS B 1452	Flexible Flanged Shaft Couplings
JIS B 2201	Pressure Ratings for Ferrous Material Pipe Flanges Replaced by B 2238 and B 2239
JIS B 2202	Dimensions for Pipe Flange Facing
JIS B 2203	Tolerances for Pipe Flanges Replaced by B 2238 and B 2239
JIS B 2205	Basis for Calculation of Pipe Flanges
JIS B 2206	Basis for Calculation of Aluminium Alloy Pipe Flanges
JIS B 2207	Basis for Calculation of Aluminium Alloy Pipe Flanges with Full Face Gasket
JIS B 2210	Basic Dimensions of Ferrous Material Pipe Flanges replaced by B 2238 and B 2239
JIS B 2220	Steel Welding Pipe Flanges
JIS B 2240	Basic Dimensions of Copper Alloy Pipe Flanges
JIS B 2241	Basic Dimensions of Aluminium Alloy Pipe Flanges
JIS B 2990	Vacuum Flanges R (1974)
JIS B 2291	21 MPa Slip-On Welding Pipe Flanges for Hydraulic Use
JIS B 2292	Hydraulic Fluid Power—Positive Displacement Pumps and Motors—Dimensions and Identification Code for Mounting Flanges and Shaft Ends Part 2: Two- and Four-Hole Flanges and Shaft Ends—Metric Series (ISO 3019-2)
JIS B 2404	Spiral-Wound Gaskets for Pipe Flanges
JIS B 8273	Bolted Flange for Pressure Vessels
JIS B 8436	Circular Flanged Mechanical Interfaces of Industrial Robots
JIS B 8602	Pipe Flanges for Refrigerants: (Errata–1994)
JIS D 3106	Sleeve Type Flanged Half Bearings for Automobile Engines
JIS D 3631	Shapes and Dimensions of Flange-Mounted and Screw-Mounted Nozzle Holders Size S for Road Vehicles
JIS D 3701	Dimensions of Carburetor Flanges for Automobiles
JIS D 4304	Dimension of Flanges to be Fitted up Clutch Housing for Automobiles R (1983)
JIS F 7381	Bronze 5 K Flanged Cocks for Marine Use
JIS F 7801	Face-To-Face Dimensions of Marine T Pieces with Flanges
JIS F 7804	Marine Silver Brazing 5 K Pipe Flanges

TABLE E10.J2 Japanese Standards for Flanges, Bolts, Nuts, and Gaskets *(Continued)*

Numbers	Title
JIS F 7805	Basic Dimensions of Steel Flanges for Marine Exhaust Gas Pipe
JIS F 7806	Ships' 280 K and 350 K Socket Welding Pipe Flanges
JIS G 3223	High Tensile Strength Steel Forgings for Tower Flanges
JIS L 5105	Single Flange Rings
JIS L 6412	Warp Beams and Beam Flanges for Looms
JIS R 6259	Coated Abrasives—Flap Wheels with Incorporated Flanges or Separate Flanges—Designation and Dimensions
JIS Z 1604	Plugs and Flanges for Steel Drums
JIS B 2238	General Rules for Steel Pipe Flanges
JIS B 2239	General Rules for Cast Iron Flanges
JIS F 0602	Shipbuilding—Non-Asbestos Gaskets to Cargo Piping System—Application Standard
JIS F 7102	Application Standard of Gaskets and Packings to Piping System in Marine Machinery

Numbers	Title
JIS B 8473	Fuel Oil Pipe Line—Solenoid Valves
JIS B 8605	Stop Valves for Refrigerants
JIS B 8619	Methods of Testing for Performance of Thermostatic Refrigerant Expansion Valves
JIS B 8651	Test Methods for Electro-Hydraulic Proportional Pressure Relief Valves
JIS B 8652	Test Methods for Electro-Hydraulic Proportional Pressure Reducing Valves and Electro-Hydraulic Proportional Pressure Reducing and Relieving Valves
JIS B 8653	Test Methods for Electro-Hydraulic Proportional Metering Valves
JIS B 8654	Test Methods for Electro-Hydraulic Proportional Series Flow Control Valves
JIS B 8655	Test Methods for Electro-Hydraulic Proportional Directional Series Flow Control Valves
JIS B 8656	Test Methods for Electro-Hydraulic Proportional Bypass Flow Control Valves
JIS B 8657	Test Methods for Electro-Hydraulic Proportional Directional Bypass Flow Control Valves
JIS B 8658	Rules of Electronic Amplifier for Electro-Hydraulic Control Valves
JIS B 8659	Test Methods for Electro-Hydraulic Servo Valves
JIS E 4102	Angle Cocks for Railway Rolling Stock
JIS E 4105	Three-Way Cocks for Railway Rolling Stock
JIS E 4115	Magnet Valves for Railway Rolling Stock
JIS E 4117	Leveling Valves for Railway Rolling Stock
JIS E 4306	Conductor's Valves for Railway Rolling Stock
JIS E 7701	Safety Valves for High Pressure Gas Tank Car Tanks
JIS F 0504	Application and Setting Pressure of Relief Valves for Ships' Machinery
JIS F 3018	Self Closing Parallel Cock Heads for Short Sounding Pipe
JIS F 3019	Self-Closing Gate Valve Heads for Short Sounding Pipe
JIS F 3024	Ships' Deck Stands for Controlling Valves
JIS F 3025	Remote Handling Fittings for Valves on Small Ships' Forepeak Bulkhead
JIS F 3026	Remote Handling Fittings for Valves in Small Ships' Cargo Oil Tank
JIS F 3056	Ships' Foot Valves R (1971)

TABLE E10.J3 Japanese Standards and Specifications for Valves *(Continued)*

Numbers	Title
JIS F 3057	Bronze Vertical Storm Valves
JIS F 3058	Cast Steel Vertical Storm Valves R (1977)
JIS F 3059	Bronze Screwdown Vertical Storm Valves
JIS F 3060	Cast Steel Screwdown Vertical Storm Valves
JIS F 3303	Flash Butt Welded Anchor Chain Cables
JIS F 5610	Forged Steel 20 K Reflex Type Water Gauges with Valves for Marine Boilers
JIS F 5611	Forged Steel 63 K Transparent Type Water Gauges with Valves for Marine Boilers
JIS F 7007	Abbreviation Used in Name Plate for Marine Valve
JIS F 7211	Marine 5 K Level Gauges with Valves
JIS F 7212	Marine Oil Level Gauges with Self Closing Valves
JIS F 7213	Marine 16 K Water Gauges with Valve
JIS F 7216	Marine Self Closing Valves for Oil Level Gauges
JIS F 7300	Application for Marine Valves and Cocks
JIS F 7301	Marine Bronze 5 K Globe Valves
JIS F 7302	Marine Bronze 5 K Angle Valves
JIS F 7303	Marine Bronze 16 K Globe Valves
JIS F 7304	Marine Bronze 16 K Angle Valves
JIS F 7305	Cast Iron 5 K Globe Valves for Marine Use
JIS F 7306	Cast Iron 5 K Angle Valves for Marine Use
JIS F 7307	Cast Iron 10 K Globe Valves for Marine Use
JIS F 7308	Cast Iron 10 K Angle Valves for Marine Use
JIS F 7309	Cast Iron 16 K Globe Valves for Marine Use
JIS F 7310	Cast Iron 16 K Angle Valves for Marine Use
JIS F 7311	Cast Steel 5 K Globe Valves for Marine Use
JIS F 7312	Cast Steel 5 K Angle Valves for Marine Use
JIS F 7313	Cast Steel 20 K Globe Valves for Marine Use
JIS F 7314	Cast Steel 20 K Angle Valves for Marine Use
JIS F 7315	Cast Steel 30 K Globe Valves for Marine Use
JIS F 7316	Cast Steel 30 K Angle Valves for Marine Use
JIS F 7317	Cast Steel 40 K Globe Valves for Marine Use
JIS F 7318	Cast Steel 40 K Angle Valves for Marine Use
JIS F 7319	Cast Steel 10 K Globe Valves for Marine Use
JIS F 7320	Cast Steel 10 K Angle Valves for Marine Use
JIS F 7321	Malleable Iron 5 K Globe Valves for Marine Use
JIS F 7322	Malleable Iron 5 K Angle Valves for Marine Use
JIS F 7323	Malleable Iron 16 K Globe Valves for Marine Use

TABLE E10.I1 International Standards and Specifications for Pipe, Tube, and Fittings

Numbers	Title
ISO 7-1	Pipe Threads Where Pressure-Tight Joints Are Made on the Threads–Part 1: Dimensions, Tolerances and Designation Third Edition
ISO 8	Pipe Threads Where Pressure-Tight Joints Are Made on the Threads–Part 2: Verification by Means of Limit Gauges First Edition
ISO 228-1	Pipe Threads Where Pressure-Tight Joints Are Not Made on the Threads–Part 1: Dimensions, Tolerances and Designation Third Edition
ISO 228-2	Pipe Threads Where Pressure-Tight Joints Are Not Made on the Threads–Part 2: Verification by Means of Limit Gauges Second Edition
ISO 392	Asbestos-Cement Pipe Fittings for Building and Sanitary Purposes First Edition
ISO 580	Injection-Moulded Unplasticized Poly(Vinyl Chloride) (PVC-U) Fittings—Oven Test—Test Method and Basic Specifications Second Edition
ISO 1179	Pipe Connections, Threaded to ISO 228/1, for Plain End Steel and Other Metal Tubes in Industrial Applications Second Edition
ISO 2035	Unplasticized Polyvinyl Chloride (PVC) Moulded Fittings for Elastic Sealing Ring Type Joints for Use Under Pressure—Pressure-Resistance Test First Edition
ISO 2044	Unplasticized Polyvinyl Chloride (PVC) Injection-Moulded Solvent-Welded Socket Fittings for Use with Pressure Pipe—Hydraulic Internal Pressure Test First Edition
ISO 2284	Hand Taps for Parallel and Taper Pipe Threads—General Dimensions and Marking Third Edition
ISO 2507-1	Thermoplastic Pipes and Fittings—Vicat Softening Temperature–Part 1: General Test Method First Edition; (Replaces ISO 2507)
ISO 2507-2	Thermoplastic Pipes and Fittings—Vicat Softening Temperature–Part 2: Test Conditoins for Unplasticized Poly(Vinyl Chloride) (PVC-U) or Chlorinated Poly(Vinyl Chloride) (PVC-C) Pipes and Fittings and for High Impact Resistance Poly(Vinyl Chloride) (PVC-HI) Pipes First Edition (Replaces ISO 2507)
ISO 2507-3	Thermoplastics Pipes and Fittings—Vicat Softening Temperature—Part 3: Test Conditions for Acrylonitrile/Butadiene/Styrene (ABS) and Acrylonitrile/Styrene/Acrylic Ester (ASA) Pipes and Fittings First Edition
ISO 2852	Stainless Steel Clamp Pipe Couplings for the Food Industry Second Edition

TABLE E10.I1 International Standards and Specifications for Pipe, Tube, and Fittings (*Continued*)

Numbers	Title
ISO 3183-1	Petroleum and Natural Gas Industries—Steel Pipe for Pipelines—Technical Delivery Conditions–Part 1: Pipes of Requirement Class A Second Edition
ISO 3183-2	Petroleum and Natural Gas Industries—Steel Pipe for Pipelines—Technical Delivery Conditions–Part 2: Pipes of Requirements Class B Second Edition
ISO TR 3313	Measurement of Pulsating Fluid Flow in a Pipe by Means of Orifice Plates, Nozzles or Venturi Tubes Second Edition
ISO 3458	Assembled Joints Between Fittings and Polyethylene (PE) Pressure Pipes—Test of Leakproofness Under Internal Pressure First Edition
ISO 3459	Polyethylene (PE) Pressure Pipes—Joints Assembled with Mechanical Fittings—Internal Under-Pressure Test Method and Requirement First Edition
ISO 3477	Polypropylene (PP) Pipes and Fittings—Density—Determination and Specification Second Edition
ISO 3503	Assembled Joints Between Fittings and Polyethylene (PE) Pressure Pipes—Test of Leakproofness Under Internal Pressure When Subjected to Bending First Edition
ISO 3514	Chlorinated Polyvinyl Chloride (CPVC) Pipes and Fittings—Specification and Determination of Density First Edition
ISO 3603	Fittings for Unplasticized Polyvinyl Chloride (PVC) Pressure Pipes with Elastic Sealing Ring Type Joints—Pressure Test for Leakproofness First Edition
ISO 3604	Fitting for Unplasticized Polyvinyl Chloride (PVC) Pressure Pipes with Elastic Sealing Ring Type Joints—Pressure Test for Leakproofness Under Conditions of External Hydraulic Pressure First Edition
ISO 4059	Polyethylene (PE) Pipes—Pressure Drop in Mechanical Pipe-Jointing Systems—Method of Test and Requirements First Edition
ISO 4230	Hand- and Machine-Operated Circular Screwing Dies for Taper Pipe Threads—R Series Second Edition
ISO 4231	Hand- and Machine-Operated Circular Screwing Dies for Parallel Pipe Threads—G Series Second Edition
ISO 4434	Unplasticized Polyvinyl Chloride (PVC) Adaptor Fittings for Pipes Under Pressure—Laying Length and Size of Threads—Metric Series First Edition
ISO 4439	Unplasticized Polyvinyl Chloride (PVC) Pipes and Fittings—Determination and Specification of Density First Edition

TABLE E10.I1 International Standards and Specifications for Pipe, Tube, and Fittings *(Continued)*

Numbers	Title
ISO 4451	Polyethylene (PE) Pipes and Fittings—Determination of Reference Density of Uncoloured and Black Polyethylenes First Edition; (Erratum–1980)
ISO 4488	Asbestos—Cement Pipes and Joints for Thrust-Boring and Pipe Jacking First Edition
ISO 5168	Measurement of Fluid Flow—Estimation of Uncertainty of a Flow-Rate Measurement First Edition
ISO 5969	Ground Thread Taps for Pipe Threads G Series and Rp Series—Tolerances on the Threaded Portion First Edition; (Corrigendum 1–1991)
ISO 6605	Hydraulic Fluid Power—Hose Assemblies—Method of Test First Edition
ISO 6964	Polyolefin Pipes and Fittings—Determination of Carbon Black Content by Calcination and Pyrolysis—Test Method and Basic Specification First Edition
ISO 7268	Pipe Components—Definition of Nominal Pressure First Edition: (Amendment 1–1984)
ISO 7278-2	Liquid Hydrocarbons—Dynamic Measurement—Proving Systems for Volumetric Meters–Part 2: Pipe Provers First Edition; (CEN EN ISO 7278-2: 1995)
ISO 7387-1	Adhesives with Solvents for Assembly of PVC-U Pipe Elements—Characterization–Part 1: Basic Test Methods First Edition
ISO 7608	Shipbuilding—Inland Navigation—Couplings for Disposal of Oily Mixture and Sewage Water First Edition
ISO 8142	Thermal Insulation—Bonded Preformed Man-Made Mineral Fibre Pipe Sections—Specification First Edition
ISO 8361-1	Thermoplastics Pipes and Fittings—Water Absorption–Part 1: General Test Method First Edition
ISO 8361-2	Thermoplastics Pipes and Fittings—Water Absorption–Part 2: Test Conditions for Unplasticized Poly(Vinyl Chloride) (PVC-U) Pipes and Fittings First Edition
ISO 8361-3	Thermoplastics Pipes and Fittings—Water Absorption–Part 3: Test Conditions for Acrylonitrile/Butadiene/Styrene (ABS) Pipes and Fittings First Edition
ISO 8497	Thermal Insulation—Determination of Steady-State Thermal Transmission Properties of Thermal Insulation for Circular Pipes First Edition CEN EN ISO 8497: 1996

ISO 683-15	Heat-Treatable Steels, Alloy Steels and Free-Cutting Steels–Part 15: Valve Steels for Internal Combustion Engines Second Edition
ISO 4126-1	Safety Valves–Part 1: General Requirements First Edition
ISO 4401	Hydraulic Fluid Power—Four-Port Directional Control Valves—Mounting Surfaces Second Edition
ISO 4411	Hydraulic Fluid Power—Valves—Determination of Pressure Differential/Flow Characteristics First Edition
ISO 4422-4	Pipes and Fittings Made of Unplasticized Poly (Vinyl Chloride) (PVC-U) for Water Supply—Specifications–Part 4: Valves and Ancillary Equipment First Edition; Supersedes ISO 4422: 1990
ISO 5208	Industrial Valves—Pressure Testing of Valves Second Edition
ISO 5209	General Purpose Industrial Valves—Marking First Edition
ISO 5210	Industrial Valves—Multi-Turn Valve Actuator Attachments First Edition
ISO 5599-1	Pneumatic Fluid Power—Five-Port Directional Control Valves–Part 1: Mounting Interface Surfaces Without Electrical Connector Second Edition
ISO 5599-2	Pneumatic Fluid Power—Five-Port Directional Control Valves–Part 2: Mounting Interface Surfaces With Optional Electrical Connector First Edition
ISO 5599-3	Pneumatic Fluid Power—Five-Port Directional Control Valves–Part 3: Code System for Communication of Valve Functions First Edition
ISO 5752	Metal Valves for Use in Flanged Pipe Systems—Face-to-Face and Centre-to-Face Dimensions Second Edition
ISO 5781	Hydraulic Fluid Power—Pressure-Control Valves (Excluding Pressure-Relief Valves), Sequences Valves, Unloading Valves, Throttle Valves and Check Valves—Mounting Surfaces First Edition
ISO 5783	Hydraulic Fluid Power—Code for Identification of Valve Mounting Surfaces and Cartridge Valve Cavities Second Edition
ISO 5996	Cast Iron Gate Valves First Edition
ISO 6002	Bolted Bonnet Steel Gate Valves First Edition
ISO 6182-2	Fire Protection—Automatic Sprinkler Systems–Part 2: Requirements and Test Methods for Wet Alarm Valves, Retard Chambers and Water Motor Alarms First Edition

TABLE E10.I3 International Standards and Specifications for Valves *(Continued)*

Numbers	Title
ISO 6182-3	Fire Protection—Automatic Sprinkler Systems–Part 3: Requirements and Test Methods for Dry Pipe Valves First Edition
ISO 6182-4	Fire Protection—Automatic Sprinkler Systems–Part 4: Requirements and Test Methods for Quick-Opening Devices First Edition
ISO 6182-5	Fire-Protection—Automatic Sprinkler Systems–Part 5: Requirements and Test Methods for Deluge Valves First Edition
ISO 6263	Hydraulic Fluid Power—Compensated Flow-Control Valves—Mounting Surfaces Second Edition
ISO 6264	Hydraulic Fluid Power—Pressure-Relief Valves—Mounting Surfaces First Edition
ISO 6403	Hydraulic Fluid Power—Valves Controlling Flow and Pressure-Test Methods First Edition; (Corrected and Reprinted–1989)
ISO 6404	Hydraulic Fluid Power—Servovalves—Test Methods First Edition
ISO 7121	Flanged Steel Ball Valves First Edition
ISO 7244	Air Distribution and Air Diffusion—Aerodynamic Testing of Dampers and Valves First Edition
ISO 7259	Predominantly Key-Operated Cast Iron Gate Valves for Underground Use First Edition
ISO 7349	Thermoplastics Valves—Connection References First Edition
ISO 7368	Hydraulic Fluid Power—Two-Port-Slip-In Cartridge Valves—Cavities First Edition
ISO 7508	Unplasticized Polyvinyl Chloride (PVC-U) Valves for Pipes Under Pressure—Basic Dimensions—Metric Series First Edition
ISO 7714	Agricultural Irrigation Equipment—Volumetric Valves—General Requirements and Test Methods Second Edition
ISO 7790	Hydraulic Fluid Power Four-Port Modular Stack Valves and Four-Port Directional Control Valves, Sizes 03 and 05—Clamping Dimensions First Edition
ISO 7967-3	Reciprocating Internal Combustion Engines—Vocabulary of Components and Systems–Part 3: Valves, Camshaft Drive and Actuating Mechanisms First Edition
ISO 8233	Thermoplastics Valves—Torque—Test Method First Edition; (Corrected and Reprinted–1989)
ISO 8242	Polypropylene (PP) Valves for Pipes Under Pressure—Basic Dimensions—Metric Series First Edition

TABLE E10.I3 International Standards and Specifications for Valves *(Continued)*

Numbers	Title
ISO 8659	Thermoplastic Valves—Fatigue Strength—Test Method First Edition
ISO 9393-1	Thermoplastic Valves—Pressure Test Methods and Requirements–Part 1: General First Edition
ISO 9393-2	Thermoplastic Valves—Pressure Test Methods and Requirements–Part 2: Test Conditions and Basic Requirements for PE, PP, PVC-U and PVDF Valves First Edition
ISO 9635	Irrigation Equipment—Hydraulically Operated Irrigation Valves First Edition
ISO 9644	Agricultural Irrigation Equipment—Pressure Losses in Irrigation Valves—Test Method First Edition
ISO 9911	Agricultural Irrigation Equipment—Manually Operated Small Plastic Valves First Edition
ISO 9952	Agricultural Irrigation Equipment—Check Valves First Edition
ISO 10418	Petroleum and Natural Gas Industries—Offshore Production Platforms—Analysis, Design, Installation and Testing of Basic Surface Safety Systems First Edition
ISO 10419	Petroleum and Natural Gas Industries—Drilling and Production Equipment—Installation, Maintenance and Repair of Surface Safety Valves and Underwater Safety Valves Offshore First Edition
ISO 10423	Petroleum and Natural Gas Industries—Drilling and Production Equipment—Specification for Valves, Wellhead and Christmas Tree Equipment First Edition
ISO 10433	Petroleum and Natural Gas Industries—Drilling and Production Equipment—Specification for Wellhead Surface Safety Valves and Underwater Safety Valves for Offshore Service First Edition
ISO 10497	Testing of Valves—Fire Type—Testing Requirements First Edition
ISO 10522	Agricultural Irrigation Equipment—Direct-Acting Pressure—Regulating Valves First Edition
ISO 10631	Metallic Butterfly Valves for General Purposes First Edition
ISO 10931-4	Plastic Piping Systems for Industrial Applications—Poly(Vinylidene Fluoride) (PVDF)–Part 4: Valves First Edition
ISO 10933	Polyethylene (PE) Valves for Gas Distribution Systems First Edition
